Horse flies, march flies or breeze flies, and deer flies are large, robust, blood-feeding flies that are widespread in both temperate and tropical regions. Only the females take blood meals, but the bites are savage and cause significant distress to large animals, particularly horses and cattle. These flies can act as mechanical vectors of diseases caused by viruses (equine infectious anemia, bovine leukosis, vesicular stomatitis, hog cholera), bacteria (anthrax, tularemia), and trypanosomes (surra). Eggs are laid on the leaves of plants growing in or near standing water. The larval and pupal stages occur in the water or mud, and the life cycle takes 4 to 5 months to complete. The flies are active in summer and attack animals principally on the legs and ventral abdomen. Duration of activity can be relative short (i.e., 3 to 4 weeks), but stress on the animals can be very high during that time. Fly attacks lead to bunching of animals with the attendant likelihood of overheating and in some cases resulting in animals stampeding through fences. Adult flies are attracted to host volatiles, including components of host urine.[1] Control is difficult unless wet areas can be drained or livestock kept away from those areas where the flies are most active. Repellents have been used and are reasonably effective in horses subject to fly worry. The use of DEET affords protection for only a few days and is costly, but its use in milking cattle gives increased milk yield and butterfat. Synthetic pyrethroid-impregnated eartags give very little protection against these flies.

RECOMMENDATION

Control is extremely difficult for both larvae and adults but should be attempted for the purpose of reducing effects of adult flies on animal welfare.

HYPODERMA SPP. INFESTATION (WARBLE FLIES)

Infestations of cattle with the larvae of *Hypoderma* spp. cause serious damage to hides and carcasses, in addition to production losses. Occasional deaths result from anaphylactic shock or toxemia and damage to the central nervous system or esophagus. Several other flies with very similar life histories affect goats (*Przhevalskiana silenus*) and semidomestic reindeer (*Hypoderma tarandi*) in addition to affecting the well-being of wild ruminants. *Dermatobia hominis* larvae affect all species of ruminants and humans (tropical bot fly) in South America.

SYNOPSIS

Etiology *Hypoderma bovis* and *H. lineatum* in cattle, *H. sinense* in cattle and yaks, *H. diana* in deer, *H. tarandi* in reindeer and caribou, *Przhevalskiana silenus* in goats. Horses are occasionally affected.

Epidemiology Eggs attached to hair in spring to late summer, larvae penetrate skin and migrate to esophagus (*H. lineatum* and *H. sinense*) or spine (*H. bovis*), where they stay for 2 to 3 months; they then move to subdermal tissue along the back and after 2 to 3 months emerge from the breathing hole, fall to the ground, pupate, and emerge as adult flies 3 to 5 weeks later. Larvae of *P.* and *H. tarandi* do not undergo migration within deep tissues of their host.

Clinical signs Reduced growth and production. Larvae in the back cause obvious swellings; larvae in the spinal cord may cause posterior paralysis. Treatment of larvae while they are in the esophagus may cause serious edema, and edema and paraplegia may occur if animals are treated when larvae are in the spinal canal.

Clinical pathology An enzyme-linked immunosorbent assay (ELISA) is available.

Lesions Larvae are found in discolored tissue.

Diagnostic confirmation Swellings along back characteristic.

Differential diagnosis Traumatic injury to the spine; aberrant *S. vulgaris* larvae in the horse.

Treatment Macrocyclic lactone endectocides.

Control Treatments are given so as to *avoid* treating when larvae are in the esophagus or spinal canal. (Usually treated in autumn and spring, but varies with location.)

ETIOLOGY

There are two species that specifically parasitize cattle: *Hypoderma bovis* and *H. lineatum*. A third species, *H. sinense*, affects cattle and yaks in central Asia.[1,2] The adult flies are robust and hairy, are about the size of a bee (12 to 18 mm long), are yellow-orange in color, and have two wings. They are not easily seen because of the rapidity of their flight. Repeated infestation results in an acquired immunity that results in older animals being less severely affected than younger animals.

Horses are occasionally infected with *Hypoderma* species of cattle. The larvae are found in subcutaneous cysts on the back, but they have not been reported to complete development. This location causes problems if they are in the saddle region.

Losses to the cattle industry caused by warble fly have not been estimated recently, but in 1965 the loss was estimated to be US$192 million per annum in the United States, and in 1976 approximately $100 million. In 1982 the cost of warble fly was estimated as £35 million for Great Britain, but the parasite has now been eradicated from the United Kingdom and Ireland. Advent of the macrocyclic lactone endectocides has greatly reduced the prevalence of the cattle species in North America, but they persist in localized areas.[2]

Hypoderma tarandi, *H. acteon*, and *H. diana* infect reindeer/caribou and deer. *H. diana* is found throughout Europe in several deer species but may also occur in sheep. *H. actaeon*, also found throughout Europe, is known only from the red deer. These species do not undergo deep tissue migrations that characterize the life cycle of the cattle species.

Przhevalskiana silenus is similar to the previously described species and is a parasite of goats in the Mediterranean basin, parts of eastern Europe, Pakistan, and India. This species also does not have a deep tissue migration, and larvae tend to develop subcutaneously very near the site of initial skin penetration. The losses resulting from this parasite are significant and result from reductions in carcass quality and reduced animal health.

The larvae of *Dermatobia hominis*, a small (12 mm long) related fly, parasitize a wide variety of hosts and cause major economic losses to cattle production in South America. They also affect humans and are a major zoonosis for travelers in the region. Mature larvae are about 2.5 cm long and develop in a subcutaneous cyst that can be quite painful. Female *Dermatobia* oviposit on zoophilous, "porter" flies such as mosquitoes and stable flies, which they catch on the wing.[2] The eggs are transported to the mammalian host, and they hatch in response to increased temperature as the fly lands. Larvae penetrate the skin, but do not migrate. Treatment and control measures are the same as for *Hypoderma* spp. of cattle.

LIFE CYCLE AND EPIDEMIOLOGY

Warble flies historically were common parasites of cattle in the northern hemisphere, including North America and Europe, and are common in parts of Asia. The distribution of these parasites has been changing recently with the widespread use of macrocyclic lactone endectocides and the adoption of eradication programs in many European countries. Infestations south of the equator are rare and are the result of imported cattle, although endemic cases have occurred in Chile.

Adult flies are active in the spring to late summer, with *H. lineatum* usually appearing 3 to 4 weeks before *H. bovis*. *H. lineatum* attaches up 600 eggs, in strings of 5 to 25, to hairs on the legs or lower parts of the body, whereas *H. bovis* attaches eggs, one at a time, to hairs on the rump and upper parts of the hindleg. The oviposition flight of *H. bovis*, darting in to lay each egg, will terrorize cattle. Eggs hatch in 4 to 6 days. The larvae penetrate the skin using protease enzymes and migrate through connective tissues to reach the esophagus (*H. lineatum*) or the epidural fat in the spine (*H. bovis*), where they stay, feeding and growing, for 2 to 4 months. They subsequently continue their migration to reach the subdermal tissue of the back in the early spring. Here they make a breathing hole and become encased in a granulomatous cyst. They complete development in 1 to 2 months, passing through second and third instars, and emerge through the hole, fall to the ground, and pupate. Adult flies emerge some 3 to 5 weeks later. The fully developed larvae are thick and long (25 to 30 mm), light cream in color, but darkening to almost black as mature third instars. A single animal may have up to 300 larvae, each developing with granulomatous cysts, with breathing holes, under the skin of the back.

Hypoderma tarandi females deposit eggs on the hair of reindeer or caribou, and larvae hatch in approximately 7 to 10 days. Larvae penetrate the skin close to where the eggs are deposited and do not migrate into deep tissues. Flies are active during arctic summer, and larvae remain in the back until early spring.

Przhevalskiana silenus eggs are attached to host hairs, and the larvae hatch after 7 to 8 days. Larvae penetrate the skin in the area where they were deposited, where they remain throughout their development period. Flies are known to be active from May through June in southern Italy and can be found in host tissues from May through the following February.

The timing of the life cycle, that is, the period when grubs are present in the animals and the time at which the flies are present in large numbers, varies with the climate and is of importance in a control program. *H. lineatum* generally is 1 to 2 months ahead of *H. bovis*, and where the two flies are present, both "grub" and "fly" seasons may be very long. In the southern United States the fly season is February and March; in Canada it is June to August. The period when grubs are present in the back is December in the south and February to May in Canada. In Europe the larvae begin to move to the back from January to July.

PATHOGENESIS

Migrating first instars cause little damage as they use their proteolytic enzymes to migrate through connective tissue. The enzymes, however, have an antiinflammatory effect, partially through cleavage of complement components. Larvae maturing under the skin of the back form holes in the skin, and the reaction of the host encloses each grub within a granulomatous cyst. On rare occasions an anaphylactic reaction may occur in a sensitized animal as the result of death of migrating larvae; chance migration into the brain may also occur. Intracranial myiasis as a result of *H. bovis* has also been recorded in the horse. Treatment of animals when the first instars are in the esophagus may cause a massive inflammatory edema that may prevent feeding and swallowing of saliva; eructation may stop and bloating may occur. Treatment of *H. bovis* while it is in the spinal canal may also cause edema and mild to severe paraplegia.

CLINICAL FINDINGS

Cattle at pasture may be worried by adult fly attacks that disrupt grazing and breeding behavior, which are exacerbated when fly populations are large. Avoidance behavior, called gadding, may result in injury as cattle run into fences and other natural obstructions. Heavy infestations with larvae are commonly associated with poor growth, poor body condition, and production losses, but such heavy infestations are often complicated by other forms of mismanagement, including malnutrition and parasitic gastroenteritis. Immunosuppression results from the effect of larval secretions. Infected cattle milk poorly, and a considerable increase in milk production and milk fat occurs after treatment.

The presence of the subcutaneous larvae causes obvious swelling, with pain on touch. The swellings are usually soft and with an opening that is usually evident. There may be as many as 200 to 300 such lesions on the back of one animal.

With involvement of the spinal cord there is a sudden onset of posterior paralysis without fever and without other systemic

signs. The suddenness of onset and the failure of the disease to progress usually suggest traumatic injury. A similar disease can occur in horses and is reputed to be more common in horses than in cattle.

CLINICAL PATHOLOGY

An ELISA that detects antibodies to the secreted enzymes of *H. lineatum* and *H. bovis* has been developed. It has been used in monitoring the eradication program in Great Britain and in France.[3] In addition, an antigen-capture ELISA, used to detect the presence of circulating quantities of the predominant larval enzyme, has been developed. This will be useful in differentiating active from cleared infestations and will be useful in detailed surveillance programs if used at the correct time in the life cycle.

NECROPSY FINDINGS

The first instars, migrating within connective tissue, are usually surrounded by a zone of yellow-green discoloration. Later larval stages lie in a subcutaneous, granulomatous cyst that may contain a pale fluid. Rarely the cyst will contain a large amount of purulent discharge. Other characteristic findings include the following:

- No other disease causes the characteristic swellings on the back.
- The differential diagnoses of posterior paralysis and anaphylaxis are discussed in detail under the respective headings of "Disease of the Spinal Cord" and "Anaphylaxis."
- The clinical signs of macrocyclic lactone poisoning have not been reported to cause these symptoms.
- Posterior paralysis as a result of destruction of the larvae in the epidural space usually occurs, but macrocyclic lactone products have not been reported to cause these symptoms.

TREATMENT

Macrocyclic Lactone Compounds

All larval stages of cattle grubs and other oestrid flies are very sensitive to macrocyclic lactone endectocides. Their widespread use in nematode control programs plays a major role in controlling warble flies. Their residual activity will persist for about 4 weeks.[4,5]

Treatment Recommendations

Treatment with a macrocyclic lactone-based product is strongly advised, both to increase productivity and to maintain population control.

Manual Removal

When small numbers of cattle are affected with relatively few warble grubs, manual removal of the larvae can be practiced. Incomplete removal or breaking the larvae during removal may cause a severe systemic reaction. This reaction and the one that sometimes occurs after systemic treatment of cattle infected with cattle grubs has been ascribed to anaphylaxis. However, there is evidence that it a direct result of toxins liberated from dead maggots and that phenylbutazone may control this toxin. The clinical signs include dullness, salivation, lacrimation, dyspnea, wrinkling of skin on the side of the neck, and edema under the jaw.

CONTROL

With the macrocyclic lactone endectocides, in general, systemic treatments are given at the end of fly activity and in the spring after first instars have left sensitive tissues. In those species that do not undergo deep tissue migration, treatment can be instituted anytime after the cessation of fly activity.

Cattle grub has been eradicated in Norway, Sweden, Denmark, Malta, Ireland, and Great Britain. Eradication programs were initiated in France.[3] Surveillance has decreased in most countries as a result of the excellent efficacy of the macrocyclic lactone products. However, evidence from Canada suggests that residual populations remain.[4] A joint Canadian–U.S. study using sterile male *Hypoderma* species eradicated these species from the test area, but the difficulty of mass producing flies, in the absence of an in vitro rearing system, makes this technique impractical for large-scale warble fly control.[6]

Vaccination of cattle using crude larval extracts has reduced both the number of warbles in the back and the number of larvae that could pupate.[7] Results of vaccination studies with recombinant antigens have been variable, and commercial development has ceased. Use of antigens derived from "hidden" sites such as the fatbody have produced excellent results,[5] and potential components have been identified, but further work has not been followed up.[8] Sequencing of the mitochondrial genome of *H. lineatum* has been completed.[9]

HORN FLIES AND BUFFALO FLIES (*HAEMATOBIA* SPP.)

ETIOLOGY

The small (6-mm) grayish flies of the *Haematobia* species, known as horn flies and buffalo flies, have distinct geographic distributions, *H. irritans exigua* in Australia and South East Asia, *H. irritans irritans* throughout North and South America and Hawaii, and *H. minuta* in Africa. *H. irritans irritans* is common in Europe, where it causes few problems. This species was transported to North America in the late 1800s, where it rapidly established and spread. It has subsequently moved into South America, where it has also become a major problem. *Haematobia* species are known as vectors for the nematodes *Stephanofilaria stilesi*, but their impact is thought to be of little importance.

LIFE CYCLE AND EPIDEMIOLOGY

These insects have a typical fly life cycle and habits. Eggs are deposited away from the animal onto freshly deposited dung, where the larval stages develop in a highly temperature-regulated manner. The onset of diapause in the pupal stage is regulated at this stage and requires that the larvae be exposed to increased hours of low temperatures for the pupae to become diapause driven. Three larval stages are spent in the dung, with larvae feeding largely on bacteria. Pupae form in the dry regions outside of the dung pat. Both sexes of these flies are obligate blood feeders, primarily attacking pastured cattle and water buffalo. They do not survive off the host, other than for short periods. They are not known as vectors for any disease agents other than the nematodes *Stephanofilaria* spp. They cause significant reductions in productivity of pastured cattle through induction of stress, changes in grazing patterns, and, in extreme cases, blood loss. Burdens of 200 to 500 flies will reduce weight gains of beef cattle (up to 14% reduction) and milk yield of dairy cows. Heavy infestations (over 1000 flies) can cause serious loss of condition and, rarely, deaths. Control results in higher feed efficiency, increased growth rate, and increased calf-weaning weights.

The flies are easily recognized by the way in which the wings are held at rest, slightly divergent and angled upward, away from the body. Adult flies stay on the host most of the time, unless disturbed. Females leave the host, as feces are passed, to deposit eggs around edges of the freshly deposited dung. Larvae develop within the dung pat, feeding primarily on bacteria. Development is regulated by environmental temperatures, and the larvae are stimulated to enter diapause (arrested development) if temperatures become too low. Mature larvae exit the dung to pupate in the dry soil below and around the pat. A complete life cycle may require up to 3 weeks under optimal environmental conditions. Thus at higher temperatures in excess of 15 generations may be produced in a single season; in more temperate climates such Canada and the upper United States, only 5 generations may occur.

PATHOGENESIS

The flies congregate chiefly on the withers, shoulders, and flanks and around the horns and eyes. Flies take numerous (15 to 20) small blood meals per day. In North America

feeding often takes place on the ventral midline and several 2- to 5-cm-diameter feeding lesions are often observed. Zebu cattle are less affected by the flies than British breeds, and although they may carry large populations of flies, they show fewer feeding lesions.

CLINICAL FINDINGS

Whereas adults rarely leave the host except for oviposition, the newly emerged flies of *H. irritans irritans* will travel up to 20 km in search of new hosts. They may be dispersed also by prevailing strong winds, and they are carried long distances by the movement of cattle to new pastures. The distribution of *H. irritans exigua* is controlled by environmental factors, particularly temperature and humidity. At temperatures below 21° C (70° F), the flies become sluggish, and at 5° C (41° F) they become comatose.

TREATMENT AND CONTROL

Infestations have been controlled by traps, insecticide sprays, back rubbers, dust bags, or eartags impregnated with insecticides. Traps have been designed for use with dairy cattle that walk through them on their way to and from the dairy. The flies are dislodged by gauze strips and are retained in the trap and killed when they rest on the insecticide-coated walls. Traps are rarely used today, but recent work with modified traps has given 80% to 90% control.

Back rubbers consist of absorbent material, impregnated with insecticide or oil, wrapped around a cable or chain suspended from a central pole and attached to ground-level supports or as a cable suspended a little over a meter above the ground between two posts 4 to 5 m apart. Cattle quickly learn to use rubbers to dislodge flies, and their coats become smeared with insecticide. Insecticidal-impregnated eartags attached to back rubbers and dust bags controlled horn fly for about 6 weeks, whereas fenvalerate tags were still effective 18 weeks after application.

Eartags impregnated with a mixture of organophosphorous compounds and synthetic pyrethroids have been widely used, but resistance has built up to levels that make this technique ineffective. Discontinuing the use of pyrethroid-impregnated eartags for one season does not allow substantial reduction in resistance to occur. Eartags impregnated with compounds of both classes have been effective in managing increases in pyrethroid resistance. Current recommendations for use of impregnated eartags note that tags should be applied to the cows (because they harbor the most flies and present the largest surface area for exposure to the insecticide) at the maximum recommended rate. Although this is less convenient, it helps to avoid one of the leading causes of insecticide resistance, which is the dilution of the insecticide as it spreads from calves to cows. Flies can also be controlled by dipping, but this technique is rarely used solely for flies. Current products are combined with synthetic pyrethroids to extend the protective period. In areas where cattle ticks require regular treatment, adequate control of flies may be gained incidentally, but if treatments are not effective cattle can be oversprayed with pyrethroids. Some research on control in North America[1] using essential oils has been conducted, and the microbiome[2] has been sequenced.

Macrocyclic lactone endectocides are highly effective against larval horn flies and the larvae of face flies, stable flies, and house-flies, often killing larvae for periods in excess of 8 weeks. However, in terms of practical control, where flies immigrate from surrounding herds, the duration of efficacy is not more than 2 weeks. In addition, the macrocyclic lactones generally cause significant reductions of nontarget insects in the dung community,[3] many of which are beneficial because they are natural enemies of the horn fly and buffalo fly. The various macrocyclic lactone products have differential effects on flies and other dung insects, and it appears that moxidectin has the least impact.[3] Virtually all of the cattle on pasture in North America are affected by horn flies, with the exception of those kept at higher elevations.[1] The effect will be altered by various factors, including both physical and biological characteristics of the flies and their hosts.

Pour-on formulations of pyrethroids are highly effective, as evidenced by application of 1% cyfluthrin. Insect growth regulators (e.g., Diflubenzuron) applied as a bolus gave 80% control of the immature stages of the face fly and horn fly in the manure for at least 20 weeks and reduced the number of dung beetles for 7 weeks. A 3% methoprene bolus was also active against flies but had no apparent effect on the dung beetles. The use of essential oils has been shown to have good fly control, but their use requires further testing.[1]

RECOMMENDATION

Treatment is necessary to keep populations below the economic threshold and to prevent this from becoming an animal welfare issue.

BLACK FLIES, BUFFALO GNATS (SIMULIIDAE)

These small gray to black flies (5 mm) are members of the family Simuliidae and include a number of species and genera. The important flies appear to be *Cnephia pecuarum*, which is common in the southern states of the United States; *Simulium arcticum* and *Simulium luggeri* in Canada; *Austrosimulium pestilens* and *Austrosimulium bancrofti* in Australia; and *Simulium ornatum* in Great Britain. These very small flies occur in most parts of the world. With the exception of *S. arcticum* and two or three other species common in northern regions of North America, black flies are primarily a concern in tropical regions.

Female flies are voracious blood feeders. They are active in the summer months, when large numbers emerge from the streams and rivers where they have spent their larval and pupal stages.

A. pestilens has adapted to reach large numbers, mate, and oviposit within a very short time to utilize the flood situations that occur in northern Australia. The flies congregate in swarms and attack all animals, causing much worry and annoyance. They tend to bite animals around the legs, on the belly, and around the head, causing wheals and papules. The annoyance may be so intense that animals stampede or mill about, and young animals may be injured or even trampled to death and are frequently separated from their dams. Cattle may spend much of their time wallowing in mud or kicking up dust to keep the flies away. Herding of cattle onto bare areas reduces fly attacks because the flies commonly rest in tall grass, but this reduces feeding. The cause of death is unknown, although swelling of the throat causing suffocation, anaphylaxis, and direct toxicity are suspected. Filarid worms of *Onchocerca* spp. are transmitted by these flies, and their role as an intermediate host of nematodes has been discussed.

A similar situation occurs in northern Canada, where large numbers of *S. arcticum* have caused severe stress and occasional deaths of cattle introduced into the area of the Athabasca River and similar regions in the province of Saskatchewan. When black fly populations are extreme, previously unexposed cattle develop symptoms of shock resulting from blood loss and cumulative effects of the fly salivary secretions. In northern Saskatchewan, *S. luggeri* causes similar problems along major waterways.

Because the larval stages of these flies are passed in flowing streams where mouthparts are developed into fan-like structures for filtering out particles from water currents, large-scale control measures must be directed at killing the larvae at this stage. In the past, annual injection of methoxychlor upstream from major larval sites proved effective in reducing black fly populations, but off-target effects were undesirable. Repellents are of some use; alcoholic or aqueous solutions and dusts of permethrin, cypermethrin, and resmethrin can be applied to the whole body and will repel black flies for some days. Recently, toxins of *Bacillus thuringiensis* var. *israelensis* have been used in river injections in northern Saskatchewan, which has kept

several species under control. An electrostatic sprayer that allows efficient application of repellents or insecticides to cattle under pasture conditions can be used. The insecticide or repellent solution is dispersed as charged droplets that are attracted to the hair of the animals.

HOUSEFLY (MUSCIDAE—*MUSCA DOMESTICA*)

The common housefly has a worldwide distribution and is of veterinary importance because it is capable of transmitting, in a mechanical manner, the causative bacteria of many infectious diseases. It is often cited as a means whereby anthrax, erysipelas, and brucellosis are spread, but its importance in this regard is largely unproven. Houseflies are intermediate hosts for the larvae of *Habronema muscae* and *Draschia megastoma.*

The eggs are laid in decaying organic matter of any kind. Larval development is temperature dependent, and a life cycle may be completed in 12 to 14 days so that in warm, wet summers the fly population may increase very rapidly, causing annoyance to livestock and farm workers.

Housefly population management requires frequent and thorough removal of manure and other rich organic matter. In dry weather the manure can be spread thinly on fields, but a more dependable method is to place it in a special fly trap (e.g., Baber's fly traps), from which larvae and adult flies cannot escape. Chemical treatments to control flies require application to resting sites on buildings and other facilities or the placement of baits containing methomyl, propoxur, naled, or dichlorvos at appropriate locations. Development of insecticide resistance can occur rapidly, and there are numerous examples of resistance to multiple classes of insecticide at a single location. Rotational use of insecticide classes is absolutely essential in the management of resistance.

Management of housefly populations can be augmented through release of parasitic wasps (family Pteromalidae) that kill pupae. These tiny wasps (1 to 2 mm long) actively search for the fly pupae and lay one or more eggs inside. The developing wasps devour the fly within the pupa. They have been found to be useful adjuncts to other fly control measures when used in confined facilities such as hog barns. Inundative releases at feedlots, where thousands of wasps are released at regular intervals throughout the fly season, have shown some efficacy but require an integrated approach with good manure management and selective application of insecticides.

Reducing the fly population in buildings is an important procedure in public health work, and many measures are recommended. It is not possible to give details of them here because so many factors have to be taken into consideration, including toxicity of the products used for humans and animals, development of resistance to the insecticides, and contamination of food products such as milk by the insecticides.

RECOMMENDATION

Fly control should always be attempted in an integrated manner with rational use of pesticides and other approaches.

BUSH FLIES (*MUSCA VETUSTISSIMA*)

Bush flies occur commonly in Australia in drier areas and are a cause of stress to livestock in the summer months. Bush flies die out in southern Australia each winter, but breeding continues in the north, and the regular northern winds that commence about September each year blow flies southward, which then repopulate the areas that are now suitable for reproduction. Larvae usually develop in fecal matter from several source animals. Adult *Musca vetustissima* occur in very large numbers and during the day congregate around the eyes, on the lips, on any visible mucous membrane, and on wounds to obtain moisture. They are thought to carry contagious ophthalmia of sheep, infectious keratoconjunctivitis of cattle, and contagious ecthyma of sheep; to delay the healing of wounds; to contribute to the lesions produced by buffalo flies (*Haematobia irritans exigua*); and to act as intermediate hosts for the larvae of *Draschia megastoma*, *Habronema muscae*, and *Thelazia* spp. Control of the fly population is virtually impossible in the areas where it occurs, but individual animals may be protected by repellents such as dimethyl phthalate or DEET. Sprays containing 1% of dichlorvos are effective but must be applied daily. Dung beetles, introduced from Africa, break up dung pats, which aids in control of larval stages and in reducing fly numbers. The bush fly has been implicated in the dissemination of several food-borne pathogens that can have serious concerns.[1]

RECOMMENDATION

Control of adults is recommended to alleviate animal welfare concerns.

FACE FLY (*MUSCA AUTUMNALIS*)

This medium-sized fly, indigenous to Europe and Asia, first appeared in North America in 1952 and is now present over large areas of Canada and the northeastern and north-central United States. The flies resemble the housefly but are slightly larger. They congregate on the face of cattle, feeding on nasal and lacrimal secretions and saliva. Very large numbers cause a certain amount of stress, cause petechiation in the eye, and are instrumental in transmitting infectious keratoconjunctivitis (pinkeye) of cattle. Face flies are vectors for the eyeworms, *Thelazia* spp., which infest the conjunctival sacs and lacrimal ducts of domestic animals.

Flies oviposit on fresh cattle manure, where larval development takes place. As with all flies, development is temperature dependent. In temperate latitudes the flies will overwinter as adults, resting inside homes and other farm structures.

Fly numbers are greatest in summer, and cattle are particularly troubled when outdoors. Repellents have been extensively used but are not highly successful. Self-applied or hand-applied dusts containing insecticides are extensively used. Reduction of face-fly populations on cattle can be achieved through use of synthetic pyrethroid-impregnated eartags, but their use is complicated by the presence of insecticide-resistant horn flies. Diflubenzuron boluses give 80% control of the immature stages of *M. autumnalis* in the manure for up to 20 weeks.

RECOMMENDATION

Control should be attempted but may be difficult in areas where resistance is a problem.

HEAD FLY (*HYDROTOEA IRRITANS*)

This medium-sized fly, similar in appearance to the housefly but having an olive abdomen and yellow wing bases, is found in the United Kingdom and Europe. It is a nonbiting muscid fly that swarms around animals and humans from late June to September. Larval development is in soil and litter, and generally there is only one life cycle per year. The lesions on sheep are self-inflicted trauma in attempts to alleviate fly irritation. Sores are often large and open, and they may be made more severe by bacterial invasion.[1] The wounds may predispose to blowfly strike by *Lucilia sericata.* The pathogens of summer mastitis of cattle can be spread mechanically by this fly as well as a number of related muscid flies, and *Trueperella (Actinomyces* or *Corynebacterium) pyogenes* has been shown to persist in *H. irritans* for up to 4 days.

Control is difficult and is similar to that used for the other nonbiting muscid fly, *M. autumnalis.* Eartags impregnated with 8.5% cypermethrin or 10% permethrin reduce the severity of fly damage in sheep, and tagged ewes give protection to their lambs. However, it is likely that resistance will quickly occur in the same manner as in the face fly. Head caps are most effective but are tedious to apply.

BITING MIDGES (CERATOPOGONIDAE)

These tiny flies (1-3 mm long) are members of the family Ceratopogonidae, of which the most important genus is *Culicoides*. These flies are blood feeders and induce stress in hosts, and they can transmit infectious diseases such as bluetongue in sheep, horse sickness, and ephemeral fever in cattle.[1] They are also intermediate hosts for nematodes of the genus *Onchocerca*. Because of their importance as vectors of arboviruses, studies have been done on their feeding habits. Cattle and sheep are the most common hosts attacked, but some species also feed on birds or dogs. Hypersensitivity to the bites of *Culicoides* spp. results in an allergic dermatitis (sweet itch) in horses in Australia and North America and is discussed elsewhere. Cattle also show considerable irritation during attacks by large numbers of midges. They react with vigorous stamping of the feet, switching of the tail, and continuous movement.

The flies are plentiful in the warmer months and are most active at dawn and dusk. Because of their small size they are capable of being carried long distances by wind. Larvae develop in rich, high-organic-matter sites with high moisture content. Control of the larvae and of flies is virtually impossible, and most measures to reduce their importance are based on preventing access of the flies to the animals. Repellents, especially dimethyl phthalate or DEET, are effective on a short-term basis. Antihistamines can be used regularly but are too expensive for general use. Keeping horses away from areas where the flies are present in large numbers is advisable. Backline pour-on treatment of horses with 4 0mL of a 4% high-CIS permethrin 3 times weekly gave a good response in 86% of horses. Ivermectin at the recommended dose of 0.2 mg/kg would not produce the serum concentration that would have noticeable effects on blood-feeding *C. variipennis*. Recently, modeling of changing weather patterns indicates that such patterns may alter the distribution of important vectors and thus alter the influence of diseases.[2]

MOSQUITOES (CULICIDAE)

A number of mosquitoes, including *Psorophora*, *Aedes*, *Mansonia*, *Culex*, and *Anopheles* spp. are important parasites of domestic animals. When the blood-feeding females are present in large numbers, they cause stress to animals and have been known to kill young pigs and puppies by the severe anemia they produce. Although such occurrences are rarely recorded, the blood loss that can occur in severe infestations is surprising. The stress associated with mosquito attack is sufficient to cause reductions in efficiency, even in mature large animals.

Their most important role is as vectors of disease. *Culex tarsalis*, *Aedes dorsalis*, and *Aedes nigromaculis* transmit equine encephalomyelitis. *Culex tritaeniorhyncus* is the principal vector of Japanese B encephalitis in Japan. Various *Culex* species vector western equine encephalitis, eastern equine encephalitis, and West Nile virus. These viruses can have serious effects on unprotected horses and are transmissible to humans via mosquito bites. Vaccines are available to protect against all of these arboviruses. *Psorophora confinnis* is instrumental in spreading the eggs of *Dermatobia hominis*, the tropical warble fly; and *Mansonia* spp. transmit Rift Valley fever. The filarid worm *Setaria digitata* is also spread by mosquitoes.

Control over a large area must include drainage of collections of still surface water or destruction of the larvae by the addition of any one of a number of insecticides. For small groups of animals, protection from the attacks of mosquitoes can only be satisfactorily effected by mosquito-proof screens. Temporary protection by repellents such as dimethyl phthalate is only partial. Permethrin, 100 mL of a 0.5% emulsion, applied with an electrostatic sprayer provided greater than 70% protection for at least 72 hours.

Tick Infestations

SYNOPSIS

Etiology Many species of ticks act as vectors of disease or cause death from anemia; others cause paralysis. Heavy burdens cause loss of production.

Epidemiology Life cycles vary widely both in the number of hosts required and the host specificity. Animals are infested by larval or nymphal states on the ground.

Clinical signs Anemia, paralysis, tick fever, and tick worry.

Clinical pathology Ticks obvious on clinical examination. Blood smears for tick fevers (*Babesia*, *Theileria*, and *Anaplasma*).

Lesions Skin damage as a result of biting and rubbing; anemia. See other chapters for lesions as a result of diseases transmitted by ticks.

Diagnostic confirmation Ticks easily found, should be identified as to species.

Treatment Dipping, spraying, application of pour-ons and injectable acaricides.

Control Regular treatment at intervals dependent on the life cycle of the tick, pasture spelling to destroy free-living stages, the use of resistant cattle, and vaccination all play a part.

Tick infestations are of great importance in the production of animal diseases, particularly in livestock housed in tropical and subtropical areas. In addition to their role as vectors of infectious diseases, as outlined in the following discussion, heavy infestations can cause direct losses. Many ticks are active blood feeders and may cause death from anemia. Some species cause tick paralysis, and it is possible that other ticks may elaborate toxins other than those causing paralysis. Heavy tick burdens cause sufficient irritation and stress such that affected animals become anorexic, which may lead reduced productivity. One tick, *Boophilus microplus*, is reported to affect in excess of 75% of the world cattle population. The economic impact has been estimated at US$7 per animal per year, and in Brazil, which has the fifth largest cattle herd, the losses are estimated at US$2 billion per year.

Ticks are divided into two groups: Argasidae (soft-body ticks) and Ixodidae (hard-body ticks). The life cycles of the ticks vary widely. Some species pass their entire lives on one host, others pass different stages of the cycle on successive hosts, and others are parasitic only at certain stages. The eggs are laid in the soil, and larvae attach themselves to a passing host, on which they may develop through one or more nymphal stages before becoming adults. Adult females engorge on blood or lymph and drop to the ground to lay their eggs. One-host ticks are more easily controlled than those that pass part of their life cycles away from the host. A list of the single- and multiple-host ticks is shown in Table 16-5.

Although many ticks favor a particular host, they are usually not completely host-specific, and many parasitize a wide variety

TABLE 16-5 Single- and multiple-host ticks

One-host ticks
Boophilus spp.
Margaropus winthemi
Otobius megnini (adults are not parasitic)
Dermacentor albipictus

Two-host ticks
Rhipicephalus evertsi
Rhipicephalus bursa
Hyalomma spp. (most have two or three hosts)

Three-host ticks
Ixodes spp.
Rhipicephalus spp. (except *R. evertsi* and *R. bursa*)
Haemaphysalis spp.
Amblyomma spp.
Hyalomma spp. (most have two or three hosts)
Ornithodorus spp.—many hosts
Dermacentor spp.

of animals. In the limited space available here, the species are listed according to whether they transmit bacterial, viral, or rickettsial diseases of livestock or only cause worry. Ticks that transmit economically important protozoan diseases of livestock, such as babesiosis and theileriosis, are discussed in Chapter 11 (Table 11-7). Ticks that cause paralysis and other neurologic signs are discussed in Chapter 15.

Bacterial, Viral, and Rickettsial Diseases Transmitted by Ticks

The transmission of diseases associated with these agents may be effected by means other than ticks. *Anaplasma marginale* can be spread by biting flies if large numbers are present when the animals are experiencing a heavy parasitemia. Outbreaks of anaplasmosis can also occur following the use of unclean instruments for dehorning, vaccination, castration, or blood sampling, and anaplasmosis is easily caused by blood transfusions. The ticks involved more commonly in transmitting bacteria, viruses, and rickettsia are listed in Table 16-6. Transmission of *Anaplasma* may be transovarially, with one stage becoming infected and a subsequent stage passing the infection to a new host, or ticks may transmit infection within the one stage if they detach and feed on a new host.

Ticks That Cause Direct Losses

Ticks cause damage to hides and loss of production, anemia, and death when they are present in large numbers. They also cause greater morbidity and mortality during periods of drought, in addition to delays in fattening, resulting in animals held longer before they can be sold. Ticks that have this effect on production but are not known to cause paralysis or transmit infectious diseases in farm animals are as follows:

- *Otobius megnini*—the "spinose ear tick" of the United States and Canada
- *Amblyomma americanum*—the "Lone Star tick" of the United States
- *A. maculatum*—the "Gulf Coast tick" of the United States
- *Margaropus winthemi*—of South America and Africa
- *Ornithodorus moubata*—of Africa and Southeast Asia
- *O. savignyi*—of Africa and Southeast Asia
- *Haemaphysalis longicornis*—of Australia and New Zealand.

TREATMENT AND CONTROL OF TICK INFESTATIONS

Four methods are now available to treat and control tick infestations, with the primary role continuing to be played by chemical acaricides:

- Administration of acaricidal agents
- Pasture management
- Use of resistant cattle
- Vaccination

Acaricidal Agents

Individual animals can be effectively treated by the application of any one of a number of acaricides applied either as a spray or by dipping. The choice of acaricide for treatment depends largely on three factors:

- The persistence of the compound on the skin and hair coat
- The likelihood of residues toxic to humans appearing in the milk or meat
- Whether or not the ticks in the area have developed resistance to the particular acaricide

Arsenicals, in the form of water-soluble arsenic salts, have been widely used to treat tick infestations but are no longer used in many parts of the world because of resistance, toxicity, and environmental concerns.

Table 16-6 Diseases associated with bacteria, viruses, and rickettsia and reported to be transmitted by ticks

Disease	Causative agent	Vector ticks	Country
Tick pyemia (lambs)	*Staphylococcus aureus*	*Ixodes ricinus*	Great Britain
Tularemia (sheep)	*Francisella tularense*	*Haemaphysalis leporispalustris*, *H. otophila*; *Dermacentor andersoni*, *D. variabilis*, *D. pictus*, *D. marginatus*; *Ixodes luguri*	United States Norway, Europe, Russia, and states of the former USSR
Anaplasmosis			
Cattle	*Anaplasma marginale*	*Boophilus annulatus*; *Argas persicus*; *Dermacentor albipictus*, *D. andersoni*, *D. occidentalis*, *D. variabilis*; *Ixodes scapularis*; *Rhipicephalus sanguineus;*	North America
		Boophilus microplus,	Australia and South America
		B. decoloratus; *Hyalomma excavatum*; *Rhipicephalus bursa*, *R. simus*;	Africa
		Haemaphysalis punctata; *Ixodes ricinus;*	Europe
		Boophilus (annulatus) calcaratus	Russia, and states of the former USSR
Sheep and goats	*Anaplasma ovis*	*Dermacentor silvarum*, *Rhipicephalus bursa*, *Ornithodorus lahorensis*	Russia, and states of the former USSR
Brucellosis	*Brucella abortus* and *Br. melitensis*	Many ticks may be infected, but infection of host appears to occur only if ticks or their feces are eaten	Russia, and states of the former USSR
Heartwater	*Ehrlichia ruminantium*	*Amblyomma* spp.	Africa and Caribbean
African swine fever	Virus	*Ornithodous* spp.	Africa, Spain, Portugal
Louping-ill	Virus	*Rhipicephalus appendiculatus* (laboratory only) *Ixodes ricinus*	Africa England
Tick-borne fever	*Anaplasma phagocytophila*	*Ixodes ricinus* *Rhipicephalus haemaphysaloides*	Great Britain, Norway India
Caseous lymphadenitis of sheep	*Corynebacterium pseudotuberculosis*	*Dermacentor albipictus*	North America
Epizootic bovine abortion	*Spirochete*	*Ornithodorus coriaceus*	United States
Nairobi sheep disease	Virus	*Rhipicephalus appendiculatus*	Africa
Lyme disease	*Borrelia burgdorferi*	*Ixodes dammini*, *I. pacifieus*, *I. rieini*	United States, Europe, Australia

Chlorinated hydrocarbons replaced the use of arsenicals but have been withdrawn from most markets because of high toxicity and long duration of effect. Resistance to chemical acaricides, including macrocyclic lactones, has become a major issue for the effective management of one cattle tick, *Boophilus microplus*. In many cases cross-resistance between chemical families occurs, further complicating the use of rotational schemes aimed at managing the development and degree of resistance.

The same criteria apply in control as in treatment except that cost becomes a limiting factor when large numbers of animals require frequent treatments, and it is obvious in some circumstances that the effect of tick infestation on Brahman-cross steers is insufficiently great to warrant treatment. It is impossible to make specific recommendations on methods of application and the most efficient insecticide to use because these vary widely between species of ticks. However, whenever possible, treatment should be given systematically in a program based on the life cycle and epidemiology of the tick. A number of treatments may be used early in the tick season to prevent the increase in tick numbers. Care must be taken in areas where tick fevers also occur, so as not to disrupt the transmission of the tick-fever organisms and leave the cattle susceptible to later infection. Other special cases include *Otobius megnini*, the nymphs of which drop off to molt and lay eggs in protected spots, necessitating the spraying of buildings, fence posts, feed troughs, and tree trunks in feedlots where heavy infestations are most common. *Ornithodorus* spp. ticks are difficult to control because the nymphs and adults attach to feed for brief periods only. Where ticks that cause paralysis are common, it may be necessary to apply an insecticide as a dust and dip at short intervals.

Organophosphates

The organophosphates as a group are effective, but tick strains resistant to many of them have appeared. Other drugs in current use include dioxathion, diazinon, carbophenothion, coumaphos, ethion, bromophos-ethyl, chlorpyrifos, and phosmet. Pour-on applications of chlorpyrifos and phosmet have been tested but were not as effective as spray applications. Addition of acaricides to the feed has also been tried but has not been successful, whereas eartags impregnated with tetrachlorvinphos did not give satisfactory control and increased the risk of development of resistance to the drug.

Preparations vary in the duration of the protection they afford, and local conditions of rainfall and tick population must be taken into account when determining the time intervals between sprayings or dippings. A special case is that of young lambs that are exposed to tick pyemia. Sprays, dips, and ointments are too toxic, and the most effective procedure is the application of a liquid emulsion cream containing the insecticide to the wool-less parts of the body. Chlorpyrifos 0.48 kg/ha markedly reduces the number of ticks on the pasture, but it is too expensive for routine use.

Pyrethroids

Amitraz, a formamidine, and the synthetic pyrethroids have been used widely in Australia and have proved to be efficient, active against organophosphate-resistant strains, and safe. In a study in the United States, 0.025% amitraz applied as a whole-body spray or by dipping gave 86.0% or 99.8% control, respectively. Ticks resistant to DDT are also resistant to the synthetic pyrethroids, and to overcome resistance pyrethroids can be combined with an organophosphate. Successful combinations in Australia are cypermethrin plus chlorfenvinphos and deltamethrin plus ethion. A synthetic pyrethroid, flumethrin, has been marketed by itself at higher use concentrations for both plunge dipping and as a pour-on treatment. As a 1% pour-on, 1 mL per 10 kg body weight gave 97% efficacy, and 0.0033% as a spray gave 99% efficacy and acted more quickly. The efficacy of synthetic pyrethroid-impregnated eartags has been reported, but these are likely to lead to resistance. Cyhalothrin also controls multiresistant strains and is used in plunge dips.

Bioassay results show lambdacyhalothrin to be as effective as cyhalothrin as a whole-body spray, although the 1% pour-on was less than 50% effective. Resistance to all pyrethroids has been reported. Three pyrethroid acaricides have been shown to markedly reduce the hatching of eggs. Permethrin 0.1% or cypermethrin and cyfluthrin 0.05% could be useful in cleansing and disinfecting premises.

Macrocyclic Lactones

Ivermectin given subcutaneously gives satisfactory control of *Boophilus microplus* for 21 days following an initial lag period of 2 days. As little as 0.015 mg/kg per day gives complete control and raises the possibility of a slow-release subcutaneous implant. Two treatments of 0.2 mg/kg at 4-day intervals is considered satisfactory in cleansing cattle under field conditions. However, ivermectin may not be effective against *Ixodes ricinus*, but a slow-release bolus active for 90 days did give good control of a variety of ticks. If given topically, 0.5 mg/kg was required to reach the efficiency achieved by 0.2 mg/kg subcutaneously.

Moxidectin 0.2 mg/kg subcutaneously at 4-week intervals or 0.5 mg/kg as a pour-on along the back gives good protection against *B. microplus* resistant to organophosphorous insecticides and DDT, and each treatment has a rapid knockdown effect on populations of buffalo fly after treatment. Doramectin 0.2 mg/kg SC is highly efficacious in removing *B. microplus* and preventing reestablishment. Closantel 22.2 mg/kg orally to cattle (greater than the typical oral dose) was shown to disrupt the life cycle of *Rhipicephalus appendiculatus*; those that oviposited laid few eggs, and most of these did not hatch. Few larvae or nymphs molted.

Ticks in the ears of **horses** should be treated by the insertion of a few drops of an oily acaricidal preparation.

Use of Resistant Cattle

It is possible to reduce the impact of ticks and tick-borne diseases by the introduction of Brahman and Brahman-cross cattle, which are more resistant than British breeds and African cattle.[1] The resistance has been shown to be largely acquired, and it is mainly expressed against the larvae in the first 24 hours after attachment. In Australia the possibility that *B. microplus* might escape from its control area because of increased resistance to acaricides has been realized. For this reason a great deal of attention is being paid to the possibility of selecting cattle for tick resistance. In most tick-infested areas, cattle should have up to 50% *Bovis indicus* breeding because this allows for a reduction in the frequency of treatments. Penalties such as reduced live-weight gains, late maturity, and poor temperament become evident when cattle have more than 50% *B. indicus*. With successive infestations cattle differ in their response to *B. microplus*. Thus there is increased irritation and more licking and a decrease in the number of ticks carried. Resistance to ticks has been shown to be related to skin thickness and other factors and is heritable.[2] Selection for tick resistance does not affect milk production.

Pasture Management

Measures other than the application of acaricides used in the control of tick infestation include burning of pasture, removal of native fauna, and plowing of fields. So little is known of the bionomics of specific ticks in specific areas that these measures have been largely unsuccessful, and it is impossible to provide details for their proper implementation.

In contrast, pasture spelling and rotational grazing are capable of greatly reducing the tick population on farms in some areas. If cattle are placed on spelled pastures early in winter when the ticks are producing f ew or no progeny and then alternated at 4-month intervals, the tick population can be controlled with a markedly lower number of treatments. The practicability of the procedure depends on a full-scale financial assessment of the increased weight gains relative to the costs of management. Duration of the spelling period varies between 2 and 3 months in summer to 3 to 4 months in the winter, but these intervals need to be

determined for each district. In practice, pasture spelling is rarely used.

In those areas where the epidemiology is known, it has been shown that in regions with a cold winter the females stop laying eggs, and the development of eggs is prolonged. This results in few larvae being available in the spring, and if repeated treatments are given at this time, pasture contamination will remain low for some months. In hot tropical areas where the required temperatures for tick breeding are always present, the dry period may cause mortality by desiccation.

Certain *Stylosanthes* spp., tropical legumes, can kill or immobilize larval ticks, and the use of these plants may simultaneously improve pasture quality and reduce the pasture contamination of larval ticks if high legume-to-grass ratios are achieved. *Brachiaria brizantha* has also been shown to be lethal to *Boophilus* larvae.

Vaccination

Crude vaccines made from extracts of semiengorged adult female *B. microplus* give effective immunity. The antibody destroys the cells lining the tick's midgut and allows blood to escape into the hemocele; some ticks die, and the fertility of those remaining is reduced by up to 70%. The fertility of males is also reduced. A recombinant vaccine based on a membrane-bound glycoprotein Bm86 from the tick's midgut has been isolated and was shown to be as effective as the native antigen in studies conducted between 1993 and 1997,[2] and to be effective against acaricidal-resistant ticks. Its major effect is a progressive control in tick numbers in successive generations through a decrease in their reproductive capacity.[2] Because the vaccine acts against an antigen in the tick's gut to which cattle are never exposed, they must be given booster injections at regular intervals. This was the first recombinant parasite vaccine sold commercially (TickGARD) and was initially marketed in 1994 in Australia.[3] A second antigen that significantly enhances efficacy and does not impair the response to Bm86has now been added to the vaccine,[4,5] which is currently available in one commercial formulation (Gavac) in North and South America.[3] Although vaccines offer long-term control, they need to be used with application of acaricides, use of tick-resistant cattle, and pasture management as part of an integrated pest management control system.

Integrated management of tick infestations requires the use of several complementary approaches to reduce populations below acceptable thresholds. One component of these strategies is the development of acaricidal pathogens that may augment other approaches such as vaccination and selective acaricide application. Fungal pathogens are under evaluation for use in this type of program, in particular *Metarhizium anisopliae* and *Beauvaria bassiana.*

ERADICATION

In most countries all that is attempted is reduction of the tick population by periodic dipping or spraying. Complete eradication is extremely difficult because of the persistence of ticks, especially multihost ticks, on wild fauna and the ability of adult ticks to live for very long periods away from a host. On the other hand, continuous treatment to restrain the tick population is highly conducive to the development of resistance, a problem that has become apparent in many tick areas.

Boophilus annulatus was eradicated from the southeastern United States by a program of continuous dipping at short intervals of all livestock in the area. *B. microplus* was also eradicated from Florida by a similar procedure, but 20,000 deer, the important alternate host in the area, had to be slaughtered. Concern has been expressed that deer and other wildlife species may threaten efforts to prevent *B. microplus* and *B. annulatus* from becoming reestablished in the southern United States after they are introduced from Mexico. Attempts to eradicate other single-host ticks in other countries generally have not been successful.

Although both dipping and spraying are recommended for the control of ticks, complete wetting of the animals, which can only be effected by dipping, is essential if eradication is to be undertaken. This adds another impediment to eradication plans because of the cost of constructing proper dips and yards. When one considers that dipping may have to be carried out every 14 days for 15 months, that every animal in the eradication area must be dipped, and that a strict quarantine of the area must be maintained, it is obvious that eradication cannot be undertaken lightly.

Deficiencies and Toxicities Affecting the Skin

ZINC DEFICIENCY (PARAKERATOSIS)

SYNOPSIS

Etiology Dietary deficiency of zinc and factors that interfere with zinc absorption or utilization.

Epidemiology Growing pigs, cattle, and sheep. Excess of calcium favors disease in pigs.

Signs

Pigs Loss of body weight gain. Symmetric, crusty skin lesions (parakeratosis) over dorsum and ears, tail; become thick and fissured. No pruritus.

Ruminants Alopecia over muzzle, ears, tail head, hindlegs, flank, and neck. Stiff gait and swelling over coronets. Loss of wool and thickened skin in sheep. Infertility in rams. Poor growth in goats and skin lesions.

Clinical pathology Serum zinc concentrations lower than normal.

Necropsy findings Parakeratosis.

Diagnostic confirmation Histology of skin lesions and serum zinc levels.

Differential diagnosis list Sarcoptic mange in cattle and pigs. Exudative epidermitis in piglets.

Treatment Add zinc to diet.

Control Supplement zinc in diet.

ETIOLOGY

Pigs

A zinc deficiency in young, growing pigs can cause parakeratosis, but it is sometimes not a result of a simple zinc deficiency. Rapidly growing pigs have a high requirement for zinc in the diet.[1] The availability of zinc in the diet is adversely affected by the presence of phytic acid, a constituent of plant protein sources such as soybean meal. Much of the zinc in plant protein is in the bound form and unavailable to the monogastric animal such as the pig. The use of meat meal or meat scraps in the diet will prevent the disease because of the high availability of the zinc. Another unique feature of the etiology of parakeratosis in swine is that an excess of dietary calcium (0.5% to 1.5%) can favor the development of the disease, and the addition of zinc to such diets at levels much higher (0.02% zinc carbonate or 100 mg/kg zinc) than those normally required by growing swine prevents the occurrence of the disease. The level of copper in the diet may also be of some significance, with increasing copper levels decreasing the requirement for zinc. A concurrent enteric infection with diarrhea exacerbates the damage done by a zinc deficiency in pigs.

Weaning can induce transient declines in the serum zinc concentration of piglets, and this can be prevented by oral supplementation with zinc oxide.[2] The clinical importance of this decline is unclear.

Ruminants

A primary zinc deficiency resulting from low dietary zinc in ruminants is rare but does occur. Many factors influence the availability of zinc from soils, including the degree of compaction of the soil and the nitrogen and

phosphorus concentration. The risk of zinc deficiency increases when soil pH rises above 6.5 and as fertilization with nitrogen and phosphorus increases. Some legumes contain less zinc than grasses grown on the same soil, and zinc concentration decreases with aging of the plant. Several factors may deleteriously affect the availability of zinc to ruminants and cause a secondary zinc deficiency. These include the consumption of immature grass, which affects digestibility; the feeding of late-cut hay, which may be poorly digestible; and the presence of excessive dietary sulfur. The contamination of silage with soil at harvesting can also affect the digestibility of zinc.

EPIDEMIOLOGY

Pigs

Parakeratosis in pigs was first recorded in North America in rapidly growing pigs, particularly those fed on diets containing growth promoters. The disease occurs most commonly during the period of rapid growth, after weaning and between 7 and 10 weeks of age. From 20% to 80% of pigs in affected herds may have lesions, and the main economic loss is a result of a decrease in growth rate. In general, the incidence is greater in pigs fed in dry lots on self-feeders of dry feed than in pigs with access to some pasture, which is preventive and curative.

A low level of dietary zinc intake during pregnancy and lactation of gilts can result in skin lesions, stressful parturition, and an increased incidence of intrapartum mortality of piglets and deleterious effects on neonatal growth.

It has been suggested that parakeratosis occurs because very rapidly growing pigs outstrip their biosynthesis of essential fatty acids, and when the diet is high in calcium the digestibility of fat in the diet is reduced at the same time. The net effect in rapidly growing pigs could be a relative deficiency of essential fatty acids.

Ruminants

There are naturally occurring cases in cattle, sheep, and goats. The disease is well recognized in Europe, especially in calves. It is common in some families of cattle, and an inherited increased dietary requirement for zinc is suspected. The inherited disease occurs in Friesian and Black Pied cattle and is known as lethal trait A46. Signs of deficiency appear at 4 to 8 weeks of age. The main defect is an almost complete inability to absorb zinc from the intestine; zinc administration is curative.

The disease in **cattle** has been produced experimentally on diets low in zinc, and naturally occurring cases have responded to supplementation of the diet with zinc. Calves remain healthy on experimental diets containing 40 mg/kg zinc, but parakeratosis has occurred in cattle grazing pastures with a zinc content of 20 to 80 mg/kg (normal 93 mg/kg) and a calcium content of 0.6%. There is also an apparently improved response in cattle to zinc administration if copper is given simultaneously. Parakeratosis has also been produced experimentally in goats and sheep.

Zinc nutrition may be involved in the immune responses of feedlot calves. When calves are stressed by transportation or challenged with the infectious bovine rhinotracheitis virus, they tend to have reduced fevers, higher dry matter intake, and less body weight loss when fed organic zinc and manganese sources than the corresponding oxide forms.

Outbreaks of the disease have occurred in **Sudanese Desert ewes** and their lambs fed on a zinc-deficient diet of Rhodes grass containing less than 10 mg/kg of zinc. The disease has also been diagnosed in **mature sheep and goats,** and the cause of the deficiency could not be determined. A marginal zinc deficiency, characterized by subnormal growth and fertility and low concentration of zinc in serum, but without other clinical signs, can occur in sheep grazing pastures containing less than 10 mg/kg zinc.

In Germany, skin lesions have occurred in alpacas and llamas with low-zinc and low-copper status. In the affected herd, the average serum zinc and copper levels were 0.17 and 0.49 µg/mL for alpacas and 0.22 and 0.38 µg/mL for llamas, respectively. The levels considered normal in llamas are 0.30 µg for zinc and 0.40 to 0.70 µg copper per mL.

PATHOGENESIS

The pathogenesis of zinc deficiency is not well understood. Zinc is a component of the enzyme carbonic anhydrase, which is located in the red blood cells and parietal cells of the stomach, and is related to the transport of respiratory carbon dioxide and the secretion of hydrochloric acid by the gastric mucosa. Zinc is also associated with RNA function and related to insulin, glucagon, and other hormones. It also has a role in keratinization, calcification, wound healing, and somatic and sexual development. Because it has a critical role in nucleic acid and protein metabolism, a deficiency may adversely affect the cell-mediated immune system.

Zinc and vitamin A deficiency can occur together, with complex interactions between the compounds affecting liver metabolism of vitamin A.[3] Zinc deficiency impairs vitamin A mobilization from the liver.

A zinc deficiency results in a decreased feed intake in all species and is probably the reason for the depression of growth rate in growing animals and body weight in mature animals. Failure of keratinization resulting in parakeratosis, loss and failure of growth of wool and hair, and lesions of the coronary bands probably reflects the importance of zinc in protein synthesis. There are lesions of the arteriolar walls of the dermis. The bones of zinc-deficient ruminants reveal abnormal mineralization and a reduction of zinc concentration in bones and cartilage and should be considered in animals with evidence of chondrodysplasia.[4] Retarded testicular development occurs in ram lambs, and complete cessation of spermatogenesis suggests impairment of protein synthesis.

CLINICAL FINDINGS

Pigs

A reduced rate and efficiency of body weight gain is characteristic. Circumscribed areas of erythema appear in the skin on the ventral abdomen and inside the thigh. These areas develop into papules 3 to 5 mm in diameter, which are soon covered with scales, followed by thick crusts. These crusts are most visible in areas about the limb joints, ears, and tail and are distributed symmetrically in all cases. The crusts develop fissures and cracks, become quite thick (5 to 7 mm), and are easily detached from the skin. They are crumbly and not flaky or scaly. No greasiness is present except in the depths of fissures. Little scratching or rubbing occurs. Diarrhea of moderate degree is common. Secondary subcutaneous abscesses occur frequently, but in uncomplicated cases, the skin lesions disappear spontaneously in 10 to 45 days if the ration is corrected. Affected boars have testicular abnormalities that impair fertility.[5]

Ruminants

In the naturally occurring disease in cattle, in severe cases, parakeratosis and alopecia may affect about 40% of the skin area. The lesions are most marked on the muzzle, vulva, anus, tailhead, ears, backs of the hindlegs, kneefolds, flank, and neck. Most animals have below-average body condition and are stunted in growth. After treatment with zinc, improvement is apparent in 1 week and complete in 3 weeks. Experimentally produced cases exhibit the following signs:

- Poor growth
- A stiff gait
- Swelling of the coronets, hocks, and knees
- Soft swelling containing fluid on the anterior aspect of the hind fetlocks
- Alopecia
- Wrinkling of the skin of the legs, scrotum, and neck and head, especially around the nostrils
- Hemorrhages around the teeth
- Ulcers on the dental pad

The experimental disease in cattle is manifested by parakeratotic skin, mainly on the hindlimbs and udder, and similar lesions on teats, which tend to become eroded during milking. The fetlocks and pasterns are covered with scabby scales. There is exudation first with matting of hair, then drying and cracking. The skin becomes thickened and inelastic. Histologically, there is

parakeratosis. Clinical signs develop about 2 weeks after calves and lambs go onto a deficient diet so that there is no evidence of storage of zinc in tissues in these animals. In goats, hair growth, testicular size, and spermatogenesis are reduced, and growth rate is less than normal. Return to a normal diet does not necessarily reverse these signs, and the case-fatality rate is high. There is a marked delay in wound healing.

Zinc deficiency increases the risk of mastitis in dairy cows, potentially because of adverse alterations in mammary duct epithelium.[6] Deficiency is associated with increased somatic-cell numbers in milk, decreased thickness of stratum corneum in ductus papillaris, and increased leukocyte infiltration of udder parenchyma.[6]

Inherited zinc deficiency in cattle (lethal trait A46), which is caused in Holstein–Friesian cattle by a splice-site variant in SLC39A4, is described under the heading "Inherited Parakeratosis of Calves" later in this chapter.[7] An inherited syndrome in Fleckvieh cattle with similar phenotype is not a result of zinc deficiency, and it does not have the same genetic abnormality.[8]

Sheep

The natural disease in sheep is characterized by loss of wool and the development of thick, wrinkled skin. Wool-eating also occurs in sheep and may be one of the earliest signs noticed in lambs after being on a zinc-deficient diet for 4 weeks. Induced cases in lambs have exhibited reduced growth rate, salivation, swollen hocks, wrinkled skin, and open skin lesions around the hoof and eyes. The experimental disease in goats is similar to that in lambs.

One of the most striking effects of zinc deficiency in **ram lambs** is impaired testicular growth and complete cessation of spermatogenesis. Diets containing 2.44 mg/kg dry matter (DM) caused poor growth, impaired testicular growth, cessation of spermatogenesis, and other signs of zinc deficiency within 20 to 24 weeks. A diet containing 17.4 mg/kg DM of zinc is adequate for growth, but a content of 32.4 mg/kg DM is necessary for normal testicular development and spermatogenesis. On severely deficient experimental diets, other clinical signs in young rams are as follows:

- Drooling copious amounts of saliva when ruminating
- Parakeratosis around eyes and on nose, feet, and scrotum
- Shedding of the hooves
- Dystrophy and shedding of wool, which showed severe staining
- Development of a pungent odor

In naturally occurring cases in rams, the animals stood with their backs arched and feet close together.

A marginal zinc deficiency in ewes may be characterized by only a reduction in feed intake and a slightly reduced body weight, and no other external signs of disease. This is important because, in grazing ruminants, the lack of external signs indicates that zinc deficiency could easily pass undetected.

Infertility in Ewes

Infertility in ewes and a dietary deficiency of zinc have not been officially linked, but a zinc-responsive infertility has been described in ewes. Again, attention is drawn to the need for response trials when soil and pasture levels of an element are marginal.

An **experimental zinc deficiency in pregnant ewes** results in a decrease in the birth weight of the lambs and a reduced concentration of zinc in the tissues of the lambs; these effects are a result of the reduced feed intake characteristic of zinc deficiency. The zinc content of the diet did not significantly influence the ability of the ewes to become pregnant or maintain pregnancy. The combination of pregnancy and zinc deficiency in the ewe leads to highly efficient utilization of ingested zinc, and the developing fetus will accumulate about 35% of the total dietary intake of zinc of the ewe during the last trimester of pregnancy. The disease is correctable by the supplementary feeding of zinc.

Goats

Experimentally induced zinc deficiency in goats results in poor growth, low food intake, testicular hypoplasia, rough dull coat with loss of hair, and the accumulation of hard, dry, keratinized skin on the hindlimbs, scrotum, head, and neck. On the lower limbs the scabs fissure, crack, and produce some exudate. In naturally occurring cases in pygmy goats there was extensive alopecia, a kyphotic stance, extensive areas of parakeratosis, abnormal hoof growth, and flaky, painful coronary bands. A zinc-responsive alopecia and hyperkeratosis occurs in Angora goats. Affected animals had recurrent pruritus; hyperemia; exfoliation, fleece loss over the hindquarters, face, and ears; and a decline in reproductive performance. Zinc supplementation (40 or 80 mg/d) increases rate of fleece growth, plasma testosterone concentrations, and serum alkaline phosphatase activity in Cashmere goats.[9]

Immediately before parturition in cows, there is a precipitate fall in plasma zinc concentration, which returns to normal slowly after calving. The depression of zinc levels is greater in cows that experience dystocia. This has led to the hypothesis that dystocia in beef heifers may be caused in some circumstances by a nutritional deficiency of zinc and that preparturient supplementation of the diet with zinc may reduce the occurrence of difficult births. This phenomenon does not appear to occur in sheep. The level of serum zinc increases in cattle during the season of facial eczema when sporidesmin intoxication causes depletion of liver zinc.

CLINICAL PATHOLOGY

Skin Scraping

Laboratory examination of skin scrapings yields negative results, but skin biopsy will confirm the diagnosis of parakeratosis.

Zinc in Serum and Hair

Serum zinc levels may have good diagnostic value. Normal levels are 80 to 120 µg/dL (12.2 to 18.2 µmol/L) in sheep and cattle. Calves and lambs on deficient diets may have levels as low as 18 µg/dL (3.0 µmol/L). Dairy cattle with serum zinc less than 9.7 µmol/L are at increased risk of changes that predispose to mastitis.[6]

Normal serum zinc levels in sheep are above 78 µg/dL (12 µmol/L), and values below 39 µg/dL (6 µmol/L) or less are considered as evidence of deficiency. There is a general relationship between the zinc content of the hair and the level of zinc in the diet, but the analysis of hair is not considered to be a sufficiently accurate indicator of an animal's zinc status. In experimental disease in piglets, there is a reduction in serum levels of zinc, calcium, and alkaline phosphatase, and it is suggested that the disease could be detected by measuring the serum alkaline phosphate and serum zinc levels. Levels of zinc in the blood are very labile, and simple estimations of levels alone are likely to be misleading. For example, other intercurrent diseases commonly depress serum calcium and copper levels. In addition, zinc levels in plasma fall precipitately at parturition in cows; they are also depressed by hyperthermal stress. After 1 week on a highly deficient diet, serum zinc levels fall to about 50% of normal, or pretreatment, levels.

NECROPSY FINDINGS

Necropsy examinations are not usually performed, but histologic examination of skin biopsy sections reveals a marked increase in thickness of all the elements of the epidermis. Tissue levels of zinc differ between deficient and normal animals, but the differences are statistical rather than diagnostic.

DIFFERENTIAL DIAGNOSIS

Sarcoptic mange may resemble parakeratosis, but is accompanied by much itching and rubbing. The parasites may be found in skin scrapings. Treatment with appropriate parasiticides relieves the condition.

Exudative epidermitis is quite similar in appearance, but occurs chiefly in unweaned pigs. The lesions have a greasy character that is quite different from the dry, crumbly lesions of parakeratosis. The mortality rate is higher.

TREATMENT

In outbreaks of parakeratosis in swine, zinc should be added to diet immediately at the rate of 50 mg/kg DM (200 mg of zinc sulfate or carbonate per kg of feed). The calcium

level of the diet should be maintained at between 0.65% and 0.75%. The injection of zinc at a rate of 2 to 4 mg/kg BW daily for 10 days is also effective.

Zinc oxide suspended in olive oil and given IM at a dose of 200 mg of zinc for adult sheep and 50 mg of zinc for lambs will result in a clinical cure within 2 months. The oral administration of zinc at the rate of 250 mg zinc sulfate daily for 4 weeks resulted in a clinical cure of zinc deficiency in goats in 12 to 14 weeks.

CONTROL

Pigs

The calcium content of diets for growing pigs should be restricted to 0.5% to 0.6%. However, rations containing as little as 0.5% calcium and with normal zinc content (30 mg/kg DM) may produce the disease. Supplementation with zinc (to 50 mg/kg DM) as sulfate or carbonate has been found to be highly effective as a preventive, and there appears to be a wide margin of safety in its use, with diets containing 1000 mg/kg DM added zinc having no apparent toxic effect. Organic and inorganic zinc supplements are handled differently by pigs, with organic forms of zinc being more bioavailable.[1] Rapidly growing pigs require 75 mg/kg of organic zinc in a complex nursery diet to maximize growth, health, and well-being.[1] The standard recommendation is to add 200 g of zinc carbonate or sulfate to each ton of feed. Weight gains in affected groups are appreciably increased by the addition of zinc to the diet. The addition of oils containing unsaturated fatty acids is also an effective preventive. Access to green pasture, reduction in food intake, and the deletion of growth stimulants from rations will lessen the incidence of the disease but are not usually practicable.

Ruminants

For cattle, the feeding of zinc sulfate (2 to 4 g daily) is recommended as an emergency measure followed by the application of a zinc-containing fertilizer. As an alternative to dietary supplementation for ruminants, an intraruminal pellet has been demonstrated in sheep. It was effective for 7 weeks only and would not be satisfactory for long-term use. The creation of subcutaneous depots of zinc by the injection of zinc oxide or zinc metal dust has been demonstrated. The zinc dust offered a greater delayed effect. A soluble glass bolus containing zinc, cobalt, and selenium was able to correct experimentally induced zinc deficiency in sheep. The bolus supplied the daily requirement of the sheep for zinc with no detrimental effect on their copper status, although high-dose zinc supplementation does impair copper absorption in cattle that are provided additional copper in the diet.[10]

Zinc-methionine, an organic zinc supplement for dairy goats, improved udder health, an enhanced the absorption of nitrogen, and increased nitrogen retention. Recommended dietary intake of zinc for Cashmere goats is 86 mg/kg DM during the breeding season and cashmere-fiber growing period.[9]

PLANT POISONING ASSOCIATED WITH KNOWN TOXINS

DIANTHRONE DERIVATIVES

Hypericin, a complex derivative of dianthrone, is found in *Hypericum perforatum* (St. John's wort or Klamath weed) and *Hypericum triquetrifolium* and is the prototypical primary photosensitizing agent.[1] All parts of these plants are associated with photosensitive dermatitis when ingested by sheep and cattle, but they have to be eaten in large quantities. They are not very palatable, and most outbreaks occur when they are in the young stage and dominate the pasture. Narrow-leaf varieties contain 2 or 3 times as much hypericin as broadleaf varieties, and the flowering tops are 6 to 9 times as toxic as other parts. Clinical signs may appear within a few days of livestock going onto affected fields and usually disappear within 1 to 2 weeks after removal from them. Experimental production of poisoning with *H. perforatum* has shown that the plant contains a primary photodynamic agent. There is neither liver damage nor loss of hepatic function.

FAGOPYRIN

Fagopyrin, a red helianthrone pigment found in *Fagopyrum sagittatum* (buckwheat), is associated with primary photosensitization in all species.

FUROCOUMARIN

Plants containing furocoumarins (including psoralens) include the following:

- *Ammi majus*—bishop's weed, meadow sweet
- *Ammi visnaga*—visnaga
- *Cooperia pedunculata*—thunder lily
- *Cymopterus longipes*
- *Cymopterus watsonii*—wild or spring parsley
- *Heracleum mantegazzianum*—giant hogweed
- *Petroselinum* spp.—parsley
- *Thamnosma texana*—Dutchman's breeches, blister weed

Similar furocoumarins, identified as 4,5,8-trimethylpsoralen, 5-methoxypsoralen, and 8-methoxypsoralen, are also present in *Pastinaca sativa* (parsnip root) infested with the fungus *Ceratocystis fimbriata*, and *Apium graveolens* (celery) infested with *Sclerotinia* spp. (pink-rot fungus). These toxins have the particular characteristic of being photosensitizing by contact, without the need for ingestion, and are associated with serious lesions in humans. *A. majus* is most poisonous to livestock when there are ripe seeds in the seedheads. Its most serious occurrence is as a contaminant in hay. *C. pedunculata*, a perennial forb of western range country in the United States, occurs at times of high humidity or after rain has wet the foliage, and the live as well as dead leaves are toxic.

The clinical syndrome associated with plants containing furocoumarins is one of photosensitizing dermatitis. It includes severe cutaneous dermatitis, sometimes as severe as cutaneous gangrene, on the white parts of the skin on the dorsal and lateral sides of the body and edema of the head and ears, the lateral aspects of the teats, the unpigmented conjunctivae, the muzzle and the oral mucosa inside the lower lip, and the undersurface of the tip of the tongue. Photosensitive dermatitis in pigs may be associated with distinctive vesicles on the snout and raise a false alarm of viral vesicular disease. One serious international incident arose out of a feeding of moldy parsnips.

PLANT POISONINGS ASSOCIATED WITH UNIDENTIFIED TOXINS

DERMATITIS

- *Entandrophragma cylindricum*—redwood; shavings as bedding associated with balanoposthitis in rams
- *Excoecaria* spp.
- *Heracleum mantegazzianum*—cow parsnip
- *Vicia benghalensis*—popany vetch; associated with dermatitis, conjunctivitis, rhinitis, fever, and multiple eosinophilic granulomas in many organs[1]
- *Vicia dasycarpa*—woolly pod vetch; same symptoms as *V. benghalensis*
- *Vicia villosa*—hairy vetch; same signs as *V. benghalensis*.

PHOTOSENSITIZATION—PRIMARY; WITHOUT HEPATIC LESIONS

- *Echinochloa utilis*—Japanese millet
- *Erodium cicutarium*—storksbill
- *Froelichia humboldtiana*[2]
- *Holocalyx glaziovii*
- *Lachnanthes tinctoria*
- *Mentha satureioides*
- *Sphenosciadium capitellatum*
- *Medicago polymorpha*—burr trefoil
- *Verbena* spp.

Photodermatitis associated with *M. polymorphia* and *F. humboldtiana* occurs in all animal species on pasture dominated by the plant, usually in the spring. Lesions on the unpigmented parts of the skin disappear quickly when animals are taken off the pasture; there is no liver damage or permanent after-effects.[2] Aphids, which commonly infest the plant in very large numbers, contain large amounts of a photodynamic agent and may be important in some outbreaks of the disease.

SELENIUM TOXICOSIS

SYNOPSIS

Etiology Ingestion of plants or feed supplements or injection of pharmaceutical agents with excessive amounts of selenium.

Epidemiology Enzootic disease where soils and pasture contain toxic amounts of selenium; outbreaks after errors in feed supplementation or oral or injection doses.

Clinical pathology: Elevated concentration of selenium in body tissues and fluids.

Lesions:

Living Animals:
Acute: dyspnea, diarrhea, prostration, short course, death.
Chronic: emaciation, rough coat, stiff gait, lame, hoof deformity.

Postmortem:
Acute: evidence of cardiovascular compromise, hemorrhages.
Chronic: skeletal and cardiac myopathies.

Diagnostic confirmation: Elevated selenium levels in body fluids and tissues.

Treatment: None; avoid pastures with selenium-containing plants; take care with medication and feed additives containing selenium.

ETIOLOGY

Selenium toxicosis in animals is a worldwide problem, either as an acute or chronic poisoning. It is associated with the ingestion or injection of organic or inorganic selenium compounds as follows:

- Inorganic selenium compounds administered as feed supplements
- Organic selenocompounds (selenomethionine and methylselenocysteine) occurring in pasture plants[1-2]
- Pharmaceutical preparations administered orally or by injection, frequently combined with vitamin E[3]

Discrepancies exist in the toxic doses quoted in the literature, and the reasons for this are not fully understood. Identified animal factors include species, age, health, reproductive status, and nutritional status.[4] Other factors include dose, route of administration, and interactions with other dietary substrates.[3] The daily intake of a diet containing 2 mg/kg BW of selenium can be marginally toxic for sheep, yet pregnant and lactating ewes tolerated doses as high as 12 mg dietary selenium (as sodium selenite) per kilogram of BW for 72 weeks without developing any clinical or pathologic signs of selenium toxicosis.[5] Oral ingestion of 1 to 2.2 mg of Se/kg BW as sodium selenite caused mortality in lambs, but other lambs have survived doses of 4 mg/kg BW.[6,7] Feed containing 44 mg/kg selenium for horses and 11 mg/kg for pigs is associated with poisoning. Toxic single acute oral doses (as mg/kg BW) are 2.2 for sheep, 1.49 for horses,[3] 9 for cattle, and 15 for pigs.

EPIDEMIOLOGY

Occurrence

Pastoral

Selenium poisoning occurs in restricted areas in North America, Ireland, Israel, Canada, Australia, and South Africa where the soils are derived from particular rock formations containing a high content of selenium. The high level in these plants occurs from the high levels of selenium found naturally in the environment.

High levels of selenium in plants can also be found in areas where the soil is not naturally high in selenium. This is associated with industrial or commercial release of selenium into the water and soil.

Dosing Errors

Substantial losses as a result of selenium poisoning also occur because of misunderstanding about the dose rates of selenium compounds used therapeutically or prophylactically.

Risk Factors

Animal Risk Factors

Cattle are more tolerant than sheep. Pigs are unlikely to be exposed but can develop the disease in the field. Young animals are less tolerant than adults.

Dietary supplementation is used in the prevention of known deficiency syndromes such as white muscle disease in lambs, as a nonspecific growth stimulant, and as a prophylactic for a large number of other vague syndromes. The concurrent administration of monensin and selenium increases the toxicity of the selenium being fed. There are many case reports of unexpected illness and mortality in animals dosed with selenium preparations, and it is apparent that not all of the factors affecting selenium toxicity are known.

Organic selenium compounds, especially those occurring naturally in plants, may be more toxic than inorganic compounds, but this difference may not be apparent in ruminants because of alterations in ingested compounds produced by digestive processes in the rumen.[4] Selenite is more toxic than selenate, and both are more damaging than selenium dioxide.

Environmental Risk Factors

Industrial deposition (e.g., fly ash from soft coal deposited in fields) has been shown to be associated with increased selenium levels in tissues from sheep grazing there.

Farm Risk Factors

Selenium poisoning in animals grazing plants growing on seleniferous soils may be restricted to very distinct areas as small as individual fields. A low rainfall predisposes to selenium poisoning because soluble, available selenium compounds are not leached out of the topsoil, and lack of competing forage may force animals to eat large quantities of selenium-containing plants.

The effective selenium is contained in the top 60 to 90 cm of the soil profile, selenium at lower levels than this not being within reach of most plants. Selenium poisoning may occur on soils containing as little selenium as 0.01 mg/kg, but some soils may contain as much as 1200 mg/kg. Most pasture plants seldom contain selenium in excess of 100 ppm, but a number of species, the so-called converter or indicator plants, take up the element in such large quantities that selenium levels may reach as high as 10,000 ppm. Included in this category are *Acacia cana*; *Artemisia canescens*; *Aster* spp.; some of the *Astragalus*, *Atriplex*, and *Castilleja* spp.; *Comandra pallida*; *Descurainia pinnata*; *Grindelia* spp.; *Machaeranthera ramosa*; *Morinda reticulata*; *Neptunia amplexicaulis*; *Oonopsis*, *Penstemon*, and *Sideranthus* spp.; *Stanleya pinnata*; and *Xylorrhiza* spp.

These plants tend to grow preferentially on selenium-rich soils and are thus "indicator" plants. They are in general unpalatable because of a strong odor, and thus an acute syndrome is unlikely, but heavy losses have been attributed in the past to a chronic form of the disease known as alkali disease.

PATHOGENESIS

Ingested selenium compounds are absorbed primarily in the duodenum, with some absorption in the remainder of the small intestine. Little, if any, absorption occurs in the rumen. The mechanism of absorption varies depending on the specific form of selenium, with selenite absorption by passive transfer and selenomethionine and selenocysteine by active transport.[1,2] Tissue distribution also depends on the form of selenium, with the kidney and liver ultimately having the highest concentration of selenium. Placental transfer occurs, especially in the last trimester; little is excreted in the milk.[5] Metabolism occurs in the red blood cells and liver; excretion is primarily through urine, with a small amount of

metabolized selenium excreted in the bile and feces.[1]

The mechanism of action is not well understood, and several different theories have been proposed.[3] Selenium occurs in plants in analogs of the sulfur-containing amino acids (e.g., selenocysteine), and a possible mechanism of intoxication is by interference with enzyme systems that contain these amino acids. Other proposed mechanisms include generation of free radicals, causing oxidative tissue damage, and incorporation into proteins, causing disruption of normal cell function.[3,4]

CLINICAL FINDINGS

Acute Poisoning

In naturally occurring and experimental poisoning there is severe respiratory distress, restlessness, complete anorexia, salivation, watery diarrhea, fever, tachycardia, abnormal posture and gait, prostration, and death after a short illness. Acutely poisoned horses showed marked central nervous system (CNS) signs, with ataxia and excitation, sweating, pyrexia, tachycardia, dyspnea, and death within 6 hours.[3] Mildly affected pigs show posterior ataxia, walking on tiptoe, difficulty in rising, sternal recumbency, tremor, and vomiting in some. Extreme cases assume a posture of lateral recumbency.

Chronic Poisoning

Chronic poisoning is manifested by dullness, emaciation, rough coat, lack of vitality, stiffness, and lameness. In cattle, horses, and mules the hair at the base of the tail and switch is lost, and in pigs, goats, and horses there may be general alopecia. There are hoof abnormalities, including swelling of the coronary band and deformity or separation and sloughing of the hooves, in all species. Lameness is severe. Congenital hoof deformities may occur in newborn animals. Hemorrhagic lesions on the proximal wall and soles of claws on all four feet may accompany these deformities. Chronic poisoning in pigs on rations containing 20 to 27 mg/kg is also associated with a syndrome of reduced feed intake and paraplegia and quadriplegia as a result of poliomyelomalacia. Pigs on marginal levels of intake of selenium (10 mg/kg) develop necrosis of the coronary band, low conception rates, and increased neonatal mortality.

CLINICAL PATHOLOGY

A moderate anemia occurs in acute and chronic poisoning, and a depression of hemoglobin levels to about 7 g/dL is one of the early indications of selenium poisoning. Selenium can be detected in the urine, milk, and hair of affected animals. Clinical illness is evident at blood levels of 3 mg/kg and at urine levels of more than 4 mg/kg of selenium. Normal serum levels of 140 to 190 ng/mL are elevated to the level of 1500 ng/mL.

Critical levels of selenium in hair include the following:

- Less than 5.0 mg/kg suggests that chronic selenosis is unlikely.
- From 5.0 to 10.0 mg/kg suggests borderline problems.
- More than 10 mg/kg is diagnostic of chronic selenosis.

NECROPSY FINDINGS

Acute

In confirmed cases of natural or experimentally produced acute selenium poisoning, most of the macroscopic findings can be attributed to cardiovascular compromise. There is pulmonary edema and congestion, petechiation of the thoracic viscera, and congestion of the liver, kidneys, and gastrointestinal tract. In parenterally overdosed lambs and piglets there is usually hydrothorax, hydropericardium, and ascites.

Histologic lesions may be minimal if the clinical course is brief. Changes that may be observed in animals surviving more than 24 hours include a serous effusion within pulmonary alveoli, mild hyaline or granular degeneration of skeletal muscle fibers, hydropic degeneration in renal tubular epithelial cells, and periacinar degeneration and necrosis of hepatocytes. Cardiac myocytes may appear swollen and contain areas of cytoplasmic granularity and lysis.

Chronic

In animals suffering from subacute to chronic selenium poisoning there is a skeletal and cardiac myopathy. Deformities of the feet and skin are usually apparent. Atrophy and dilatation of the heart and pulmonary edema, cirrhosis and atrophy of the liver, glomerulonephritis, mild gastroenteritis, and erosion of articular surfaces have also been recorded.

Symmetric poliomyelomalacia has been identified in both natural and experimental settings in pigs fed excessive selenium. The areas primarily affected are the ventral horns of the cervical and lumbar enlargements, with lesser damage in brainstem nuclei. The microscopic appearance of affected spinal cord includes vacuolation of the neuropil and sometimes of the cytoplasm of neurons. Neuronal chromatolysis, axonal swelling, and endothelial cell swelling and proliferation are consistently present.

Samples for Confirmation of Diagnosis

- **Toxicology**—50 g liver, kidney; 500 g of suspect feed (ASSAY [Se])
- **Histology**—formalin-fixed skeletal muscle, heart, liver, kidney, +/– spinal cord from cervical and lumbar enlargements (LM)

Selenium Levels in Tissue. In chronic selenosis in sheep, hepatic and renal levels of selenium are about 20 to 30 mg/kg, and levels in wool are in the range of 0.6 to 2.3 mg/kg. In horses, hair levels of more than 5 mg/kg are recorded.

The diagnosis of selenium poisoning rests largely on the recognition of the typical syndromes in animals in areas where the soil content of selenium is high or when there has been administration of selenium as medication or as a feed additive. The clinical and necropsy lesions associated with the poisoning cover a wide range of signs, and lesions and are not easily summarized. Diagnostic confirmation depends on an assay of toxic levels of selenium in body tissues or fluids.

DIFFERENTIAL DIAGNOSIS

Differential diagnostic list:

Acute poisoning

- Acute arsenic toxicosis
- Anaphylaxis
- Ionophores/tiamulin in swine
- Septicemia
- Toxemia

Chronic poisoning

- Hypovitaminosis A
- Laminitis
- Sodium chloride toxicosis

TREATMENT

A number of substances have been tried in the treatment of selenium poisoning, including potassium iodide, ascorbic acid, and beet pectin, but without apparent effect. The use of BAL is contraindicated.

CONTROL

Selenium in feeds should not exceed 5 mg/kg dry matter if danger is to be avoided, and feeding on pasture containing 25 mg/kg dry matter for several weeks can be expected to be associated with chronic selenium poisoning. Pasture may contain as much as 2000 to 6000 mg/kg of selenium and is associated with the acute form of the disease when fed for a few days.

Protection against the toxic effects of selenium in amounts up to 10 mg/kg in the diet has been obtained by the inclusion in the ration fed to pigs of 0.01% to 0.02% of arsanilic acid or 0.005% of 3-nitro-4-hydroxyphenyl arsonic acid. In cattle, 0.01% arsanilic acid in the ration or 550 mg/day to grazing steers gives only slight protection. The addition of linseed oil to the ration improves the efficiency of this protection. A high-protein diet also has a general protective effect.

When using selenium as a pharmaceutical agent, strict attention should be paid to the recommended dose and route of administration.

IODINE TOXICOSIS

ETIOLOGY

Iodine is found in low concentrations in nature both as inorganic and organic forms. Common sources of iodine include iodized salt (100 ppm iodine), ethylenediamine dihydroiodide (EDDI), and iodine containing feed additives such as calcium iodate, potassium iodide, and sodium iodine.[1] Potassium iodide, the most water-soluble and chemically unstable form, is the least commonly used product in cattle feed; calcium iodate is the most stable product. Ethylenediamine dihydroiodide is often used to prevent or treat footrot in cattle but has been used in other countries to treat pythiosis in horses.[2]

Poisoning with inorganic iodine products is rarely associated with illness in animals. Excretion in milk and eggs is linear, and the toxic dose is large. As the amount of inorganic iodine ingested increases, so does the amount excreted in milk, with a fairly constant excretion ratio of 8% to 12% iodine.[3] Doses of 10 mg/kg BW daily are usually required to produce fatal illness in calves. There is a special occurrence of goiter in foals when the foal and the dam are fed excessive amounts of iodine, especially when kelp is fed as a dietary supplement. Intakes of 35 to 40 mg iodine/day in a mare can be associated with the development of goiter in her foal.

Toxicity with organic iodides has also occurred at much lower levels of intake (e.g., 160 mg/day per cow) and appears to be a practical risk when cows or calves are fed EDDI constantly as a prophylactic against footrot.

CLINICAL FINDINGS

Clinical signs vary depending on the species and form of iodine. Horses appear to be the most sensitive to iodine toxicosis, followed by ruminants and then pigs.[1,2] In cattle and sheep, signs include heavy dusting of the hair coat with large-sized dandruff scales, hair loss, dryness of the coat, coughing, and profuse nasal discharge.[1] Feed intake and milk production are often decreased. Other common signs in ruminants include lacrimation, hyperthermia, and hypersalivation. Exophthalmos occurs in some cases, and severely affected animals may die of bronchopneumonia. In horses, alopecia and heavy dandruff are characteristic. Anhidrosis, rhabdomyolysis, and exercise intolerance have also been reported.[2]

CLINICAL PATHOLOGY/NECROPSY

Serum iodine levels are elevated above the normal level[3] of 5 µg/100 mL up to 20 to 130 µg/mL.

Most of the postmortem lesions are associated with changes in the respiratory tract, with tracheitis, bronchopneumonia, and pleurisy reported in cattle. Lung tissue shows exudative inflammation, hypertrophy of the bronchial mucous membranes, bronchiole necrosis, and fibrinous exudate in the alveoli. Sheep with iodine toxicosis showed suppurative bronchopneumonia and fibrinous pneumonia.

Cutaneous Neoplasms

PAPILLOMA AND SARCOID

Sarcoid of horses and cutaneous papillomatosis of horses, goats, and cattle are specific diseases (see also "Sarcoid" and "Papillomatosis"). The lesions are characteristically nodular growths of viable tissue and, if there is no traumatic injury, with no discontinuity of the covering epidermis.

Aural flat warts (aural plaques) occur commonly in the horse and are caused by papillomavirus. Blackflies may serve as a vector. Lesions consist of one to several gray or white plaques involving the inner surface of the pinna. Similar lesions may occur around the anus, vulva, and inguinal regions. The lesions are usually asymptomatic, may persist indefinitely, may regress spontaneously, and are refractory to treatment.

SQUAMOUS-CELL CARCINOMA

Squamous-cell carcinoma can occur anywhere on the skin, and also in the mouth and maxillary sinus. Squamous-cell carcinoma in cattle and horses may develop as an uncommon complication of an infection with bovine papillomavirus type 1 and 2.[1] Common types are as follows:

- **Ocular squamous-cell carcinoma (cancer—eye)** is the commonest lesion, on the eyelids and the eyeball in horses and cattle (see also "Bovine Ocular Squamous-Cell Carcinoma" and "Equine Ocular Squamous-Cell Carcinoma")
- **Squamous-cell carcinomas in horses** are the second most common cutaneous neoplasia (after the equine sarcoid) in this species and primarily affect the glans penis and prepuce and the perianal region of aged horses.[2] Squamous-cell carcinoma can cause fatal metastases unless the primary tumor is resected in the early stages. Grossly similar lesions are caused by epithelial hyperplasia, habronemiasis, and squamous papillomata.
- **Vulvar squamous-cell carcinoma** appears frequently in Merino ewes as a result of excessive exposure of vulvar skin to sunlight after radical perineal surgery to help control blow-fly strike. Squamous-cell carcinomas also occur on the vulva of cattle, and a greater incidence has been observed on unpigmented than on pigmented vulvas.
- **Horn cancer** in cattle and rarely in sheep, goats, and buffaloes is a squamous-cell carcinoma arising from the pseudostratified columnar epithelium of the horn core mucosa; it is most prevalent in *Bos indicus* breeds. This tumor affects approximately 1% of the Indian cattle population and accounts for over 80% of reported tumors in Indian cattle. Steers have been reported to be affected more frequently than female animals. In the early stages, affected animals may rub the horns against a fixed object or shake the head frequently. A bloody discharge begins from the nostril on the affected side, or from the base of the horn, and the animal holds its head down and toward one side. The horn becomes loosened and falls off, leaving the tumor exposed to infection and fly infestation. Secondary metastases are common. The high prevalence of metastases in regional lymph nodes and internal organs discourages treatment, but a phenol extract of horn core tissue is immunogenic, and immunotherapy may be a successful treatment technique. Other forms of therapy are also practiced for squamous-cell carcinoma generally, including surgical excision,

preferably by cryotherapy, and radiofrequency hyperthermia.

- **Ear cancer** in sheep is in most cases a squamous-cell carcinoma. The lesion commences around the free edge of the ear and then invades the entire ear, which becomes a large, cauliflower-shaped mass. A high incidence may occur in some flocks. but the cause is not known; the presence of papillomavirus in many aural precancerous lesions suggests that the virus may participate in the etiology.
- **Ovine skin cancer**: A high incidence of epitheliomas has been recorded in some families of merino sheep in Australia. The lesions occur on the woolled skin and are accompanied by many cutaneous cysts. It has been suggested that predisposition to the neoplasm is inherited. Metastasis is common with both epitheliomas and squamous-cell carcinomas.
- "**Brand cancer**," which occurs as a granulomatous mass at the site of a skin fire or freeze brand, is usually considered to be of chronic inflammatory rather than neoplastic origin, but squamous-cell carcinomas are recorded at branding sites in sheep and cattle.
- **In goats**, the perineum is a common site for squamous-cell carcinoma. The udder, ears, and base of the horns may also be affected. Ulceration, flystrike, and matting of hair are unattractive sequelae. A bilaterally symmetric vulvar swelling as a result of ectopic mammary tissue that enlarges at parturition is likely to be confused with squamous-cell carcinoma. Milk can be aspirated from the swellings.

MELANOMA

Melanomas are skin neoplasias commonly occurring in pigs, horses, cattle, small ruminants, and camelids.[1] In horses, between 4% and 15% and in cattle approximately 6% of all tumors were reported to be melanomas.[1-3] In horses, melanomas primarily occur in mature gray- and white-coated horses, reaching a prevalence of over 80% in this subgroup of animals.[4] Although historically melanomas were considered to be benign skin proliferations, more recently the concept of melanoma as a neoplasia with malignant potential has become more accepted. Some sources claim that at least 66% of melanocytic tumors in horses eventually become malignant.[4]

Four types of melanocytic abnormalities are recognized in horses:[2,4]

- **Melanocytic nevi** are seen in younger horses independent of the coat color and are discrete and benign discolorations of the skin. Presence of several nevi is considered a predisposing factor for the development of dermal melanoma.[1]
- **Discrete dermal melanomas** present as single masses, most commonly in typical locations such as the tail, anal, perianal, perineal, and genital region. They are most common in mature gray horses with an average age of 13 years. Although dermal melanomas frequently are benign, malignant forms occur. Surgical excision at early stages is recommended and is curative in most cases.[1,4]
- **Dermal melanomatosis** refers to the occurrence of several dermal melanomas, and it has a high incidence of metastasis. Melanomatosis in general affects horses that are older than 15 years and is not amenable to surgical resection. Visceral metastasis is a not uncommon complication; this type of melanoma is considered to be potentially fatal.[4]
- **Anaplastic malignant melanomas** occur in older nongray horses, with a high incidence of metastasis.

The presentation of discrete dermal melanoma and dermal melanomatosis is referred to as **dermal melanoma.**

PATHOPHYSIOLOGY

Although the initiation of most animal melanomas is still poorly understood, the development of melanomas is epidemiologically linked to mutations generated by both UV-A and UV-B solar radiation. Malignant cells can infiltrate surrounding tissue and metastasize via lymphatic or blood vessels, with regional lymph nodes being the usual first target.[1] A genetic predisposition to the development of melanomas is recognized in Sinclair miniature pigs, Duroc pigs, and Angora goats, which have been proposed as potential models for human melanoma.[1] In horses, the well-recognized connection between gray coat color and the increased risk of melanoma has led to the assumption that specific genetic mutations in gray-coated horses may either predispose to or facilitate the development of melanoma. Presence of multiple melanocytic nevi is considered to increase the risk of melanoma. Melanocytic tumors can also be congenital (see also "Inherited Melanoma").

CLINICAL FINDINGS

Melanomas initially present as single, small, firm, raised nodule with a slow growth rate. They are frequently found incidentally during grooming or routine physical examination. Melanomas may be of any color, ranging from gray or brown to black, red, or even dark blue.[1] Typical locations for melanomas are the perineum, tail base, sheath, commissures of the lips, jugular furrow, and subauricular lymph nodes.[4] Although in many cases tumors may exist for many years without causing any clinical signs, the skin may ulcerate in rapidly growing tumors, leading to secondary bacterial infection. Large masses in the perianal region may impair defecation and result in fecal impaction. Similarly, large tumors in the neck area may impair head movement and the ability to eat, drink, and swallow. Visceral metastatic masses may occur in more advanced cases.[4]

CLINICAL PATHOLOGY

Although the location, appearance, and color of a mass can be highly suggestive, an excisional biopsy, which involves surgically removing small tumors integrally and submitting them to a diagnostic laboratory for histologic confirmation of the diagnosis, has been recommended whenever possible.[4]

TREATMENT

Single noninvasive tumors of small to moderate size have been surgically excised with good success and good prognosis. Surgical excision is unrewarding in cases with multiple tumors, infiltrating masses, or masses located around the parotid salivary gland, which complicate the surgical approach considerably.[4]

In horses, treatment with oral cimetidine, a histamine type 2 receptor antagonist, either at a dose of 2.5 mg/kg BW q8h or 7.5 mg/kg BW q24h p.os, for at least 60 days has yielded variable results.[3] Promising results were reported with the use of cisplatin, either as repeated intratumoral injection or as biodegradables beads in horses.[4]

LIPOMA

Lipomas are benign subcutaneous or submucosal tumors that can be locally extensive and consist of well-differentiated adipocytes. Lipomas are occasionally seen in horses but are rare in cattle. In horses, lipomas occur either as mesenteric or cutaneous lipomas. Mesenteric lipomas predominantly develop in older horses, presenting as pedunculated lipomas that may cause secondary complications such as intestinal strangulation.

Subcutaneous lipomas are the predominant form in young horses less than 2 years of age. The large majority of cutaneous lipomas are encapsulated and well demarcated from surrounding tissue, making them easily resectable, with minimal risk for recurrence. Occasionally lipomas may grow invasively, infiltrating surrounding tissue such as muscles, tendons, joints, and even bone. Despite their invasive growth, infiltrative lipomas are benign because they do not metastasize.[1] The invasive growth pattern makes integral resection of tumorous tissue impossible and results in high recurrence rates after surgical intervention.[1] Differentiating between lipomas and infiltrative lipomas is important to determine the eligibility for surgical resection and the prognosis but can be challenging under field conditions.[1]

In foals and calves, congenital external infiltrating lipomas have been reported.[2,3]

MAST CELL TUMORS

A mast cell tumor (mastocytoma) is a rare neoplasia primarily affecting the skin in cattle, horses, swine, and New World camelids. The large majority of mast cell tumors in cattle and horses are benign, but malignant forms have been described. Less than 6% of all equine and less than 1% of all bovine neoplasias have been identified as mastocytomas.[1-3] Incidental case of mast cell tumors have been reported in pigs, small ruminants, and New World camelids. Mast cell tumors in the species just mentioned are most frequently located in the skin, with no apparent site of predilection. Other than on the skin, mastocytomas in horses have also been identified in the gastrointestinal tract, salivary glands, eyes, testes, and spleen.[1] In cattle, apart from the cutaneous form, mast cell tumors have been found in spleen, lung, liver, lymph nodes, muscle tissue, omentum, abomasum, tongue, and uterus.

CLINICAL FINDINGS

Animals of all ages can be affected, and neither a gender nor a breed predilection has been reported.[2] Single lesions are the most common presentation, but cases of multicentric mastocytoma have been reported in different species.[1,4,5] In most instances a mastocytoma presents as slow-growing, indolent cutaneous or subcutaneous mass. Lesions typically are well demarcated and vary from 0.5 to 20 cm in diameter and feel firm or fluctuating on palpation. Masses located on the limbs are often firm and immovable.[1] The overlying skin is usually intact, although alopecia, hyperpigmentation, or ulceration may be present.[1]

CLINICAL PATHOLOGY

Diagnosis of cutaneous mastocytoma is either by fine-needle aspiration or excisional biopsy, removing the mass integrally. Histologically mast cell tumors are characterized by the predominance of well-differentiated mast cells. Mitotic figures are few in number, and eosinophilic infiltration of the mass is a consistent finding.[1] Older lesions may contain considerable amount of fibrosis, mineralization, and necrosis.[1]

TREATMENT

Cutaneous mastocytomas in cattle and horses in general are benign and indolent, but they rarely resolve spontaneously. Surgical excision may therefore be indicated for cosmetic reasons or when masses cause discomfort, and surgery is usually curative.

Other reported treatments include cryosurgery and the intra- or sublesional injection of corticosteroids (e.g., 10 to 20 mg methylprednisolone acetate).[1]

LYMPHOMATOSIS

In cattle and horses, skin lesions occur as nodules in the subcutaneous tissue, most commonly in the paralumbar fossae and the perineum. In cattle, the lesions are associated with the virus of enzootic bovine leukosis (EBL) and are only one manifestation of the disease, usually being accompanied by lesions in other organs. In horses, there are no leukemic lesions in lymph nodes or visceral organs.

NEUROFIBROMATOSIS

This common lesion of nerves in cattle usually attracts attention only in abattoir specimens but can occur in a cutaneous form resembling a similar disease of humans; a particularly high prevalence of this benign disease is recorded in breeds of European pied cattle. Clinical cases are usually recorded in calves, in which there are cutaneous lesions that appear as tumor-like lumps between the eyes and on the cheeks. They are flat, round tumors up to 8 cm in diameter and of a lumpy, elastic consistency.

HISTIOCYTOMA

Histiocytomas originate from epidermal Langerhans cells of antigen-presenting lineage. This is a very rare benign neoplasm in farm animals but is recorded as cutaneous nodules or plaques, which bleed easily, in goats and cattle. The lesions regress spontaneously.

CUTANEOUS ANGIOMATOSIS

Angiomatosis is vasoproliferation originating from endothelial cells from blood vessels. The etiology of this condition that is rarely observed in horses, cattle, swine, small ruminants, and New World camelids is not yet understood. Causes discussed in the literature are inflammatory reactions, bacterial or viral infection, congenital abnormalities, and hyper- or neoplastic transformations.

In cattle, cutaneous angiomatosis most commonly presents as single or multiple cutaneous lesions situated most commonly along the dorsum of the neck characterized by recurrent profuse hemorrhage. The lesions consist of what appears to be protruding granulation tissue and are benign. Histologically angiomas are characterized by the nonencapsulated proliferation of vascular tissue that may or may not be infiltrated with inflammatory cells.

A juvenile version of angiomatosis in calves is characterized by similar lesions but in many organs, sometimes including the skin.

Surgical excision is effective.

HEMANGIOMA AND HEMANGIOSARCOMA

Benign vascular proliferations are occasionally encountered in most animal species. Cutaneous hemangiomas of young horses are morphologically the same as bovine cutaneous angiomatosis lesions. Young horses usually present with solitary lesions between 1 and up to 30 cm in diameter on distal parts of the limbs. The lesions can consist of nodules or plaques with firm to fluctuating consistency that bleed easily. The skin overlying the proliferation tends to be dark colored, hyperkeratotic, and associated with local alopecia.

Hemangiosarcomas (hemangioepithelioma) are malignant tumors recorded relatively frequently in older horses. They are large, highly vascular, subcutaneous masses, usually associated with one or more internal lesions. The primary lesion may be internal, commonly in the spleen, or cutaneous. Recurrence after excision, extensive local infiltration, and death as a result of anemia are common sequelae.

CONGENITAL SKIN TUMORS

Congenital tumors are defined as those existing at birth. A broader definition is that congenital tumors can be detected in fetuses and in newborns until 2 months of age. Embryonic tumors are those that arise during embryonic, fetal, or early postnatal development from a particular organ rudiment or tissue while it is still immature. Hamartomas are benign, tumor-like nodules composed of

overgrowth of mature cells, which normally occur in the affected part but often with one element predominating. Hamartomas include hemangiomas, ameloblastomas, and rhabdomyomas. Teratomas are true neoplasms consisting of different types of tissue not native to the area in which they occur.

Cattle

Congenital skin neoplasms of cattle described include mast cell tumors, lymphosarcoma, myxoma, and vascular hamartoma. Benign melanomas, mastocytomas, hemangiomas and lymphangiomas, fibrosarcomas, neurofibromatosis, subcutaneous lipomas, multiple lipomas, and retroperitoneal lipomas have also been recorded in calves. The comparative aspects of tumors in calves have been described.

Pigs

The literature on congenital and hereditary tumors in piglets has been reviewed. Spindle-cell sarcoma, malignant melanoma, and papillomatosis are common congenital tumors of the skin of piglets. Congenital cutaneous papillomatosis of the head and neck of a newborn piglet has been described on a pig-breeding farm where sporadic cutaneous papillomatosis of the prepuce and scrotum had previously occurred in several boars.

Foals

Congenital tumors in foals are rare. Congenital skin tumors are of the papillomatous, vascular, and melanocytic types. The vascular tumors are capillary hemangiomas, cavernous hemangiomas, and hemangiosarcomas.

Congenital and Inherited Defects of the Skin

Examples of common inherited skin defects that are present at birth are as follows:

- **Inherited parakeratosis** (lethal trait A46, adema disease, inherited nutritional zinc deficiency) occurs in cattle.
- **Dermatosis vegetans** of Landrace breed pigs is a hereditary skin disease characterized by well-demarcated, raised, roughened skin lesions; enlarged, ridged, discolored hooves; and characteristic giant-cell pneumonia.
- **Inherited congenital ichthyosis** (fish-scale disease) of calves is characterized by diffuse cutaneous hyperkeratosis, giving the skin an appearance of fish scale. Two forms, the more severe and lethal **ichthyosis fetalis** (bovine harlequin fetus) and the milder **ichthyosis congenitalis,** are recognized.[1]
- **Inherited hypotrichoses and alopecias** have been described in numerous cattle breeds. Inherited hypotrichosis is often associated with other congenital defects, such as dental anomalies, absent horn development, abnormal coat coloration, and others.
- **Epitheliogenesis imperfecta**, a rare congenital defect reported in calves, pigs, lambs, and foals, is characterized by a discontinuity of the squamous epithelium. There are sharply demarcated areas in which there is absence of epidermis. The condition is inherited as a single autosomal-recessive trait and is fatal if skin lesions are extensive.
- **Epitheliogenesis imperfect (aplasia cutis)** occurs in piglets as a result of ingestion of *Fusarium* spp. toxin.
- **Epidermolysis bullosa syndrome** is observed in calves, lambs, and foals (especially the Belgian breed) and is characterized by separation of the dermal–epidermal junction beneath the basal epithelium. Lesions involve the skin, mucocutaneous junctions, and oral mucosa. The defect is present at birth, but it may be several months before the disease is clinically apparent.
- **Hereditary equine regional dermal asthenia (hyperelastosis cutis)** is an inherited connective tissue disorder primarily seen in Quarter horses. The condition is characterized by sharply demarcated areas of loose skin, which is hyperfragile, tears easily, and exhibits impaired healing. The underlying cause is a faulty collagen fiber production.
- **Congenital dyserythropoiesis and dyskeratosis** of Polled Hereford calves is a congenital syndrome of alopecia and anemia. The condition is characterized by nonregenerative anemia that is accompanied by progressively worsening cutaneous lesions in the form of generalized alopecia and hyperkeratotic dermatitis.
- **Hair-coat-color-linked follicular dysplasia**
- **Familial acantholysis** in New Zealand Angus calves is characterized by defective cell-to-cell adhesion in the epidermis. The skin is normal at birth, but erosions and crusts develop on exposed skin. Partial separation of the hooves and skin shedding over the carpus may occur.
- **Cutaneous asthenia, dermatosparaxis,** and the **Ehlers–Danlos syndrome** are reported in cattle sheep, pigs, and horses and are characterized by faulty collagen production. Skin is fragile and hyperextensible from birth on, with disturbed wound healing.
- **Nevus** is an irregularly shaped, cutaneous defect, present at birth and originally covered with hair, but subsequently hairless. Depending on which cells are involved, a nevus is referred to as vascular, epidermal, connective tissue, or melanotic nevus. Individual lesions are 3 to 4 cm in diameter, bright pink, ulcerated, and inflamed. Vascular nevi consist of densely packed convoluted blood vessels, which bleed easily. Most lesions are on the lower limbs, especially at the coronet.
- **Dermoid cysts** are cystic structures occasionally observed in horses and other species containing hair, exfoliated skin, and glandular debris. Dermoid cysts are present at birth but may become apparent later in life as they grow in size.
- **Inherited epidermal dysplasia (baldy calf syndrome)** of Holstein–Friesian calves is an autosomal-recessive inherited lethal condition. Calves appear normal at birth but progressively loose hair and condition; they have elongated and narrow hooves and scaly skin. Secondary skin ulceration and failure of horn development occur.[2]

INHERITED ALBINISM

Albinism is a congenital lack of melanin pigment in the skin, hair, and other normally pigmented structures such as the uveal tract. Albinism is classified as generalized or localized and as complete, partial, or incomplete. The affected skin in albinism is characterized microscopically as melanopenic rather than melanocytopenic, which distinguishes partial albinism from piebaldism. Most of the normal, inherited white markings that occur on horses are localized forms of piebaldism. Generalized and complete albino animals (oculocutaneous albinism) have white hair, white skin, and pink irides, and they usually exhibit photophobia. Generalized albinism in the horse is inherited as an autosomal-dominant trait that is only viable in the heterozygous states. These horses have incomplete albinism because there is some coloration to the iris.

DISORDERS OF COAT COLOR, PSEUDOALBINISM, AND LETHAL WHITES

There are a number of forms of pseudoalbinism and disorders of coat color in domestic animals that involve congenital systemic

disease.[1-5] There is a nonlethal form in cattle and a lethal dominant form in horses in which 25% of conceptions produced by mating dominant white horses die in utero in early gestation. The only pigment in the affected foals is in the eyes.

The disease in **cattle** occurs in Angus, Brown Swiss, Holstein, and Hereford cattle. The Angus cattle have a brown coat and two-tone irises with an outer pale brown ring and an inner blue one. There appears to be no defect in digestion or metabolism. Hereford incomplete albinos have the Chediak–Higashi syndrome. The other breeds do not appear to have defects other than in pigmentation, and the defect in Angus is probably more accurately called "oculocutaneous hypopigmentation." They do have one problem; they are photophobic and prefer to be out of the sun.

A complete albinism in Icelandic **sheep** is manifested by white skin color, pink eyes, and impaired vision in bright light. It is an autosomal recessive. Albinism occurs in Karakul sheep. White lambs of an inbred flock of the Cameroon breed born with light blue eyes died within hours to days of birth, with signs of intestinal obstruction. Affected lambs had deletion of both copies of the gene for endothelin type-B receptor and deletion of a single copy of the gene in the phenotypically normal dams and several other unaffected sheep from the same flock.[6,7]

True albino **horses** rarely if ever occur in nature, but white horses with pigmented eyes do. They are more accurately called pseudo-albinos. See "Lethal White" for discussion of colonic aganglionosis caused by a mutation in the endothelin type-B receptor gene in overo white Paint horses.[5]

INHERITED SYMMETRIC ALOPECIA

Inherited symmetric alopecia is an inherited skin defect of cattle in which animals born with a normal hair coat lose hair from areas distributed symmetrically over the body. It has been observed in Holstein cattle as a rare disease, but its appearance among valuable purebred cattle has economic importance. It appears to be inherited as a single autosomal-recessive character. Loss of hair commences at 6 weeks to 6 months of age. The alopecia is symmetric and commences on the head, neck, back, and hindquarters, and progresses to the root of the tail, down the legs, and over the forelimbs. Affected skin areas become completely bald. Pigmented and unpigmented skin is equally affected; there is no irritation, and the animals are normal in other respects. Failure of hair fibers to develop in apparently normal follicles can be detected by skin biopsy.

INHERITED CONGENITAL HYPOTRICHOSIS

In inherited congenital hypotrichosis there is partial or complete absence of the hair coat with or without other defects of development. The main importance of the disease is in cattle, in which there are six syndromes, but it is also inherited in **pigs**, in which it is associated with low birth weight, weakness, and high mortality, and in Poll Dorset **sheep**, in which the face, ears, and lower legs are bald; there are no eyelashes; and the patient lacrimates excessively. The skin is thick, wrinkled, greasy, scaly, and erythematous. Hair fibers are completely absent from the follicles, but wool fibers and follicles are normal.

Viable Hypotrichosis

Viable hypotrichosis is recorded in North America in Guernsey and Jersey cattle. Calves are viable provided they are sheltered. They grow normally but are unable to withstand exposure to cold weather or hot sun. In most instances hair is completely absent from most of the body at birth, but eyelashes are present in addition to tactile hair around the feet and head. Occasionally hair may be present in varying amounts at birth but is lost soon afterward. There is no defect of horn or hoof growth. The skin is normal but has a shiny, tanned appearance and on sections no hair follicles are present in the skin. The condition is inherited as a single recessive character.

Congenital hypotrichosis has been reported in a Perheron draught horse. At birth there were circumscribed patchy areas of alopecia that was progressive, becoming almost complete by 1 year of age. Skin biopsy at 7 months of age revealed severe follicular hypoplasia, and the animal was still alive at 6 years of age.

Nonviable Hypotrichosis

Nonviable hypotrichosis is a complete hypotrichosis in which the thyroid is abnormally small and hypofunctional and the calves die shortly after birth.

Congenital Hypotrichosis and Anodontia (Anhidrotic Ectodermal Dysplasia)

Congenital X-linked hypotrichosis with missing teeth in bull calves is characterized by abnormal morphogenesis of the teeth, hair follicles, and eccrine sweat glands.[1-4] The disease has also been recognized in a cross-bred calf in Canada.[5] Two different forms can be distinguished according to the severity of the tooth defects: (1) congenital hypotrichosis with complete or almost complete anodontia, and (2) congenital hypotrichosis with completely missing incisors or defective incisors. Impaired body condition and growth of the affected animals result from missing teeth. In addition, animals with sparse hair are more susceptible to cold and more prone to skin lesions.

The phenotype and inheritance of hypotrichosis with nearly complete anodontia has been recorded in pedigreed Canadian and German Holstein calves. The phenotype is inherited as a monogenic X-linked recessive trait. An RT-PCR assay was used to identify the causative large genomic deletion in the bovine *EDA* gene. The bovine *EDA* gene encodes ectodysplasin A, a membrane protein expressed in keratinocytes, hair follicles, and sweat glands, which is involved in the interactions between cell and cell and/or cell and matrix.[1] A single-nucleotide polymorphism (SNP) at the 9(th) base of exon 8 in the EDA gene is located in the exonic splicing enhancers (ESEs) recognized by SRp40 protein. Consequently, the spliceosome machinery is no longer able to recognize the sequence as exonic and causes exon skipping.[1] The mutation determines the deletion of the entire exon (131 bp) in the RNA processing, causing a severe alteration of the protein structure and thus the disease. Analysis of the SNP allows the identification of carriers that can transmit the disease to the offspring.[1]

Streaked Hairlessness

A sex-linked semidominant gene causes development of a streaked hairlessness in which irregular narrow streaks of hypotrichosis occur in female Holsteins.

Partial Hypotrichosis

Partial hypotrichosis has been recorded in polled and horned Hereford cattle. At birth there is a fine coat of short, curly hair that later is added to by the appearance of some very coarse, wiry hair. The calves survive but do not grow well. It is inherited as a simple recessive character. The disease in Poll Herefords results in the same short curly coat, but there is also a deficiency of hair in the switch and over the poll, brisket, neck, and legs in some cattle. Some have a much lighter hair-coat color. Histologically, there is a characteristic accumulation of large trichohyalin granules in the hair follicles.

Hypotrichosis and Coat-Color Dilution—"Rat-Tail Syndrome" in Calves

The abnormality is characterized by short, curly, malformed, sometimes sparse hair and lack of normal tail-switch development. Coat-color dilution and hypotrichosis occur

when red animals, particularly of the Simmental breed and carrying the mutation responsible, are crossed with black or black-pied cattle.[1] Inherited as a dominant trait, 50% of progeny of such matings have black diluted to a charcoal- or chocolate-colored coat and variable degrees of hypotrichosis. This condition also occurs in offspring of Hereford–Friesian crosses and is evident as dilution of the dark coat color and hypotrichosis affecting particularly the tail switch when the hair of the tail is colored (hence "rat tail"). White hair is not affected.

The abnormality is in the premelanosome protein 17 gene (PMel17), and affected animals are heterozygous. Cattle that express the syndrome must have at least one dominant gene for black color and be heterozygous at the other locus.

A study of the inheritance of the abnormality found that all rat-tail calves were sired by Simmental bulls and were from cows with various percentages of Angus breeding. The abnormality had no effect on birth weight, weaning weight, or gain from birth to weaning. However, rat-tail calves had significantly lower rates of gain during the winter months from weaning to yearling than non-rat-tail calves. Histologically, there are enlarged, irregularly distributed, and clumped melanin granules in the hair shafts, which are asymmetric, short, curled, and small. The scale surface is rough and pitted, and scale fails to form in some areas.

INHERITED HAIR-COAT-COLOR-LINKED FOLLICLE DYSPLASIA

Some **"buckskin"-colored follicular dysplasia** occurs in so-called "Portuguese" Holstein cattle, a grade variant of Red Holsteins with a tan color instead of the red. This defect consists of a coat-color-linked hair follicle dysplasia, in which the colored hairs are shorter and less lustrous than the white hair, making the coat much finer and smoother. Test matings seem to confirm an autosomal-dominant inheritance.

A **black-hair-colored follicular dysplasia** is also recorded in Holstein cattle. Patches of hair loss varying from hypotrichosis to complete alopecia occur in a random fashion but only on black areas. Follicular dysplasia is evident in biopsy samples. The abnormality persists for the life of the animal and is of cosmetic importance only. An inherited etiology is assumed.

A follicular dysplasia in a mature Brangus-cross cow and a mature Angus cow has been described. Adult-onset alopecia occurred, and skin biopsy revealed follicular distortion and atrophy, with melanin clumping in follicular epithelium, hair bulb matrix cells, hair shafts, and infundibular keratin.

INHERITED BIRTHCOAT RETENTION

Inherited birthcoat retention is recorded in Merino and Welsh mountain sheep and characterized by a coat of hairy medullated fibers in contrast with the nonmedullated wool fibers of the normal sheep fleece.

INHERITED LEUKODERMA

The **Arab fading syndrome** commences in young horses, in particular families of Arab horses, as round, unpigmented patches of skin around the lips, eyes, perineum, and preputial orifice. Some cases recover spontaneously, but the blemish is usually permanent.

INHERITED EPIDERMAL DYSPLASIA (BALDY CALVES)

This is a lethal defect of Holstein–Friesian calves inherited as an autosomal-recessive character. The calves, most commonly heifers, are normal at birth but at 1 to 2 months of age begin to lose condition in spite of good appetites. The skin over most of the body is slightly thickened, scaly, and relatively hairless. There are also patches of scaly, thickened, and folded skin, especially over the neck and shoulders, and hairless, scaly, and often raw areas in the axillae and flanks and over the knees, hocks, and elbow joints. The skin over the joints is immovable. There is usually alopecia around the base of the ears and eyes. The tips of the ears are curled backward. The horns fail to develop, and there is persistent slobbering, although there are no mouth lesions. The hooves are long, narrow, and pointed because of gross overgrowth of the walls; these and stiffness of joints cause a shuffling, restricted gait. Calves assume a recumbent posture most of the time. Severe emaciation leads to destruction at about 6 months of age.

Histologic changes in the skin include acanthosis, hyperkeratosis, and patchy neutrophil invasion. The similarity of this condition to inherited parakeratosis and to experimental zinc deficiency suggests an error in zinc metabolism, but treatment with zinc had no effect on the course of the disease.

INHERITED PARAKERATOSIS OF CALVES (LETHAL TRAIT A46, ADEMA DISEASE)

See "Inherited deficiency of lymphocyte maturation in Chapter 11."

INHERITED DYSERYTHROPOIESIS–DYSKERATOSIS

See "Inherited Blood Diseases."

INHERITED CONGENITAL ABSENCE OF THE SKIN

Epitheliogenesis Imperfecta (Aplasia Cutis)

Absence of mucous membrane or, more commonly, absence of skin over an area of the body surface has been recorded at birth in pigs, calves, lambs, and foals. There is complete absence of all layers of the skin in patches of varying size and distribution. In **cattle** the defect is usually on the lower parts of the limbs and sometimes on the muzzle and extending onto the buccal mucosa. The disease is best known in Holstein–Friesians, but is also recorded in Japanese Black, Shorthorn, Sahiwal, and Angus cattle. In **pigs** the skinless areas are seen on the flanks, sides, back, and other parts of the body, and these areas develop into ulcers and are often secondarily infected, necessitating casualty slaughter.[1] The defect is usually incompatible with life, and most affected animals die within a few days. Inheritance of the defect in cattle is conditioned by a single autosomal-recessive gene, and pigs are thought to have the same genetic cause. Tissue-cultured fibroblasts from affected animals produce subnormal amounts of collagen and lipids.

Familial Acantholysis

Suspected of being an inherited disease, familial acantholysis in Angus calves is characterized by defective collagen bridges in the basal and prickle layers of the epidermis so that skin, normal at birth, is subsequently shed at the carpal and metacarpophalangeal joints and coronet, and there is separation of the horn at the coronet.

Epidermolysis Bullosa

Epidermolysis bullosa is a congenital disease of Suffolk and South Dorset Down sheep and Simmental and Brangus calves and is characterized by the formation of epidermal bullae in the mouth and on exposed areas of skin, such as the extremities of the limbs, muzzle, and ears, leading to shedding of the covering surface and separation of the horn from the coronet. Lesions may be present at birth. Simmental calves grow poorly, have hypotrichosis, and suffer repeated breaks in the skin, apparently as a result of an abnormal susceptibility to trauma. Most calves die, but some survive and the lesions subside. In Simmentals the disease is inherited as an autosomal-dominant trait. The disease in Brangus calves is very similar to familial acantholysis in Angus cattle.

The severe form of Herlitz junctional epidermolysis bullosa, which occurs in humans, has been recorded in foals of the French draft horse breeds. A mutation in the *LAMC2* gene is responsible for the defect. Affected foals were born with skin blistering and skin and

buccal ulceration, followed by loss of hooves. In the affected skin, there was disjunction of the epidermis from the underlying dermis at the dermal–epidermal junction. Genomic DNA testing is used to determine the presence of the mutation in carrier animals.

Junctional Epidermolysis Bullosa (Hereditary Junctional Mechanobullous Disease)

Junctional epidermolysis bullosa (JEB) is inherited in Belgian foals; Danish Hereford, Belgian Blue, Charolais, Angus, and Simmental calves; and Suffolk, Churra, and South Dorset Down lambs.[1-4] The disease is inherited in an autosomal-recessive pattern.

JEB in horses is an autosomal-recessive trait affecting Belgians, other draft breeds, and American Saddlebred horses.[5,6] The heterozygous haplotype is common in draft breeds, with 17% of Belgian horses being carriers in North America and 8% to 27% of horses of the Breton, Comtois, Vlaams Paard, and Belgische Koudbloed Flander draft horse breeds being carriers in Europe.

The genetic defect responsible for JEB in the Belgian and European draft breeds is a cytosine insertion (1368insC) creating a premature stop codon in the *Lamc2* gene, which encodes the laminin γ2 subunit chain. The truncated laminin γ2 subunit chains lacks the C-terminal domain so it cannot interact with the other two subunits, thereby preventing the formation of laminin 5. The defect in Belgian Blue cattle is in the *LAMA3* gene, which encodes the alpha 3 subunit of the heterotrimeric laminin-332.[4] Laminin is widely distributed in the basement membrane of epithelial tissues, and lack of this family of proteins results in loss of cell adhesion between the dermis and epidermis.[4] The disease in Charolais calves is a result of a mutation in the integrin beta 4 gene (as for the disease in humans) and loss of function of this protein.[2] The disease in Hereford cattle is a result of a mutation in the *LAMC2* gene, encoding for laminin gamma 2 protein, which results in loss of function of the gene and lack of laminin gamma 2 protein.[3]

Foals are typically born alive, but irregular, reddened erosions and ulcerations develop in the skin and mouth over pressure points or after mild trauma. There are often extensive erosions along the coronary bands, with sloughing of hooves, and at mucocutaneous junctions of the mouth, rectum, and vulva. Dystrophic teeth that are visible at birth are white with irregular serrated edges and pitted enamel. Definitive diagnosis in draft horses requires DNA testing for JEB.

There is no treatment for affected foals, lambs, or calves, and they will eventually succumb to secondary infections or complete sloughing of the hooves.

Red Foot Disease of Sheep

Red foot disease of sheep is similar to junctional epidermolysis bullosa and occurs in Scottish Blackface and Welsh mountain sheep. The lesions are not present at birth but become apparent at 2 to 4 days of age when there is sloughing of skin of the limbs, the accessory digits, the ear pinna, and the epidermal layers of the cornea and buccal mucosa, especially the dorsum of the tongue. There is also an absence of head horn and a separation of hoof horn from the coronet. Pieces of horn become completely detached, exposing the red corium below, hence the term "red foot." The cutaneous and mucosal lesions often commence as blood-filled or fluid-filled blisters. The corneal lesions are similarly the result of sloughing of epidermal layers. Although the cause is unknown, there are indications that it is inherited.

INHERITED HYPERBILIRUBINEMIA AND PHOTOSENSITIZATION

An inherited photosensitization with hyperbilirubinemia has been observed in Southdown sheep in New Zealand and the United States, and in Corriedales in California. It is inherited as an autosomal-recessive trait.

Liver insufficiency is present, but the liver is histologically normal. Phylloerythrin and bilirubin excretion by the liver is impeded, and the accumulation of phylloerythrin in the bloodstream causes the photosensitization. There is also a significant deficiency in renal function. Symptomatic treatment of photosensitization and confining the animals indoors may enable the lambs to fatten to market weight. The persistent hyperbilirubinemia is accompanied by an inability of the kidneys of these sheep to concentrate urine and the eventual death of the sheep from renal insufficiency.

Affected sheep live for several years if they are protected from sunlight and tend to die of renal failure associated with progressive fibrosis of the kidney.

A similar disease in Corriedale sheep in California is inherited as an autosomal-recessive trait. The functional defect is not in the uptake of unconjugated bilirubin and phylloerythrin, but rather its excretion from liver into bile. It affects lambs as they begin to eat pasture. Lambs live until 6 months of age if provided with some shade. There is also marked melanin-like pigmentation of the liver.

These two diseases are examples of the involvement of external environmental disease factors with a genetic disease: a diet of green forage (chlorophyll) and sunlight working in concert with the inborn error of metabolism to induce photosensitization.

INHERITED CONGENITAL ICHTHYOSIS (FISH-SCALE DISEASES)

Congenital ichthyosis is a disease characterized by alopecia and the presence of plates of horny epidermis covering the entire skin surface. It has been recorded only in Holstein and Norwegian Red Poll and probably in Brown Swiss calves among the domestic animals, although it occurs also in humans.

The newborn calf appears to be either partly or completely hairless, and the skin is covered with thick, horny scales separated by fissures that follow the wrinkle lines of the skin. These may penetrate deeply and become ulcerated. There are plenty of normal hair follicles and normal hairs, but these are lost in the areas covered by the growth of scales. A skin biopsy section will show a thick, tightly adherent layer of keratinized cells. The disease is incurable, and although it may be compatible with life, most affected animals are disposed of for esthetic reasons. The defect has been shown to be hereditary and to result from the influence of a single recessive gene.

INHERITED DERMATOSIS VEGETANS OF PIGS

Inherited dermatosis vegetans of pigs appears to be conditioned by the inheritance of a recessive, semilethal factor. Affected pigs may show defects at birth but in most instances lesions appear after birth and up to 3weeks of age. The lesions occur at the coronets and on the skin. Those on the coronets consist of erythema and edema with a thickened, brittle, uneven hoof wall. Lesions on the belly and inner surface of the thigh commence as areas of erythema and become wart-like and covered with gray-brown crusts.

Many affected pigs die, but some appear to recover completely. Many of the deaths appear to be a result of the giant-cell pneumonitis that is an essential part of the disease. The pathology of the disease indicates that it is the result of a genetic defect that selectively affects mesodermal tissue. It is known to have originated in the Danish Landrace breed.

DERMATOSPARAXIS (HYPERELASTOSIS CUTIS)

Dermatosparaxis is an extraordinary fragility of skin and connective tissue in general, with or without edema. It is probably inherited as a recessive character. It occurs in cattle, in horses (see "Hereditary Equine Regional Dermal Asthenia"), in Finnish and White Dorper sheep, and in a mild form in Merino sheep. The latter is inherited as a

simple autosomal-recessive trait. The skin is hyperelastic, as are the articular ligaments; marked cutaneous fragility, delayed healing of skin wounds, and the development of papyraceous scars are also characteristic. Pieces of skin may be ripped off when affected sheep are being handled. In horses the skin in some parts of the body is thinner than elsewhere (e.g., the skin of the ventral abdomen) and the collagen bundles in the area are more loosely packed and are curved rather than straight. The proportion of acid-soluble collagen is also much higher in this abnormal skin. The disease involves a molecular defect of a collagen-binding protein and is related to a recognized problem in dogs and cats identified as "dominant collagen packing defect."

Hereditary equine regional dermal asthenia is discussed under that heading in the following section.[1] Ehlers–Danlos syndrome, recorded in Charolais and Simmental cattle, Quarter horses (cyclophilin-B gene independent),[2] Warmblood foals (cyclophilin-B gene independent),[3,4] and Rippolesa sheep, is also characterized by extreme fragility of the skin and laxness of joints in the newborn. There is a defect in collagen synthesis, and histopathological findings include fragmentation and disorganization of collagen fibers. The disease in Warmblood foals is well recognized and is caused by a defect in the equine procollagen-lysine, 2-oxoglutarate 5-dioxygenase 1 (PLOD1, or lysyl hydroxylase 1) gene.[5] Affected foals born at term have thin and friable skin, skin lesions on the legs and the head, and an open abdomen.[5] Histologic examination reveals abnormally thin dermis and markedly reduced amounts of dermal collagen bundles, with loose orientation and abnormally large spaces between deep dermal fibers. A genetic test is available and should be considered for Warmblood mares that abort, have stillborn foals, or have foals with characteristic lesions.[5] A case of dermal asthenia reported in a Warmblood in Australia was in a 6-week-old foal. Confirmatory genetic testing was not undertaken.[3]

The syndrome has also been recorded in lambs. The skin was loose and present in excessive amounts, with folds over the carpal joints and lower regions of the legs. In some lambs, there may be separation of the epidermis from the dermis with blood-filled cavitations and intact skin that can be easily torn.

INHERITED MELANOMA

Inherited cutaneous malignant melanoma is found in National Institute for Health (NIH miniature) and Sinclair miniature swine. Its expression is associated with two genetic loci, one of which is associated with the swine major histocompatibility complex. Familial melanomas have also been recorded in members of successive litters from an individual Duroc × Slovak White sow.

INHERITED HYPERHIDROSIS

Inherited hyperhidrosis, a condition characterized by excessive sweating and thought to be inherited, is recorded in beef Shorthorn calves. The syndrome includes conjunctivitis, with some cases progressing to complete opacity of the cornea, heavy dandruff, and persistent wetness of the hair coat.

LAVENDER FOAL SYNDROME

Lavender foal syndrome is a congenital, inherited, autosomal-recessive disease of Egyptian Arab foals characterized by an unusual dilute coat color and signs of neurologic disease evident at birth. Additional details provided in Chapter 14 ("Diseases of the Nervous System").

HEREDITARY EQUINE REGIONAL DERMAL ASTHENIA (HYPERELASTOSIS CUTIS)

Hereditary equine regional dermal asthenia (HERDA) is a degenerative skin disease caused by an autosomal-recessive trait of Quarter horses and related breeds attributable to a mutation in *Equus caballus* chromosome 1 (ECA1).[1] The abnormality is a c.115G>A mutation in the peptidyl-propyl isomerase cis-trans B (PPIB) gene.[2] Resultant abnormalities in cyclophilin B cause a two- to threefold reduction in the tensile strength and elastic modulus of skin of affected horses.[3,4] The allele frequency in 651 elite performance American Quarter horses, 200 control (nonelite) American Quarter horses, and 180 control American Paint horses was 0.021, with cutting horses having a frequency of 0.142 and 28% of cutting horses being carriers.[5] The frequency of carriers is estimated to be 3.5% of Quarter horses in the United States and 1.6% in France.[1,6] Allele frequency is estimated at 2.9%, and carrier frequency at 5.8%, in American Quarter horses in Brazil.[2] A similar inherited disease of Warmbloods is reported, although the genetic basis has not been determined.[7,8] The disease can occur in Quarter horses without the PPIB mutation.[9]

Clinical signs typically appear at 1 to 2 years of age, at about the time of breaking for riding, and are evident as open wounds, sloughing of skin, hematomas, and seromas. Clinical signs can develop in foals. The skin of affected animals is "stretchy" and remains deformed for considerable periods of time when stretched. The lesions are most severe over the dorsum, although the mechanical abnormalities are present at all sites.[4] Horses with HERDA have a greater incidence of corneal ulcers than do unaffected horses.[10] The cornea of horses with HERDA is thinner than that of normal horses.[10]

Diagnosis is based on clinical signs, histologic examination of skin, and genetic testing. Histologic examination of skin of animals before the development of clinical signs is not conclusive in detecting the disease, although affected horses have thinner skin, on histologic examination, than do unaffected horses.[11,12] Measurement of skin thickness has sensitivity of 73% to 88% and specificity of 35% to 75%.[12] Skin thickness is not regionally distributed in affected horses. The genetic test is definitive.

There is no definitive treatment. Affected mares can carry foals to term and deliver safely.[11] Control involves the selective breeding of unaffected animals and those not carrying the disease, bearing in mind that it is an autosomal-recessive disease. However, the high prevalence of the disease in some uses of horses (cutting horses) suggests selection for the trait, perhaps because it is closely associated with a desired phenotype.

DERMATOSIS VEGETANS

Dermatosis vegetans is a rare condition of pigs first described in 1967 and originating in the Swedish Landrace import to the United Kingdom. It is governed by a semilethal factor with autosomal-recessive inheritance. Often only two to three pigs per litter are affected. Pigs will often first show a decline in growth and then die after 7 to 8 weeks, but some occasionally recover. It is seen as three clinical conditions:

- There is an erythematous maculopapular dermatitis often present at birth or around 2 to 3 weeks of age. Lesions are found on the abdomen or inside of the thighs and may spread and pass through a Pityriasis-like phase. After 5 to 8 weeks the lesions become thickened and covered with crusts.
- The second group of lesions, usually present at birth, occur in the form of "clubfeet," with swelling and erythema and defective horn on the walls, sole, and bulb of the foot.

- The third major clinical condition is respiratory dysfunction, which is caused by a giant-cell pneumonitis. It is characteristic of the condition in pigs older than 1 week of age. There are granules present throughout the lung, and these heal by fibrosis. The differential diagnoses include pityriasis rosea, chronic exudative dermatitis, and vitamin deficiencies.

There is no treatment, and control is through culling of breeding stock that have been affected.

Done JT, et al. Dermatosis vegetans in the pig. *Vet Rec.* 1967;80:292.

PUSTULAR PSORIAFORM DERMATITIS (PITYRIASIS ROSEA)

The condition of pityriasis rosea in humans is not like the condition in pigs; thus, pustular psoriaform dermatitis (PPD) is a much better term for what is in fact a ring or rings of keratinized cells that are erythematous initially and raised surrounding a central crater. The condition occurs in young pigs, 3 to 14 weeks of age, is self-limiting, and is usually gone by 4 to 6 weeks following appearance.

The etiology is thought to be an autosomal-dominant gene with incomplete penetrance. It is definitely familial and may be more common in Landrace.

Clinically, there is a superficial accumulation of scales in a dry, lusterless coat.

Pityriasis scales are accumulations of keratinized epithelial cells, sometimes softened and made greasy by the exudation of serum or sebum. Overproduction, when it occurs, begins around the orifices of the hair follicles and spreads to the surrounding stratum corneum. The lesions are not itchy.

Diagnosis is based on age, clinical appearance, lack of itching and failure to demonstrate mites or ringworm on skin scrapings. Skin biopsy also helps in that there is an epidermal hyperplasia and superficial perivascular dermatitis.

Pityriasis is identified by the absence of parasites and fungi on skin scrapings.

DIFFERENTIAL DIAGNOSIS

Differential diagnosis of excessive bran-like scales on the skin, characterized by overproduction of keratinized epithelial cells, can be caused by deficiency of B vitamins, especially riboflavin and nicotinic acid, or linoleic acid and possibly other essential fatty acids, and poisoning by iodine. It can also be secondary to flea, louse, and mange infestations and ringworm infections. Also, hyperkeratosis and parakeratosis conditions should be considered.

TREATMENT

Treatment does not appear to have any effect, and self-cure is the norm. If there is secondary infection under conditions of bad hygiene, supportive therapy may help. Culling of the breeding stock producing the affected stock is advisable.

Eye and Conjunctival Diseases

CONJUNCTIVITIS AND KERATOCONJUNCTIVITIS

Conjunctivitis refers to inflammation of the covering membrane of the eye, including the orbit and the inner surface of the eyelids. The inflammation commonly extends to layers below the conjunctiva, referred to as keratoconjunctivitis.

ETIOLOGY

Causes of inflammation of the conjunctiva can be various and include bacterial, viral, parasitic, or mycotic infections; allergic and immune reactions; conjunctival foreign bodies; and trauma.

Specific Conjunctivitis

Cattle

- **Infectious bovine keratoconjunctivitis (IBK, pinkeye)** a common and highly contagious form of keratoconjunctivitis that is associated with *Moraxella bovis* (see also "Infectious Bovine Keratoconjunctivitis")
- **Listerial keratoconjunctivitis and uveitis (silage eye)** is associated with *Listeria monocytogenes*[1] (see also "Listerial Keratoconjunctivitis")
- **Ulcerative blepharitis and conjunctivitis** associated with *Moraxella bovoculi* in cattle[2,3]

Sheep and Goats

- **Infectious keratoconjunctivitis (pinkeye) of sheep and goats** associated with *Mycoplasma conjunctivae* and *Chlamydia psittaci.*

Pigs

- Chlamydial-associated conjunctivitis in pigs associated with *Chlamydia spp*[4]

Horses

- Eosinophilic keratoconjunctivitis of unknown etiology[5]
- Conjunctival habronemiasis caused by larval invasion of *Habronema spp.*
- Ocular onchocerciasis associated with microfilaria of *Omcocerca* spp. The causative association between these microfilaria and equine ocular disease is under debate.
- Fungal keratomycosis in foals and adult horses; *Aspergillus flavus* has been identified in some cases.

A. fumigatus is listed among the causes of mycotic keratitis in animals. Most cases begin as traumatic injuries with secondary infections or begin in eyes treated for long periods with broad-spectrum antibiotics.

Secondary Diseases in Which Conjunctivitis Is a Significant but Secondary Part of the Syndrome

Cattle

- Bovine viral diarrhea
- Malignant catarrhal fever
- Rinderpest
- Infectious bovine rhinotracheitis
- Viral pneumonia as a result of various viruses
- Bluetongue (specifically BTV-8)
- Besnoitiosis

Sheep

- Bluetongue

Pigs

- Swine influenza
- Inclusion-body rhinitis

Horses

- Equine viral arteritis
- Equine viral rhinopneumonitis

Nonspecific Conjunctivitis

Nonspecific conjunctivitis refers to inflammation caused by foreign bodies or chemicals, or secondarily as exposure keratitis, and conjunctivitis/keratitis in paralysis of eyelids as in listeriosis. Ant-bite conjunctivitis occurs in similar circumstances.

CLINICAL FINDINGS

Blepharospasm and weeping from the affected eye are the initial signs. Watery tears are followed by mucopurulent, then purulent ocular discharge if the lesion extends below the conjunctiva. Varying degrees of opacity of the conjunctiva may develop, depending on the severity of the inflammation. In the severest lesions there is underrunning of the conjunctiva with pus accompanied by vascularization of the cornea. During the recovery stage there is often long-lasting, diffuse opacity of the eye and terminally a chronic white scar in some cases.

CLINICAL PATHOLOGY

In herd or flock outbreaks, conjunctival swabs and/or scrapings should be taken for culture and examination of cells using special stains and histologic techniques.

LISTERIAL KERATOCONJUNCTIVITIS AND UVEITIS (SILAGE EYE, BOVINE IRITIS)

SYNOPSIS

Etiology *Listeria monocytogenes* is the causative pathogen, presumably reaching the eye with contaminated feed particles. The condition is the result of a local listerial infection specifically affecting the eye and is not associated with systemic infection with *L. monocytogenes.* Cattle, sheep, and horses are affected.

Epidemiology Cattle fed poor-quality silage from round bales or ring feeders are at risk of developing the condition; allowing feed to fall on the cows' heads increases risk. In most cases individual animals are affected, but outbreaks have occurred. Incidence is highest in winter and early spring when animals are housed inside and fed silage.

Clinical findings Epiphora, conjunctivitis, blepharospasm, photophobia, corneal edema, uveitis. The condition is usually not associated with systemic disease.

Diagnostic confirmation Culture, polymerase chain reaction (PCR).

Treatment Self-limiting disease. Topical and systemic antibiotics.

Control Avoid feeding poor-quality silage, avoid feeding systems providing feed at or above the height of the animals' eyes.

ETIOLOGY

Listeria monocytogenes is the only causative agent associated with listerial conjunctivitis, which is a condition specifically affecting the eye.[1] It is unrelated to systemic infection with *L. monocytogenes* causing the classic forms of listeriosis (see also "Listeriosis"). Local uveitis associated with *L. monocytogenes* has been reported to occur in cattle, sheep, horses, fallow deer, and humans.[2]

Listeria is a ubiquitously occurring gram-positive, asporogenic bacterium easily surviving in organic material at temperatures between 3° and 45°C (37° to 113°F) and at pH as low as 3.8 in an aerobic environment. Silage of poor quality that is either not conserved anaerobically or not sufficiently acidic facilitates growth of *Listeria.* Listerial conjunctivitis is almost invariably associated with feeding poor-quality silage either directly as big bale or from ring feeders. With these feeding systems animals tend to burrow their heads into the bales, which not only exposes the eyes to the pathogen but also has the potential to mechanically damage the conjunctiva, thereby creating a portal of entry.[1]

EPIDEMIOLOGY

Occurrence

The disease has been reported to occur in different parts of the world, although most cases are recorded in the United Kingdom, probably because of greater awareness of the existence of this condition. The disease incidence is highest in **late fall, winter, and early spring** when animals are kept inside and fed silage. Frequently only individual cases occur, but outbreaks with morbidity rates far above 25% have been reported.[1,2] In the United Kingdom an overall animal incidence of 3.4% and an average incidence in affected herds of 66.5% was reported.[1]

Source of Infection

Because most cases of listerial keratoconjunctivitis have been linked to silage feeding, grass silage of poor quality contaminated with *L. monocytogens* is widely accepted as the primary source of infection.

Environmental Risk Factors

Feeding grass silage form big bales or ring feeders is considered a major predisposing factor. With cows starting to feed on the lower part of the bale, feed particles from the upper part continuously fall onto the head of the feeding animal, thereby increasing the risk of ocular contact with the pathogen.

CLINICAL FINDINGS

Although in most cases only one eye is affected, bilateral lesions can occur. Systemic disease is usually absent. First clinical signs include increased lacrimation and catarrhal conjunctivitis with photophobia and blepharospasm. Inflammation of the cornea, starting at the limbic border and spreading centripetally, results in a bluish-white opacity of the cornea. Corneal ulcers are uncommon.[1] In advanced cases focal aggregation of fibrin accumulating in the anterior eye chamber may become visible as white foci beneath the corneal surface. The course of the disease, which is considered to be self-limiting, is between 1 and 3 weeks when left untreated.[2]

CLINICAL PATHOLOGY

The tentative diagnosis can be made based on the clinical presentation in combination of the history (season and silage feeding) but should be confirmed by identifying *L. monocytogenes* from swab obtained from affected eyes. Cultures or PCR are used to identify the pathogen.

DIFFERENTIAL DIAGNOSIS

Infectious bovine keratoconjunctivitis (IBK) has a different seasonality (peaks occurring in the warm season of the year). Evaluation of housing and feeding system may provide further clues to differentiate between these conditions. Corneal ulceration is a common finding with IBK but not with listerial conjunctivitis.

***Pasteurella multocida* (capsular type A)** has been isolated from the eyes of housed heifers that experienced outbreaks of severe keratitis with severe loss of corneal stroma within 72 hours of onset.

Mycoplasma bovis has been isolated from the eyes of steers with an outbreak of severe conjunctivitis with corneal opacity and ulceration, with disease being followed by serologic conversion in affected animals. Involvement of the eyelids with marked swelling was prominent. Conjunctivitis is prominent in other mycoplasmal infections that produce keratoconjunctivitis.

Chlamydial keratoconjunctivitis presents with identical clinical findings but has a protracted course despite treatment and a higher morbidity. *Chlamydophila* DNA can be detected by polymerase chain reaction (PCR) in conjunctival swabs. This disease is a possible zoonosis.

Infectious bovine rhinotracheitis

Bovine malignant catarrhal fever

Bovine viral diarrhea

Bluetongue (BTV-8)

Thelaziasis

Squamous-cell carcinoma

TREATMENT

A number of empirical treatment approaches have been reported, with variable outcome. Listerial keratoconjunctivitis is considered to be a self-limiting disease, and it is difficult to determine whether reported treatments were effective or if recovery was primarily a result of removing access to the primary cause.[3]

Proposed treatments include the topical use of eye ointments containing oxytetracycline or cloxacillin as well as the parenteral administration of repeated doses of oxytetracycline, procaine-penicillin, or ampicillin. The use of topical or subconjunctival dexamethasone application has been proposed, with variable outcome.[1-3]

TREATMENT

Topical treatment:
Benzathine cloxacillin eye ointment (250 mg q48) (R-2)
Oxytetracycline eye ointment (q24h) (R-2)

Systemic treatment:
Procaine-penicillin-G (40,000 IU/kg q24 IM) (R-3)
Oxytetracycline (10 mg/kg q24h IM) (R-3)
Ampicillin (10 mg/kg q24 SC) (R-3)

CONTROL

The most important control measures are to avoid feeding poor-quality silage and to use

feeding systems that provide feed at a height that is below the animals' heads.

INFECTIOUS BOVINE KERATOCONJUNCTIVITIS OF CATTLE (PINKEYE, BLIGHT)

SYNOPSIS

Etiology *Moraxella bovis* is the primary infectious agent. Pili and hemolysin are the main virulence factors. Solar radiation, flies, and dust are contributing factors.

Epidemiology Cattle of all ages are susceptible. Source is asymptomatic carrier cattle, with transmission by mediate contagion and by flies. More common in summer months. Usually multiple cases in a herd.

Clinical findings Conjunctivitis, lacrimation, blepharospasm, photophobia, corneal edema, corneal ulceration.

Diagnostic confirmation Culture.

Treatment Self-limiting disease. Topical antibiotics, subconjunctival penicillin G, parenteral oxytetracyclines, florfenicol, tulathromycin. Protection of eye from sunlight.

Control Current vaccines have limited efficacy. Fly control.

ETIOLOGY

Hemolytic *Moraxella bovis* is the only infectious agent for which Koch's postulates have been established for infectious bovine keratoconjunctivitis (IBK), although other organisms, such as *Moraxella ovis*, *Moraxella bovoculi*, *Neisseria* spp., *Mycoplasma* spp., and *Chlamydia* spp. have been implicated.[1] Experimental infections in calves and studies on corneal tissue culture show a great variation in virulence between strains. Two virulence factors are determinants of cause in clinical disease. These are the **presence of fimbriae, so-called pili,** on the bacterial surface and the **production of β-hemolysin**. Other contributing virulence factors include phospholipases, iron acquisition systems, and hydrolytic and proteolytic enzymes.[1] *M. bovis* has serologically distinct shared and variable pilus epitopes, and strains can be distinguished by their pilus antigens into seven distinct **serogroups**. There are two distinct types of **pilus**, I and Q (formerly α and β). **Q pili mediate bacterial adhesion** to the cornea and the establishment of infection by preventing removal of the pathogen by the continual flushing effect of ocular secretions and the mechanical action of blinking. Beta-hemolysin is **cytotoxic** and produces corneal damage. In some outbreaks of pinkeye more than one serotype can be isolated from affected eyes.

In addition to *M. bovis*, other pathogens, such as *M. bovoculi*, *M. ovis*, *Chlamydia* spp., *Neisseria* spp., *Mycoplasma* spp., *Acholeplasma* spp., and viruses have been identified as common participants and are likely to contribute to the development of clinical disease. Infectious bovine rhinotracheitis virus causes ocular disease in its own right, but it may also be involved with *M. bovis* in causing the more severe disease. Clinical disease in experimentally induced IBK has been shown to be more severe when the calves are concurrently given a modified live infectious bovine rhinotracheitis virus vaccine.

Conjunctival infection with *M. bovoculi* has been proposed to play a role in the pathophysiology of IBK by some authors.[2-3] The evidence in support of this assumption is inconsistent. A clinical study consistently demonstrated the development of corneal ulcers after inoculation with hemolytic *M. bovis* but not with *M. bovoculi*.[3] *Branhamella ovis* causes a severe conjunctivitis in sheep and goats and is also recorded from outbreaks of keratoconjunctivitis in cattle in Israel; it may be a cause of vaccine breakdown in other countries.

Because the naturally occurring disease is usually much more severe than that produced experimentally, factors other than infectious agents have been examined. **Solar radiation**, **flies**, and **dust** have been shown to have an enhancing effect. Cultural characteristics of the organisms isolated from the conjunctiva can change with the level of solar ultraviolet radiation.

EPIDEMIOLOGY

Occurrence

The disease occurs in most countries of the world. Although it can occur in all seasons, it is most common in **summer and autumn**. The prevalence and severity of the disease vary greatly from year to year, and it may reach epizootic proportions in feedlots and in cattle running at pasture. There is no mortality, and cases in which there is permanent blindness or loss of an eye are rare. However, the morbidity rate can be as high as 80%, with the peak infection rate at weeks 3 to 4 of the outbreak. Severe outbreaks can be experienced in winter, especially if the cattle are confined in close quarters, such as barns or intensive feedlots.

Source of Infection

Cattle are the only known reservoir, and the organism is carried on the conjunctiva and also in the nares and vagina of cattle. Persistence of the disease from year to year is by means of infected but asymptomatic animals, which can act as carriers for periods exceeding 1 year. Receptors for I-pili may be found on tissues other than the cornea and facilitate colonization of noncorneal tissue and inapparent infection, and the organism can switch from expression of one pilus type to the other.

Environmental Risk Factors

The disease incidence shows a **clear seasonality,** with the highest incidence in the warmer months of the year. This seasonal expression has been associated with prolonged exposure of the eye to **UV radiation**, the increased **fly population,** and **long grass**.[1] The exposure of the eye to UV radiation increases the susceptibility to the disease and the severity of signs resulting from it. The face fly (*Musca autumnalis*) and Asian face fly (*Musca bezzii*), because of feeding preference for the area around the eyes, are important vectors.

Other environmental factors, such as dust, wind, and tall grass, can increase the disease incidence by causing mechanical irritation of the cornea.

Transmission

Transmission is thought to be by means of flies contaminated by the ocular and nasal discharge of infected cattle. Under experimental conditions, transmission is unusual in the absence of flies and occurs generally in their presence. *M. autumnalis* is known to remain infected for periods of up to 3 days. *M. bovis* can be isolated from the crops of *M. autumnalis* that have fed on the eyes of infected cattle.

Animal Risk Factors

Only cattle are affected, the young being most susceptible, but in a susceptible population, cattle of all ages are likely to be affected.

It is commonly observed that there is a much higher prevalence of the disease in *B. taurus* cattle as distinct from *B. indicus* cattle, and the severity and proportion of bilateral infections is much greater in *B. taurus* cattle than in crossbreeds. Hereford and Hereford crossbreed cattle have a significantly higher risk of developing IBK than other breeds or crossbreeds not containing Hereford.[1] This higher predisposition is thought to be based on a relationship between rate and severity of infection and the degree of **eyelid pigmentation**; eyes with complete pigmentation are less affected.

Immune Mechanisms

Previous infection appears to confer a significant immunity that lasts through to the next season, when further reinfection, usually with minimal clinical disease, confers further immunity. Lacrimal secretions contain antibody, and antibody directed against the **pilus antigens** of *M. bovis* will prevent adherence of the organism to the cornea. In experimental infections, significant protection against challenge can be

achieved by prior vaccination with pilus antigens of the homologous strain.

However, there is antigenic diversity in pili from different strains of *M. bovis*, and vaccines composed of pili from one strain only confer protection to challenge with organisms of the same serogroup. Further, *M. bovis* in the eye can **switch** their pilus antigenicity in response to antibody presence and render monovalent vaccines ineffective. A polyvalent vaccine might provide protection, but polyvalent vaccines are less immunogenic than monovalent vaccines because of antigenic competition.

Economic Importance

Infectious bovine keratoconjunctivitis is a prominent disease in surveys of the predominant diseases in cattle and is considered the economically most important ocular disease of cattle. Losses result from reduced weight gain or loss of body condition; loss of milk production; costs of drugs, labor, and veterinary care; and loss of value of show animals. The conditions under which calves are reared can affect the importance of the disease. In veal calves, the disease may have no measurable effect on growth, but in calves running at pasture it can result in a significant reduction of weaning weight. Occasionally, animals become completely blind, and those at pasture may die of starvation. Animal welfare presents an increasing concern.

PATHOGENESIS

As mentioned, only piliated and hemolytic strains of *M. bovis* are pathogenic to cattle (determinant virulence factors). Attachment of *M. bovis* to the corneal epithelium requires the presence of pili and Q-piliated organisms that are more infectious than I-piliated strains. Hemolysins produced by these virulent strains are cytotoxic and cause the development of corneal ulcers by destroying corneal epithelial cells.

Microscopic corneal erosions are present within 12 hours of infection and occur at this time in the absence of a significant inflammatory response, indicating that the initial production of the corneal ulceration is a result of the direct cytotoxic activity of the organism. This is followed by focal loss of corneal epithelium, degeneration of keratocytes, and invasion of the corneal stroma with fibrillar destruction. An inflammatory reaction occurs several days postinfection and results in enlargement of the corneal ulcers with deeper stromal involvement, corneal edema, and corneal neovascularization. The lesions are localized in the eye, and there is no systemic infection.

CLINICAL FINDINGS

An incubation period of 2 to 3 days is usual, although longer intervals, up to 3 weeks, have been observed after experimental introduction of the bacteria. Injection of the corneal vessels and edema of the conjunctiva are the early signs and are accompanied by a copious watery lacrimation, blepharospasm, photophobia, and, in some cases, a slight to moderate fever with fall in milk yield and depression of appetite.

Fig. 16-10 **Infectious bovine keratoconjunctivitis (IBK) in a beef steer. Note the extensive lacrimation and blepharospasm and the centrally located corneal ulcer with keratitis and conjunctivitis.**

In 1 to 2 days, corneal edema presenting as a small opacity appears in the center of the cornea, and this may become elevated and ulcerated during the next 2 days, although spontaneous recovery at this stage is quite common. With progressive disease the opacity becomes quite extensive, and at the peak of the inflammation, about 6 days after signs first appear, it may cover the entire cornea. The color of the opacity varies from white to deep yellow (Fig. 16-10). As the acute inflammation subsides, the ocular discharge becomes purulent and the opacity begins to shrink, complete recovery occurring after a total course of 3 to 5 weeks.

One or both eyes may be affected. The degree of ulceration in the early stages can be readily determined by the infusion of a 2% fluorescein solution into the conjunctival sac, the ulcerated area retaining the stain.

About 2% of eyes have complete **residual opacity,** but most heal completely with a small, white scar persisting in some. In severe cases the cornea becomes conical in shape, there is marked vascularization of the cornea, and ulceration at the tip of the swelling leads to underrunning of the cornea with bright yellow pus surrounded by a zone of erythema. These eyes may rupture and result in complete blindness.

A proportion of cases will develop minimal clinical lesions and heal spontaneously, and the severity of clinical disease can also vary between outbreaks.

CLINICAL PATHOLOGY

The organism can be identified by culture or fluorescent antibody. The hemolytic form of the bacterium is noticeably more pathogenic than the nonhemolytic form. Serum agglutinins (1:80 to 1:640) are present 2 to 3 weeks after clinical signs commence, and a modified gel diffusion precipitin test is capable of detecting *M. bovis* antibodies. An ELISA test is also used for antibody detection in experimental studies; however, neither agglutinating antibody nor antibody detected by ELISA correlates well with individual animal resistance to infection. There is little indication for serologic examinations in clinical practice. Necropsy examinations are not usually necessary.

DIFFERENTIAL DIAGNOSIS

Traumatic conjunctivitis is usually easily differentiated because of the presence of foreign matter in the eye or the conjunctival sac or evidence of a physical injury.

***Pasteurella multocida* (capsular type A)** has been isolated from the eyes of housed heifers that experienced outbreaks of severe keratitis with severe loss of corneal stroma within 72 hours of onset.

Mycoplasma bovis has been isolated from the eyes of steers with an outbreak of severe conjunctivitis with corneal opacity and ulceration, with disease being followed by serologic conversion in affected animals. Involvement of the eyelids with marked swelling was prominent. Conjunctivitis is prominent in other mycoplasmal infections that produce keratoconjunctivitis.

Continued

Listerial keratoconjunctivitis and uveitis (silage eye) has a different seasonality and is associated with the use of specific feeding systems. Corneal ulcers are uncommon with listerial keratoconjunctivitis.

Chlamydial keratoconjunctivitis presents with identical clinical findings but has a protracted course despite treatment and a higher morbidity. *Chlamydophila* DNA can be detected by polymerase chain reaction (PCR) in conjunctival swabs. This disease is a possible zoonosis.

Infectious bovine rhinotracheitis

Bovine malignant catarrhal fever

Bovine viral diarrhea

Bluetongue (BTV-8)

Thelaziasis

Squamous-cell carcinoma

TREATMENT

Infectious bovine keratoconjunctivitis is frequently a **self-limiting disease**. Recovery commonly occurs without treatment, although early treatment will reduce the incidence of scarring of the eyes. Antibacterial treatment is commonly used, and mass treatment of the herd as opposed to just affected individuals may halt the occurrence of further cases. The route of administration is often determined by efficiency of the available treatment options, ease of access to the animals, availability of facilities to restrain animals for treatment, labor intensity of treatment, cost of the drug, and withhold times.

Topical Therapy

Early, acute cases respond to treatment with ophthalmic ointments and solutions containing antibiotics, but they need to be instilled in the conjunctival sacs at frequent intervals, which may be impractical under field conditions. The organism is **sensitive** to most antibiotics and sulfonamides but is resistant to erythromycin, lincomycin, and tylosin. The administration of an oil-based formulation of benzathine cloxacillin (250 to 375 mg per treatment dose) was found to be effective in therapy in controlled trials. Two doses, 72 hours apart, treating both eyes, even if only one eye is affected, is recommended. The use of the same ointment tube in affected and unaffected eyes is likely to present a risk for transmission of the pathogen.

Subconjunctival Therapy

The objective of subconjunctival treatment is to reduce the treatment dose and number of treatments while achieving higher antimicrobial tissue concentrations.[4] Although subconjunctival therapy with antibiotic was found to be effective in treating IBK in several studies, it is under contentious debate if the treatment effect is obtained through direct diffusion of the drug to the surrounding tissue or rather through continuous leakage of the antibiotic onto the conjunctiva from the injection site.[4] A small volume (1 to 2 mL) of procaine-penicillin G (300,000 IU/mL) is commonly injected under the scleral conjunctiva. Two treatments 48 to 72 hours apart were found to be equally effective as a single parenteral treatment with long-acting formulation of oxytetracycline (20 mg/kg).[4] Therapy must be administered under the bulbar conjunctiva but was found to be ineffective if given in the superior palpebral conjunctiva. A controlled trial found that subconjunctival penicillin was effective in treatment, but recurrence was higher than with treatment with parenteral oxytetracycline, and mass treatment of calves with subconjunctival penicillin does not eliminate infection.

The intrapalpebral injection of 2 mL of a 10% oxytetracycline formulation was found equally effective as the systemic treatment with oxytetracycline (20 mg/kg).[5] Transient swelling of the eyelids, leading to complete closure of the palpebral fissure, was observed in some cases after intrapalpebral injection of oxytetracycline. It was suggested that this transient closure of the eye may favor healing by protecting the cornea and conjunctiva.[5]

Another technique for prolonging the maintenance of high levels of antibiotic in the conjunctival sac is the use of collagen inserts impregnated with an antibiotic.

Parenteral Therapy

Parenteral treatment with two doses of long-acting oxytetracycline (20 mg/kg) 72 hours apart has been shown to ameliorate clinical signs of naturally occurring IBK.[4,5]

Recent studies have documented that florfenicol when administered either as a single subcutaneous dose of 40 mg/kg or two doses of 20 mg/kg administered 48 hours apart is effective for treatment of clinical IBK in calves. Healing times were shorter and relapses were fewer when using florefenicol instead of long-acting oxytetracycline for treatment of IBK in calves.

The use of tulathromycin, a macrolide antibiotic, was found to be effective to treat experimentally induced IBK in calves in one study.[6] A single dose of 2.5 mg/kg resulted in faster healing and higher bacteriologic cure compared with untreated control animals.

Tilmicosin administered at a dose of 5 or 10 mg/kg SC was found effective to treat IBK in one field study.[4]

The efficacy of a long-acting formulation of ceftiofur crystalline-free acid (CCFA) administered as a single subcutaneous dose at the base of the ear to treat naturally occurring IBK has been examined in one study. A dose of 6.6 mg of ceftiofur equivalents/kg was found to result in higher healing rates and faster healing times of naturally occurring IBK compared with untreated control animals.[7]

Ancillary Therapy

Severe cases should be placed in a dark shelter out of direct sunlight. If housing is not possible, eye flap **patches** are available and effective. They are glued on above the eye and can be flipped up for medication of the eye.

When corneal ulceration has occurred, recovery is always protracted. The use of topical ophthalmic anesthetics combined with atropine administration may be indicated to minimize ciliary spasm and pain. Severe cases may require that the third eyelid be temporarily sutured across the globe of the eye for several days to promote healing. The use of NSAIDs should be considered in more advanced and severe cases.

TREATMENT AND TREATMENT

Treatment

Topical treatment:
- Benzathine cloxacillin ointment (250 to 375 mg topical q72h, 2 treatments) (R-1)

Subconjunctival injection:
- Procaine-penicillin G (300,000 to 600,000 IU subconjunctival q48-72 h, 2 treatments) (R-1)

Intrapalpebral injection:
- Oxytetracycline (treatment 1 to 2 mL of 10% solution intrapalpebral, single treatment) (R-2)

Systemic treatment:
- Oxytetracycline long-acting formulation (20 mg/kg q48h IM, two treatments) (R-1)
- Florfenicol (20 mg/kg q48 SC, 2 treatments or 40 mg/kg SC, single treatment) (R-1)
- Tulathromycin (2.5 mg/kg SC, single treatment) (R-2)
- Tilmicosin (5 mg/kg SC, single treatment) (R-3)

Treatment

Decrease exposure to dust and implement fly control, particularly against face flies (R-2)

Vaccination with commercially available or autogenous bacterins (R-3)

CONTROL

Eradication or prevention of the disease does not seem possible under extensive range conditions because of the method of spread, but if **fly control** can be fitted into the farm's management program this should significantly reduce the infection rate. Insecticide-impregnated eartags may help in the control of the disease but do not prevent it. In many herds the best that can be done is to keep animals under close surveillance and isolate and treat any cattle that show excessive lacrimation and blepharospasm. Cattle that have had the disease should not be mixed with those that have not until after the fly season.

Vaccination

There has been considerable effort to develop methods of immunoprophylaxis; however, the commercial bacterins, although available for over 30 years, have given inconsistent results, providing at best limited protection from subsequent infection and clinical disease. Killed, whole-cell vaccines require repeat injections, may be associated with anaphylactic reactions, and have not proven effective in the field. To avoid the need for repeated injections an adjuvant vaccine has been tested, but without apparent benefit.

Vaccines containing pilus antigens, with or without cornea-degrading enzyme antigens, protect against challenge with homologous strains of *M. bovis*, and some field trials report efficacy in naturally occurring outbreaks. However, others do not, and the results of field studies that have shown a beneficial effect from vaccination have been criticized on the basis of bias in the selection of controls. It is probable that currently available vaccines do not contain the diversity of antigens required to protect against the variety of strains that occur in natural outbreaks. Autogenous vaccines are a consideration in individual herds, but a recent controlled trial of an autogenous vaccine administered by subcutaneous or subconjunctival injection found no significant effect of either route or the vaccine on the incidence of disease.

Weekly treatment of both eyes of calves, but not the cows, with a furazolidone eye spray has been shown to be a more effective prophylaxis than vaccination with a commercial bacterin in some areas.

Total eyelid pigmentation may reduce the incidence of this disease, but the recorded differences are unlikely to arouse enthusiasm for a genetic approach to the problem.

OVINE AND CAPRINE CONTAGIOUS OPHTHALMIA (OVINE AND CAPRINE INFECTIOUS KERATOCONJUNCTIVITIS, CONTAGIOUS CONJUNCTIVO-KERATITIS, PINKEYE IN SHEEP AND GOATS)

SYNOPSIS

Etiology *Mycoplasma conjunctivae* is a significant cause, but other agents, in particular *Chlamydia pecorum*, *Moraxella ovis*, and other *Mycoplasma* spp., can produce clinically identical disease.

Epidemiology Rapid spread by contact with carrier animals. Usually occurs as outbreak in summer and when conditions are dry and dusty. Disease is most severe in weaned lambs.

Clinical findings Lacrimation, conjunctival hyperemia, pannus, neovascularization, iritis, keratitis in one or both eyes.

Diagnostic confirmation Clinical examination of the flock, exfoliative cytology, culture and polymerase chain reaction (PCR).

Treatment Topical or preferably parenteral tetracycline.

Control Avoid confinement and movement in dusty conditions. Fly control.

ETIOLOGY

A variety of organisms have been isolated from the eyes of sheep and goats with keratoconjunctivitis. Some are primary pathogens and others secondary invaders. It is difficult to attribute a primary etiological cause to a single agent because all the putative causal organisms have also been isolated from the eyes of normal sheep. Mixed infections occur during an outbreak, with potential synergism between *Mycoplasma* spp. and other infectious agents. The management circumstances that lead to outbreaks of disease with each agent, and the clinical syndromes that result, are not sufficiently distinct to allow the differentiation of the various etiologies on clinical or epidemiological grounds. There have been limited studies on the relative prevalence of flock outbreaks of disease associated with the various putative causes, but there is a strong evidence to incriminate *Mycoplasma* spp., particularly *M. conjunctivae*, as the major cause in domesticated sheep and goats, and wild ruminants such as chamois, Alpine ibex, European mouflon, and Bighorn sheep.

Mycoplasma conjunctivae

Mycoplasma conjunctivae is a common isolate in outbreaks of the disease. However, it is not present in all affected sheep and can also be isolated, with lesser frequency, from the eyes of clinically normal sheep. Disease can be reproduced with the inoculation of pure cultures of this organism into the eye of sheep and is then spread to other sheep by contact transmission. Consequently, it is thought to be a principal cause of pinkeye in sheep and goats.

Other Mycoplasmas

Other *Mycoplasma* spp. are frequently identified in the eyes of sheep and goats with pinkeye. *M. agalactiae* was considered a primary cause of an outbreak in Spain, whereas *M. arginini* and *Acholeplasma oculi* have been isolated from clinical cases of contagious ophthalmia. Infection with other mycoplasmas, such as *M. capricolum* subspp. *capricolum* and *M. mycoides* subspp. *capri*, can be accompanied by conjunctivitis, but other clinical signs, such as pneumonia, predominate.

Chlamydophila pecorum

Chlamydophila pecorum (*Colesiota conjunctivae*) was initially incriminated as a cause of contagious ophthalmia in sheep and goats in South Africa and Australia. It has been isolated from outbreaks of keratoconjunctivitis in sheep in the United States and the United Kingdom, and the disease has been reproduced experimentally. The strains are related to those associated with polyarthritis in sheep rather than abortion. A rickettsial agent, *Rupricapra rupricapae*, has been isolated from keratoconjunctivitis in chamois (*R. tragis*) and ibex (*Capra ibex*) in the French Alps. In Egypt, *Chlamydophila psittaci* was isolated at a higher rate from diseased eyes, compared with asymptomatic eyes, in both sheep (80% and 68%, respectively) and goats (92% and 76%, respectively).[1]

A number of bacteria, including *Branhamella* (*Neisseria*) *ovis*, *S. aureus* and *E. coli*, can be isolated from the eyes of animals with contagious ophthalmia, with rates of isolation from affected eyes higher than those from normal sheep. They have not always produced disease following experimental challenge. Consequently, they are considered to be secondary infections rather than having a primary causal role, exacerbating the lesions produced by the primary agent. *B. ovis* is considered a cause of follicular conjunctivitis. Similarly, *Moraxella bovis*, which is associated with contagious keratoconjunctivitis in cattle, has no apparent causal association with the disease in sheep, although it was isolated from clinical cases in goats in Nigeria.[2] *Listeria monocytogenes* may be a primary cause of keratoconjunctivitis and iritis in sheep.

EPIDEMIOLOGY

Occurrence

The disease is widespread in sheep of all breeds in most countries. Recently weaned animals are often the most severely affected.

Source of Infection and Transmission

The source of infection is infected or carrier animals. The disease is spread indirectly by flies, long grass, and dust contaminated by the tears of infected sheep, or directly by means of exhaled droplets or immediate contact. *M. conjunctivae* infects many wild small ruminant species and can be transmitted between domestic and wild animals.[3,4]

Risk Factors

The prevalence is highest during the warm, summer months and when conditions are dry and dusty and flies are abundant. The morbidity rate varies widely depending on seasonal conditions; it is usually about 10% to 15% but may be as high as 80%. Resistance to infection is reduced by other disease, poor nutrition, and adverse weather. Widespread outbreaks occur in some years where the disease contributes to poor growth and illthrift, presumably from reduce foraging ability, especially in young stock. Outbreaks during mating can reduce conception and lambing rates.

In many flocks at pasture the disease causes little disruption to grazing, and so only minor inconvenience. However, in other flocks, and in some years, higher morbidity, severe lesions, and detrimental effects on production occur. Clinical experience suggests that the incidence and the severity of the disease in an affected flock are increased by the stress, dust, and close contact associated with gathering and yarding of the flock. Thus a decision to treat during an outbreak can be associated with an apparent exacerbation of clinical disease.

PATHOGENESIS

Rapid onset of acute inflammation of the conjunctiva is followed by hyperemia of the sclera and pannus and opacity of the cornea.

CLINICAL FINDINGS

Clinical findings are similar with all agents associated with the disease. There is conjunctivitis, lacrimation, and blepharospasm, followed by keratitis with cloudiness of the cornea and some increase in vascularity. There is profuse lacrimation, and thus initial signs in the flock may be a brown discoloration below the eye associated with dust accumulating on lacrimal discharges.

Corneal opacity is initially most pronounced at the dorsal corneal–scleral junction. This is followed by vascularization, to produce a horizontal zone of opacity associated with an area of vertical-oriented vascularization in the upper area of the eye. In severe cases, the whole cornea is affected, and there may be corneal ulceration.

In flocks experiencing an outbreak, the disease in most sheep is mild if there are no complicating circumstances; the initial watery discharge from the eye becomes purulent, but recovery commences in 3 to 4 days and is complete at about 20 days. In some animals the cloudiness of the cornea may persist for several weeks or even permanently. Local ulceration of the cornea may cause collapse of the eyeball. One or both eyes may be affected, but many sheep have both eyes affected in outbreaks, and spread through the flock is rapid.

Conjunctivitis is followed by the development of granular lesions of follicular conjunctivitis on the palpebral conjunctiva and third eyelid, which are thought by some to be specific for infections involving *B. ovis*.

In goats, the disease is milder with little apparent ophthalmia or keratitis. A more severe keratoconjunctivitis than that associated with *M. conjunctivae*, and manifest with corneal edema, occurs in some outbreaks in goats, but its cause has not been established. All age groups are affected, and although the morbidity is usually 12% to 20%, it may reach 50%. Direct contact between animals appears to be necessary for spread of the infection, but the disease has not been transmitted experimentally. Conjunctivitis, opacity, vascularization, and sometimes ulceration of the cornea are accompanied by an ocular discharge and blepharospasm. In some goats there is severe corneal edema with intracorneal edema accumulating to a degree to produce corneal vesicles. In mildly affected goats, recovery begins in 4 to 7 days, but in severe cases, healing may not be complete for 2 to 4 weeks or longer.

CLINICAL PATHOLOGY

Scrapings can be taken for exfoliative cytology from the palpebral conjunctiva, preferably from early clinical cases. *Mycoplasma*, *Branhamella*, and *Chlamydophila* have characteristic morphology and can be demonstrated in Giemsa- or immunofluorescent-stained smears. Samples can also be submitted for culture identification, and paired serum samples can be submitted for examination for antibodies to *Chlamydophila*.

The determination of the etiologic agent currently has limited significance to the subsequent approach to the control and treatment of the disease, and so is largely academic. However, conventional and real-time PCR can be used to detect *M. conjunctivae* and *Moraxella* spp., and PCR is a more sensitive way of detecting of infection than culture.[5,6]

TREATMENT

A decision for treatment needs to be taken with consideration of the adverse effects on the disease of the associated movement and close yarding of the flock. Repeated treatments of sheep pastured under extensive grazing are impractical, and spontaneous recovery will occur within 3 weeks. Consequently, in extensive grazing conditions a decision for no treatment is often made.

A single intramuscular injection of long-acting tetracycline at 20 mg/kg halts further development of clinical conjunctivitis when given as clinical signs develop and results in rapid clinical cure in animals affected with keratoconjunctivitis produced by *M. conjunctivae*. Florfenicol readily penetrates tear fluid, with doses greater than 20 mg/kg needed to provide minimum inhibitory concentrations against most *Mycoplasma* spp.[7] However, neither parenteral or topical antibiotic treatment eliminates infection; thus, repeated infections in individual animals and recurrence of outbreaks in flocks are common. Where the etiology is not known and treatment is deemed desirable, tetracyclines administered either topically or parenterally, or topical treatment with cloxacillin or erythromycin ophthalmic ointments, have been shown to be of benefit.

CONTROL

Complete eradication of the disease is not attempted, but isolation of affected sheep and removal to grassier, less dusty pasture may reduce the rate of spread. Confinement of affected sheep should also be avoided.

DISEASES OF THE EYES ASSOCIATED WITH *MYCOPLASMA* SPP.

Mycoplasma conjunctivae is the etiologic agent causing **infectious keratoconjunctivitis of small and wild ruminants** (see also "Ovine and Caprine Infectious Keratoconjunctivitis").

In cattle *M. bovoculi* is frequently isolated from conjunctival swabs without necessarily being associated with clinical disease. The recovery rate of *M. bovoculi* from eye swabs obtained from clinically healthy cattle and animals with conjunctivitis was approximately 40% in both instances. *M. bovoculi* was isolated more frequently from animals younger than 2 years of age than from older animals, whereas the disease incidence of infectious keratoconjunctivitis was similar in both age groups. The higher recovery rate of *M. bovoculi* in younger animals was explained

by the development of immunity after initial infection.

Other *Mycoplasma* spp. that have been isolated from cattle with keratoconjunctivitis are *M. bovis*, *M. bovigenitalium*, *M. bovirhinis*, *M. verecundum*, *Ureaplasma diversum*, *Acholeplasma laidlawii*, and *Acholeplasma oculi*, some of which have been incriminated as contributing to the development of **infectious bovine keratoconjunctivitis**.

THELAZIASIS (EYEWORM)

A number of species of the nematode genus *Thelazia* occur in the conjunctival sac and tear ducts of mammals throughout the world. *T. gulosa* and *T. skrjabini* are the main species in cattle in the New World, *T. rhodesi* is the commonest in the Old World, and *T. lacrymalis* is common in horses. They are thin worms up to 2 cm long. Infestation is often inapparent, but they may cause excessive lacrimation, photophobia, conjunctivitis,[1] corneal opacity,[2] keratitis, corneal ulceration, and abscess formation on the eyelids. In horses, this condition mainly occurs in young animals.[3] One U.S. survey in Kentucky found 43% of horses up to 4 years old to be infected. In those species that have been studied, the life cycles are indirect, with muscid flies, particularly the face fly *M. autumnalis*, being the intermediate hosts. These flies deposit larvae on the conjunctiva when feeding on fluid around the eye. The disease is mainly seen in summer and autumn when the flies are active. It is usually more common in cattle[1] and African buffalo[2] than horses, and worms may be more abundant in beef than in dairy cattle. Eyeworm in cattle is differentiated from infectious keratitis by observing the adult worm in the conjunctival sac or demonstrating first-stage larvae in eye washings. Ivermectin (0.2 mg/kg, repeated three times at 1-month intervals) is active against worms in African buffalo.[2] Ivermectin and doramectin are active against the adult worm in cattle, but anecdotal reports suggest that it may be less effective in horses.[3]

"BRIGHT BLINDNESS" OF SHEEP CAUSED BY BRACKEN INGESTION

A progressive retinal degeneration associated with ptaquiloside was observed in sheep kept for more than 3 years on pastures heavily infested with bracken in the United Kingdom, and the disease has been produced experimentally in sheep fed bracken. Affected sheep are blind, reluctant to move, but bright and alert. The pupils are dilated and show poor light and menace reflexes, and on ophthalmoscopic examination there is retinal degeneration. This degeneration may be observable in many more sheep than the clinically blind ones. Leukopenia is a characteristic.

BOVINE OCULAR SQUAMOUS-CELL CARCINOMA

Bovine ocular squamous-cell carcinoma (BOSCC), often referred to as "cancer eye," is one of the most common neoplasms of cattle.

SYNOPSIS

Etiology Genetic–environmental interaction. Lack of pigmentation around the eye and solar radiation.

Epidemiology One of most common neoplasms of cattle; mostly in beef cattle breeds with white on their heads (Hereford, Simmental) and lacking pigment around the eye; animals over 5 years of age. Solar radiation is a major risk factor.

Signs Precursor lesions; single or multiple plaques on eyelid or conjunctiva, except the cornea or pigmented lid; may regress or lead to carcinomas of sclera resembling papillomas with crumbly, necrotic ulcerated mass attached to the eyelid, causing irritation to eye and conjunctiva and excessive lacrimation and pus. Invasion of surrounding tissues of eye and possibly to nearby lymph nodes.

Clinical pathology Histology of lesion.

Lesions Squamous-cell carcinoma.

Diagnostic confirmation Biopsy and histology.

Differential diagnosis list
Pinkeye
Lymphoma of periorbital tissues

Treatment Excision by cryosurgery. Radical surgery may be necessary. Immunotherapy with vaccines has been attempted.

Control Breeding program to increase degree of periocular pigmentation in white-faced beef cattle and remove genetically susceptible cattle from the breeding herd.

ETIOLOGY

A genetic–environmental interaction has been proposed as the cause. A relative **lack of circumocular and corneoscleral pigmentation**, both of which are highly heritable, increases the probability of lesion development when the animal is exposed to a carcinogenic agent such as the **ultraviolet component of sunlight**.[1] The carcinoma has been regarded as a papilloma-associated tumor because papillomavirus can be found in the precursor lesions, and papillomavirus DNA in the carcinomas. It is possible the papillomavirus infection predisposes to BOSCC by induction of precursor lesions, but papillomavirus does not appear to be needed for maintenance of the tumor. Moreover, advanced virological techniques have failed to reveal any association between the virus and the tumor.[2]

The *p53* gene product is highly expressed in bovine BOSCC, which provides support for its role in BOSCC tumor development.

EPIDEMIOLOGY

Occurrence

Bovine ocular squamous-cell carcinoma is a very common neoplasm of the eyelids and the eyeball of cattle and one of the most common neoplasms of cattle. The disease is most common in beef cattle, which are exposed to more sunlight than dairy cattle. Breeds affected most commonly are Hereford and Simmental, but BOSCC has also been recorded in Shorthorn, Holstein–Friesian, Guernsey, Jersey, Ayrshire, Brown Swiss, Normandy, Hollandensa, Javanese-Mongolian, and Brahman cattle.

The tumors are uncommon in cattle younger than 5 years and are almost never seen in cattle younger than 3 years. The condemnation rate at slaughter of cattle with ocular squamous-cell carcinoma in Canada is about 30% of cases. A squamous-cell carcinoma of the anal and perianal area of a 15-year-old bull has been recorded.

Risk Factors

The heritabilities and phenotypic and genetic correlations of eyelid and corneoscleral pigment and eye lesions associated with eye cancer were investigated in 2831 Herefords from 34 herds in 21 U.S. states and one Canadian province. The results indicated that periocular pigmentation and eyelid and corneoscleral pigment were highly heritable and genetically correlated. These findings lead to the general conclusion that the genetic effect on pigment determines to a large extent the degree to which the eye is susceptible to an environmental carcinogenic agent such as ultraviolet light. A very high heritability estimate ($h^2 = 0.79$) was reported for circumocular pigmentation in 3579 Simmental cattle in Germany.[1]

In Zimbabwe, ocular squamous-cell carcinoma was frequently observed in five breeding herds of Simmental cattle. In these herds, initial signs of the disease were evident in cattle of about 3 years of age, and gradually the prevalence increased to over 50% in animals over 7 years of age. It is suggested that because most cattle in Zimbabwe are slaughtered by 10 years of age, that more than 67% of cattle without periorbital skin pigmentation would develop the tumor. The tumors were multiple and commonly bilateral. Simmental cattle have a complete or partly white face, and the lack of facial pigmentation risks exposure to intense solar radiation when they are kept at a high altitude (1500 m) in a sunny and warm climate. The prevalence was much lower in white-faced Friesian cattle in the same

environment, which indicates a genetic predisposition for the tumors in Simmental cattle, separate from periocular pigmentation. In Zimbabwe, the tumor is not recorded in fully pigmented cattle breeds.

The positive association between prevalence of BOSCC and various measures of solar radiation indicate a significant association between increasing risks of developing eye cancer and increasing levels of radiation. Ultraviolet light is generally regarded as an important risk factor. Most tumors are located only in the sun-exposed mucocutaneous areas not protected by hair. Tumors are predominantly localized in the third eyelid and the lateral limbus, and tumor growth usually starts at the outer edge, which receives the most sunlight. Cattle exposed to higher levels of ultraviolet radiation develop the disease at younger ages.

Economic Importance

The disease results in serious economic consequences through lessened productivity and carcass condemnations. Commercial cattle can be culled early without much loss, because only the head is condemned. Purebred cattle are more of a problem because of the difficulty of deciding when euthanasia must be the humane decision, rather than another attempted extirpation of the eye. An additional issue in purebred cattle is whether the bloodline of affected cattle should be preserved.

PATHOGENESIS

The initial lesion may be on the eyelid or any structure in the conjunctival sac, except the avascular cornea or pigmented eyelid. Lesions can encroach on these tissues from others nearby, carrying a blood supply with them.

The lesions develop through four stages. The first three, plaque, keratoma, and papilloma, are nonmalignant and have relatively high spontaneous regression rates. The fourth stage is the squamous-cell carcinoma, which does not regress. The tumor is located in the sclera adjacent to the lateral limbus, in the membrana nictitans (third eyelid), or in the lower eyelid (Fig. 16-11A-C). It is an invasive tumor, metastasizing along the draining lymphatics into cervical lymph nodes. Primary lesions of the lids are most likely to metastasize to these nodes.

Animals do not appear to develop resistance to the cancer; only a few cows with the disease develop measurable antibodies in their sera. It is one of the characteristics of this disease that the carcinomas appear to produce immunosuppressive substances, and removal of tumor mass reduces their blood concentrations.

In countries and in herds where ocular carcinoma is common, it is not unusual to encounter lesions on the labia of the vulva, especially if there are patches of unpigmented skin.

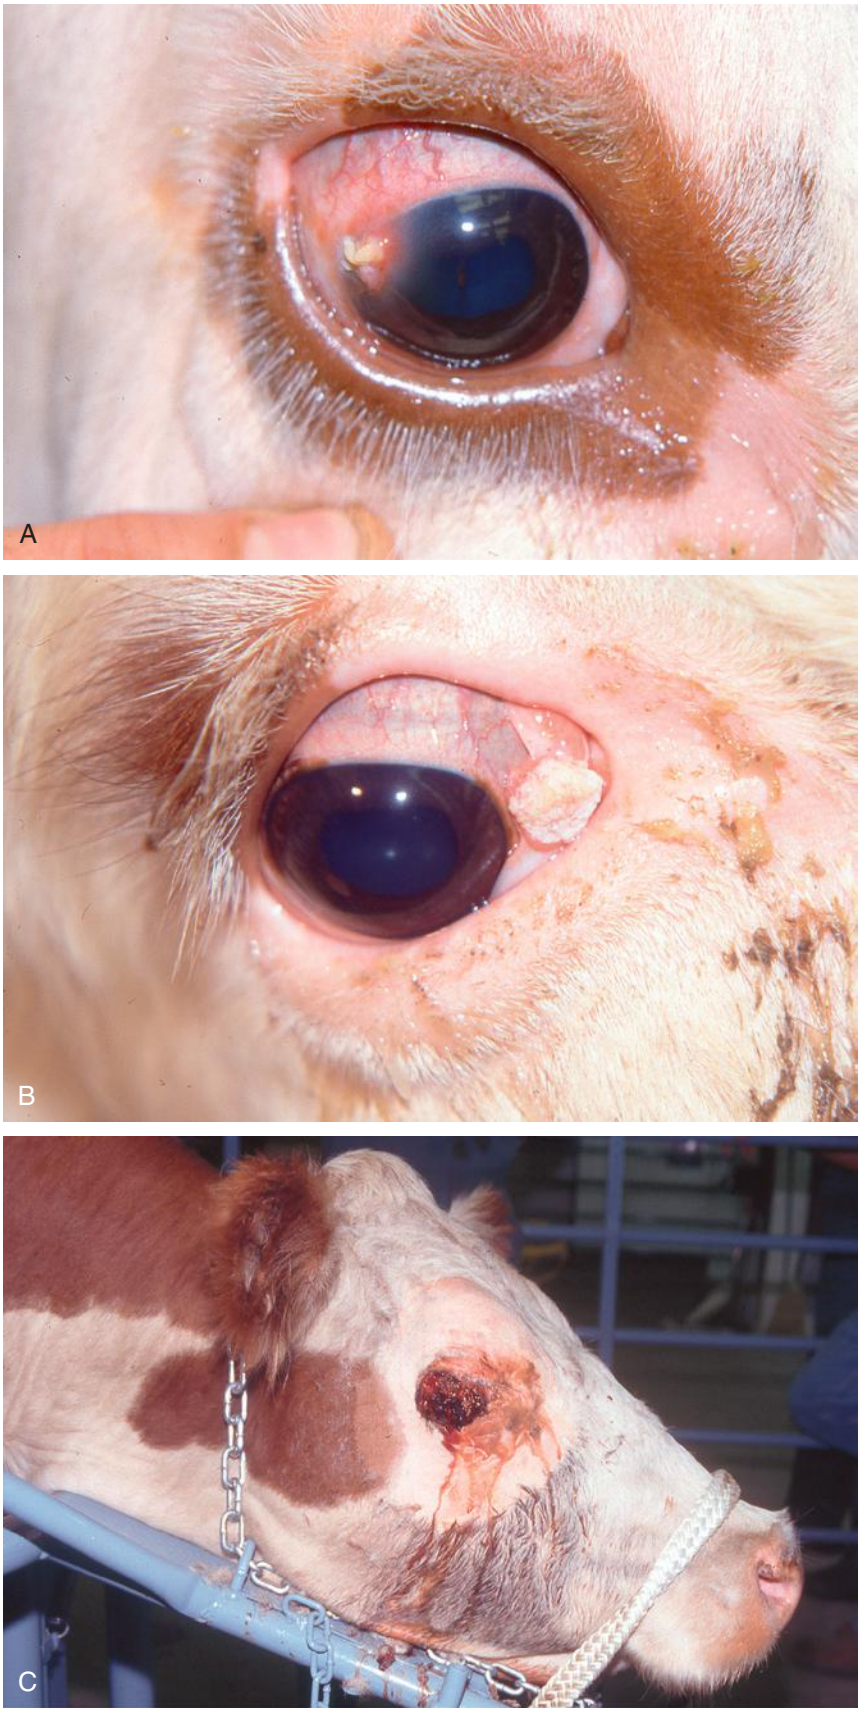

Fig. 16-11 **A, Advanced plaque on the lateral limbus of the right eye from a Simmental cow. This is a precursor to ocular squamous-cell carcinoma. B, Advanced papilloma on the third eyelid of the right eye from a Simmental cow. This is a precursor to squamous-cell carcinoma. Note the small amount of periocular eyelid pigmentation. C, Advanced squamous-cell carcinoma of the right lower eyelid of a Simmental cow. The tumor mass is large enough that metastasis to the regional lymph node was likely.**

CLINICAL FINDINGS

Typical precursor lesions are single or multiple plaques of gray–white, smooth or rough, hyperplastic to hyperkeratinized tissue anywhere in the conjunctiva (stage 1). Plaques may develop into keratoma or keratoacanthomas (stage 2) and papillomas (stage 3), which are also regarded as precursor lesions. Squamous-cell carcinomas (stage 4) may develop from any of these precursor stages, which may also regress spontaneously. **Classic ocular squamous-cell carcinoma lesions** resemble papillomas, with a fleshy, sometimes crumbly, often necrotic and ulcerated mass attached to the lid or the orbit by a wide base. They are visible even when the eyelids are closed, and they cause obvious irritation to the surrounding conjunctiva, resulting in increased lacrimation and sometimes in the discharge of pus. Invasion of surrounding tissues is common, but metastases to nearby lymph nodes and to viscera occur in only a few cases and then only late in the course of the disease. In general, all lesions with a dimension greater than 2 cm are cancerous (stage 4). The proportion of small precursor lesions that regress without specific treatment is up to 88%, which complicates evaluation of treatment efficacy.

The most common location for tumor development is the lateral corneoscleral junction (limbus), which usually accounts for three-fourths of all lesions. Other predilection sites are the nictating membrane (third eyelid) and middle to medial aspect of the lower eyelid. Tumors on the nictating membrane appear to grow more quickly than tumors located elsewhere.[3] Tumors in the eyelids have a higher frequency of metastasis than tumors of the cornea or limbus; this most likely reflects total tumor volume at diagnosis, with eyelid lesions typically being more extensive when the animal is first examined for treatment.

CLINICAL PATHOLOGY

Differentiation between carcinomas and precursor lesions is difficult clinically, and cytologic examination or biopsy is recommended for definitive diagnoses. The cytology of squamous-cell carcinomas in domestic animals has been described.

DIFFERENTIAL DIAGNOSIS

One of the difficulties encountered in the field is the clinical differentiation of benign precursor lesions from the malignant carcinomas; failure to do so may account for the high rates of spontaneous regression recorded, especially in Hereford cattle, where a spontaneous recovery rate of 88% has been recorded. To avoid this inaccuracy, exfoliative cytology by the examination of smears of lesions is helpful. Combined with a clinical assessment, this is the recommended method of confirming the diagnosis. Differentiation from similar lesions that are not BOSCC can only be achieved by proper laboratory examination of tissues.

BOSCC must be differentiated clinically from:

Pinkeye and its complications, which result in excessive lacrimation and purulent material

Lymphoma of the periorbital tissues, which usually manifests as exophthalmos

TREATMENT

Surgical excision of small lesions with a margin of 2 to 3 mm, accompanied by cryonecrosis (two freeze–thaw cycles) of the tumor site using appropriately sized copper probes placed in liquid nitrogen, is widely practiced in cattle. Results are good to excellent in cattle with small lesions (<2 cm in dimension). Enucleation (removal of the eye) and extirpation or exenteration (removal of the eye and para-orbital tissue) is commonly performed in animals with larger lesions (>2 cm in dimension) that indicate presence of carcinoma in situ that are locally invasive. The major challenges with enucleation are intraoperative hemorrhage and postoperative infection, which occurred in 19% of 53 cattle.[4] Radical surgery, including removal of the local lymph nodes and parts of the salivary gland, may be desirable in advanced cases of BOSCC.

Recurrence, or the development of new lesions at the same site, is common. Treatment can also be combined with immunotherapy, for example, with **bacillus Calmette–Guérin** (BCG) vaccine injected systemically or into the lesion, or with vaccination with BOSCC tumor material. There is a significant cell-mediated immune response in cattle with BOSCC, and it is thought that this immune process plays an important role in the rejection of the tumors. One controlled trial in cattle showed that intralesional injection of BCG vaccine can interrupt neoplastic progression and prevent malignant disease. A permanent regression after BCG vaccination can be expected in 37% of cases, recurrence at the same site in 26%, and continued growth in 37%.

A favorable response to a single injection of a saline phenol extract of fresh tumor tissue can induce a high rate of regression of ocular tumors, with a higher recovery rate after the use of 200 mg of lyophilized tumor extract compared with an injection of 100 mg. The injection may need to be repeated. Occasional tumors show enhancement of growth after vaccination, especially if it is repeated. The vaccine does not need to be autologous, and only one injection is required. A freeze-dried preparation of tumor antigen has been used successfully. In general, the use of a vaccine seems likely to provide a satisfactory method for controlling an esthetically distressing and financially important disease. Reports on the effect of vaccination with a tumor vaccine on the vulvar form of squamous-cell carcinoma vary.

Daily peritumoral injections of BOSCC lesions up to 2.8 cm^2 in area with interleukin-2 for 10 days at 5000 to 1,000,000 U was effective in inducing complete tumor regression in 50% to 69% of tumors at 20 months, compared with 14% regression in control cattle injected with solvent.[3] Lower daily IL-2 doses (<200,000 U) were similarly effective as higher doses in inducing tumor regression at 9 months, but their effectiveness was not maintained at 20 months. Interleukin-2 is thought to induce tumor regression by initially inducing edema, then angiogenesis, recruitment of monocytes, and macrophage and lymphocyte activation. However, the tumor response rate to IL-2 treatment is lower than that achieved by surgery, which remains the preferred treatment for BOSCC.

Treatment by the use of radioactive implants or topically applied radiation has also been successful, but reduced availability and concerns about the use of radioactivity in a meat-producing animal has markedly decreased the application of localized radiation therapy. Other treatments that have received favorable comment, but need to be evaluated in the light of the known natural recovery rate of the benign precursor lesions, include radiofrequency hyperthermia and combinations of the previously described procedures.

TREATMENT AND CONTROL

Treatment

Surgical excision of lesions > 2 cm in dimension (stage 4) (R-1)

Surgical excision of lesions < 2 cm in dimension (stages 1, 2, 3, or 4) (R-1)

Cryonecrosis (2 freeze–thaw cycles) (R-2)

Intralesional BCG injection(s) (R-2)

Intralesional IL-2 injections (200,000 to 2,000,000 U daily for 10 days) (R-2)

Local radiofrequency hyperthermia (2 heating cycles) (R-2)

Local radiation therapy (if available and permitted) (R-2)

Prophylaxis

Decrease exposure to ultraviolet light (usually not practical) (R-1)

Implement breeding program based on increasing periocular pigmentation (R-1)

Remove direct descendants and sires and dams of cattle diagnosed with BOSCC (R-2)

CONTROL

Because of the strong correlation between absence of pigmentation of the eyelids and the occurrence of the disease, and because of the high heritability of this pigmentation in Hereford and Simmental cattle, it is

suggested that a breeding program aimed at increasing the degree of pigmentation of eyelids could quickly reduce the incidence of the disease in this breed. A positive approach to the problem would be to crossbreed susceptible *B. taurus* cattle with *B. indicus* cattle, which always have pigmented eyelids and have much lower rates of eye cancer. In Ayrshires there is a corresponding predilection for squamous-cell carcinomata of the vulva, but the neoplasm does not occur on both sites in the same cow. Selection on the basis of the occurrence of lesions alone results in only limited reduction in incidence.

EQUINE OCULAR SQUAMOUS-CELL CARCINOMA

Squamous-cell carcinoma is one of the most common neoplasms of the horse and is the most common neoplastic tumor of the eye and orbit.

Equine ocular squamous-cell carcinoma (EOSC) is associated with a number of factors, including lack of pigmentation around the eye, exposure to solar radiation, mutations in the *p53* gene, and presence of equine caballus papillomavirus type 2 (EcPV-2) and bovine papillomavirus type 1 (BPV-1) DNA.[1,2] EcPV-2 is also found in squamous carcinoma of the penis of horses, but not in clinically normal nictitating membrane tissue (75 horses).[3] Although DNA of BPV-1 can be found in normal equine skin, there is increasing evidence of an etiologic link between mucocutaneous squamous-cell carcinoma (SCC) in horses and EcPV-2 infection. Approximately 25% of these tumors express cyclooxygenase-2 activity.[4-6]

The reported frequency has been highest in animals lacking periocular pigmentation and is more common in Appaloosa, albino, and color-dilute horses. An increased prevalence for ocular and adnexal SCC has been reported in Belgian draft horse breeds, Appaloosas, Paint horses, Thoroughbreds, and Quarter horses. A predisposition for the development of ocular and adnexal SCC has also been reported in geldings. The risk has been higher in draft breeds than in other pigmented breeds, probably related to the large expanses of white skin on the face and around the eye of the heavy draft breeds. The overall mean age range of affected animals is 8 to 10 years. In a series of limbal neoplasms in horses admitted to the Veterinary Teaching Hospital in the Netherlands, SCC was the most predominant tumor type, and Haflinger horses accounted for 69%, whereas their occurrence in the hospital population was 5%.

In a retrospective study of 50 cases submitted to the University of Florida Veterinary Medical Teaching Hospital, the Appaloosa accounted for the majority of cases, which may be a reflection of the high level of solar radiation in southeastern United States. The average age at which the tumor was diagnosed initially was 11.8 years; males accounted for 64% and females 36% of the cases. The rate of metastasis was 18%.

In the Florida study, higher cure rates were associated with surgical excision followed by radiation therapy for a cure rate of 75%, whereas with only surgical excision the cure rate was 55%. Best results with treatment are seen when surgical intervention is early. In horses, treatment is largely surgical, but all of the immunologic techniques developed for cattle have been used, including local irradiation therapy.

The most frequent site for ocular involvement is the nictitating membrane and conjunctiva, but the eyelids and cornea are also involved.

Treatment of ocular and adnexal SCC has included various types of therapy, with and without adjuvant radiation therapy. Types of treatment without adjuvant radiation therapy include excision, cryotherapy, radiofrequency hyperthermia, immunotherapy, chemotherapy with cisplatin, and carbon dioxide laser ablation. Treatment with adjuvant radiation therapy includes use of strontium 90 (Sr), cobalt 60 (Co), gold 198, iridium 192 (Ir), cesium 137, iodine 125 (I), and radon 222 (Rn). In a series of 157 cases of ocular and adnexa SCC, those treated with adjuvant radiation therapy had a significantly lower recurrence rate compared with those treated without adjuvant radiation therapy, independent of anatomic location.

Superficial keratectomy followed by cryosurgery is a simple and effective procedure for the treatment of small-sized limbal tumors (less than 2 cm) in horses. Sophisticated equipment is not required, and the legal restrictions associated with the use of radioactive substances in many countries are not a consideration.

Prevention is through reduction of exposure to sunlight through use of fly masks and tattooing of ocular tissue.

Ocular pseudotumors have been described in horses. They are proliferative inflammatory lesions involving the eye, adnexa, or orbit, which clinically mimic true neoplasms. Cases are characterized by a unilocular, pink, proliferative limbal or perilimbal lesion. Affected horses may be from 5 to 9 years of age. Most cases occurred during the summer months and none of the affected animals had a history of trauma or recent deworming. The dorsal bulbar conjunctiva was most commonly affected, followed by the third eyelid. Lesions were relatively flat with indistinct margins or discrete and nodular. Histologically, the lesion is inflammatory and characterized by predominantly lymphocytic infiltrates. The cause is unknown, but an immune-mediated pathogenesis is suspected based on the preponderance of immunocytes consisting primarily of lymphocytes. Treatment consists of surgical excision alone, partial resection with antiinflammatory therapy, or antiinflammatory therapy alone.

INHERITED EYE DEFECTS

Inherited eye defects of farm animals and horses are not uncommon and typically occur in breeds that originate from a small founder base, such as, for example, with the complex ocular abnormalities of "Rocky Mountain horses" (which actually originated in the Ohio Valley of the United States) or Texel sheep.[1,2] Abnormalities of the eyes include strabismus; microphthalmia; single, multiple, or complex intraocular abnormalities; cataracts; retinal abnormalities (night blindness); corneal lesions, including abnormal tissue on the surface of the cornea (dermoids) or corneal opacity; abnormal eyelid conformation (entropion); distichiasis; and absence of the nasolacrimal duct. The genetic basis for some of the more common lesions has been determined.[3-7]

Inherited convergent **medial strabismus with exophthalmos** occurs in German Brown, Jersey, Shorthorn, Ayrshire, Bulgarian Grey, Irish Friesian, German Fleckvieh, German Black and White, and Dutch Black Pied breeds.[7] The incidence of BCSE in German Brown cattle is 0.9% in adult cows and 0.1% in young animals. The disease appears to be inherited in an autosomal-dominant manner with incomplete penetrance, with a relative decrease in neurons in the nuclear region of the abducens nerve. This decrease in neurons induces paresis of the lateral rectus muscles and the lateral part of the retractor bulbi muscles, resulting in the clinical signs of exophthalmos and strabismus. Candidate genes for the defect are thought to be on bovine chromosomes 5 and 18.[8,9]

The disease is characterized by late onset (>1 year of age) of clinical signs that are

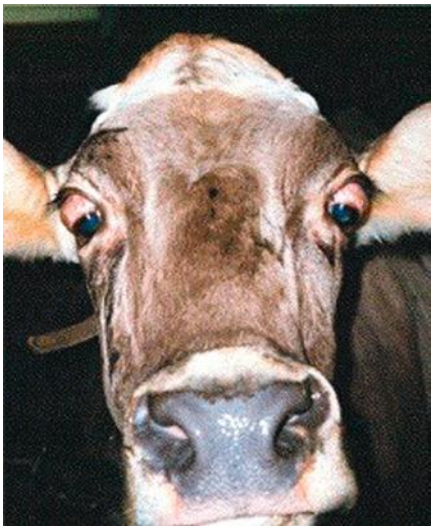

Fig. 16-12 Advanced case of bilateral convergent strabismus with exophthalmos in a German Brown cow. (Reproduced, with permission, from Mömke S, Distl O. Bilateral convergent strabismus with exophthalmus [BCSE] in cattle. An overview of clinical signs and genetic traits. *Vet J* 2007; 173:272-277.[7])

progressive, including bilateral, symmetric, permanent rotation of the eyeballs in an anterior-medial direction and slight to severe laterodorsal exophthalmos (Fig. 16-12).[7] Parts of the lateral rectus muscle or retrobulbar fat pad can become visible in severely affected animals. Epiphora is common in cattle with advanced BCSE. The sclera becomes darkly dark pigmented. Mildly affected animals compensate well and can be difficult to detect without close examination of the eyes, whereas more severely affected animals clearly have visual impairment up to and including blindness. There is no effective treatment.

An inherited, congenital **corneal opacity** occurs in Holstein cattle. The cornea is a cloudy blue color at birth, and both eyes are equally affected. Although the sight of affected animals is restricted they are not completely blind, and there are no other abnormalities of the orbit or the eyelids. Histologically there is edema and disruption of the corneal lamellae.

Lens dystrophy occurs in Brown Swiss cattle that are affected by an inherited congenital blindness. Japanese Black cattle also suffer from an inherited blindness caused by defects in the pupil, retina, and optic disk.

Congenital cataracts occur in a variety of breeds of cattle, and some have a suspected genetic component.[10] Multiple cataracts in a herd of Ayrshire cattle in Ireland were not clearly inherited, but the cause was not determined.[10] The condition of bilateral cataracts has been observed to be an inherited defect in Romney sheep. It is inherited as an autosomal-dominant trait and can be eradicated easily by culling. Congenital cataracts in Exmoor ponies in Canada are inherited in a sex-linked fashion, with the disease being significantly more common in females.[11]

Complete **absence of the iris** (aniridia) in both eyes is also recorded as an inherited defect in Belgian horses. Affected foals develop secondary cataracts at about 2 months of age. Total **absence of the retina** in foals has also been recorded as being inherited in a recessive manner.

Congenital stationary night blindness (CSNB) in Appaloosa horses is associated with homozygosity for the gene conferring the coat spotting pattern in horses, which itself is caused by a single incomplete dominant gene (LP).[5,12] LP maps to a 6-cM region on ECAl. Expression of transient receptor potential cation channel, subfamily m, member 1 (TRPM1) in the retina of homozygous Appaloosa horses is 0.05% the level found in non-Appaloosa horses. Decreased expression of TRPM1 in the eye and the skin may alter bipolar cell signaling and melanocyte function, thus causing both CSNB and LP in horses.[5]

Microphthalmia is reported to be an inherited defect in Texel sheep, but the incidence is low. It is a well-recognized genetic defect of Texel sheep in Europe. Following importation and "breeding up" of the breed in New Zealand in the 1990s, animals were released from quarantine for further expansion of the breed. The abnormality has occurred in a number of flocks in New Zealand, and an experimental breeding flock is maintained to study the molecular genetics. It is inherited as an autosomal-recessive trait. An outbreak in Texel sheep in New Zealand has been recorded. The optic globes are approximately one-half normal size, and the optic nerves at the chiasma are approximately one-half normal size. No other lesions are present in any organs. The retina is composed of an irregular mass attached to and continuous with the ciliary apparatus at one pole and connected to the optic nerve posteriorly by a short stalk. The morphology and morphogenesis of the defect has been followed in embryos at different ages from ewes known to be carriers of the microphthalmia factor. The primary event was abnormal development of the lens vesicle, with disintegration of the lens and subsequent overgrowth of mesenchymal tissue. The mesenchymal tissue later differentiated in various directions, whereas the epithelial structures found in the microphthalmic eyes at days 56 and 132 of gestation and in newborn lambs appeared to be remnants of the epithelial lens vesicle.

Typical colobomata, ophthalmoscopically visible defects of one or more structures of the eye, caused by an absence of tissue, have assumed a more prominent position than previously because of their high level of occurrence in Charolais cattle. The lesions are present at birth and do not progress beyond that stage. They affect vision very little, if at all. However, because they are defects they should be named in certificates of health, but they are not usually considered as being a reason for disqualification from breeding programs. In Charolais cattle the inheritance of the defect is via an autosomal-dominant gene with complete penetrance in males and partial (52%) penetrance in females. The prevalence may be as high as 6%, and in most cases both eyes are affected. The defect is a result of incomplete closure of one of the ocular structures at or near the line of the embryonic choroidal fissure. Failure of the fissure to close represents the beginnings of the coloboma. The retina, choroid, and sclera are usually all involved.

Entropion is inherited in a number of sheep breeds, including Oxfords, Hampshires, and Suffolks. Affected lambs are not observed until about 3 weeks of age when attention is drawn to the eyelids of the apparent conjunctivitis. A temporary blindness results, but even without treatment there is a marked improvement in the eyelids. Congenital entropion occurs in related Boer goat kids, but the mode of inheritance, if any, is unknown.[13]

Distichiasis, in which aberrant cilia are present at the eyelid margin, appears to occur with greater frequency in Friesian horses, in which rigid cilia cause corneal irritation or corneal ulceration. Although an inherited cause is suspected, the etiology is unclear.[14]

Ocular dermoids are recorded as genetically transmitted in Hereford cattle. They occur as multiple small masses of dystrophic skin complete with hair on the conjunctiva of both eyes of affected cattle. They can be anywhere on the cornea, on the third eyelid, or the eyelid, and they may completely replace the cornea; there may be a resulting marked dysplasia of the internal ocular structures.

Ocular dermoid cysts are single, solid, skin-like masses of tissue, adherent usually to the anterior surface of the eye, causing irritation and interfering with vision (Fig. 16-13). The eyelid, the third eyelid, and the canthus may also be involved, and the lesions may be unilateral or bilateral. When they occur at a high frequency in a population, it is likely they are inherited, as they can be in Hereford cattle. It is also recorded in foals. The defect is sometimes associated with microphthalmos. Surgical ablation is recommended.

Nasolacrimal duct fistulae, either unilateral or bilateral, occur in Brown Swiss cattle. The defect, evidenced by persistent epiphora and presence of a nasolacrimal fistula medial to the medial canthus of the eye, is inherited, although the mode of inheritance is unclear.[15,16]

Combined Ocular Defects

Although the vision appears unaffected, a large number of congenital defects of the eye

Fig. 16-13 **Ocular dermoid cyst on the ventral corneal and limbus of the left eye of a Simmental calf.**

have been observed in cattle, including Herefords, affected by partial albinism. The defects include iridal heterochromia, tapetum fibrosum, and colobomas. Congenital blindness is also seen in cattle with white coat color, especially Shorthorns. The lesions are multiple and include retinal detachment, cataract, microphthalmia, persistent pupillary membrane, and vitreous hemorrhage. Internal hydrocephalus is present in some, and hypoplasia of optic nerves also occurs.

A combination of **iridal hypoplasia, limbic dermoids, and cataracts** occurred in the progeny of a Quarter horse stallion, presumably as a result of a mutation in the stallion and transmission to the foals via an autosomal-dominant gene. The inheritance is simple autosomal recessive.

Irideremia (total or partial absence of iris), **microphakia** (smallness of the lens), ectopia lentis, and cataract have been reported to occur together in Jersey calves. The mode of inheritance of the characters is as a simple recessive trait. The calves are almost completely blind but are normal in other respects and can be reared satisfactorily if they are hand-fed. Although the condition has been recorded only in Jerseys, similar defects, possibly inherited, have also been seen in Holsteins and Shorthorns.

Multiple congenital ocular abnormalities occur with high frequency in Rocky Mountain horses and the closely related breeds Kentucky Mountain Saddle horse and Mountain Pleasure horse.[1,12,17,18] The cause is a missense mutation in the PMEL gene that has pleiotropic effects on the eye and coat color, causing a dilute or "silver" coat.[17] Similar to the silver mutation, MCOA is controlled by a dominant gene, with some reports demonstrating a codominant mode of inheritance and incomplete penetrance.[3,18] Homozygotes are thought to be more severely affected, having multiple abnormalities, whereas heterozygotes have cysts only, although this may not always be the case. Incomplete penetrance of this disorder has made studying the molecular mechanism behind these eye phenotypes difficult. Individuals carrying the causative mutation that are phenotyped as normal may either have cysts that were too small to detect or be true cases of nonpenetrance.[18] Equine MCOA is characterized by a diverse set of ocular phenotypes.[18] The predominant phenotype consists of large cysts, which are often bilateral, originating from the temporal ciliary body or peripheral retina, and additional phenotypes include abnormalities of the cornea, iris, lens, and iridocorneal angle.[18]

INHERITED NYSTAGMUS

Familial Undulatory Nystagmus

Familial undulatory nystagmus is an inherited defect of Finnish Ayrshire cattle characterized by a tremor-like, synchronous movement of the eyeballs. The tremor has small amplitude (1 to 2 mm) and fast (200/min) rate and is usually vertical. Nystagmus is present at all times, there is no sign of impaired vision, and the eye reflexes are normal. The condition is a blemish rather than a disease because there is no functional deficiency.

Pendular Nystagmus

Pendular nystagmus is an inherited defect of Holstein–Friesian cattle observed primarily in North America. A report from 1981 utilizing a convenience sample in New York state reported a prevalence of 0.51% in 2932 cattle from 62 herds. Affected cattle have a high-frequency (approximately 100 to 200 horizontal oscillations/minute) nystagmus of both eyes, with the eyes moving approximately 1 mm. Nystagmus has been observed shortly after birth in some calves, but the age of onset is not accurately known. Adult animals appear to be unaffected by the nystagmus and appear to have normal vision and balance and ocular reflexes. Pendular nystagmus is not thought to affect production and should not be mistaken as indicating the presence of a serious neurologic disease.

External Ear Diseases

OTITIS EXTERNA

Otitis externa, inflammation of the skin and external auditory canal, can affect cattle of all ages, in isolated cases, an entire herd, or in entire regions.

Arthropod parasites, foreign bodies, and sporadic miscellaneous infections may cause irritation in the ear, accompanied by rubbing of the head against objects and frequent head-shaking.

In tropical and subtropical regions, parasitic otitis is more important than in other more temperate regions. The mites *Raillietia auris* and *Dermanyssus avium*, the tick *Otobius magnini*, larvae (*Stephanofilaria zahaeeri*), free-living nematodes (*Rhabditis bovis*), and the blue fly (*Chrysomia bezziana*) are of importance in Europe, Africa, India, and America. *Malassezia* spp., *Candida* spp., *Rhodotorula mucilaginosa*, *Aspergillus* spp., and *Micelia sterilia* are common causes of otitis externa in cattle in Brazil.

When the syndrome occurs in a large number of animals in a herd, as it does in tropical countries, it is necessary to identify the specific causative agent. *R. bovis* is a common cause. Affected animals are depressed, eat little, and appear to experience

pain when they swallow, and they shake their heads frequently. Both ears are affected in most cases, and there is a stinky, blood-stained discharge that creates a patch of alopecia below the ear. The area is painful when touched, the external meatus of the aural canal is obviously inflamed, and the parotid lymph nodes are enlarged. Extension to the middle ear is an unusual sequel. Topical treatment with ivermectin and a broad-spectrum antibiotic is effective.

Circumscribed ulcerative lesions on the ears with raised edges frequently associated with secondary bacterial or fungal infection are a common finding in cattle and buffaloes affected by buffalopox virus infection (see also "Coxpox and Bufallopox").

EAR-TIP NECROSIS

Currently, ear-tip necrosis of pigs appears to be a more common condition.

ETIOLOGY

The condition may be associated with the presence of *Treponema pedis*. It can be cultured from the lesions and from the gingivae of pigs. It is anaerobic, fastidious, 4 mm to 6 mm in length, and 0.25 microns in diameter. There may be a sequence of infections when *Staphylococcus hyicus* is followed by the spirochetes and then infected with streptococci. In a recent study of putative agents, no single cause could be found, and it was suggested that the condition is multifactorial.[1]

EPIDEMIOLOGY

Ear-tip necrosis is usually seen in pigs at 1 to 16 weeks of age with a peak around 8 to 10 weeks. It may also occur in older pigs, when it is usually seen at the base of the ear. Typically it may occur in only one litter of pigs, and 80% may be affected. It may be associated with mixing and moving when a lot of pigs show ear biting.

Contributing factors are thought to include poor hygiene, high humidity, low air changes, overstocking, abrasions on feeders and pen divisions, and fighting associated with moving and mixing.

CLINICAL SIGNS

The affected pigs appear to show little evidence of distress and often recover spontaneously, and in these cases the only evidence of the condition is a crinkled edge to the ears. When it first appears, if the grease on the ear is removed you can see a crack in the skin, which obviously then allows bacterial penetration. Some persistent lesions may enlarge and spread. Occasionally, pigs show inappetence, unthriftiness, fever, or even death, often as a result of secondary infections.

PATHOLOGY

The lesions are black areas of necrosis with ulcers on the tips of the ears and the caudal edge of the ears. The lesions are dry and crusty, and in some cases there may be loss of the whole ear or part of the ear. This is caused by progressive thrombi formation leading to ischemia because there is a poor collateral circulation in the ear. In cases reported in Sweden, spirochetes were observed in silver-stained histologic sections, and a spirochete isolate was obtained and identified as a yet unnamed species of the genus *Treponema* closely resembling those found in digital dermatitis in cattle. The same organism was isolated from oral samples, along with *T. socranskii*.[2]

DIFFERENTIAL DIAGNOSIS

Simple ear biting is the main differential, but this usually starts at the base of the ear. Other septicemic causes of ear tissue loss, such as *H. parasuis*, *Salmonella*, or *S. suis*, may be suspected when ears are discolored, congested, or necrotic.

TREATMENT

Antibiotic sprays may or may not help.[2,3] A recent study has suggested that vaccination for PCV-2 infections may reduce the incidence of ear-tip necrosis.[4]

INHERITED CROP EARS

Inherited as a single autosomal-dominant incomplete character in Bavarian Highland cattle, the crop ear anomaly affects both ears, appears at birth, and varies from a minor trimming up to a complete deformity and reduction in size.

17 Metabolic and Endocrine Diseases

Introduction

Metabolic diseases are very important in dairy cows and pregnant ewes. In the other livestock species, metabolic diseases occur only sporadically. The high-producing dairy cow always verges on abnormal homeostasis, and the breeding and feeding of dairy cattle for high milk yields is etiologically related to metabolic disease so common in these animals. The salient features of the common metabolic diseases of farm animals are summarized in Table 17-1.

The term ***production disease*** includes those diseases previously known as ***metabolic diseases***, such as parturient paresis (milk fever), hypokalemia, hypomagnesemia, hyperketonemia and ketosis, hyperlipemia, and other conditions that are attributable to an imbalance between the rates of **input** of dietary nutrients and the **output** of production. When the imbalance is maintained, it may lead to a change in the amount of the body's reserves of certain metabolites and their "throughput." This generalization applies principally to energy balance (such as ketosis and hypoglycemia), in addition to hypomagnesemia, and to a lesser extent hypocalcemia. In these diseases output is greater than input, either because of the selection of cattle that produce so heavily that no naturally occurring diet can maintain the cow in nutritional balance or because the diet is insufficient in nutrient density or unevenly balanced. For example, a ration may contain sufficient protein for milk production but contains insufficient precursors of glucose to replace the energy excreted in the milk. Although we agree with the generalization on which the term *production disease* is based, we prefer to continue to use the expression *metabolic disease* because of common usage and the clinical focus that metabolism must match the level of production.

Metabolic Diseases of Ruminants

PERIPARTURIENT PERIOD IN CATTLE AND SHEEP

The incidence of metabolic disease in dairy cattle increases as milk production increases and, in particular, as the rate of increase in milk production increases (called **milk yield acceleration**). In dairy cows, the total disease incidence rapidly increases in the very late periparturient period, peaks on the day of parturition, and then rapidly declines until day 7 of lactation (Fig. 17-1). This critical 7-day window starting with parturition has a tremendous influence on morbidity, lactation production, reproductive performance, and mortality.

The susceptibility of dairy cows to metabolic disease appears to be related to the extremely high turnover of water, electrolytes, and soluble organic materials during the early part of lactation. With this rapid rate of exchange of water, sodium, calcium, magnesium, chloride, and phosphate, a sudden variation in their excretion or secretion in milk or by other routes, or a sudden variation in their intake because of changes in ingestion, digestion, or absorption, may cause abrupt, damaging changes in the internal environment of the animal. It is the volume of the changes in intake and secretion and the rapidity with which they can occur that affect the metabolic stability of the cow. In addition, if the continued nutritional demands of pregnancy are exacerbated by an inadequate diet in the dry period, the incidence of metabolic disease will increase. The effect of pregnancy is particularly important in ewes, especially those carrying more than one lamb.

Transition Period in Dairy Cows

The transition period is a crucial stage in the production cycle of the dairy cow; no other

Table 17-1 Salient features of metabolic diseases of farm animals

Disease	Etiology and epidemiology	Diagnosis	Treatment	Control
Milk fever of cattle	Hypocalcemia Occurs primarily in dairy cows after third lactation Also in beef cows 48 hours before or after calving and in midlactation	Low serum calcium concentration	Calcium salts IV, SC	Dietary management of anions–cations
Downer cow	Complication of milk fever; recumbent too long before treatment	Clinical findings Serum CK activity	Supportive therapy	Early treatment of milk-fever cases
Acute hypokalemia of cattle	In lactating dairy cows treated with corticosteroids for recurrent ketosis, and mastitis	Low serum potassium concentration	Potassium chloride IV	Avoid excessive use of isoflupredone for recurrent ketosis
Lactation tetany of mares	High-producing lactating mares being nursed by vigorous well-nourished foal a few weeks of age	Low serum calcium concentration	Calcium borogluconate	No reliable method available
Hypomagnesemic tetany (lactation tetany)	Lactating dairy cows on lush fertilized pastures Also in beef cows before and after calving	Low serum magnesium concentration	Magnesium salts IV	Supplementation of diets at strategic times with magnesium salts
Ketosis of cattle	Before and after parturition in cattle	Blood, urine, and milk levels of ketone bodies during the transition period 3 weeks before and after parturition	Glucose IV Propylene glycol and electrolyte solutions orally	Prepartum dietary management of energy intake
Pregnancy toxemia of sheep	Declining plane of nutrition in ewes in late pregnancy	Urinary ketones Hypoglycemia Metabolic acidosis and terminal uremia	Cesarean section or induction of parturition	Nutritional management of pregnant ewes to ensure a rising plane of nutrition in the second half of pregnancy
Fatty liver of cattle	High-producing dairy cows overfed during the dry period In well-conditioned beef cattle in late pregnancy when energy intake suddenly decreased	Ketonemia, ketonuria, hypoglycemia	Poor prognosis in severe cases Fluid and electrolyte therapy, glucose IV, propylene glycol orally and insulin	Nutritional management of pregnant cows to avoid excessive weight gain Avoid situations that reduce feed intake at time of parturition
Equine hyperlipidemia	Deranged fat metabolism Pregnant or lactating middle-aged ponies, donkeys, and American miniature horses worldwide Sporadic	Hyperlipidemia	Enteral or parenteral feeding, insulin, heparin Treat underlying disease	Maintain optimal body condition Prevent disease and nutritional stress in pregnancy
Postparturient hemoglobinuria	Dietary deficiency in high-producing dairy cows 2–4 weeks after calving Copper-deficient area Cruciferous crops	Low serum inorganic phosphorus concentration Low PCV Hemoglobinuria	Whole blood transfusion Sodium acid phosphate IV Dicalcium phosphate orally	Ensure adequate dietary phosphorous intake

period can affect subsequent production, health, and reproductive performance so greatly. The success of the transition period effectively determines the profitability of the cow during that lactation. Nutritional or management limitations during this time may impede the ability of the cow to reach maximal milk production. The primary challenge faced by cows is a sudden and marked increase of nutrient requirements for milk production, at a time when dry matter intake, and thus nutrient supply, lags far behind. Dry matter intake typically declines during the final week before parturition. This decline and changes in endocrine profiles contribute to elevated plasma nonesterified fatty acid (NEFA) concentrations, which have been related to the occurrence of fat-mobilization-related metabolic diseases such as fatty liver and ketosis. The magnitude of the decline in feed intake as parturition approaches may be a better indicator of metabolic health of postpartum cows than the actual level of feed intake. Diet, body-condition score, and parity influence dry matter intake and energy balance. The occurrence of diseases during the transition period results in lost milk production during the time of illness and often for the entire lactation.

A key area of the biology of transition cows is lipid metabolism. Excessive lipid metabolism from adipose tissue is linked with a higher incidence of periparturient diseases. Fatty livers were described in ketotic cows in the 1950s. Hepatic fat accumulation was then noted in normal cows during early lactation. This was followed by a description of a **fat-mobilization syndrome** in early lactation, in which cows mobilized body lipids from adipose tissue and deposited lipids in the liver, muscle, and other tissues. This was followed by descriptions of elevated nonesterified fatty acid concentrations during the last 7 days before calving being associated with a higher incidence of ketosis, displaced abomasum, and retained fetal membranes, but not associated with the incidence of milk fever. Understanding the metabolism of NEFA by the liver is a critical component of understanding the biology of the transition cow. Extreme rates of lipid

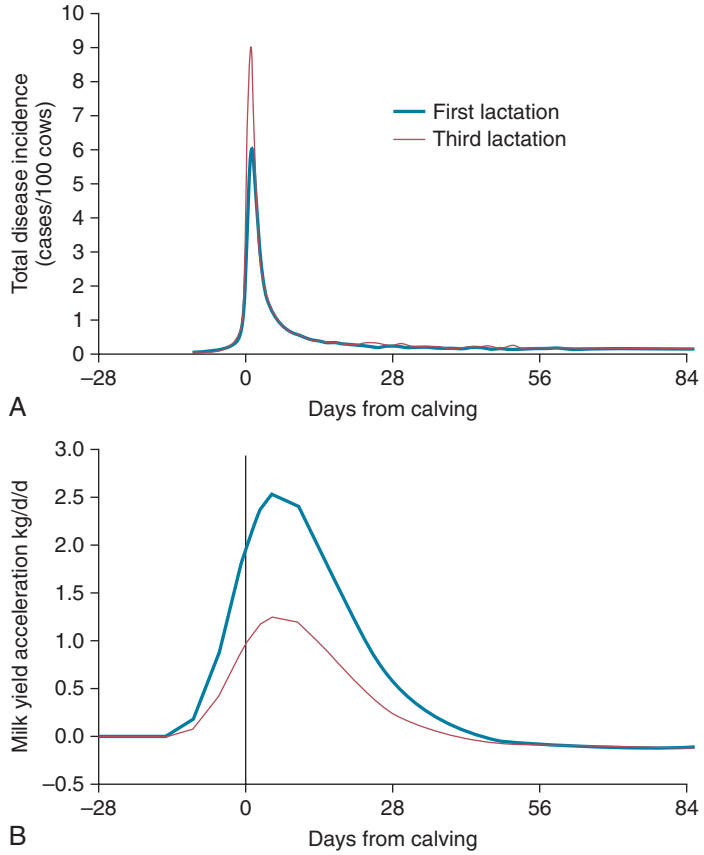

Fig. 17-1 **A,** Total disease incidence (sum of mastitis, ketosis, digestive disorders, and laminitis) relative to days from calving for first- and third-lactation cows in Danish dairy herds that calved in 1998. **B,** Acceleration in milk yield through lactation for cows peaking at 30 kg or 60 kg (bold line) of milk daily. (Reproduced with permission from Ingvartsen KL. Anim Feed Sci Technol 2006; 126:175-213.)

mobilization lead to increased uptake of NEFA by the liver and an increased rate of triglyceride accumulation in the liver. If this lipid infiltration becomes severe, the syndrome of hepatic lipidosis or fatty liver may result, which can then result in prolonged recovery from other diseases, increased incidence of other diseases, and increased susceptibility to induction of ketosis.

During the transition period, dairy cows undergo large metabolic adaptations in glucose, fatty acid, and mineral metabolism. The practical goal of nutritional management during this period is to support these metabolic adaptations. There are two different philosophic approaches for feeding transition cows in animals fed a total mixed ration. The first approach increases the energy density of the diet to "correct" for the anticipated decrease in dry matter intake in late gestation. Increasing the amount of energy supplied through dietary carbohydrate during the prepartum period results in generally positive effects on metabolism and performance of transition cows. In contrast, the second approach focuses on decreasing the energy density and increasing forage (by the daily provision of 2 to 4 kg of straw) in far-off cattle in an attempt to promote dry matter intake. Attempts to increase energy supply by feeding dietary fat sources or decrease energy expenditure by supplying specific fatty acids such as *trans*-10, *cis*-12conjugated linoleic acid to decrease milkfat output during early lactation do not decrease the release of NEFAs from adipose tissue.

In addition to nutritional management strategies to optimize the health of the transition cow, certain feed additives are in use to reduce subclinical ketosis and reduce the incidence of displaced abomasum. **Monensin** is a carboxylic polyether ionophore produced by a naturally occurring strain of *Streptomyces cinnamonesis*. Monensin exerts its many effects by shifting the microbial populations in the rumen; this results in changes in the proportions of short-chain volatile fatty acids in the rumen, specifically increasing propionic acid and reducing the molar percentages of butyric acid and acetic acid. Increased rumen propionic acid concentrations directly lead to increased gluconeogenesis and should therefore decrease the incidence of ketosis and hyperketonemia in early lactation and improve energy balance. In Canada, monensin is approved to be administered as a controlled-release capsule (CRC) as an aid in the prevention of subclinical ketosis in lactating dairy cattle. The monensin CRC delivers 335 mg of monensin daily for 95 days, improves energy balance, and decreases the incidence of all three energy-associated diseases of lactating dairy cows: retained placenta, displaced abomasum, and clinical ketosis. Cows treated with the monensin CRC at 3 weeks before the anticipated calving date had decreased serum NEFA and β-hydroxybutyrate (BHB) concentrations and increased serum cholesterol and urea concentrations in the week immediately preceding precalving. Monensin has no effect on serum calcium, phosphorus, or glucose concentration in the precalving period. After calving, serum concentrations of BHB and phosphorus concentrations were lower and serum concentrations of cholesterol and urea higher in monensin-treated cows. The lower NEFA values indicate less fat mobilization, and the higher cholesterol suggests greater lipoprotein export from the liver. The higher urea levels are thought to result from a protein-sparing effect in the rumen, resulting in an increased supply of amino acids in the small intestine. There was no effect of treatment on serum NEFA, glucose, or calcium concentrations in the first week postcalving. Daily monensin ingestion starting before calving therefore improves indicators of energy balance in both the immediate precalving and postcalving periods.

Voluntary Dry Matter Intake in Periparturient Dairy Cattle

The factors affecting voluntary dry matter intake (DMI) of lactating cattle are extremely important and have received much attention for many decades. A substantial decrease in DMI is initiated in late pregnancy and continues into early lactation, with the lowest DMI occurring on the day of calving. Postpartum DMI is considerably higher in multiparous cows compared with primiparous cows and increases after lactation in both groups, but the rate of increases varies widely. In cows given diets of constant composition, the milk yield typically peaks at 5 to 7 weeks postpartum, and the maximum intake is reached between 8 and 22 weeks after calving. The increase in DMI from week 1 postpartum to time of peak intake is affected by the diet fed during lactation and also by prepartum feeding; the latter influences the amount of fat stored and therefore the body-condition score of the animal. The normal pattern of feed intake may be severely influenced by disease states because both clinical and subclinical infections are known to substantially reduce appetite and performance.

The decrease in DMI has traditionally been attributed to physical constraints such

as the enlarging uterus, but this role may be overemphasized. The decrease in DMI coincides with changes in reproductive status, changes in fat mass, and metabolic changes in support of lactation. A number of metabolic signals may have a role in intake regulation. These signals include nutrients, metabolites, reproductive hormones, stress hormones, leptin, insulin, gut peptides, cytokines and neuropeptides such as neuropeptide Y, galanin, and corticotrophin-releasing factor.

Immunosuppression During the Transition Period

In addition to the adaptations in classical metabolism, cows during the transition period also undergo a period of reduced immunologic capacity during the periparturient period. The immune dysfunction is broad in scope, affects multiple functions of various cell types, and lasts from approximately 3 weeks before calving until approximately 3 weeks after calving. Cows during this period are more susceptible to mastitis. The etiology of periparturient immunosuppression is multifactorial and not well understood, but it seems to be related to physiologic changes associated with parturition and the initiation of lactation and to metabolic factors related to these events. Glucocorticoids are immunosuppressants, plasma cortisol concentration is increased at parturition, and endogenous glucocorticoids have been postulated to play a role in periparturient immunosuppression. Periparturient cattle have impaired expression of adhesion molecules and decreased migration capacity of blood neutrophils. Because the rapid recruitment of neutrophils into newly infected mammary tissue is the key immunologic defense against mastitis-causing pathogens in ruminants, periparturient neutrophil dysfunction may contribute to the increased susceptibility to mastitis at this time. Metabolic challenges around calving may also play in role in increased susceptibility, as nonesterified fatty acids significantly reduce the in vitro immunosuppressiveness of mononuclear cells of ewes, potentially resulting in impairment of cell-mediated and humoral immunity in sheep and cattle with ketosis.

Vitamin E is a fat-soluble membrane antioxidant that enhances the functional efficiency of neutrophils by protecting them from oxidative damage following intracellular killing of ingested bacteria. The parenteral administration of vitamin E has been investigated for the prevention of peripartum diseases such as retained placenta, metritis, and clinical mastitis. Only cows with marginal vitamin E status (serum α-tocopherol $< 2.5 \times 10^{-3}$) 1 week before calving will have a reduction in the risk of retained placenta following a subcutaneous injection of 3000 IU of vitamin E. In cows with an adequate serum vitamin E concentration there was no reduction, and primiparous animals were most likely to benefit from vitamin E 1 week before parturition. The associations between peripartum serum vitamin E, retinol, and β-carotene concentrations in dairy cattle and disease risk indicated that an increase in α-tocopherol of 1 μg/ML in the last week prepartum reduced the risk of retained placenta by 20%, whereas serum NEFA concentrations ≥ 0.5 mEq/L tended to increase the risk of retained placenta by 80%. In the last week prepartum, a 100-ng/mL increase in serum retinol was associated with a 60%decrease in the risk of early-lactation clinical mastitis.

Diseases of Lactation

Parturition is followed by the sudden onset of a profuse lactation, which, if the nutrient reserves have already been seriously depleted, may result in clinical metabolic disease. The essential metabolite that is reduced below the critical level determines the clinical syndrome that will occur. Most attention has been paid to variations in balances of calcium and inorganic phosphates relative to parturient paresis, magnesium relative to lactation tetany, and plasma glucose and ketone concentration and hepatic lipidosis relative to ketosis, but it is probable that other imbalances are important in the production of as yet unidentified syndromes.

The vast majority of production diseases of dairy cows occur very early in lactation. At this time, the cow is producing milk at a rate that is substantially less than her maximum. In terms of rate, high- and low-milk-yielding cows are producing rather similar amounts at this time. However, in terms of acceleration, the change in milk yield per day, it is highest immediately after calving. During the succeeding period of lactation, particularly in cows on test schedules and under the strain of producing large quantities of milk, there is often variable food intake, especially when pasture is the sole source of food, and instability of the internal environment inevitably follows. The period of early lactation is an unstable one in all species. Hormonal stimulation at this stage is so strong that nutritional deficiency often does not limit milk production, and a serious drain on reserves of metabolites may occur.

Recombinant bovine somatotrophin (rBST, sometribove zinc) is a synthetically derived hormone that may be identical to naturally occurring bovine growth hormone, or slightly modified by the addition of extra amino acids. The product was approved in the United States in 1993, and its use began commercially in 1994 in dairy herds to increase milk production. The product is a sterile, prolonged-release injectable formulation of rBST in single-dose syringes that each contain 500 mg of sometribove zinc. The recommended dosage protocol is one syringe injected subcutaneously (SC) in the postscapular region (behind the shoulders) or in the ischiorectal fossa (depression on either side of the tailhead) every 14 days beginning during the 9th week after calving and continuing until the end of lactation.[2] Approximately 15% of dairy herds in the United States used rBST in 2013. The product has been licensed for use in at least 20 other countries, including Argentina, Brazil, Chile, Colombia, Costa Rica, Ecuador, Egypt, Guatemala, Honduras, Jamaica, Lebanon, Mexico, Panama, Pakistan, Paraguay, Peru, Salvador, South Africa, South Korea, Uruguay, and Venezuela. In comparison, a number of countries, including Australia, Canada, Israel, Japan, New Zealand, and all European Union countries, have not approved its use.

A meta-analysis of the effects of rBST on milk production, animal health, reproductive performance, and culling was undertaken. Recombinant bovine somatotrophin was found to increase milk production by 11% in primiparous cows and 15% in multiparous cows, although there was considerable variation in the magnitude of the milk production increase between studies. Some statistically significant effects on milk composition (percentage of butterfat, protein, and lactose) were found; however, they were all very small. Treatment increased dry matter intake by an average of 1.5 kg/d during the treatment period, and dry matter intake remained elevated for the first 60 days of the subsequent lactation. Despite the increase in dry matter intake, treated animals had lower body-condition scores at the end of the treatment period, and the reduced scores persisted until the start of the subsequent lactation. Recombinant bovine somatotrophin increased the risk of clinical mastitis by approximately 25% during the treatment period, but there were insufficient data to draw firm conclusions about the effects of the drug on the prevalence of subclinical intramammary infections as assessed by somatic cell count. The increase in the incidence of clinical mastitis in cattle administered rBST appears similar to that expected from an increase in milk production alone using genetic selection and improved nutrition, milking frequency, and management practices. Use of rBST increased the risk of a cow failing to conceive by approximately 40%. For cows that did conceive, there was no effect on services per conception and only a small increase in average days open. Use of the drug had no effect on gestation length, but the information about a possible effect on twinning was equivocal. Cows treated with rBST had an estimated 55% increase in the risk of developing clinical signs of lameness. There appeared to be an increased risk of culling in multiparous cows. Use of the drug in one lactation period appeared to reduce the risk of metabolic diseases (particularly ketosis) in the early period of the subsequent lactation. It was found that the reproductive effects of the drug could be

controlled by delaying its use until the cows were confirmed pregnant.

In 1998, an expert panel appointed by the Canadian Veterinary Medical Association at the request of Health Canada found a number of legitimate animal welfare concerns associated with the use of rBST. In 1999 Health Canada announced that it would not approve the use of rBST for sale in Canada on the basis of the health and welfare of cattle. The Royal College of Physicians and Surgeons of Canada's Expert Panel on Human Safety of rBST found no biologically plausible reason for concern about human safety if rBST were to be approved for sale in Canada. In 1999 a working group from within the Scientific Committee on Animal Health and Animal Welfare of the European Commission presented a more extensive report on rBST that summarized similar results and engaged substantive discussion of animal welfare issues. It concluded that rBST should not be used in dairy cattle in Europe. In October 1999, the European Commission banned the use and marketing of rBST in the European Union as of January 1, 2000.

Relationship Between Lactational Performance and Health of Dairy Cattle

There is little evidence that high-yielding cows have increased risk of dystocia, retained placenta, metritis, and left-side displacement of the abomasum. The association between high levels of production and periparturient diseases is inconsistent; in general, high levels of management (including nutrition and housing) are usually associated with high levels of production. Although no phenotypical relationship between milk yield and the risk of ketosis and lameness has been found, selection for higher milk yield will probably increase the lactational incidence risk for both diseases. Mastitis is the only disease for which a clear relationship between increased milk yield and increased risk of infection has been found. Continued selection for high milk yield should therefore be expected to increase the incidence of clinical mastitis in dairy cattle.

However, some authors have stated that "Reviewing existing literature, even with structured literature selection, is inadequate to the task of elucidating the relationship between the lactational performance and risk of production diseases."[3] The most notable feature of the literature evaluation is the large variability that exists between studies. This strongly suggests that there are important factors that need to be considered before meaningful conclusions concerning the relationship between lactational performance and risk of disease can be drawn.

Breed Susceptibility

The fact that some dams are affected much more by these variations than others is probably explainable on the basis of variations in internal metabolism and degree of milk production among species and among individuals. Among groups of cows, variations in susceptibility appear to depend on either genetic or management factors. Certainly, Jersey cows are more susceptible to parturient paresis than cows of other breeds. Even within breeds, considerable variation is evident in susceptibility between families. Under these circumstances, it seems necessary to invoke genetic factors as predisposing causes for metabolic diseases.

Management Practices

The management practices of most importance are nutrition and housing. In those sections of North America where cattle are housed during the winter and in poor pasture areas, ketosis is prevalent. In the Channel Islands, local cattle are unaffected by lactation tetany, whereas the disease is prevalent in the United Kingdom. In New Zealand, metabolic diseases are complex and the incidence is high, both of which are probably related to the practice of having the cows calve in late winter when feed is poor, the practice of depending entirely on pasture for feed, and the high proportion of Jerseys in the cattle population.

Detailed knowledge of the nutrition and housing factors is essential before any reasonable scheme of prevention can be undertaken. For example, knowledge of the complex behavioral needs of the dairy cow is essential to provide adequate housing during the transition period. In North American dairy herds, the flow of cows through the transition period often necessitates many changes of pens, which are disruptive to the social organization of cow groups. Stocking rates that exceed stall and feed bunk capacity place even greater challenges on the dairy cow at this time. Current free-stall recommendations include providing 75 cm (30 in.) of bunk space for close-up and fresh cows to ensure that overcrowding does not occur, moving preparturient cows to a new pen at least 8 to 10 days ahead of the anticipated calving date or when calving is imminent, adding cows to groups on a minimum of a weekly basis (it takes up to 1.5 days for a new social order to be determined after the addition of a new animal), and keeping a clean and comfortable environment.

The diagnosis and treatment of dairy cows with periparturient diseases requires a program suited to the particular herd. Particularly in large herds, there is a need for collaboration between the veterinarian, nutritionist, manager of the herd, and animal attendants. Specific procedures should be developed for each herd based on past experience with the problems of recently calved cows, the facilities, the skills of the workers, the priorities of management, and the flow patterns of the cows in the herd. Every effort must be made to prevent periparturient diseases in the cows. In general, diseases in the early postpartum period originate in the feeding and management of the dry cow. Important principles include a protocol of grouping parturient cows according to the feeding program and handling facilities on the farm. Groups of cows can be screened for mastitis, visual evidence of illness, daily milk yield, body temperature, and urine pH, and they can be palpated for evidence of metritis. Individual cows that have been identified by a screening method must be examined individually to make a diagnosis and decide on a treatment protocol based on the particular diagnosis.

Management and environmental factors can be manipulated to ease the transition into lactation. For example, the photoperiod, defined as the duration of light exposure an animal receives within a day, can be adjusted to produce clinically significant effects on periparturient health and subsequent lactational efficiency. Increasing the frequency of milking in the immediate postpartum period also produces persistent increases in milk yield and improvements in mammary health. In both techniques, evidence is emerging to support the concept that alteration of prolactin sensitivity is the mechanism underlying health and production responses. The reader is directed to publications related to production for more information on these and related topics.

Occurrence and Incidence of Metabolic Diseases

Knowledge of the etiologic and epidemiologic factors involved will help in understanding the occurrence and incidence of the various metabolic diseases. Largely because of variations in climate, the occurrence of metabolic disease varies from season to season and from year to year. In the same manner, variations in the types of disease occur. For example, in some seasons, most cases of parturient paresis will be tetanic; in others, most cases of ketosis will be complicated by hypocalcemia. Further, the incidence of metabolic disease and the incidence of the different syndromes will vary from region to region. Ketosis may be common in areas of low rainfall and on poor pasture. Lactation tetany may be common in colder areas and where natural shelter is poor. Recognition of these factors can make it possible to devise a means whereby the incidence of the diseases can be reduced.

The metabolic diseases, because of high prevalence and high mortality rate, are of major importance in some countries, so much so that predictive systems are being set up. Rapid analysis of stored feed samples, pasture, and soil is commonly used in Europe and North America, but the interesting development has been the recognition of "production diseases" and the consequent development of metabolic profile tests, particularly in the United Kingdom and Europe.

Record Keeping

The use of reliable records to monitor the health and production of dairy cows during the transition period is essential to evaluate the efficacy of programs at the farm level. Transition cow management programs will assist in determining how well cows are prepared for milk production and good health in the coming lactation. Appropriate monitoring should focus on three areas: **cows that die or are culled in early lactation, the productivity of the surviving cows in early lactation, and the rates of disease in the periparturient period.**

Cows that leave the herd in the first 60 days of lactation are usually culled because of disease or injury. Removal rates and their causes can be a critical monitor of the efficacy of transition cow management programs. Measuring productivity and health of cows in early lactation involves monitoring daily milk yields, first-test mature-equivalent 305-day projected milk, milk components at first Dairy Herd Improvement Association (DHIA) test day, milk-fat percentage, ratios of test-day components, somatic cell count at first DHIA test day, and peak milk (also called summit milk). DHIA records also allow comparison of the performance of each cow in early lactation to her performance in the prior lactation. Comparisons can be made of the changes in somatic cell count between the last test of the prior lactation and the first test of the current lactation and mature-equivalent 305-day difference from the prior lactation to the first test of the current lactation.

Health and production records in dairy herds have traditionally emphasized reproductive events and administered treatments for specific diseases. The records should capture the information about the common diseases that occur in most dairy herds. The record system should be set up to do the following:

- Monitor rates of well-defined disease events as a measure of the effectiveness of health and production programs and to aid in problem solving.
- Determine the clinical efficacy of treatments by monitoring retreatment rates for specific diseases.
- Maintain an individual cow history record for cow-side use to enhance treatment decisions.
- Measure compliance and consistency of implementation of the health program being used.
- Reconcile pharmaceutical purchases with treatment protocol entries and to meet regulatory requirements on the use of pharmaceuticals in food animals.
- Determine the costs of certain disease rates over achievable targets. The costs of specific diseases are compelling to most dairy herd producers. Good records can generate an incidence rate of common diseases. These costs include the immediate cost of treatment, the cost of the veterinarian's and herdsman's time. and the cost of milk withheld from the market. For the majority of diseases of recently calved cows, the cost per disease in the United States was estimated in 2001 at approximately US$320, with a range from $150 to $450.

An adequate record system will allow producers and veterinarians to determine the differences between actual performance and benchmark performance and then determine the causes of the shortfall. The most important determinants of profitability on dairy farms are milk income and feed cost, and the difference between milk income and feed costs is the **return-over-feed** index (**ROF**). Many factors affect the ROF index. These include three-times-daily milking, component percentages in the herd milk test, milk-fat and protein percentages, use of a core lipopolysaccharide antigen mastitis vaccine, and use of monensin in the lactating-cow diet (if permitted). One of the most important factors associated with profitability is milk production. From 80% to 95% of the income on dairy farms is derived from milk sales. Thus it is critical that the producer, the veterinarian, and other advisors collaborate to plan an animal health and production program that will result in the optimum ROF.

METABOLIC PROFILE TESTING

Methods are needed to monitor the nutritional and metabolic status of dairy herds. The most valuable methods will be those that are sensitive enough to detect change before clinical or economic consequences are manifested. A major challenge in the application of metabolic profile testing is dealing with extraneous sources of variation. Successful management of extraneous variation requires sampling strategies based on animal grouping and testing of multiple animals. Larger herds are more suitable for monitoring because they allow for better design sampling strategies and spread the costs of testing across more animals. Statistical process control methods offer a unique approach to interpretation that may increase the usefulness of metabolic profiles.

The traditional approach to herd-based assessment of metabolic status (also called the **Compton metabolic profile test**) is based on the concept that the laboratory measurement of certain components of plasma or serum of 7 to 10 cows per subgroup will reflect the nutritional status of the subgroup, with or without the presence of clinical abnormalities.[1] For example, a lower-than-normal mean plasma glucose concentration in a group of dairy cows in early lactation may indicate an insufficient intake of energy, which may or may not be detectable clinically. On a theoretical basis, the ability of the laboratory to make an objective assessment of the input–output (nutrient–productivity) relationships is an attractive tool for the veterinarian engaged in providing a complete health management service to a herd. The test would theoretically be able to detect the qualitative and quantitative adequacy of the diet of cows expected to produce a certain quantity of milk or return to estrus within a desirable length of time following parturition. A reliable test for the early diagnosis of nutritional deficiency or metabolic disease would therefore be a major step forward in attempting to optimize livestock production and obtain maximum yields at minimum costs.

There was considerable interest in metabolic profile testing following its earlier descriptions, which stimulated considerable field research. The results of the research have thus far indicated that the test may be useful only as an aid in the diagnosis of nutritional imbalance and production diseases. The results of metabolic profile testing are usually difficult to interpret without a careful conventional assessment of the nutritional status and reproductive performance of the herd, and it appears doubtful that such testing would reveal significant abnormalities that could not be detected using conventional clinical methods. Because of the cost of the test, the profile testing must be carefully planned with specific objectives. A regional diagnostic laboratory with automated analytical equipment should be available, and this is often a major limiting factor. The test should not be undertaken unless reference values for each laboratory measurement are available from the population within the area. The results from the groups within the herd are compared with local population means. Metabolic profiles have also been suggested as an aid in the selection of superior individuals.

The prediction of whether an individual cow is metabolically prepared to undergo a stressful lactation at a high level of production would seem to be a useful undertaking. This could be particularly important under management conditions of heavy concentrate feeding, lead feeding, zero grazing, or even indoor housing. There are no well-established, low-cost, practical protocols for conducting such profile tests.

Usefulness of Metabolic Profile Testing

Metabolic profiles in dairy cows were used initially in the United Kingdom in the 1960s. Success was limited primarily by the unjustified expectation that all biochemical concentrations in the blood of cows would reflect nutritional intake and status at all times. However, the practical value was found in the approach as an aid to nutritional management. In the 1970s the approach was reassessed and revised, culminating in a program for farmers evaluating health and productivity using metabolic profile testing as an

integral part of a health management program involving a multidisciplinary approach. The UK Dairy Herd Health and Productivity Service (DHHPS) provides the opportunity for veterinarians to lead a multidisciplinary team that can monitor health, fertility, and production and can plan, when necessary, corrective action. Effectively the approach has been to **"ask the cows"** what they think of their nutrition by following a set of guidelines on timing, cow selection, and the use of background information. Metabolic profiling and body-condition scoring found that at least a third of the cows sampled were mobilizing excessive fat during the transition from the dry period to early lactation. Improving both health and nutrition, before and after calving, would improve reproductive performance in many herds. The DHHPS method now utilizes a team approach involving farmer, veterinarian, and agricultural advisor. If useful information is to be obtained, the blood-testing aspect depends critically on following a set of firm criteria for selection of small groups of typical cows within each herd; the timing of testing in relation to concentrate feeds, feed changes, and stage of lactation; and the collection of other data about the cows, such as body weight and condition, productivity, and feeding. The successful approach has been to look, following specific times of nutritional change, at metabolite levels in strictly defined small representative groups of cows within each herd in conjunction with information on body condition and weight, milk performance, and feeding. Comparison with optimum values, the degree of variation from them, and comparisons between groups within herds have allowed information about nutritional constraints on productivity to be made available to farmers more quickly and more specifically than by other means.

Biological and Statistical Basis for Herd Testing

The interpretation of herd-based tests for metabolic diseases is different from interpreting laboratory tests for metabolites from individual cows. Test results from individual cows are interpreted by comparing the value to a normal reference range established by the laboratory that did the testing. Normal ranges are often derived by calculating a 95% confidence interval (or a similar statistic) of test results from 100 or more clinically normal animals.

Herd test results for metabolic diseases can be interpreted as either the **mean test result of the subgroup** sampled or as the **proportion of animals above or below a certain cut-point within the subgroup**. There is a major philosophic difference and marked cost difference between the two approaches. At the moment, there does not appear to be a clear preference for either approach, and this area should be a focus of future investigation. An important difference in the approaches is that the cost of determining the mean value of a subgroup is very low if the samples from the subgroup are pooled and then analyzed. The only advantage of analyzing individual samples instead of pooled samples is that individual samples provide an estimate of the proportion of abnormal values. Whether knowing the proportion is worth the marked increased in analytical cost remains to be determined.

If a metabolite is associated with disease when it is above or below a biologic threshold (cut-point), then it should be evaluated as a proportional outcome. For example, hyperketonemia (subclinical ketosis) in dairy herds can be monitored by testing for β-hydroxybutyrate (BHB) or other ketone bodies in blood, plasma, serum, urine, or milk. Subclinical ketosis is a threshold disease, and cows are affected only when ketone concentrations are elevated. Plasma BHB concentrations above 1.0, 1.2, or 1.4 mmol/L (equivalent to 9.7, 11.7, or 14.4 mg/dL, respectively) are the most commonly used cut-points for detecting hyperketonemia (subclinical ketosis) in lactating dairy cattle. Early-lactation cows with plasma BHB concentrations above the selected cut-point have a four- to eightfold greater risk of developing displaced abomasum, a threefold greater risk of developing clinical ketosis, decreased 305-day milk production, increased severity of mastitis, a 50% increase in anestrus at 60 days in milk, and a 50% decrease in pregnancy at first insemination. NEFA concentrations in plasma are an indicator of negative energy balance in prepartum cows. Elevated plasma NEFA concentration before calving (>0.4 mEq/L for cows between 2 and 14 days before the anticipated calving date) is associated with a 4-fold increased risk for displaced abomasum, a 2- to 3-fold increase in the risk of subclinical ketosis, and 1.5-fold increased risk of retained placenta after calving.

It is also necessary to determine the alarm level for the proportion of animals above or below the described cut-point. The alarm level is determined from research results or clinical experience. The suggested alarm-level proportion for plasma BHB concentration with a cut-point of 1.4 mmol/L is greater than 10%; the proportion for plasma NEFA concentration with a cut-point of 0.4 mmol/L is greater than 10%.

Herd-based testing is useful only when a sufficient number of cows within the herd are tested, which gives reasonable confidence that the results truly represent the entire population of eligible cows in the herd. In the United States, the minimum sample size for herd-based tests with proportional outcomes has been estimated as 12 cows, based on 75% confidence intervals and a general detection cut-point of greater than 10%. Cows to be sampled need to be selected from the appropriate eligible or at-risk group. Obviously, measurement of a homogeneous group requires a large herd size; to sample 12 cows consistently between day 4 and day 14 of lactation requires a milking herd of at least 428 cows, assuming equal monthly calving rates. The subgroup size recommendation of 12 cows in the United States contrasts with the subgroup size recommendation of 7 to 10 cows in the United Kingdom. The difference in recommendations has not been reconciled.

The proper use of metabolic profiles depends on the timing of blood tests, the selection of cows to be included, and the collection and use of background information about the farm, feeding and feeding system, and physical state and performance of the cows.

Variables in Dairy-Herd Metabolic Profile Testing

There are five main areas of interest for metabolic profile testing:

1. Energy balance
2. Protein evaluation
3. Liver function
4. Macromineral evaluation
5. Urine evaluation

In general terms, measurement of analytes in urine has been greatly underutilized in metabolic profile testing, and it is clear that current testing protocols are not economically optimized.

Energy Balance

Strategic use of metabolic testing to monitor transition dairy cows should focus on measuring plasma NEFA concentration in the last week prepartum and plasma/serum BHB and urine acetoacetate concentration in the first and second weeks postpartum.

Nonesterified Fatty Acids

Plasma NEFA concentration provides the most sensitive indicator of energy balance, particularly in the last 2 weeks of gestation. Plasma NEFA concentration is useful for monitoring the energy status of dry cows in the last month of gestation, when rapid changes in energy-balance status may not be detectable from changes in body-condition score. Plasma NEFA concentrations start to increase 3 days before parturition and remain elevated for the first 9 days of lactation[7] (Fig. 17-2). High plasma concentrations of NEFAs indicate negative energy balance, which occurs in animals that are inappetent as a result of illness.

The serum concentrations of NEFAs have been monitored in dairy cows as predictors of displaced abomasum. In cows with left-displaced abomasum (LDA), mean NEFA concentration began to diverge from the mean in cows without LDA 14 days before calving, whereas mean serum BHB concentrations did not diverge until the day of calving. Prepartum, only NEFA concentration was associated with risk of LDA. Between day 0 and 6 days after calving, cows

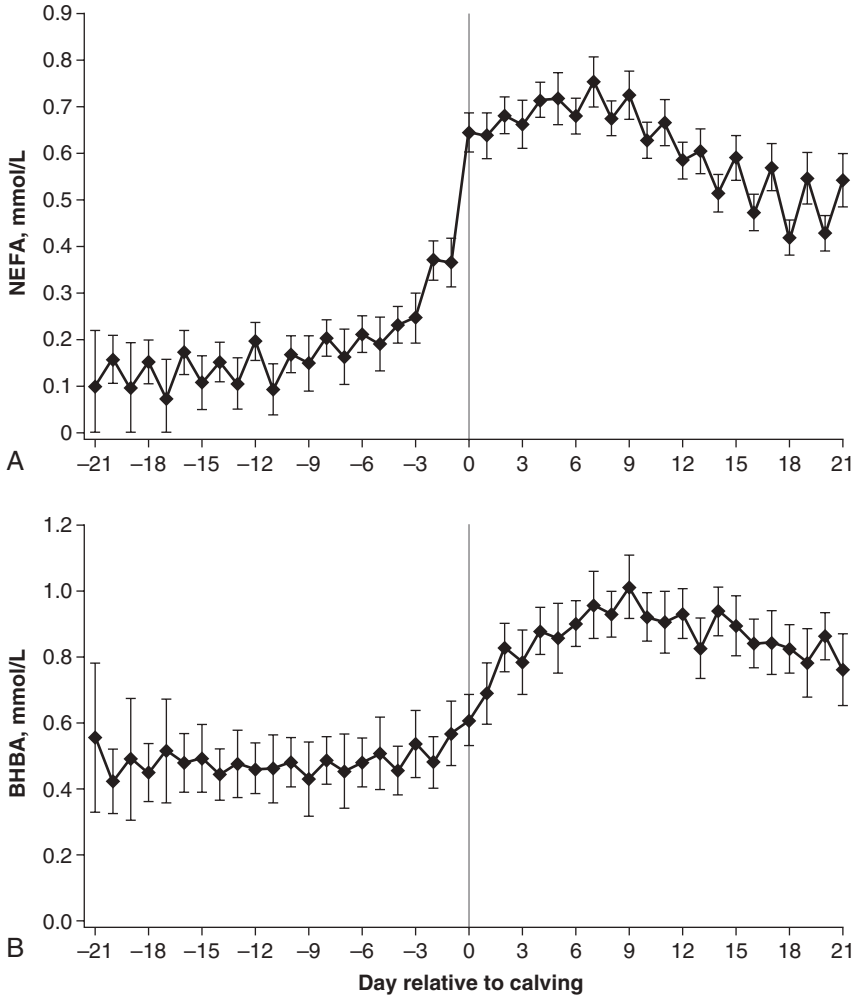

Fig. 17-2 Least-squares means and 95% confidence interval (error bars) for plasma nonesterified fatty acid concentration and β-hydroxybutyrate concentration in 269 multiparous Holstein–Friesian cows from 21 days prepartum to 21 days postpartum. (Reproduced with permission from McCarthy MM, Mann S, Nydam DV, Overton TR, McArt JAA. J Dairy Sci 2015; 98:6284-6290.)

with serum NEFA concentration of 0.5 mEq/L or greater were 3.6 times more likely to develop LDA after calving. In another study, cows with plasma NEFA greater than 0.3 mEq/L between 3 and 35 days before calving were twice as likely to subsequently have LDA. Strategic use of metabolic tests to monitor energy balance in prepartum dairy cows should therefore focus on measurement of plasma/serum NEFA concentration. There are three major drawbacks with this approach: the high cost of testing (US$8/test), the need to centrifuge blood to harvest serum or plasma, and the lack of a cow-side test. Until all three issues are satisfactorily resolved, plasma/serum NEFA testing will remain a research tool with minimal practical application.

β-Hydroxybutyrate

Plasma/serum BHB concentrations are affected by energy and glucose balance and are a less sensitive indicator of energy balance than plasma NEFA. High plasma BHB concentrations are associated with reduced milk production, increased incidence of clinical ketosis and LDA, and reduced fertility. The gold-standard test for hyperketonemia (subclinical ketosis) is plasma/serum BHB concentration, which is more stable after collection than plasma/serum acetone or acetoacetate concentrations. Prepartum BHB concentrations are relatively stable before parturition, but increase rapidly after parturition to peak at around 9 days in milk, after which time BHB concentration gradually declines (Fig. 17-2).

Subclinical ketosis may start at serum concentrations above 1.0 mmol/L. The alarm level for the proportion of cows above the cut-point of 1.0, 1.2, or 1.4 mmol/L has not been validated, but it is suggested that no more than 10% of early-lactation cows should have hyperketonemia (subclinical ketosis). In cows with serum BHB concentrations of 1.2 mmol/L or greater or 1.4 mmol/L or greater in the first week postpartum, the odds of LDA were three and four times greater, respectively, than in cows with BHB below the cut-points.[7]

Glucose

Plasma/serum glucose concentrations are usually lower in early lactation[4] and during the winter months; in early lactation, there is a heavy demand for glucose, and during the winter the energy intake is likely to be lower than necessary to meet requirements. One major cause of variation in blood glucose may be the major fluctuations in daily feed intake. Investigations of feed intake of dairy cows on commercial farms have shown that concentrate dispensers are commonly incorrectly adjusted, and errors of more than 50% in feed intake are sometimes found. In situations of marginal energy imbalance, glucose concentrations may be unreliable as an index of the adequacy of energy intake. Several factors may cause short-term changes in glucose concentration. Blood glucose may be influenced by the chemical nature of the carbohydrate and physical form of the feed and the roughage content of the feed. In addition, elevation of plasma glucose concentration has been associated with excitement and low environmental temperature.

There is some conflicting evidence about the relationship between the mean plasma glucose concentrations of a lactational group and insufficient energy intake and reproductive inefficiency. In some work, there is an expected relationship between low plasma glucose concentration and an increased incidence of ketosis. In others, the relationship is not clear; however, there was a more consistent relationship between the actual energy intake as a percentage of requirement and the plasma NEFA concentration, but this finding was not sufficiently reliable to be useful. The mean plasma glucose concentrations within 3 days before or after first service of cows that conceived on first service was higher than that of cows that returned, but the difference was only approaching significance at the 5% level, and it is doubtful whether this could be of practical value. Although plasma NEFA concentration is more sensitive than plasma glucose concentration as an indicator of energy status of the lactating cow, the excessive variability of this relationship during early lactation limits its usefulness. Plasma NEFA concentration begins to increase several weeks prepartum, peaks at parturition, and decreases gradually to normal concentrations after several weeks of lactation. Plasma glucose concentrations follow a similar pattern. The main disadvantage of using plasma glucose concentration as an index of metabolic balance is that glucose concentration is a tightly regulated variable, and marked metabolic imbalances need to be present before plasma glucose

concentration is altered. However, this means that decreased plasma/serum glucose concentrations provide an unequivocal and specific indicator of negative energy balance.

Protein Evaluation

Currently, there is not a single biochemical factor that accurately reflects the protein status of dairy cattle. A number of indices have therefore been monitored, including milk urea nitrogen and plasma/serum urea nitrogen, creatinine, albumin, and total protein concentrations. Of these indices, milk urea nitrogen concentration in the bulk tank provides the best global picture of protein balance in a dairy herd.

Urea Nitrogen

Plasma urea nitrogen and milk urea nitrogen (MUN) concentration are useful indicators of protein status, particularly when the diet contains adequate energy.

Increases in plasma urea nitrogen concentration and ammonia occur primarily as a result of inefficient nitrogen utilization. An excess of rumen degradable protein results in an increase in the concentration of rumen ammonia, which is absorbed through the rumen wall and transported to the liver, where it is converted to urea. The catabolism of body protein for gluconeogenesis can also result in the production of ammonia, which is also converted to urea in the liver. Plasma urea nitrogen concentration has therefore been the most commonly used blood constituent for monitoring protein status and intake. Values greater than 19 mg/dL suggest excessive protein intake in the diet, whereas values less than 10 mg/dL suggest inadequate protein intake in the diet.

MUN concentration can be used as a management aid to improve dairy-herd nutrition and monitor the nutritional status of lactating dairy cows. Elevated MUN concentration indicates that excess protein has been fed to the dairy cow for a given level of production. Milk samples should be submitted to an accredited diagnostic laboratory for MUN analysis. The Azotest Strip, an on-farm dipstick test, lacks accuracy and is not recommended. The MUN target concentrations for lactating dairy cows fed according to National Research Council recommendations have been evaluated. The target MUN concentrations are 8.5 to 11.5 mg/dL for most dairy herds compared with the previous target concentrations of 12 to 16 mg/dL. MUN, together with percentage milk protein, is being used increasingly as an indicator of the dietary protein–energy balance. The time of sampling can have a significant effect on MUN concentrations; the highest concentration was found to occur in the morning, and the diurnal pattern was not influenced by intrinsic factors such as parity, days postpartum or daily milk yield. MUN concentration was significantly increased after refrigeration for 1 week.

Several reviews of the literature have examined the effect of protein nutrition on reproduction in dairy cows. The reported effect of high nitrogen intake on fertility is inconsistent. Experimentally, the ingestion of a high level of degradable protein commencing 10 days before insemination in lactating dairy cows had no effect on the reproductive performance of the lactating high-yielding dairy cow. The relationship between MUN concentration and the fertility of dairy cows from 250 herds in the United Kingdom found no relationship between bulk-tank MUN concentration and fertility, or between changes in bulk-tank MUN concentrations and fertility.

A meta-analysis of the literature evaluated the associations between dietary requirements for protein for dairy cattle, the metabolism of protein in cattle, factors influencing the degradability of protein in ruminant feeds, and factors influencing MUN concentrations. There are good correlations between dietary protein intake and rumen ammonia, blood urea, and milk urea concentrations. Ryegrass clover pastures provide feed in many of the temperate dairy regions of the world, and for much of the year pasture crude protein may exceed 30%, of which a high proportion is rapidly degradable. High dietary protein intakes may have a negative effect on reproductive performance in lactating dairy cows, but the role of milk urea as a predictor of fertility needs further definition given the high conception rates in many Australasian dairy herds. High intakes of dietary protein may induce adaptations in urea metabolism, and the negative relationship identified between high intakes of dietary protein and fertility for northern hemisphere dairy herds may not necessarily apply in Australasian dairy herds. Because of the potential for cows to adapt to high-protein diets, the use of a single MUN determination on a herd will have limited value as an indicator of nutritional status and little value as a predictor of fertility. The differing observations between various production systems indicate the need for careful consideration in applying recommendations for dietary protein management based on milk urea concentrations. MUN determinations may, however, have value, particularly when used in conjunction with other herd and nutritional data to assess the protein nutrition of dairy herds. It is unlikely that single or even serial determinations of MUN concentration in single cows or bulk-tank milk will have a high predictive value for determining the risk of conception in the cow or herd.

Albumin

Plasma/serum albumin concentration is related to the protein status of the animal and whether an acute-phase reaction has been induced. Lactation stage has a substantial effect on serum albumin concentration. Animals should be grouped into dry cows, early lactation (1 to 10 weeks), and later lactation. Minimal values for dry-cow means are from 2.9 to 3.1 g/dL, from 2.7 to 2.9 g/dL for recently calved cows, and from 3.0 to 3.2 g/dL for cows in later lactation.

Liver Function and Injury

The presence of liver injury can be evaluated by measuring plasma/serum aspartate amino-transferase (AST), sorbitol dehydrogenase (SDH), alkaline phosphatase, and gamma-glutamyl-transferase (GGT) activities. Of these enzyme activities, the plasma/serum AST activity is the most clinically useful, with plasma AST greater than 162 U/L being indicative of hepatic lipidosis. Because increased AST activity also reflects damaged skeletal muscle, AST activity is not a specific test for liver injury in cattle at calving or for a few days after calving because of the potential for parturition-related muscle damage.

Liver function can be assessed by measuring the plasma/serum total bilirubin, cholesterol, and albumin concentrations. Serum bile acid concentration is not a useful index of liver function in cattle. Calculation of the ratio of plasma NEFA to cholesterol on a molar basis appears to provide a clinically useful index to evaluate the degree of hepatic lipidosis and the liver's ability to export mobilized peripheral fat reserves, and has been able to predict the incidence of postpartum disease. The major drawback with measuring the NEFA:cholesterol concentration is the cost, in that each analysis costs approximately US$8/test, for a total test cost of US$16. Plasma/serum albumin concentrations are decreased for the first month after calving as a result of plasma volume expansion to accommodate the nutrient flow for milk production, loss into the uterine lumen associated with uterine involution, catabolism of body protein resulting from negative energy balance, and decreased hepatic function as a result of hepatic lipidosis. The major clinical utility of plasma/serum albumin concentration is therefore in the first 4 weeks of lactation.

Macromineral Evaluation

Abnormalities of the blood levels of the four macrominerals, calcium, phosphorus, magnesium, and potassium, in the cow during the transition period are involved in subclinical hypocalcemia, clinical milk fever, hypomagnesemia, and acute hypokalemia.

Calcium

Serum calcium concentrations are tightly regulated and are not sensitive indicators of input–output balance. Measurement of plasma/serum calcium concentrations during the first 24 hours after calving, particularly in multiparous dairy cows, can provide useful insight into the effectiveness of control programs for periparturient hypocalcemia.

Phosphorus
Serum inorganic phosphate concentrations tend to fall following long-term insufficient dietary intake.

Magnesium
Serum magnesium concentrations are usually low during the winter months, and subclinical hypomagnesemia exists in many herds, especially pregnant beef cattle. This can be converted into clinical hypomagnesemia with a sudden deprivation of feed or a sudden fall in environmental temperature. Supplementation of the diet with magnesium salts is protective.

Sodium
Low serum sodium concentrations occur in early lactation in cows grazing on summer pastures without supplementation with salt. Levels down to 135 mmol/L may be associated with depraved appetite and polydipsia and polyuria.

Potassium
Serum potassium concentrations have been difficult to interpret because the levels of the electrolyte in serum are not necessarily indicative of potassium deficiency. The normal serum potassium concentration is much more variable than that of sodium, and its average concentration in roughages of all kinds is nearly always in excess of requirements; any abnormalities are usually in the direction of excess.

Hematology
Hematocrit (Packed Cell Volume)
The hematocrit can be used as a general reflection of health. In most dairy herds, a low hematocrit may be a reflection of suboptimal energy and protein nutrition. Mean values of packed cell volume (PCV), hemoglobin, and serum iron are consistently higher in nonlactating cows than in lactating cows. Parasitism causing blood loss will result in a low hematocrit. The hematocrit varies with lactation stage, being highest in dry cows and lowest at peak (summit) milk. Cows should be grouped by lactation stage when evaluating hematocrit.

Urine Evaluation
Urine samples are easier to obtain than blood samples, although stimulation of the perineal area to induce urination is usually only 75% to 90% successful. Higher success rates in obtaining a urine sample are obtained in cattle that have been sitting down and that are encouraged to stand.

Urine appears to be the optimal fluid to monitor acid–base and calcium status in dairy cattle. The most accurate insight into acid–base homeostasis in healthy cattle is obtained by measuring urine net acid excretion (NAE) or net base excretion (NBE) (see Chapter 5). However, when urine pH is between 6.3 and 7.6, urine pH measured by urine dipsticks or pH papers provides an inexpensive and clinically useful insight into acid–base homeostasis in cattle.[5] This is because the change in urine pH over this pH range accurately reflects the change in NAE or NBE. Optimum target values for urine pH to decrease the incidence of milk fever in dairy herds have not been identified, and recommendations for optimal urine pH values vary widely.[5]

Feeding rations with low dietary cation-anion difference (DCAD) to dairy cows for at least 2 weeks before calving decreases the incidence of periparturient hypocalcemia. The most likely reason for this effect is that ingestion of a low-DCAD diet increases calcium (Ca) flux, which in nonlactating cows is most readily detected as an increase in urinary calcium excretion. Low urine pH decreases calcium uptake from the tubular lumen into the renal epithelial cell and therefore decreases calcium absorption in the distal convoluted tubule and connecting tubule, thereby directly resulting in hypercalciuria. It remains to be determined whether laboratory measurement of urinary calcium concentration is more accurate and cost-effective than cow-side measurement of urine pH or laboratory determination of urinary strong ion difference and NBE when evaluating the effectiveness of milk-fever control programs.

Timing of Blood Tests
In Relation to Feed Changes
Because changes in the diet of ruminants cause changes in the character of rumen activity, blood samples for metabolic profile testing should not be done until 2 weeks after a major dietary change. Minor changes such as an increase in the quantity of an existing component or in access to the same ration do not require a wait of more than 7 to 10 days. Changes in forage type, such as turnout to pasture, housing, or the introduction of silage, require the full 2 weeks. The same applies for introduction of concentrates or of a new type of concentrate.

In Relation to Feeding
There can be changes in biochemical values in blood associated with feeding. These are most marked in cows receiving their entire concentrate ration at milking time. In such cases, 2 hours should be allowed to elapse after milking before blood sampling. In circumstances where the major part of the concentrate input is mixed with the forages and is available for most of each 24 hours, the timing of tests in relation to feeding is less critical. If lower-yielding midlactation cows are included (see later discussion), their results can be used as a check to see if there is an effect of feeding on the biochemical values in the blood samples. Cows should not be separated at milking time and confined for hours without access to food while waiting for blood sampling because this can also affect the results.

The available recommendations regarding the timing of blood collection relative to feeding are somewhat confusing. A common recommendation is that blood samples should be obtained 5 hours after feeding if animals are fed a fresh total mixed ration once daily. This recommendation does not seem logical in that plasma BHB concentration is increased at this time in cattle fed rations based on corn (maize) silage because of the metabolism of absorbed butyrate by ruminal epithelial cells. In most nutritional studies, blood samples are collected in a preprandial state because this is most consistent, but this will give the highest plasma NEFA concentrations over a 24-hour period. On this basis, sampling should be done in the morning immediately before or at the time of feeding of a fresh total mixed ration.

In Relation to Calving Pattern and Seasonal Feeding Changes
The cow in early lactation is the most important because what happens to her in the first few weeks after calving has the major influence on her subsequent productivity, including her future fertility efficiency. Therefore blood sampling for metabolic profiles should be carried out at the beginning of each new calving season, with the first cows checked so that the majority can benefit from the information derived. Of equal importance is the need to test as soon as possible after the introduction of a new ration, so that evaluation of the cows' biochemistry can be made available as quickly as possible to determine **what the cows, the end users, think of the ration.** Therefore planning of metabolic profile tests needs to be done in advance and should take into account both expected calving pattern and feed changes. Without planning along these lines, time may be lost, and productivity with it.

Selection of Cows
Picking appropriate cows for blood sampling is very important. This is because some of the metabolites looked at, particularly those relating to energy balance, can quickly return to the optimum range as cows adapt themselves, including their productivity, to a nutritional constraint. It is possible for cows to experience a significant energy deficit in the first 2 to 3 weeks of lactation because of intake problems, lose excessive body condition, perhaps have their milk yield modified, and have their subsequent fertility efficiency suppressed, but yet still arrive at 4 weeks calved with all biochemical measurements within the optimum ranges. If blood is sampled at 4 weeks after calving or longer, a producer could see thin, underproducing cows with poor fertility but with nothing abnormal about their biochemistry. Thus the farmer would be entitled to feel the

metabolic profile test was of no value. However, if those cows had been blood sampled at 14 days calved instead of 28 days, the blood results would have been quite different and would have identified the nutritional constraint on productivity.

The guidelines for metabolic profiling of dairy cattle recommend sampling from the following groups:

- Dry period (D): between 7 and 10 days before anticipated date of calving
- Early lactation (EL): between 3 and 14 days of lactation
- Midlactation (ML): between 50 and 120 days of lactation.

Individual variations in biochemical values are such that single cows should not be tested. **Groups of no less than five should be sampled.** They should not be picked at random, but rather should be typical, average cows of their stage of lactation. Cows with extremes of performance—either very high or very low—should not be selected. Cows with problems should also not be included because the type of analysis carried out is not designed to clarify individual problems. It is important to make all this clear to farmers in advance because they cannot be expected to appreciate the limitations of the analyses made. Experience in the Dairy Herd Health and Productivity Service in the United Kingdom suggests that selecting cows for metabolic profiles may be best done by the veterinarian in advance of the test after looking at the calving and production records. If there is a specific concern of poor conception rate, for example, farmers may expect only cows that failed to conceive to be sampled. This tactic hardly ever delivers helpful information because any nutritional constraints have by then been compensated for, and blood biochemical values are usually within optimum ranges. The best approach may be to include such cows as the midlactation group.

Dry-Cow Group

Because the dry period is so important to the success of the following lactation, blood sampling to make sure nutrition is adequate is essential. However, the nature of the measurements that can be made means that primarily **cows in the last 7 to 10 days of gestation should be sampled.** Blood sampling a group of dry cows with 1 month or longer to go to calving at the same time can sometimes provide a useful within-herd comparison with respect to energy balance. Such sampling may also identify the presence of dietary protein inadequacy—specifically, rumen degradable—in the early part of the dry period.

Early-Lactation Group

The definition used for the early-lactation group is most critical for the reasons given in the previous paragraph. Since the original Compton metabolic profile, in which a high-yielding cow was used as the definition, the importance of this group has become increasingly apparent. The definition also has had to be changed to take into account changes in farm practice. The way cows are fed now—total mixed rations, increased out-of-parlor concentrate feeding—has reduced the time after calving by when they can adapt themselves to an unsatisfactory diet. **To be sure of detecting the presence of an energy constraint in particular, blood sampling should be carried out between 3 and 14 days calved**—at less than 3 days, the metabolic impact of hypercortisolemia associated with parturition is still present; at more than 14 days, some cows will be thin, unproductive, and subfertile but may have compensated for their nutrition and thus have normal blood metabolite values.

Midlactation Group

Some cows that have past the period of peak yield and so past the greatest period of potential nutritional stress should always be included. **They should be between 50 and 120 days calved** so that they are still relatively high yielding. This group provides a within-herd comparison with the early-lactation cows. Without this it is very difficult to distinguish between problems caused by constraints on intake of food or protein and energy content; to identify changes in biochemical values caused by mistiming of tests in relation to feeding or by oddities in the diet, such as silage with a high butyric acid content; and to make judgments on concentrate/forage usage within the herd.

In the DHHPS program, a majority of farms do metabolic profiles three to four times a year at critical times as a check, or "**ask-the-cows-what-they-think**" exercise. Thus metabolic profiles are used as part of a proactive preventive health and productivity program. Some of the larger farms may do more than 10 tests a year to cover feed changes and to check on the success of any corrective action.

In the DHHPS program, a standard DHHPS metabolic profile includes analysis of plasma for NEFA, BHB, glucose, urea nitrogen (urea N), albumin, globulin, magnesium, and inorganic phosphate. Analyses for copper and glutathione peroxidase (GSHPx) are done on approximately one-third of samples received and thyroxine T4 on even fewer. Biochemical analysis is performed using two biochemical auto-analyzers, with standard internal controls. It also employs an independent, external quality control system. Derivation of optimum metabolite values are summarized in Table 17-2. They are BHB less than 0.6 mmol/L in dry cows and less than 1.0 mmol/L in cows in milk; glucose greater than 3.0 mmol/L; NEFA less than 0.5 mmol/L in dry cows and less than 0.7 mmol/L in cows in milk; urea N greater than 1.7 mmol/L; albumin greater than 30 g/L; globulin less than 50 g/L; magnesium greater than 0.7 mmol/L; phosphate greater than 1.3 mmol/L; copper greater than 9.2 µmol/L; glutathione peroxidase (GSHPx) greater than 50U/g HB; and thyroxine T4 greater than 20 nmol/L.

Table 17-2 Metabolic profile parameters in cattle—optimum values

Parameter	SI units
BHB	
Milkers	Below 1.0 mmol/L
Dry cows	Below 0.6 mmol/L
Plasma glucose	Over 3.0 mmol/L
NEFA	
Milkers	Below 0.7 mmol/L
Dry cows	Below 0.4 mmol/L
Urea nitrogen	1.7–5.0 mmol/L
Albumin	Over 30 g/L
Globulin	Under 50 g/L
Magnesium	0.8–1.3 mmol/L
Phosphate (inorganic)	1.4–2.5 mmol/L
Copper	9.4–19.0 µmol/L
Thyroxine T4 (iodine)	Over 20 nmol/L
GSHPx (selenium)	Over 50 units/g Hb

Energy. The data in Table 17-3 use only the cows fitting precisely the definitions of D, EL, and ML. The table shows that, overall, an average of 30% EL cows had metabolite results reflecting satisfactory energy status, as did 61% of ML cows and 43% of D cows. In both EL and ML groups, glucose is the metabolite most commonly outside its optimum range, followed by BHB and NEFA. The percentage of NEFA values above optimum is low in ML cows. The most common finding is high BHB and low glucose in the same cow. In tests showing most cows in an EL group having these results, there is usually one or two with high NEFAs as well. Some EL cows show only low glucose or only high NEFA. Where low glucose only predominates in EL cows, ML cows often show the same picture.

Protein. The plasma urea concentration results in Table 17-3 show that the EL stage is more vulnerable to low values than later in lactation, even though the cows would have been on the same diets in virtually every case. In fact, an even greater average percentage of the blood of 1361 cows sampled between 0 and 9 days after calving over the 5 years showed low urea concentration.

The proportion of low-urea-concentration results in D cows is high (Table 17-3). In addition to the category shown of 10 days or less before calving, 4335 cows were sampled at more than 10 days

Table 17-3 Annual (April–March) percentages outside optimum ranges of metabolite results in blood plasma in adult dairy cows[8]

	EARLY LACTATION (EL) (10–20 DAYS CALVED)					MID LACTATION (ML) (50–120 DAYS CALVED)					DRY (D) (7–10 DAYS PREPARTUM)				
	1999 /00	2000 /01	2001 /02	2002 /03	2003 /04	1999 /00	2000 /01	2001 /02	2002 /03	2003 /04	1999 /00	2000 /01	2001 /02	2002 /03	2003 /04
β-hydroxybutyrate (BHB)	19.5	16.6	22.3	22.9	17.5	11.2	10.5	14.3	10.6	9.6	34.5	24.7	38.5	28.5	22.7
Glucose	46.0	48.7	43.1	49.0	59.3	21.8	25.9	14.5	22.5	25.4	23.9	27.3	21.7	27.3	33.8
Non-esterified fatty acid (NEFA)	19.1	22.2	24.9	27.4	28.0	0.6	2.1	1.8	2.7	3.1	10.8	15.0	14.2	13.0	14.8
One or more energy metabolite per cow	65	70	67	72	78	34	39	32	40	44	59	57	63	46	63
Urea-nitrogen (UreaN)	0.8	17.3	18.3	16.7	16.7	4.4	6.4	6.0	5.3	5.6	18.4	20.4	20.2	20.8	22.3
Number of cows	1295	1421	1248	1285	1530	914	1066	849	1179	1494	1160	1379	1253	1358	1543

prepartum, and 22% of them had low plasma urea concentrations.

Results outside the optimum ranges for albumin (0.6%), magnesium (2.5%), phosphate (1.0%), copper (10%), and GSHPx (3%) are relatively uncommon. Thyroxine T4 analysis was carried out in 836 samples on specific request, and only 3% were below optimum.

Background Information

So that full value can be obtained by the farmer from the metabolic-profile approach, information about the cows and the farm should accompany the blood samples to the laboratory. This should include cow identification; last calving date for milkers/expected for dry cows; body weight (calculation from heart-girth measurement with a weighband pulled to a constant 5-kg tension is the best because it is not affected by gutfill and usually most practical because no mechanical weighing device/crush is required); body-condition score by a palpation method; current daily milk yield; expected current daily milk yield; lactation number; daily supplementary feed intakes; daily estimated forage intakes; analytical description of feeds; and current herd milk solids percentages. It is useful to have information on herd size, breed, feeding systems, and health and fertility. A note of what concerns the farmer has, if any, should also be made.

Interpretation of Results at the Farm

Circumstances where the diagnosis of a nutritional constraint from blood samples is clearly correct, but the cause(s) are unclear from a distance and could be many, are common. Therefore it is very important that a final interpretation of what is not working and what are the best and most economic solutions ought to be made at the farm with the information from the laboratory in hand. Farm advisory visits should be made as soon as the results are available and discussions made, including farm staff and any other advisors involved. Experience in the DHHPS suggests that such a team approach produces a more balanced strategy and is more beneficial than each party working in isolation.

Written Advice

Any advice given should be recorded concisely in writing and copies given to all participants on the farm. This ensures that the agreed path is followed, creates a record, and ensures that the fee is for something tangible.

Milk Production, Activity Meters, and Rumination Monitors

The application of real-time monitoring of dairy cattle has great potential to provide low-cost and immediate insight into health and production. Of all potential indices, daily milk production (relative to previous production during the lactation or the previous lactation, or to peers) appears to provide the most sensitive and specific measure of dry matter intake and health. Milk production can be measured noninvasively and at very low cost using automated procedures at milking time. As diagnostic algorithms are refined, it is likely that monitoring of daily milk production will provide the most practical and low-cost method for evaluating health and production and for early disease detection.

Activity meters can detect standing and lying periods in cattle and from that information can infer time spent feeding in cows housed in free stalls or tie stalls. Rumination monitors detect the time spent ruminating each day, which is strongly associated with dry matter intake and health.

Body-Condition Score

Managing body reserves is critical for successful cow management and requires an accurate assessment of the cow's "condition." Body-condition scoring is an important aspect of metabolic diseases of farm animals. Body weight alone is not a valid indicator of body reserves because cows of a specific weight may be tall and thin or short and fat. The energy stores may vary by as much as 40% in cows of similar body weight, which emphasizes the futility and inaccuracy of relying on body weight alone as an index of cow condition. In addition, because tissue mobilization in early lactation occurs as feed intake is increasing, decreases in body-tissue weight can be masked by enhanced fill of the gastrointestinal tract, so that body-weight changes do not reflect changes in adipose tissue and lean-tissue weight.

There is a strong positive relationship ($R^2 = 0.86$) between BCS and the proportion of physically dissected fat in Friesian cows. Therefore the visual or tactile (palpation) appraisal of the cow's BCS provides a good assessment of body-fat reserves, ignoring—or minimizing the effect of—frame size and intestinal contents. Most animal and dairy scientists acknowledge the successful manipulation of BCS as an important management factor that influences or has a relationship to animal health, milk production, and reproduction in the modern dairy cow. For example, cows that lost 0.5 to 1.0 point in BCS between parturition and first service achieved a pregnancy-to-first-service rate of 53%, whereas those losing more than 1.0 point achieved a rate of 17%. In a seasonal pasture-based system for Holstein–Friesian cows, it is necessary to maintain the BCS at 2.75 or greater during the breeding season. BCS is important in achieving good reproductive performance. Loss of body condition between calving and first service should be restricted to 0.5 BCS to avoid a detrimental effect on reproductive performance.

BCS is a subjective method of assessing the amount of metabolizable energy stored

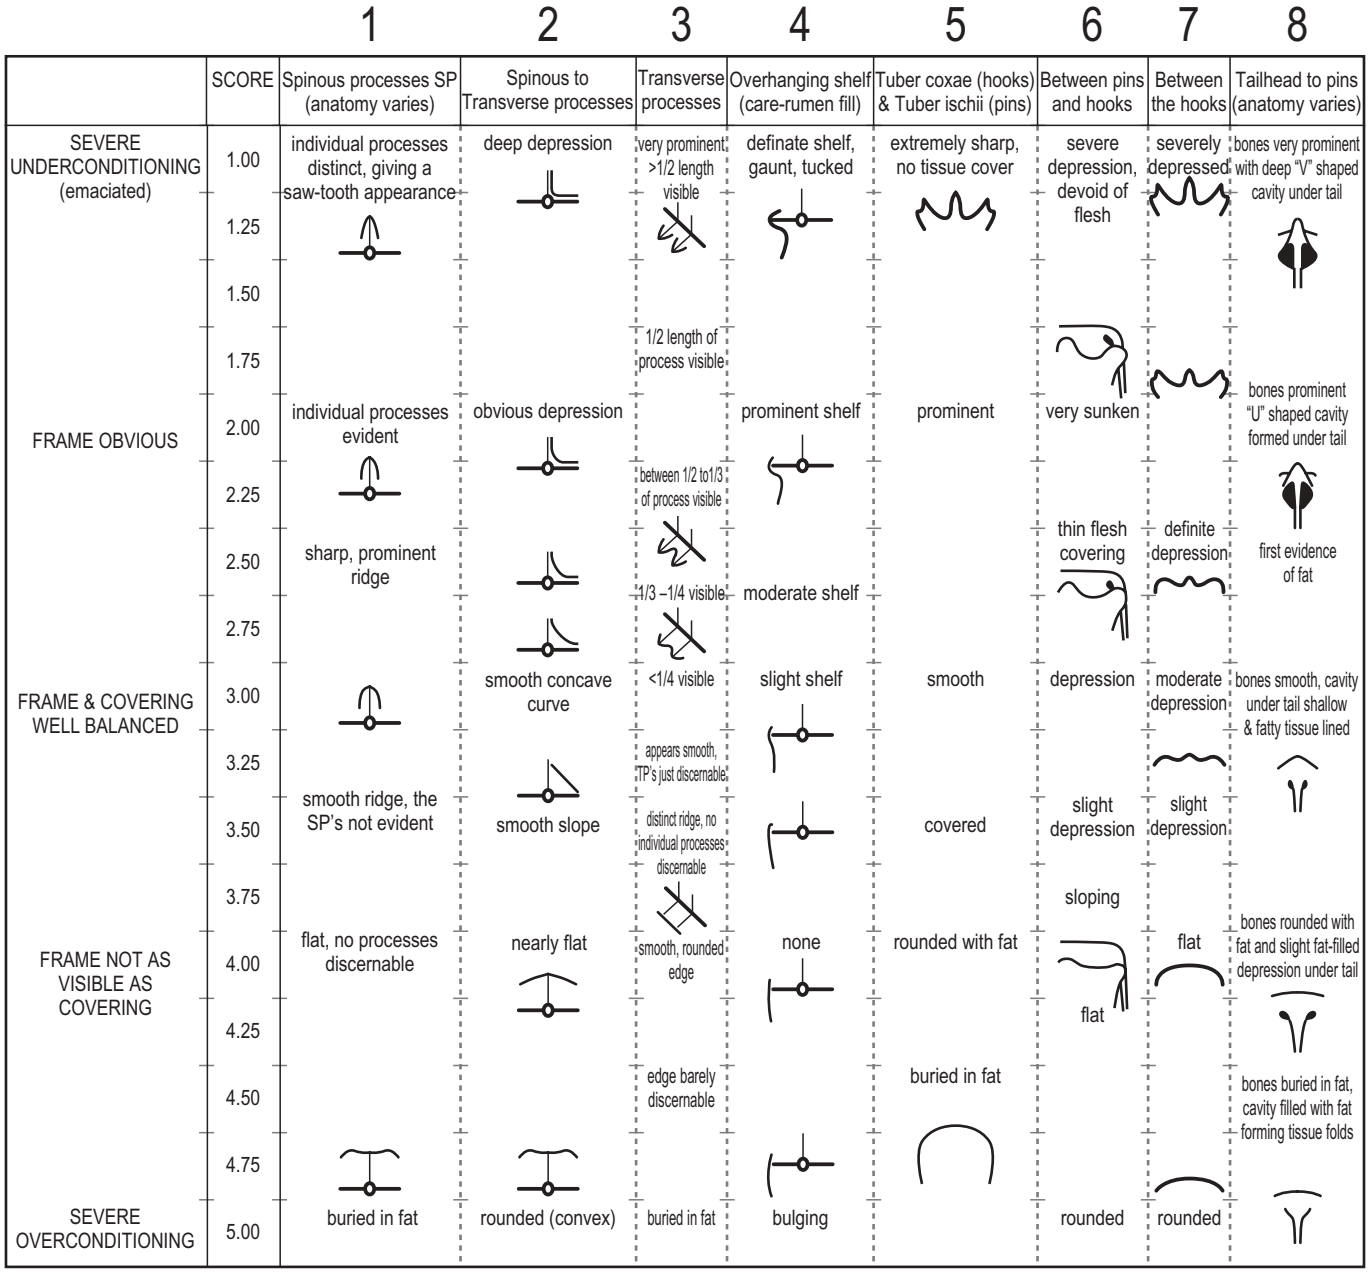

Fig. 17-3 Body-condition scoring chart. (Adapted from Edmonson AJ, Lean IJ, Weaver LD, Farver T, Webster G. A body condition scoring chart for Holstein dairy cows. *J Dairy Sci*. 1989; 72:68–78.).

in fat and muscle (body reserves) in a live animal. BCS in dairy cows is done using a variety of scales and systems. This method involves palpating the cow to assess the amount of tissue under the skin. Scoring body condition and assessing changes in the body condition of dairy cattle have become strategic tools in both farm management and research. BCS is being researched worldwide. But international sharing, comparing, and use of generated data are limited because different BCS systems are used. There is difficulty in interpreting the literature because of variability in the way authors apply scoring methods. In the United States, Canada, and Ireland, a 5-point BCS system is used for dairy cows, whereas Australia and New Zealand use 8- and 10-point scales, respectively. The following scoring method is recommended for the 0-to-5 scale. A BCS chart[6] appears in Fig. 17-3.

Score: 1

- Condition: Poor.
- Tailhead area: Cavity present around tailhead. No fatty tissue felt between skin and pelvis, but skin is supple.
- Loin area: Ends of transverse processes sharp to touch and dorsal surfaces can be easily felt. Deep depression in loin.

Score: 2

- Condition: Moderate.
- Tailhead area: Shallow cavity lined with fatty tissue apparent at tailhead. Some fatty tissue felt under the skin. Pelvis easily felt.
- Loin area: Ends of transverse processes feel rounded, but dorsal surfaces felt only with pressure. Depression visible in loin.

Score: 3

- Condition: Good.
- Tailhead area: Fatty tissue easily felt over the whole area. Skin appears smooth, but pelvis can be felt.

- Loin area: Ends of transverse processes can be felt with pressure, but thick layer of tissue dorsum. Slight depression visible in loin.

Score: 4

- Condition: Fat.
- Tailhead area: Folds of soft fatty tissue present.
- Patches of fat apparent under skin. Pelvis felt only with firm pressure.
- Loin area: Transverse processes cannot be felt even with firm pressure. No depression visible in loin between backbone and hip bones.

Score: 5

- Condition: Grossly fat.
- Tailhead area: Tailhead buried in fatty tissue. Skin distended. No part of pelvis felt even with firm pressure.
- Loin area: Folds of fatty tissue over transverse processes. Bone structure cannot be felt.

Relationships Among International Body-Condition Scoring Systems

The New Zealand 10-point scale was compared with the scoring systems in the United States, Ireland, and Australia by trained assessors. Cows were assessed visually in the United States and Australia; in Ireland, cows were assessed by palpating key areas of the cow's body. Significant positive linear relationships were found between the New Zealand 10-point scale and the other scoring systems. The relationships between the 10-point BCS scale used in New Zealand and the scales used in Ireland and the United States are summarized in Table 17-4.

Table 17-4 Relationship between the 10-point BCS scale used in New Zealand and the 5-point BCS scale used in Ireland and the United States, and the 8-point scale used in Australia

New Zealand	USA	Ireland	Australia
1.0	1.83	1.21	2.74
1.5	1.98	1.41	3.01
2.0	2.14	1.61	3.28
2.5	2.30	1.81	3.55
3.0	2.46	2.01	3.82
3.5	2.62	2.21	4.09
4.0	2.78	2.41	4.36
4.5	2.94	2.61	4.63
5.0	3.10	2.81	4.90
5.5	3.26	3.01	5.17
6.0	3.42	3.21	5.44
6.5	3.58	3.41	5.71
7.0	3.74	3.61	5.98
7.5	3.90	3.81	6.25
8.0	4.06	4.01	6.52
8.5	4.22	4.21	6.79
9.0	4.38	4.41	7.06
9.5	4.54	4.61	7.33
10.0	4.70	4.81	7.60

PARTURIENT PARESIS (MILK FEVER)

SYNOPSIS

Etiology Hypocalcemia just before, around, or after parturition.

Epidemiology Adult dairy cows in third parity and older; clinical case incidence of 4% to 9%, with low case fatality, but up to 50% of multiparous periparturient dairy cows affected subclinically. Most commonly occurs within 48 hours after calving, but also occurs several weeks before or after. Occurs in beef cattle in epidemics. Occurs in sheep and goats in epidemics, usually following stressors. Prepartum diets high in calcium.

Signs Three progressively worse stages including early signs such as restlessness, muscle fasciculation over shoulder and neck, cool skin, anorexia, rumen atony with mild bloat, and insecure gait. More advanced stages with general muscle weakness leading to sternal recumbency with head resting on the chest, mental depression, dilated pupils, weak heartbeat und pulse, increased heart rate, dry muzzle, dry feces, and hypothermia. Last stage characterized by lateral recumbency, severe obtundation, severe rumen bloat, barely audible heart, tachycardia, circulatory collapse, coma, and death.

Diagnostic confirmation Hypocalcemia and response to treatment with calcium borogluconate.

Treatment Calcium borogluconate IV, oral calcium salts.

Control Dietary management to reduce dietary potassium intake prepartum, while increasing the content of anions in the ration (low dietary cation–anion difference rations). Reducing dietary calcium content below requirements prepartum to prepare the organism for a negative calcium balance. Oral administration of calcium salts immediately before, at, and after calving. Oral or parenteral vitamin D and analogs before calving.

ETIOLOGY

A depression in the levels of ionized calcium in the extracellular space, including plasma, is the basic biochemical disturbance in milk fever. A transient period of subclinical hypocalcemia (total plasma calcium [Ca] < 2.0 mmol/L or 8 mg/dL) occurs at the onset of lactation caused by an imbalance between calcium influx to the extracellular pool from gut and bone and output in colostrum and milk. The sudden increase of Ca losses through the mammary gland at the onset of lactation presents a considerable challenge for the circuits regulating Ca homeostasis. With milk containing approximately 2 g of Ca per kg and colostrum approximately 2.3 g of Ca per kg, the production of 10 kg of milk or colostrum requires the equivalent of the entire amount of Ca available in the extracellular space of an adult cow. Calcium lost from the extracellular pool must be replaced by increasing intestinal absorption and bone resorption of calcium. Whereas the calcium requirements of a cow in late gestation are minimal at about 30 g/d, a dairy cow must mobilize an additional 30 g or more of calcium per day for milk production from parturition on. A certain degree of hypocalcemia around parturition is unavoidable and is a result of the lag time of counter-regulatory mechanisms reacting to the sudden imbalance of Ca homeostasis at the onset of lactation. Most cows adapt within 48 hours after calving by increases in plasma concentrations of parathyroid hormone (PTH) and 1,25-$(OH)_2D$, the biologically active form of vitamin D_3. The incidence of subclinical hypocalcemia, with serum Ca concentrations between 1.4 and 2.0 mmol/L (5.5 to 8.0 mg/dL) in multiparous periparturient cows has been estimated at 50%.[1] Clinical milk fever is estimated to occur in 5% of periparturient dairy cows in the United States.[2]

EPIDEMIOLOGY

Occurrence

Cattle

The disease occurs most commonly in high-producing multiparous lactating dairy cattle. Lactating beef cows also are affected, but less commonly.

Age. Hypocalcemia at calving is age related and most marked in cows at their third to seventh parturition, although rare cases have been observed at the first and second calvings.

Breed. Field observations have for many years suggested that Jersey, Swedish Red and White, and Norwegian Red breeds develop clinical milk fever more frequently than Holstein–Friesian cows.[3] The higher Ca concentration in milk from Jersey compared with Holstein cows has been proposed as possible explanation, although the absolute differences in Ca excreted through the mammary gland per day between breeds are negligible when considering the higher milk yield of Holstein–Friesian cows.[3] Differences in the number of intestinal vitamin D receptors regulating the intestinal Ca uptake have been reported in some studies.[3] The disease in beef cattle breeds occurs either in individual cows or in herd outbreaks.

Individual Cows. Individual cows, and to some extent families of cows, are more susceptible than others; the disease tends to recur at successive parturitions. The heritability of susceptibility to milk fever and hypocalcemia has been assessed as insignificant; different studies reported heritabilities of 0%, 4%, and 12.8%.[4] Complete milking in the first 48 hours after calving, as opposed to normal sucking by a calf, appears to be a precipitating factor. Several studies have reported that the incidence of milk fever is positively associated with the level of milk production.

Time of Occurrence. In cattle, milk fever occurs at three main stages in the lactation cycle. Most prepartum cases occur in the last few days of pregnancy and during parturition, but rare cases occur several weeks before calving. Some cases will occur a few hours before parturition or at the time of parturition when the attendant expects the cow to calve and the second stage of parturition does not occur because of uterine inertia resulting from hypocalcemia. Most cases occur within the first 48 hours after calving, and the danger period extends up to about the 10th postpartum day. Up to 20% of cases can occur subsequent to the 8th day after calving. In such cases the declines in serum Ca levels are smaller than in parturient cows. The clinical signs are also less severe, and there are fewer relapses after treatment. Occasional cases occur during mid- or even late lactation. Such cases are often recurrences of the disease in highly susceptible cows that were affected at calving. Undue fatigue and excitement may precipitate such attacks, and there is a special susceptibility at estrus. In the latter case, the depression of appetite by the elevation of blood estrogen levels may be a contributing factor.

Hypocalcemic episodes lasting 1 to 2 days may occur two or three times with a periodicity of about 9 days. Fluctuations in the intestinal absorption of Ca during this period may be the cause of Ca cycling. Subclinical hypocalcemia is of major significance because it inhibits reticulorumen motility, which affects appetite, delays intestinal absorption of nutrients, and exacerbates the negative energy balance already existing in the cow in the first month of lactation.

Stressors. Feed intake depression for 48 hours contributes to the depression of serum Ca levels, and this may be of importance in the production of hypocalcemic paresis in this species at times other than in the postparturient period. Pregnant beef cattle may develop hypocalcemic paresis during the winter months when they are fed on poor-quality roughage; within a group of such cows, lower-ranked individuals of the herd may suffer selective malnutrition. The disease has also occurred in beef cows affected with diarrhea of undetermined etiology. As another explanation of the heightened susceptibility of cows at estrus, a possible depression of the degree of ionization of calcium under the influence of estrogens has been proposed. Differences in total serum Ca or plasma ionized Ca values in cows during estrus, however, are not documented.

The intravenous administration of certain aminoglycosides, especially neomycin, elihydrostreptomycin, and gentamicin, may cause a reduction in the degree of ionization of serum calcium and a syndrome similar to milk fever. Oral dosing with zinc oxide (40 or 120 mg Zn/kg body weight [BW]) as a prophylaxis against facial eczema in ewes causes a serious drop in serum calcium levels 24 hours after treatment. Caution is recommended with the use of these drugs in parturient cows.

Sheep and Goats

In sheep, the disease commonly occurs in outbreaks in groups of ewes exposed to forced exercise, long-distance transport, sudden feed deprivation, and grazing on oxalate-containing plants or green cereal crops. These circumstances commonly precipitate outbreaks of hypocalcemic paresis in sheep; mature ewes are the most susceptible, particularly in the period from 6 weeks before to 10 weeks after lambing. Up to 25% of the flock may be affected at one time. The disease also occurs in young sheep up to about 1 year of age, especially when they graze green oats, but also when pasture is short in winter and spring, as in southeast Australia. The disease is manifested by paresis, but poor growth, lameness, and bone fragility can be detected in the rest of the flock. A sudden deprivation of feed or forced exercise of ewes can cause marked depression of the serum Ca levels. However, ewes are in a susceptible state in early lactation because they are in negative Ca balance. In late lactation a state of positive balance is a result of a low rate of bone resorption. There is an unexplained occurrence of hypocalcemia in sheep fed on hay when they are supplemented with an energy-rich concentrate, which increases their calcium intake. Another occurrence in ewes is at the end of a drought when the pasture growth is lush and very low in Ca content. The incidence may be as high as 10% and the case-fatality rate 20% in ewe flocks in late pregnancy or early lactation.

Hypocalcemia in sheep depresses endogenous glucose production and insulin release, and in late pregnancy in combination with hyperketonemia, it facilitates the development of pregnancy toxemia.

In does, a depression in serum levels of Ca and phosphorus occurs similar to that in cows, but in ewes no such depression occurs at lambing, and the intervention of a precipitating factor appears to be necessary to reduce the serum Ca level below a critical point.

Milking goats become affected mostly during the 4- to 6-year-old age group. Cases occur before and after kidding, some later than 3 weeks after parturition. Clinical syndromes are identical to those in cows, including the two stages of ataxia and recumbency. Serum Ca levels are reduced from normal levels for parturient does.

Morbidity and Case Fatality

Clinical Hypocalcemia

Several epidemiologic studies of milk fever have reported incidence rates between 5% and 10% for clinical milk fever in cattle, calculated either as the lactational incidence or incidence per cow year.[2,5] Overall clinical disease is sporadic, but on individual farms the incidence may occasionally reach 25% to 30% of high-risk cows. With early treatment mortality is low in uncomplicated cases, but incidental losses as a result of aspiration pneumonia, mastitis, and limb injuries may occur. From 75% to 85% of uncomplicated cases respond to parenteral Ca therapy alone. A proportion of these animals require more than one treatment, either because complete recovery is delayed or because relapse occurs. The remaining 15% to 25% are either complicated by other conditions or incorrectly diagnosed.

Subclinical Hypocalcemia

Subclinical hypocalcemia, defined as total plasma Ca between 1.4 and 2.0 mmol/L (5.5 and 8.0 mg/dL), is common in dairy cattle during the first few weeks of lactation. The incidence rates of subclinical postparturient hypocalcemia reported in the literature are in the range of 33% and may even increase to 50% in older cows.[1,5]

Risk Factors

Animal Risk Factors

Serum Ca levels decline in all adult cows at calving as a result of the Ca loss through the mammary gland at the onset of lactation. This decline is more pronounced in some cows than in others, and it is this difference that results in the varying susceptibility of animals to parturient paresis. First-calf heifers rarely develop milk fever because

they are able to adapt more effectively to the high Ca demand at the onset of lactation. With increasing age, this adaptation process is hampered and results in moderate to severe hypocalcemia in older cows. The adaptation mechanism is directly related to the efficiency of intestinal absorption of Ca, which decreases with increasing age.

Calcium Homeostasis. The following three factors affect Ca homeostasis, and variations in one or more of them may contribute to the development of clinical disease in any individual:

1. Excessive loss of calcium in colostrum beyond the capacity of absorption from the intestines and mobilization from the bones to replace it. Variations in susceptibility between cows could be the result of variations in the Ca concentration in colostrum or milk and the volume of milk produced.
2. Impairment of absorption of Ca from the intestine at parturition.
3. Mobilization of Ca from storage in the skeleton may not be sufficiently rapid or efficient to maintain normal plasma Ca levels. The Ca mobilization rate is markedly reduced in cows in later pregnancy in response to the low requirements in the weeks before parturition. The lag time in reinitiating bone resorption at the moment Ca losses through the mammary gland suddenly begin contributes to the transient depression of the plasma Ca concentration. Bone resorption makes only a minor contribution to the total rate of Ca mobilization at parturition and is therefore of minor importance for the prevention of periparturient hypocalcemia. Osteoblasts are the only type of bone cell to express the 1,25-$(OH)_2$D receptor protein, and the decrease in the numbers of osteoblasts with increasing age could delay the ability of bone to contribute Ca to the plasma Ca pool. Bone resorption shortly before and around calving can furthermore be hampered in states of metabolic alkalosis as it occurs in cows fed a ration with high potassium content. Animals with mild to moderate forms of compensated metabolic acidosis, in contrast, have enhanced bone-resorption activity, releasing additional Ca to the extracellular pool. Preventing alkalization by avoiding excessive dietary potassium and inducing mild to moderate acidosis by adding so-called anionic salts to the diet in late gestation are common strategies for prevention of milk fever in cattle (see also the discussion under "Control" in this chapter).

Historically it was proposed that failure to secrete sufficient levels of PTH or insufficient availability of 1,25-$(OH)_2$D was the primary defect in cows that developed milk fever. More recent research has shown that the secretion of PTH and the production of 1,25-$(OH)_2$D are similar in most cows with or without milk fever. However, about 20% of cows treated for parturient paresis experience relapsing episodes of hypocalcemia that require further treatment. These cows appear to be less efficient in producing adequate amounts of 1,25-$(OH)_2$D at the onset of lactation. Both relapsing and nonrelapsing cows develop the same degree of hypocalcemia and secondary hyperparathyroidism, but production of 1,25-$(OH)_2$D is about twofold greater in nonrelapsing cows than relapsing cows. Following treatment of parturient hypocalcemia with intravenous Ca salts and restoration of ruminal and intestinal motility, nonrelapsing cows establish Ca homeostasis over the next 3 to 4 days by increasing intestinal absorption of Ca, which is activated by a sufficient level of 1,25-$(OH)_2$D. In relapsing cows, even when rumen and intestinal motility are restored after treatment, hypocalcemia and paresis are likely to occur because of insufficient plasma 1,25-$(OH)_2$D. These cows may remain in this stage of prolonged hypocalcemia for several days, and only after a few days and several repeated treatments with Ca will the plasma levels of 1,25-$(OH)_2$D increase to an adequate level to maintain Ca homeostasis. Tissue 1,25-$(OH)_2$D receptor concentrations decline with age, which renders older cows less able to respond to the hormone; thus it will take longer for older cows to adapt intestinal Ca absorption mechanisms to meet lactational demands for Ca.

Body-Condition Score. A high BCS increases the risk of milk fever. The odds ratio of milk fever with a BCS greater than 4/5 on the first milk recording day after calving was 4.3, and cows with milk fever had a postpartum predisease body weight 12 kg higher compared with healthy cows, indicating an increased risk of milk fever as a result of higher body weight. Cows with subclinical hypocalcemia in the winter period had significantly higher mean body weight over the 60 days postpartum than normocalcemic cows, but the effect was not significant in cows calving during the summer months.

Dietary and Environmental Risk Factors

Several dietary factors of the pregnant cow during the prepartum period (last 4 weeks of gestation) can influence the incidence of milk fever in cattle.

Dietary Calcium. Feeding more than 100 g of calcium daily during the dry period is associated with an increased incidence of milk fever. The daily dietary Ca requirements of an adult cow in late gestation are in the range of 30 g Ca/d. When supplying Ca far in excess of the daily requirements (>100 g Ca/d), the active absorption of Ca from the digestive tract and mobilization from bone are homeostatically depressed and become quiescent. As a consequence, at calving when sudden changes of the Ca balance occur, the cow is unable to rapidly return to bone Ca stores or intestinal Ca absorption mechanisms and is susceptible to severe hypocalcemia until these mechanisms can be activated, which may take several days.

Feeding prepartum diets with a Ca concentration low enough to induce a negative Ca balance already before calving prevents milk fever by activating Ca transport mechanisms in the intestine and bone before parturition, thus allowing the animal to adapt more rapidly to the lactational drain of Ca. The challenge of this approach is to formulate a balanced dry-cow ration with a sufficiently low Ca concentration providing less than 20 g/d of absorbable Ca (see also the discussion under "Control" in this chapter).

Supplementing dietary Ca immediately before and around parturition may also lower the incidence of milk fever by providing additional dietary Ca at the moment intestinal Ca absorption is upregulated (see also the discussion under "Control" in this chapter).

Dietary Potassium. The dietary potassium content of the ration fed in late gestation is a major contributing factor to the risk of periparturient hypocalcemia. Positively charged electrolytes (cations) contained in the diet and absorbed from the digestive tract tend to alkalinize the organism, whereas electrolytes with a negative charge (anions) are acidifying.[6] Studies of the 1970s furthermore demonstrated that alkalization of the organism by increasing the amount of dietary cations increased the incidence of milk fever, whereas acidification by increasing the dietary anion content reduced the milk-fever incidence, which is the basis of the so-called dietary cation–anion difference (DCAD) concept (see also the discussion under "Control" in this chapter). With potassium being the quantitatively most important cation in a standard ruminant diet, it follows that high potassium concentrations (>2% of the ingested dry matter) in the ration fed to cows in their last weeks of gestation can considerably increase the incidence of periparturient hypocalcemia.

Dietary Magnesium. Magnesium deficiency during late gestation is a major risk factor for periparturient hypocalcemia, and hypomagnesemia is considered to be the most common cause of milk fever occurring in midlactating dairy cows.[3] Because magnesium is required for the release PTH from the parathyroid glands and furthermore influences the tissue sensitivity to PTH, the efficacy of PTH for the correction of hypocalcemia greatly depends on an adequate supply of magnesium.

Dietary Phosphorus. Prepartum diets high in phosphorus (P; > 80 g P/d) greatly increase the incidence of milk fever and the severity of hypocalcemia. High dietary levels of P increase the serum level of P, which is inhibitory to the renal enzymes that catalyze the conversion of vitamin D to its active form 1,25-$(OH)_2$D. Decreased amounts of 1,25-$(OH)_2$D will not only reduce the intestinal absorption of P, but also of Ca, and thereby predispose to periparturient hypocalcemia.[7]

Dietary Cation–Anion Difference. Studies in the 1960s and 1970s showed that experimentally increasing the dietary cation concentration or decreasing the dietary anion concentration had an alkalinizing effect on the organisms, whereas feeding diets with a higher anion or lower cation concentration resulted in acidification. It was furthermore demonstrated that alkalization achieved through feeding high-cation/low-anion diets increased the incidence of milk fever, whereas acidification by increasing the ration of anions to cations caused the milk-fever incidence to decline.[6] Accordingly the basis of the DCAD concept is to modulate the ratio of cations to anions in the diet to reduce the risk of milk fever in cattle. The cation–anion difference of a diet is commonly given in milliequivalents (mEq) per kilogram of feed dry matter (DM; mEq/kg DM) or sometimes in mEq/100 g DM. Although several different equations have been proposed for the calculation of the DCAD, the most commonly used only considers the four quantitatively most important dietary ions: sodium (Na^+), potassium (K^+), chloride (Cl^-), and sulfur (S^{2-}). Other electrolytes, such as Ca, P, and magnesium, also affect the actual DCAD and thereby the effect on the acid–base status of the animal consuming the diet, and these compounds are included in some of the equations proposed in the literature to calculate the DCAD. However, because these minerals are present in relatively low amounts in the ruminant diet, their effect is considered to be minor. They are therefore commonly disregarded for practicability reasons.

The DCAD exerts a strong linear effect on the incidence of milk fever and is more important than the level of dietary Ca as a risk factor for milk fever. Prepartum diets high in cations such as potassium are associated with an increased incidence of milk fever, whereas diets high in anions, especially chloride and sulfur, result in a decrease in the incidence of the disease. Most forages, such as legumes and grasses, are high in potassium and are alkaline. The addition of anions, specifically chloride and sulfur, to the diet of dairy cows before parturition can effectively reduce the incidence of milk fever (see also the discussion under "Control" in this chapter).

Systemic acidification induced by anionic supplementation affects the function of PTH hormone, the major effect being an increased tissue response to PTH, which results in increased retention of Ca and enhanced mobilization of Ca from bone. A meta-analysis of 75 feeding trials designed to study the nutritional risk factors for milk fever in dairy cattle found that the prepartum dietary concentrations of S and dietary anion–cation balance ([Na + K]—[Cl + S]) were the two nutritional factors most strongly correlated to the incidence of milk fever. Dietary S acts as a strong anion and reduces the risk of milk fever, and increasing the dietary S concentrations lowers the odds ratio of developing milk fever.

ECONOMIC IMPORTANCE

Although economic losses from milk fever have decreased considerably since the introduction of intravenous treatment with Ca salts many years ago, the disease incidences reported in recent years remain similar to values reported decades ago.[2,5] The most obvious costs are associated with drugs, veterinary intervention, and losses resulting from complications in clinical cases. Costs associated with subclinical hypocalcemia are, however, considered to be far more important. Incidence rates between 3.5% and 7% for clinical disease and over 30% for subclinical hypocalcemia have been reported, and hypocalcemia is considered to be a so-called "gateway disease" that predisposes to a number of common fresh-cow disorders, such as dystocia, uterine prolapse, retained fetal membranes, mastitis, ketosis, abomasal displacement, ketosis, and immune suppression.[5] The costs per clinical case of milk fever have been estimated at US$300, whereas subclinical cases may cost around US$125 per case, based on estimates accounting for reduced milk production and increased risk of developing periparturient disorders such as ketosis or abomasal displacement.[8]

The literature on the effects of clinical and subclinical hypocalcemia is difficult to interpret because of the complex relationships between milk production, parity of lactation, breed of cattle, epidemiologic methods used, and management systems used, in addition to the reproducibility of the clinical observations and the accuracy of the recording systems used. In general, there is insufficient information available to document the consequences of milk fever and subclinical hypocalcemia. A summary of several consequences that have been examined follows here.

Milk Fever Relapses. Milk fever cases that need repeat treatment because of relapses increase the costs.

Downer-Cow Complications. The downer-cow syndrome associated with those milk fever cases that fail to respond to intravenous (IV) Ca treatment and remain recumbent for days before subsequently standing, those that die, or those that require destruction represents an important cause of economic loss. The literature reports incidence rates for the downer-cow syndrome ranging from 3.8% to 28.2% of milk-fever cows, with a case fatality rate of 20% to 67%.[9]

Dystocia and Reproductive Disease. Hypocalcemia at the time of parturition can result in uterine inertia, which may cause dystocia and uterine prolapse. In general, there is an increased risk of dystocia associated with milk fever, whether the farmer or the veterinarian attends to the dystocia.[5]

Retained Placenta. Several studies have found an increased risk of retained placenta following milk fever.

Metritis. A few studies have found an indirect relationship between milk fever and subsequent metritis.

Milk Production. There is no reliable evidence that the occurrence of milk fever or subclinical hypocalcemia in cows that recover following treatment affects milk production in the subsequent lactation. Some studies have found a limited effect, no effect, or even positive effect of milk fever on milk production.

Mastitis. Hypocalcemia not only impairs immune function but furthermore may weaken the tone of the teat sphincter, which has been proposed to facilitate intramammary infection, particularly in recumbent cows that are not milked or milked less frequently.[3] An odds ratio of 8.1 for mastitis has been estimated, for coliform mastitis the odds ratio is estimated at 9.0, and for acute clinical mastitis a relative risk of 1.5 following milk fever has been found.

Displacement of Abomasum. Odds ratios ranging from 2.3 to 3.4 for left-side displacement of the abomasum occurring in dairy cows with hypocalcemia at parturition have been estimated.

Ketosis. Studies on the occurrence of ketosis following milk fever have found relative risks or odds ratios ranging from 1.3 to 8.9; using all the confidence intervals, the relative risks/odds ratios range from 1.1 to 15.3.

Body Weight. A temporary drop in body weight occurs in cows with milk fever, but there is no long-term effect. In cows with subclinical hypocalcemia in early lactation, there may be some weight loss compared with cows with normal levels of calcium.

Culling. There may be an increased probability of culling cows that have had milk fever because of the complications or direct or indirect consequences associated with the disease. There is some evidence of culling cows in early lactation because of milk fever, but not in late lactation.

PATHOGENESIS

Hypocalcemia

Calcium has several functions relevant for the pathophysiology of periparturient hypocalcemia, which include the following:

- Cell membrane stability: Calcium bound to cell membranes contributes to the maintenance of adequate membrane stability. In excitable cells the decreased availability of ionized Ca results in higher cell membrane permeability, thereby altering the resting membrane potential and making nerve cells more excitable.
- Muscle contractility: Calcium is required to clear the binding site for myosin on the actin molecule inside the muscle fibers. The cross-bridging between actin and myosin is the basis for the contraction of muscle fibers. Decreased availability of Ca can therefore affect muscle contractility.
- Release of acetylcholine: Calcium is required for the neuronal release of the neurotransmitter acetylcholine into the synaptic cleft of the neuromuscular junctions. Calcium depletion can thus hamper the signal transmission at the level of the neuromuscular endplate.

Whereas decreased membrane stability and ensuing increased excitability are the probable underlying cause of hypocalcemic tetany of monogastric species and the muscle twitching observed in the early stages of milk fever in cattle, disturbed muscle fiber contractility and neurotransmitter release are considered the basis of the flaccid paresis observed in advanced stages of milk fever in ruminants.

The plasma Ca concentration is normally maintained between 2.1 and 2.6 mmol/L (8.4 to 10.4 mg/dL). Almost all multiparous dairy cows will experience at least transient and subclinical hypocalcemia, less than 1.8 mmol/L (7.5 mg/dL), within 24 hours after calving. In some cows, hypocalcemia is more pronounced, causing neuromuscular dysfunction resulting in clinical milk fever. Without treatment, levels may continue to decline to values as low as or even below 0.5 mmol/L (2 mg/dL), which is usually incompatible with life.

Hypocalcemia is the cause of the signs of typical milk fever. Atony of skeletal muscle and plain muscle are well-known physiologic effects of hypocalcemia in ruminants.

Experimental Hypocalcemia

Hypocalcemia can be induced experimentally by administering Na_2-EDTA intravenously, which results in the complex binding or chelation of ionized Ca. The IV infusion of Na_2-EDTA into cows over a period of 4 to 8 hours results in severe hypocalcemia and paresis and has been used extensively as a model for the reproduction of the disease. A standardized flow rate of 1.2 mL/kg per hour of a 5% solution of Na_2-EDTA until recumbency results in changes in plasma ionized Ca, total Ca, inorganic phosphate (Pi), and magnesium comparable to what is observed in spontaneous cases of milk fever. Induced hypocalcemia results in depression of the frequency and amplitude of rumen contractions as early as 1.0 mmol/L of ionized serum Ca, well before any clinical signs of hypocalcemia are detectable and while feeding behavior and rumination are still normal. The induction of subclinical hypocalcemia in cows results in a linear decrease in feed intake and chewing activity as the plasma ionized calcium decreases. Feed intake depression was observed with ionized Ca concentrations below 0.9 mmol/L and before other signs commonly associated with hypocalcemia were recorded. Feed intake approached zero when ionized Ca concentrations declined to 0.6 mmol/L. This suggests that hypocalcemia may contribute to the reduction in feed intake prepartum and depresses the rumination process, ultimately leading to anorexia. Experimental hypocalcemia in cattle furthermore resulted in a marked reduction in cardiac stroke volume, a 50% reduction in arterial blood pressure, and a significant reduction in ruminal and abomasal tone and motility.

In experimental hypocalcemia in sheep, blood flow is reduced by about 60% to all tissues except the kidney, heart, lung, and bladder, in which the reduction is not as high. During periods of prolonged hypocalcemia in cows and ewes, blood flow to skeletal muscles and the alimentary tract may be reduced to 60% to 70% of normal for a long period, which may present a predisposing factor for the downer-cow syndrome. Serum Ca and Pi levels are significantly lower in clinical cases than in comparable normal cows, and there is some relationship between the severity of the signs and the degree of biochemical change.

Signs of hypocalcemic tetany, presumably attributable the increased membrane instability, commonly recognized in nonruminant species are observed in the initial stages of milk fever in cattle:

- Nervousness and early excitement
- Muscle twitching
- Tetany, particularly of the hindlimbs
- Hypersensitivity and convulsive movements of the head and limbs

There are additional signs in the experimental disease, such as excessive salivation, excessive lip and tongue actions, and tail lifting. The serum muscle enzyme levels of creatine phosphokinase (CPK) and aminotransferase (AST) increase as a result of muscle injury associated with prolonged recumbency. Blood glucose levels increase, and serum Pi and potassium levels decrease.

The prolonged infusion of Na_2-EDTA in sheep over 18 hours at a rate to induce hypocalcemia and maintain recumbency resulted in prolonged periods of recumbency ranging from 36 to 64 hours before the animals were able to stand. There are also decreases in plasma sodium, plasma potassium, and erythrocyte potassium and prolonged increases in PCVs, suggesting that fluid replacement therapy may be indicated in cattle with prolonged recumbency associated with hypocalcemia. The activity of AST and CPK, the PCVs, and white blood cell (WBC) counts were elevated 24 hours later.

Hypomagnesemia

Hypomagnesemia is recognized as an importing contributing factor to periparturient hypocalcemia and has been proposed to be the major risk factor for milk fever occurring in cattle in mid- to late lactation.[3] The two mechanism through which Mg deficiency may predispose to hypocalcemia are an impaired release of PTH in response to hypocalcemia and decreased tissue sensitivity to PTH in hypomagnesemic states.[3] Hypomagnesemia can therefore predispose to clinical or subclinical milk fever by blunting the main counter-regulatory mechanism of hypocalcemia.

Hypophosphatemia

Low serum Pi concentrations are commonly observed in milk-fever cows, but also in healthy dairy cows, around parturition.[7] Although the clinical relevance of hypophosphatemia in recumbent cattle remains uncertain, empirical associations between hypophosphatemia and recumbency have been established.[9] Anecdotal reports from field veterinarians suggest that the numbers of recumbent periparturient dairy cows not responding to standard therapy with intravenous Ca salts and showing pronounced hypophosphatemia have increased in recent years. To date, however, there is no unequivocal evidence corroborating the hypothesis that hypophosphatemia plays a role in periparturient recumbency or confirming the treatment efficacy of oral or parenteral Pi supplementation to recumbent cattle.[7]

CLINICAL FINDINGS

Cattle

Three stages of milk fever in cattle are commonly recognized and described.

Stage 1

In the first stage, the cow is still standing. This is also the brief stage of nervousness, excitement, and tetany with hypersensitivity and muscle tremor of the head and limbs. The animal is disinclined to move and often has a decreased or no feed intake. There may be a slight shaking of the head, protrusion of the tongue, and grinding of the teeth. The rectal temperature is usually normal to slightly above normal; the skin may feel cool to the touch. The animal appears ataxic, with a stiff and insecure gait, and falls easily. Close examination reveals agalactia, rumen stasis, and scant feces. Heart rate and respirations may be within normal limits or slightly elevated.

Stage 2

The second stage is characterized by sternal recumbency with depressed consciousness; the cow has a drowsy appearance in sternal recumbency, usually with a lateral kink in the neck or the head turned into the flank (Fig. 17-4). When approached, some of these cows will open their mouths, extend the head and neck, and protrude their tongues, which may be an expression of apprehension and fear in an animal unable to stand. The tetany of the limbs present in the first stage is not present, and the cow is unable to stand. The muzzle is dry, the skin and extremities cool, and the rectal temperature subnormal (36 to 38°C, 97 to 101°F). There is a marked decrease in the absolute intensity of the heart sounds, whereas the heart rate is increased (about 80 bpm). The arterial pulse is weak and the venous pressure is also low, making it difficult to raise the jugular veins. The respirations are not markedly affected, although a mild forced expiratory grunt or groan is sometimes audible. Ruminal stasis and secondary bloat are common, and constipation is characteristic. There is also relaxation of the anus and loss of the anal reflex.

The eyes are usually dry and staring. The pupillary light reflex is incomplete or absent, and the diameter of the pupil varies from normal to maximum dilatation. A detailed examination of the pupils of cows with parturient paresis, nonparetic disorders, and nonparturient paresis found that the mean sizes of the pupils were not significantly different from one another. Rather, disparity of the size of the pupils was common. In cows that develop hypocalcemia a few hours before or at the time of parturition, the second stage of parturition may be delayed. Vaginal examination usually reveals a fully dilated cervix and normal presentation of the fetus. The cow may be in any stage of milk fever, and administration of Ca-salts IV will usually result in a rapid beneficial response and normal parturition.

Prolapse of the uterus is a common complication of milk fever, and often the Ca levels are lower than in parturient cows without uterine prolapse. Thus it is standard practice to treat cases of uterine prolapse with IV calcium salts.

Stage 3

The third stage is characterized by a severely obtunded or even comatose cow in lateral recumbency. There is complete flaccidity on passive movement, and the cow cannot assume sternal recumbency on its own. In general, the depression of temperature and the cardiovascular system are more marked. The heart sounds are almost inaudible, and the rate is increased up to 120 bpm; the pulse is almost impalpable, and it may be impossible to raise the jugular veins. Bloat is common because of prolonged rumen stasis and lateral recumbency. Without treatment, a few animals remain unchanged for several hours, but most become progressively worse during a period of several hours and die quietly from shock in a state of complete collapse.

Concurrent Hypomagnesemia. Mild to moderate tetany and hyperesthesia persisting beyond the first stage suggests a concurrent hypomagnesemia. There is excitement and fibrillary twitching of the eyelids, and tetanic convulsions are readily precipitated by sound or touch. Trismus may be present. The heart and respiratory rates are increased, and the heart sounds are much louder than normal. Without treatment, death occurs during a convulsion.

Fig. 17-4 Friesian cow with stage 2 periparturient hypocalcemia. The cow is unable to stand without assistance.

Sheep and Goats

The disease in pastured ewes is similar to that in cattle. The early signs include a stilty, proppy gait and tremor of the shoulder muscles. Recumbency follows, sometimes with tetany of the limbs, but the proportion of ewes with hypocalcemia that are recumbent in the early stages is much less than in cattle. A similar generalization applies to female goats. The characteristic posture is sternal recumbency, with the legs under the body or stretched out behind. The head is rested on the ground, and there may be an accumulation of mucus exudate in the nostrils. The venous blood pressure is low and the pulse impalpable. Mental depression is evidenced by a drowsy appearance and depression of the corneal reflex. There is loss of the anal reflex, constipation, tachycardia, hyposensitivity, ruminal stasis and tympany, salivation, and tachypnea. Response to parenteral treatment with Ca salts is rapid; the ewe is normal 30 minutes after an SC injection. Death often occurs within 6 to 12 hours if treatment is not administered. The syndrome is usually more severe in pregnant than in lactating ewes, possibly because of the simultaneous occurrence of pregnancy toxemia or hypomagnesemia. Fat late-pregnant ewes on high-grain diets indoors or in feedlots show a similar syndrome accompanied by prolapses of the vagina and intestine.

CLINICAL PATHOLOGY

Total serum Ca levels are reduced to below 2.0 mmol/L (8 mg/dL), usually to below 1.2 mmol/L (5 mg/dL), and sometimes to as low as 0.5 mmol/L (2 mg/dL). The reduction is usually, but not always, proportional to the severity of the clinical syndrome. Average figures for total serum Ca levels in the three species are as follows: cows, 1.30 ± 0.30 mmol/L (5.2 ± 1.2 mg/dL); ewes, 1.15 ± 0.37 mmol/L (4.6 ± 1. 5 mg/dL); goat does, 0.94 ± 0.15 mmol/L (3.8 ± 0.6 mg/dL).

Although the concentration of ionized Ca, which is the biologically active fraction of the total Ca pool, is the factor determining the presence and severity of clinical signs in hypocalcemic animals, the total serum Ca concentration is commonly used for convenience. Measurement of ionized Ca concentration requires the use of ion-selective electrodes, which have become much more accessible in recent decades. Nonetheless, the association between ionized and total Ca in serum is tight, with excellent correlation between the two, which is why total Ca concentration in serum is considered clinically useful and sufficiently accurate in practice.[3] Between 42% and 48% of the total Ca content in the extracellular space is available as biologically active ionized Ca. A decrease in serum albumin or acidemia tends to increase the ionized Ca fraction, whereas alkalemia or an increase in serum albumin tends to decrease the proportion of ionized Ca.[3] Equine, bovine, and ovine blood may be

stored for up to 48 hours without any clinically relevant alteration of blood Ca ion concentration.

Levels of ionized Ca in the venous whole blood of cows are as follows: normal, 1.06 to 1.26 mmol/L (4.3 to 5.1 mg/dL); slight hypocalcemia, 1.05 to 0.80 mmol/L (4.2 to 3.2 mg/dL); moderate, 0.79 to 0.50 mmol/L (3.2 to 2.0 mg/dL); severe hypocalcemia, less than 0.50 mmol/L (<2.0 mg/dL). Total serum Ca levels are reduced below normal in all cows at calving, whether they have milk fever or not, but not in ewes.

Serum **magnesium** levels are usually moderately elevated to 1.65 to 2.06 mmol/L (4 to 5 mg/dL), but in some areas low levels may be encountered, especially in cows at pasture.

Serum **inorganic phosphorus (Pi)** levels are usually depressed to 0.48 to 0.97 mmol/L (1.5 to 3.0 mg/dL).

Blood glucose levels are usually normal, although they may be depressed if ketosis occurs concurrently. Higher-than-normal blood glucose levels are likely to occur in cases of long duration and are presumable because Ca is required for the release of insulin from the pancreas.

Serum Muscle Enzyme Activity

Prolonged recumbency results in ischemic muscle trauma and necrosis and increases in the serum muscle enzyme activity of creatine kinase (CK) and aspartate aminotransferase (AST). During prolonged recumbency following treatment for milk fever, the levels of CK will remain elevated if muscle trauma is progressive in animals that are not rolled from side to side every few hours to reduce the effects of compression on the large muscle groups of the pelvic limbs (see also the discussion under "Downer-Cow Syndrome" in this chapter).

Hemogram

Changes in the leukocyte count include eosinopenia, neutrophilia, and lymphopenia suggestive of adrenal cortical hyperactivity, but similar changes occur at calving in cows that do not develop parturient paresis. High plasma cortisol levels and PCVs occur in cows with milk fever and are higher still in cows that do not respond to treatment. They are expressions of stress and dehydration. Clinicopathological findings in the other species are not described in detail except with regard to depression of total serum calcium levels.

NECROPSY FINDINGS

There are no gross or histologic changes unless concurrent disease is present.

DIFFERENTIAL DIAGNOSIS

A diagnosis of milk fever is based on the occurrence of paresis and depression of consciousness in animals following parturition. The diagnosis is supported by a favorable response to treatment with parenteral injections of calcium solutions and by biochemical examination of the blood. In ewes, the history usually contains some reference to recent physical stress, and the disease is more common in the period preceding lambing.

There are several diseases that cause recumbency in cows in the immediate postpartum period, and their differentiation is summarized in Table 17-5.

Several diseases that occur at the time of parturition must be differentiated from milk fever in cattle. These are grouped here according to the following categories:

- Other metabolic diseases
- Diseases associated with toxemia and shock
- Injuries to the pelvis and pelvic limbs
- Degenerative myopathy
- Downer-cow syndrome

Metabolic Diseases

Hypomagnesemia may occur as the sole cause of recumbency; it may accompany a primary hypocalcemia or result in secondary hypocalcemia so that the case presented is one of parturient paresis complicated by lactation tetany. Hyperesthesia, tetany, tachycardia, and convulsions are common instead of the typical findings of depression and paresis in milk fever.

Hypophosphatemia, which commonly accompanies milk fever, is suggested as a cause of continued recumbency in cows after partial response to Ca therapy; serum Pi levels are low and return to normal if the cow stands or following treatment with calcium salts. The role of hypophosphatemia in the etiology of periparturient recumbency in cattle is under contentious debate. Although there is no unequivocal evidence available supporting the role of P in the etiology of recumbency in cattle, cows not responding to IV Ca were found to have lower serum Pi levels.[7,9]

Severe hypokalemia (<2.5 mmol/L) in dairy cows is characterized by extreme weakness or recumbency, especially after treatment for ketosis with isoflupredone.[10] Clinical signs tend to resemble botulism rather than hypocalcemia, with flaccid paralysis of the tongue and masticatory muscles and the head resting on the ground rather than on the chest of the cow. The case-fatality rate is high in spite of therapy with potassium. Hypokalemic myopathy is present at necropsy.

Ketosis may complicate milk fever, in which case the animal responds to Ca therapy by standing but continues to manifest the clinical signs of ketosis, including in some cases the nervous signs of licking, circling, and abnormal voice.

Diseases Associated With Toxemia and Shock

During the immediate postparturient period, several diseases occur commonly and are characterized by toxemia.

Acute or peracute coliform mastitis is characterized by one or several obviously enlarged and inflamed mammary glands with watery and serouslike secretions that may be overlooked if the cow is recumbent. Other signs include fever in early stages that may be followed by hypothermia in advanced stages of toxemia or septicemia, tachycardia, dehydration, depression and weakness up to the point of recumbency, ruminal stasis, and frequently also watery diarrhea.

Aspiration pneumonia secondary to regurgitation and aspiration of rumen contents is a complication of third-stage milk fever, or accidental aspiration or fluid administration into the trachea of periparturient cattle that were meant to be drenched. Fever, dyspnea, expiratory grunt, severe depression, and anxiety are common. Auscultation of the lungs reveals the presence of abnormal lung sounds. Aspiration pneumonia should be suspected if the animal has been lying on its side, especially if there is evidence of regurgitation of ruminal contents from the nostrils, no matter how small the amount, or if there is a history of the animal having been drenched. Abnormal auscultatory findings may not be detectable until the second day. Early diagnosis is imperative if the animal is to be saved, and the mortality rate is always high.

Acute diffuse peritonitis resulting from traumatic perforation of the abomasum or uterus is characterized by severe depression, tachycardia, dehydration, rumen stasis, fever, weakness and recumbency, grunting or groaning with respiration, and possibly splashing sounds on ballottement of the abdomen.

Carbohydrate engorgement (grain overload) results in depression, dehydration, tachycardia, hypothermia, diarrhea, and weakness up to the point of recumbency. The rumen is atonic and mildly to moderately bloated. the rumen content is watery. and the fiber matt is absent. A positive steelband sound and splashing sounds may be audible over the rumen on auscultation and percussion of the left flank. Examination of the rumen fluid will reveal a sour smell with low pH (<5.0). Microscopic examination of a smear will reveal absence of living protozoa and a predominance of gram-positive microorganisms if a stain is performed.

Toxemic septic metritis occurs most commonly within a few days after parturition and is characterized by depression, anorexia, fever, tachycardia (100 to 120 bpm), ruminal stasis, and presence of foul-smelling uterine discharge found on vaginal examination. The fetal placenta may be retained. Some affected cows are weak and prefer recumbency, which resembles milk fever.

Prolapse and rupture of the uterus cause varying degrees of shock, with tachycardia, hypothermia and cool extremities, weakness and recumbency, and rapid death. A history of difficult parturition or assisted dystocia

Table 17-5 Parturient paresis: Differential diagnosis of common causes of recumbency in parturient adult cattle

Disease	Epidemiology	Clinical signs	Clinical pathology	Response to treatment
Milk fever (parturient paresis)	Mature cows, within 48 hours of calving, some in midlactation	Early excitement and tetany, then depression, coma, hypothermia, flaccidity, pupil dilatation, weak heart sounds No rumen movements HR increases as state worsens	Hypocalcemia, with total Ca < 5 mg/dL (1.25 mmol/L) calcium frequently combined with hypophosphatemia with low inorganic phosphate, < 3 mg/dL (0.9 mmol/L)	Rapid, characteristic response (muscle tremor, sweating on muzzle, defecation, urination, pulse amplitude and heart rate decrease and heart sound intensity improves after IV administration of Ca salt solutions)
Downer cows following milk fever	Most common in situation where milk fever and lactation tetany are common and intensity of treatment is lax; cows are left down too long before treatment	Moderately bright, active, eating Temp. slightly raised, HR 80–100 Unable to stand but tries—creepers or alert downer cows When dull and depressed—nonalert downers Long course, 1–2 weeks	Variable May be low inorganic phosphate, or potassium, or glucose Ketonuria, plasma CPK, and AST elevated	Variable response to calcium, phosphorus, and potassium salts Fluid therapy and provision of deep bedding and hourly rolling from side to side are necessary
Carbohydrate engorgement	Access to large amount readily fermentable carbohydrate when not accustomed Enzootic in high-grain rations in feedlots Intensive IV fluid and electrolyte therapy necessary for survival	Severe gastrointestinal atony with complete cessation of ruminal activity Fluid splashing sounds in rumen Severe dehydration, circulatory failure Apparent blindness, then recumbency and too weak to rise Soft, odoriferous feces	Hemoconcentration with severe acidosis, pH of rumen fluid below 5, serum calcium may be depressed No living protozoa in rumen	Rumenotomy or rumen lavage may be necessary Oral antibiotics, alkalinizing agents per os and IV
Hypomagnesemia (lactation, grass tetany)	All classes and ages of cattle, but most recently calved cows May occur in pregnant beef cattle	Excitement, hypersensitivity, muscle tremor, tetany Recumbent with tetanic convulsions, loud heart sounds, rapid rate Subacute cases remain standing	Low serum magnesium, < 1.2 mg/dL (0.5 mmol/L), low (undetectable) urine magnesium	Even after IV injection, response in a severe case may take 30 min, much slower than response to calcium in milk fever
Severe toxemia (acute diffuse peritonitis, coliform mastitis)	Sporadic only Mastitis most common where hygiene poor Peritonitis as a result of foreign body perforation of reticulum, perforation of abomasal ulcus, rupture of uterus or vagina	Recumbency, depression to coma, sleepy, dry nose, hypothermia, gut stasis, heart rate > 100 beats/min, may be grunting Examine mammary gland Examine abdomen for abdominal disease	Profound leukopenia Serum calcium may be as low as 7–8 mg/dL (1.75–2.0 mmol/L) Examine milk	Require supportive response for toxemia and shock Response is poor and temporary Prognosis very bad May die if treated IV with calcium or magnesium salts
Fat-cow syndrome	Fat dairy or beef cows in late gestation or at parturition Some predisposing cause precipitates illness in fat animals	Excessive body condition, anorexia, apathy, depression, recumbency that looks like milk fever, scant soft feces, ketonuria	Evidence of hepatic disease	Will recover if begin to eat Treat with fluids, glucose, insulin Provide good-quality palatable roughage
Physical injuries	Ruptured gastrocnemius, dislocation of hip, etc. Sporadic sequelae to milk fever, may be contributed to by osteoporosis, slippery ground surface, stimulating to rise too early	As for Maternal obstetric paresis with ruptured gastrocnemius, hock remains on ground when standing Excessive lateral mobility of limb with hip dislocation	Increase serum CK and AST activity	Supportive therapy, deep bedding, and frequent rolling
Acute hypokalemia	Dairy cattle treated for ketosis with isoflupredone acetate Calved within previous 30 days	Recumbent, very weak, appear flaccid, in sternal or lateral recumbency, unable to support head off ground, hold head in flank, anorexia; cardiac arrhythmia may present Most die or are euthanized	Serum potassium below 2.5 mEq/L Muscle necrosis at necropsy	Potassium chloride orally or very carefully IV (drip infusion)

AST, aspartate aminotransferase; CK, creatine kinase; IV, intravenous.

with fetotomy may be associated with rupture of the uterus. The administration of calcium salts may cause ventricular fibrillation and sudden death.

Although some elevation of the temperature may be observed in these severe toxemic states, it is more usual to find a subnormal temperature. The response to Ca therapy is usually a marked increase in heart rate, and death during the injection is common. Every case of recumbency must be carefully examined because these conditions may occur either independently or as complications of parturient paresis. In our experience, about 25% of cases of postparturient recumbency in cows are attributable primarily to toxemia or injury rather than to hypocalcemia.

Injuries to the Pelvis and Pelvic Limbs

Injuries to the pelvis and pelvic limbs are common at parturition because of the marked relaxation of the ligaments of the pelvic girdle. Seven types of leg abnormalities have been described in this group at an incidence level of 8.5% in 400 consecutive cases of parturient paresis. The described abnormalities include radial paralysis, hip dislocation, and rupture of gastrocnemius muscle. In most instances the affected animals are down and unable to stand, but they mentally alert; eat, drink, urinate, and defecate normally; have a normal temperature and heart rate; and make strong efforts to stand, particularly with the forelimbs.

Maternal obstetric paralysis is the most common injury. Although this occurs most frequently in heifers after a difficult parturition, it may also occur in adult animals following an easy birth and occasionally before parturition, especially in cows in poor body condition. The mildest form is evidenced by a frequent kicking movement of a hindleg, as though something was stuck between the claws. All degrees of severity—from the mild kicking through knuckling and weakness of one or both hindlegs, to complete inability to rise—may occur, but sensation in the affected limb is usually normal. There is traumatic injury to the pelvic nerves during passage of the calf. There are often gross hemorrhages, both deep and superficial, and histopathological degeneration of the sciatic nerves. In individual animals, injury to the obturator nerves is common and results in defective adduction of the hindlimbs. The position of the hindlimbs may be normal, but in severe cases, especially those with extensive hematoma along the sciatic nerve trunk, the leg may be held extended with the toe reaching the elbow as in a dislocation of the hip; however, in the latter case there is exaggerated lateral mobility of the limb. Additional injuries causing recumbency near parturition include those associated with degenerative myopathy, dislocation of the hip, and ventral hernia.

Dislocation of the coxofemoral joint can cause recumbency and inability to stand in some cows, whereas others can stand and move around. Recumbent cows are usually in sternal recumbency, and the affected limb is abducted excessively. In standing cows, the affected limb is usually extended, often difficult to flex, and often rotated about its long axis. The diagnostic criteria are as follows:

- Sudden onset of lameness with the affected limb extended and possibly rotated
- Displacement of the greater trochanter of the femur from its normal position relative to the ischiatic tuber and coxal tuber of the pelvis (compare left and right rear limb)
- Ability to abduct the limb manually beyond its normal range
- Crepitus in the hip on abduction and rotation of the limb
- Ability to palpate the femoral head per rectum or per vaginum against the cranial border of the ilium or pubis in cases of cranioventral dislocation, or in the obturator foramen in cases of caudoventral dislocation

Manual replacement by closed reduction is successful in 80% of cases of craniodorsal dislocation and in 65% of cases of caudodorsal dislocation; relapses are, however, common. The ability to stand before reduction is the most useful prognostic aid.

Degenerative Myopathy (Ischemic Muscle Necrosis)

Degenerative myopathy, affecting primarily the large muscles of the thighs, occurs commonly in cattle that have been recumbent for more than several hours. At necropsy, large masses of pale muscle are present, surrounded by muscle of normal color. Clinically it is indistinguishable from sciatic nerve paralysis. Markedly increased serum activities of CK occur in cows recumbent for several hours following the initial episode of milk fever as a result of ischemic necrosis. Persistent elevation of CK activity indicates progressive ischemic muscle necrosis as a result of continued compression of the large muscle masses of the pelvic limbs. Rupture of the gastrocnemius muscle or separation of its tendon from either the muscle or the tuber calcis may also cause myopathy.

Downer-Cow Syndrome

Downer-cow syndrome is a common sequel to milk fever in which postparturient cows that may initially have been hypocalcemic remain recumbent for unknown reason after repeated intravenous treatment with Ca salts. Following treatment, most of the clinical findings associated with milk fever resolve, but the animal remains unable to stand. Clinically, the animal may be alert with normal or slightly decreased appetite and will commonly recover and stand normally within several hours or a few days. The animal's vital signs are within the normal range, and its alimentary tract function is normal. However, some affected animals are anorexic, may not drink, exhibit bizarre movements of lying in lateral recumbency, dorsally extend the head and neck frequently, moan and groan frequently, assume a frog-legged posture with the pelvic limbs, and crawl or creep around the stall; these animals may die or are euthanized for humane reasons within a few days. The diagnostic dilemma with these cows is that, at least initially, they resemble cows with milk fever, and whether or not to treat them with additional amounts of calcium salts is questionable.

Nonparturient Hypocalcemia

Paresis with mental depression and associated with low total serum Ca levels can occur in cows at times other than at parturition. The cause is largely unexplained, but hypomagnesemia has been proposed as a major risk factor for this atypical form of clinical milk fever in cattle.[3] Hypocalcemia may also occur after gorging on grain and may be a significant factor in particular cases. Sudden rumen stasis as a result of traumatic reticulitis may rarely cause hypocalcemic paresis. Diarrhea, particularly when cattle or sheep are placed on new lush pasture, may also precipitate an attack. Access to plants rich in oxalates may have a similar effect, particularly if the animals are unaccustomed to the plants. Affected animals respond well to Ca therapy, but relapse is likely unless the primary cause is corrected. The differential diagnosis of diseases of nonparturient cows manifested principally by recumbency is also summarized in Table 17-5.

Hypocalcemic Paresis in Sheep and Goats

Hypocalcemia in sheep must be differentiated from pregnancy toxemia, in which the course is much longer, the signs indicate cerebral involvement, and the disease is restricted to pregnant ewes. There is no response to Ca therapy, and a positive test for ketonuria is almost diagnostic of pregnancy toxemia. At parturition, goats are susceptible to enterotoxemia and hypoglycemia (rarely), both of which present clinical signs similar to parturient paresis.

Hypocalcemia in Sows

Hypocalcemia is rare in sows. The disease must be differentiated from the mastitis, metritis, and agalactia complex, which is characterized by fever, agalactia, anorexia, toxemia, and enlarged and inflamed mammary glands.

Treatment

Every effort must be made to treat affected cows as soon as possible after clinical signs are obvious. Treatment during the first stage of the disease, before the cow is recumbent, is the ideal situation. The longer the interval between the time the cow first becomes recumbent and treatment, the greater the incidence of downer-cow syndrome as a result of ischemic muscle necrosis from prolonged recumbency. Complications of milk fever occur when cows have been in sternal recumbency for more than 4 hours. Farmers must be educated to appreciate the importance of early treatment. Cows found in lateral recumbency (third stage) should be placed in sternal recumbency until treatment is available. This will facilitate eructation and reduce the risk of aspiration if the cow regurgitates. Cows that have difficulty finding solid, nonslip footing beneath them will often not try to stand and may develop ischemic myonecrosis. Avoidance of this complication necessitates the placement of rubber or other mats under the cow or

transportation of the cow to a piece of pasture with a dense sward on it.

Standard Treatment

IV with solutions containing Ca as Ca-gluconate, Ca-borogluconate, and—nowadays less commonly—as Ca-chloride is the treatment of choice. Most cows with milk fever can be treated successfully with Ca salt solutions providing 8 to 10 g of Ca (Ca-borogluconate is 8.3% Ca). The dose rate of Ca is frequently under discussion. A typical treatment for an adult lactating dairy cow with periparturient hypocalcemia is 500 mL of 23% Ca-borogluconate by slow IV injection with cardiac auscultation; this provides 10.7 g of Ca. Although the calculated Ca deficit in a recumbent periparturient dairy cow is 4 g Ca, additional Ca should be provided to overcome the ongoing losses in milk.[6] Underdosing increases the chances of incomplete response, with inability of the cow to rise, or of relapse, whereas considerable overdosing may result in potentially fatal cardiac toxicity. Additional subcutaneous administration of Ca-borogluconate (500 mL) markedly decreased the relapse rate in cattle receiving 500 mL of Ca-borogluconate IV for the treatment of hypocalcemia.[6]

The standard rate of administration is a rapid IV administration of the calculated dose of Ca-borogluconate over a period of 15 minutes. The maximum safe rate of Ca administration in cattle was determined to be 0.07 mEq of ionized Ca per kg body weight per minute, which is equivalent to 0.065 mL of a 23% Ca-borogluconate per kg body weight per minute.[6] An average nonhypocalcemic 600-kg cow could therefore safely be treated with intravenous Ca-borogluconate (23%) at an infusion rate of 39 mL/min. Immediately following IV administration of Ca-borogluconate over a period of 12 to 15 minutes, treated animals are commonly markedly hypercalcemic (up to 6 mmol/L or 24 mg/dL). The plasma Ca concentration will then gradually decline over a period of several hours. Although the direct effect of intravenously administered Ca does not last for more than 6 to 8 hours, this transient correction of hypocalcemia in most cases is not only associated with clinical recovery of recumbent animals, but also with improved feed intake and enhanced gastrointestinal motility, which will result in improved intestinal Ca absorption. This latter effect, which relies on the availability of adequate amounts of Ca for absorption in the digestive tract, is responsible for the sustained correction of hypocalcemia observed in most cases. However, in some cows, mechanisms regulating the Ca homeostasis are less effective or the oral Ca supply is insufficient, and subclinical or clinical hypocalcemia may recur. For this reason, it is astute to follow up on intravenously treated animals with oral supplementation of Ca salts for 1 to 2 days.

Because of concerns with these rapid and short-lived peaks in plasma Ca after rapid infusion of Ca salt solutions, it has been suggested that slower IV infusion might be safer and more effective. The slow infusion of a Ca solution via an IV indwelling catheter over 6 hours was compared with the conventional single IV administration of 600 mL of a 40% Ca-borogluconate and 6% Mg-hypophosphite solution over 15 minutes in cows recumbent with milk fever. Cows receiving the rapid infusion responded more quickly, stood sooner, and returned to normal demeanor more quickly. The slow infusion consisted of 200 ml IV over a 10-minute period, with the remaining 400 ml added to 10 L of a solution of 90 g sodium chloride and 500 g glucose and given via IV drip over a 6-hour period at a rate of 1.7 L/h. In cows treated rapidly, the serum Ca and magnesium levels increased rapidly compared with the infused cows. In sheep and goats, the recommended amount is 15 to 20 g IV with an optional 5 to 10 g SC. Sows should receive 100 to 150 mL of a similar solution IV or SC.

Routes of Administration

IV Route

The IV route is preferred because the response is rapid and obvious. The heart should be auscultated throughout the IV administration for evidence of gross arrhythmia, bradycardia, and tachycardia. Although bradycardia is a normal response to Ca administration in hypocalcemic animals and is of no concern, the IV administration should be interrupted in case arrhythmia or pronounced tachycardia is noticed. If the cardiac irregularity continues, the remainder of the solution can be given subcutaneously. The best recommendation is to give as much of the solution as possible intravenously and the remainder subcutaneously. The common practice of giving half the dose intravenously and half subcutaneously is a reasonable compromise because with this method there are fewer relapses. If a cow has been previously treated subcutaneously by the farmer, additional Ca given intravenously may cause toxicity if the improved circulation enhances the absorption of the subcutaneous Ca.

Toxemic cows are very susceptible to the IV administration of Ca-borogluconate, and death may occur. In such cases the heart rate increases markedly (up to 160 bpm); there is respiratory distress, trembling, and collapse; and the cow dies within a few minutes. SC or IV administration is preferred in cows with severe toxemia as a result of aspiration pneumonia, metritis, and mastitis.

Typical Response to Intravenous Ca-Borogluconate

Cows with milk fever exhibit a typical pattern of response to Ca-borogluconate IV if the response is favorable, including:

- Belching
- Muscle tremor, particularly of the flanks and often extending to the whole body
- Slowing and improvement in the amplitude and pressures of the pulse
- Decrease of the heart rate
- Increase in the intensity of the heart sounds
- Sweating of the muzzle
- Defecation

The feces are in the form of a firm fecal ball with a firm crust and covered with mucus. Urination usually does not follow until the cow stands. A slight transitory tetany of the limbs may also be observed. Many cows will eat and drink within minutes following successful treatment if offered feed and water.

In general, recovery can be expected in 75% of cases within 2 hours; in 10% recovery is complicated by one of the diseases discussed earlier, and 15% can be expected either to die or to require disposal. Of those that recover after one treatment, 25% to 30% can be expected to relapse and require further treatment.

Unfavorable Response to Intravenous Ca-Borogluconate

An unfavorable response is characterized by a marked increase in heart rate in cows affected with toxemia and bradyarrhythmia in animals developing an atrial block as a result of Ca overdosage. Overdosage may occur when a standard dose is administered to quickly, when an excessive dose is administered, when repeated doses are administered in excess of requirements, or when an individual with increased sensitivity to Ca is treated. Toxicity can, for instance, occur when farmers treat cases unsuccessfully by multiple SC injections and these are followed by an IV dose. When the peripheral circulation is poor, it is probable that the calcium administered subcutaneously is not absorbed until the circulation improves following the IV injection, and the large doses of Ca then absorbed cause acute toxicity.

Increased sensitivity to Ca has been reported in toxic animals with coliform mastitis or toxic metritis and in cows with severe ketosis or hepatic lipidosis. Hypokalemia that is common in anorectic animals may present a further factor predisposing to increased sensitivity of the heart muscle to excessive Ca doses. Sudden death may also occur after calcium injections if the cow is excited or frightened, which may be the result of an increased sensitivity to epinephrine. When affected cows are exposed to the sun or a hot, humid atmosphere, heatstroke may be a complicating factor. In such cases an attempt should be made to reduce the temperature to below 39.5°C (103°F) before the calcium is administered.

In all cases of IV treatment with Ca salts, the circulation must be monitored closely. If there is gross arrhythmia or a sudden increase in heart rate, the injection should be

discontinued. In normal circumstances at least 15 minutes should be taken to administer the standard dose. The acute toxic effect of calcium salts seems to be exerted specifically on heart muscle, with a great variety of defects occurring in cardiac action; the defect type depends on the specific Ca salt used and the speed of injection. Electrocardiogram (ECG) changes after induced hypercalcemia show increased ventricular activity and reduced atrial activity. Atropine is capable of abolishing the resulting arrhythmia.

SC Route

The SC route is commonly used by farmers who treat affected cows at the first sign of hypocalcemia, preferably during the first stage when the cow is still standing. The SC route has also been used by veterinarians when the effects of IV administration of Ca are uncertain or if an unusual response occurs during IV administration. The main inconvenience of the SC route of administration is that the absorption is difficult to predict because of the often comprised blood flow to the periphery in affected animals.[11] Subcutaneous treatment with Ca solutions is inappropriate with severe hypocalcemia or dehydration because absorption in these animals is impaired, which may result in a markedly delayed treatment effect.[8] The amount of Ca administered per injection site should be limited to 1 to 1.5 g, which is equivalent to 50 to 75 mL of most commercial Ca infusion solutions.[11] Although most solutions containing Ca-gluconate or Ca-borogluconate are suitable for SC administration, the SC administration of salt solutions containing Ca-chloride should be avoided because these formulations are highly caustic. The SC administration of Ca solutions also containing glucose, particularly at higher concentrations, is discouraged because concentrated glucose can result in pronounced tissue irritation.[8] Administration of 500 mL of a 23% Ca-borogluconate solution over 10 injection sites was associated with an increase of the plasma Ca concentration of over 15% within 30 minutes; the plasma Ca concentration returned to baseline concentrations within 6 hours of treatment.[8]

Oral Route

Or administration of different Ca salts has been practiced for decades. Oral formulations are commonly based on Ca-chloride ($CaCl_2$) and Ca-propionate. Calcium chloride formulations have the advantage of low cost and a small volume required to administer an appropriate dose of 50 g Ca, but they are highly caustic and may cause severe damage of the digestive tract mucosa exposed to the concentrated formulation. Repeated treatment with $CaCl_2$ may furthermore result in uncompensated metabolic acidosis in treated animals.[11] In contrast, Ca-propionate formulations require a higher volume to provide the same amount of Ca and are absorbed at a slower rate but are less injurious to tissue and do not alter the acid–base equilibrium. In these formulations, the availability of propionate, which is a glucose precursor, has been marketed as a further potential advantage, but studies investigating the effect of the gluconate contained in these products failed to identify any positive effects on plasma glucose, insulin, or NEFA concentration in cows treated with Ca-gluconate.[12] Oral $CaCl_2$ formulations typically contain 50 g of Ca and increase the plasma Ca concentration within 30 minutes and for at least 6 hours.[6,8] Oral Ca formulations should only be administered to cattle with undisturbed swallowing ability, which precludes their use as first-line treatment in animals in an advanced stage of clinical hypocalcemia.

Failure to Respond to Treatment

A failure to respond favorably to treatment may be the result of an incorrect or incomplete diagnosis, or inadequate treatment. A poor response to treatment includes: (1) no observable changes in the clinical findings immediately following the calcium administration, or (2) the animal may respond to the calcium in all respects with the exception of being unable to stand for varying periods of time following treatment. An inadequate response also includes relapse after successful recovery, which usually occurs within 48 hours of the previous treatment. The needs of individual animals for Ca replacement vary widely depending on many factors, such as the body weight, milk yield, age, and degree of hypocalcemia. Incomplete responses may be more common in older cows and in cases of inability of the normal mechanisms to maintain serum Ca levels during the period of sudden changes in the equilibrium input and output of the extracellular Ca pool. The duration of the illness and the severity of clinical signs at the time of first treatment also affect the treatment response. In an extensive field study, there were no downer cows or deaths in cows still standing when first treated, 13% of downers and 2% of deaths occurred in cows in sternal recumbency when first treated, and 37% of downers and 12% of deaths occurred in cows in lateral recumbency when first treated. Therefore, in general, the longer the period from onset of milk fever to treatment, the longer the period of posttreatment recumbency and the higher the case-fatality rate. The best procedure to follow if response does not occur is to revisit the animal at 6- to 12-hour intervals and check the diagnosis. If no other cause of the recumbency can be determined, the initial treatment can be repeated on a maximum of three occasions. Beyond this point, further calcium therapy is seldom effective.

GENERAL MANAGEMENT AND CLINICAL CARE PROCEDURES

The care of the cow and the calf following milk fever is important. If the cow is recumbent for any length of time, she must be kept propped up in sternal recumbency and not left in lateral recumbency, which may result in tympany, regurgitation, and aspiration pneumonia. The cow should be rolled from side to side every few hours and provided with adequate bedding or moved to a suitable nonslip ground surface. In extreme climatic conditions, erection of a shelter over the cow is advisable if she cannot be moved to permanent shelter. If a cow is recumbent for more than 48 hours, occasional assisted lifting using appropriate cow lifters should be considered. However, heroic measures to get cows to stand should be avoided. Gentle nudging in the ribs or the use of an electric prod are the maximum stimulants advised. The best assistance that can be given to a cow attempting to stand is a good heave at the base of the tail when she is halfway up.

TREATMENT AND CONTROL

Treatment

Calcium gluconate (equivalent to 8 to 12 g Ca/cow IV or SC as single dose) (R-1)

Calcium borogluconate (equivalent to 8 to 12 g Ca/cow IV or SC as single dose) (R-1)

Calcium chloride (equivalent to 8 to 12 g Ca/cow IV as single dose) (R-2)

Calcium chloride (equivalent to 50 g Ca/cow) PO q12 for 48h (R-1)

Calcium propionate (equivalent to 50 g Ca/cow) PO q12 for 48h (R-2)

Control

Reduce dietary calcium intake 2 to 3 weeks before calving to less than 20 g Ca/cow/day (R-1)

Reduce dietary potassium content as much as possible in late gestation (in any case, below 2% in feed dry matter) (R-1)

Provide adequate dietary magnesium in late gestation (≈0.4% of feed dry matter) (R-1)

Anionic salts mixed into feed to obtain a dietary cation–anion difference of –100 to –150 mEq/kg of feed dry matter for at least 2 weeks before calving (R-1)

Zeolite A (250 to 500 g/cow/day) PO q24h for at least 2 weeks before calving (R-2)

Supplement diet in late gestation with vitamin D (R-1)

Vitamin D_3 (10 million IU/cow IM as single dose 3 to 7 days before expected calving) (R-2)

Vitamin D_2 (10 to 20 million IU/cow PO for at least 7 days before expected calving) (R-2)

Calcium chloride (equivalent to 50 g Ca/cow PO q12h for 48 hours from the time of parturition) (R-1)

Calcium propionate (equivalent to 50 g Ca/cow PO q12h for 48 hours from the time of parturition) (R-2)

Partial milking during the first days of lactation (R-3)

Udder insufflation in the first days of lactation (R-3)

CONTROL

When the incidence of milk fever increases to above 10% of high-risk cows (third or later lactations), a specific control program is necessary. When the incidence is low, a specific control program may not be economical, and the alternative is to monitor cows carefully at the time of parturition and for 48 hours after parturition and treat affected animals during the first stage of the disease if possible.

Strategies for prevention of periparturient hypocalcemia in general are based on one of following approaches:

- Reduction of dietary Ca available for intestinal absorption during the dry period
- Induction of mild to moderate acidosis during the last weeks of gestation
- Supplementation of vitamin D during the dry period
- Oral Ca supplementation around parturition
- Parenteral Ca administration around parturition
- Partial milking

For purposes of optimal nutritional management of dairy cows that are fed prepared feeds (not pasture based), the dry period is frequently divided into two distinct portions: cows in the early and middle part of the dry period (*far-off* or *regular* dry-cow group) and cows in the final 2 to 3 weeks before their calving date (*prefresh, transition, close-up, near, lead-feeding,* or *steam-up* group). Large herds may have additional subgroups of dry cows depending on management circumstances and facilities available. Special attention must be given to the mineral nutrition of the close-up group. Minerals should be provided to close-up cows in known quantities, either as part of a grain mixture or a total mixed ration (TMR).

Reduction of Dietary Calcium Available for Intestinal Absorption

Dietary Calcium Concentration in Late Gestation

Diets high in Ca during the prepartum period can result in a high incidence of milk fever, and diets low in Ca will reduce the incidence of milk fever in dairy cows. Feeding more than 100 g of Ca per cow per day during the dry period is associated with an increased incidence of milk fever. An adult cow requires only around 30 g/daily of Ca to meet maintenance and fetal demands in the last 2 months of late gestation. Low-Ca diets (<20 g [Ca/cow]/d) fed during the last 2 weeks before parturition are effective in reducing the occurrence of clinical milk fever. The low levels of dietary Ca push the organism into a negative Ca balance before calving, which activates the homeostatic mechanisms before the Ca losses through the mammary gland begin. These mechanisms include the secretion of PTH, which increases renal reabsorption of Ca within minutes, stimulates Ca resorption from bone within hours to days, and stimulates renal vitamin D metabolism to toward production of 1,25-$(OH)_2D$ within hours or days. The 1,25-$(OH)_2D$ stimulates the active transport of Ca across the intestinal epithelial cells. At the time of calving, the cow is more efficient in absorbing Ca from the digestive tract and mobilizing Ca from bone reserves. At least 14 days of a low-Ca diet are required to be effective in minimizing the incidence of milk fever.

Practicality of Feeding Diets Low in Calcium

There are practical problems with the implementation of the recommendation to feed diets low in Ca. Most farms utilizing homegrown forages, especially alfalfa, find it difficult to obtain forages that are low in Ca. A low-Ca diet can be achieved by replacing some or all alfalfa hay in the dry-cow diet with grass hay and using additional corn silage and concentrates. When feeding grass hay to dry cows, attention must be paid to the dietary potassium content of the dry-cow ration because high potassium intake tends to alkalinize the organism and thereby impair the efficacy of bone mobilization.

Binding Dietary Calcium

If formulating a diet low enough in Ca to induce a negative Ca balance is a problem, it is possible to reduce the digestibility of dietary Ca by adding a substance to the feed capable of binding dietary Ca and making it less available for intestinal absorption. The oral administration of sodium aluminum silicate or zinc oxide to cows in late lactation binds dietary Ca, thereby inducing a negative Ca balance. Supplementing the dry-cow ration with sodium aluminium silicate (zeolite A) at the rate of 1.4 kg of zeolite pellets per day (700 g of pure zeolite A) for the last 2 weeks of pregnancy results in a significant increase in plasma Ca and 1,25-$(OH)_2D$ around calving. It should, however, be noted that this amount of pellets is equivalent to over 10% of the dry matter feed intake of a dairy cow in the last days before calving. Plasma magnesium and inorganic phosphate levels also decrease, which has raised concerns with the use of these salts. Feed intake was decreased by over 20% in zeolite-treated cows compared with control cows, which was associated with significantly increased betahydroxybutyrate concentrations after calving.[13] Lower doses of zeolite A in the range of 250 g of pure zeolite A resulted in a less pronounced feed intake depression while significantly increasing the plasma Ca concentration around calving in cattle in third or higher lactation. This lower dose of zeolite A still was associated with decreased plasma inorganic phosphate concentrations, whereas plasma magnesium was unaffected.[13]

Feeding a vegetable oil supplement (soya bean oil) to pregnant pastured dairy cattle during the last 2 to 3 weeks of pregnancy is effective in preventing milk fever and increases milk solids production in early lactation. The same supplement has been used to stimulate Ca absorption and reduction in susceptibility to fasting-induced hypocalcemia in pregnant ewes. Following supplementation, the ewes are fasted overnight to challenge calcium homeostasis. Following fasting, there is a greatly increased capacity to absorb calcium.

Level of Phosphorus in Diet

Increased levels of dietary phosphorus, greater than 0.5% kg dry matter, can increase the incidence of milk fever. The increased intake increases the serum level of phosphorus, which has an inhibitory effect on renal enzymes catalyzing the activation of vitamin D_3. Decreased availability of bioactive vitamin D_3 results not only in reduced intestinal phosphate, but also reduced Ca absorption.

Calcium-to-Phosphorus Ratio in Diet

Although the ratio of Ca to phosphorus in the diet is of relevance in monogastric species, it is now recognized that this ratio is of little importance in ruminants, provided that the minimum requirements for both minerals are met. The presumable explanation for this difference from monogastric species is the high concentration of phosphorus in saliva in combination with the large volumes of saliva produced per day that are entering the rumen. The salivary P content will thus greatly distort the ratio of calcium to phosphate of the ingested diet.

Induction of Mild to Moderate Acidosis During Late Gestation: Cation–Anion Difference

A more reliable method of controlling milk fever in dairy cows is to manipulate the dietary cation–anion difference (DCAD) during the prepartum period. Diets high in cations, especially potassium and sodium, tend to induce milk fever compared with those high in anions, primarily chloride and sulfur, which can reduce the milk-fever incidence. When the dietary cation concentration is increased and these cations are absorbed from the digestive tract, they tend to increase the plasma strong ion difference (SID), thereby creating a metabolic (or strong ion) alkalosis. Conversely, dietary anions absorbed from the gut decrease the SID, which causes metabolic acidosis.[6] The feeding of diets containing an excess of anions relative to cations, thus with a low DCAD, will result in metabolic acidosis. Two PTH-dependent functions, bone resorption and renal production of 1,25-$(OH)_2D$, are enhanced in cows fed diets with added anions, and thus a low DCAD, which increases their resistance to milk fever and hypocalcemia.

The DCAD is expressed in milliequivalents per kilogram of dry matter (mEq/kg DM) or in some instances in mEq/100 g DM. Several different equations have been proposed for the calculation of the DCAD; for convenience, the most commonly used is $DCAD_4 = (Na^+ + K^+) - (Cl^- + S^{-2})$, which only considers the four (thus $DCAD_4$) quantitatively most important dietary ions. Other electrolytes, such as calcium, magnesium, and phosphorus, also affect the acid–base status and are included in some of the DCAD equations proposed in the literature. The impact of these minerals on the actual DCAD value is, however, considered to be minor because of the relatively low content of these elements in the ruminant diet.

The equation assigns the same acidification potency to each milliequivalent of Cl and S, although Cl is absorbed to a greater extent than S and thus has a higher potential of acidification. Such effects are considered in more developed DCAD equations that include a corrective factor for each element accounting for these differences in digestibility.

Calculation of the DCAD requires converting the dietary content of each mineral from g/kg or mg/kg to into charges per kg (equivalents/kg). The mass expressed in mmol/kg DM is equal to mEq/kg for all monovalent elements, with only one charge per molecule, such as Na^+, K^+, and Cl^-. Divalent elements, such as Mg^{+2}, Ca^{2+}, and S^{2-}, have two valences per molecule; thus 1 mmol is equivalent to 2 mEq. Table 17-6 provides reference values for determining the mEq of important electrolytes and converting from g/kg or percent diet dry matter (DM) to mEq/kg. Once milliequivalents are calculated, the DCAD can then be determined by subtracting the anions from the cations. The following equation can be used to calculate the DCAD from the percent element in the diet dry matter: mEq/100 g DM = [(%Na ÷ 0.023) + (%K ÷ 0.039)] − [(%Cl ÷ 0.0355) + (%S ÷ 0.016)].

Based on current evidence, the range that achieves the lowest incidence of milk fever is a DCAD of −10 to −15 mEq/100 g DM (−100 to 150 mEq/kg DM). Such a diet should be fed for 2 to 3 weeks before calving. This rate of supplementation is reported not to affect DM intake or energy balance before or after calving. A more moderate rate of supplementation to reduce the DCAD to 0 mEq/100 g dietary DM also did not decrease feed intake or energy status, but was less effective in preventing parturient hypocalcemia.

Most typical diets fed to dry cows have a DCAD of about +100 to +250 mEq/kg DM. Addition of a cationic salt such as sodium bicarbonate to the dry-cow diets increases the DCAD and thereby increases the incidence rate of milk fever. Decreasing the dietary potassium content, by choosing ration ingredients low in potassium or adding an anion source or a mixture of anionic salts containing Cl and S to the diet, lowers the DCAD and reduces the incidence of milk fever. Commonly used sources of anion salts include the Cl and SO_4 salts of calcium, ammonium, and magnesium. The phosphate salts have not been used because they are only weakly acidifying.

Table 17-6 Parturient paresis: Molecular weights, equivalent weights, and conversions from percent to milliequivalents (%–mEq) of anions and cations used in calculating dietary cation–anion difference

Element	Molecular weight (g/mol)	Valence	Equivalent weight (g/Eq)	To convert from % diet DM to mEq. Multiply by: (mEq/kg)
Sodium	23.0	1	23.0	434.98
Potassium	39.1	1	39.1	255.74
Chloride	35.5	1	35.5	282.06
Sulfur	32.1	2	16.0	623.75
Calcium	40.1	2	20.0	499.00
Magnesium	24.3	2	12.2	822.64
Phosphorus	31.0	1.8	17.2	581.14

The addition of anions to the diet to reduce dietary DCAD is limited in quantity because of problems with the palatability of the anionic salt sources commonly used. If the DCAD is greater than 250 mEq/kg, for instance, because of excessive amounts of dietary potassium, it is difficult to add enough anionic salts to lower the DCAD to the recommended −100 mEq/kg of the diet without affecting palatability. In these cases the first objective should be to reduce the dietary cation content as much as possible and only then determine the amount of anions required to achieve the proposed DCAD.

In one study, the incidence of milk fever was 47% when prepartum cows were fed a ration with a DCAD of +330.5 mEq/kg dietary DM and 0% when the prepartum ration had a balance of −128.5 mEq/kg dietary DM. The incidence of milk fever was reduced by the addition of chloride and sulfur in excess relative to sodium and potassium in the diet.

Although it has been proposed that dry cows on low-DCAD diets to control milk fever need to be supplemented with dietary Ca to compensate for increased renal Ca losses resulting from acidification, this recommendation is not undisputed. Several studies showed that the dietary Ca content of dry cows on a high-chloride diet had no effect on the occurrence rate of clinical hypocalcemia. Feeding rations with a dietary Ca between 0.5% and 1.5% did not alter the efficacy of low-DCAD diets, but high-Ca diets fed to dry cows were associated with slightly decreased feed intakes compared with control cows.[3] In any case, DCAD diets should not be combined with low-Ca diets or the use of Ca binding compounds in the feed before calving.

Monitoring the urine pH can be a useful aid to find the effective dose of anionic salts in the close-up ration. Adequate activation of mechanisms increasing Ca absorption from the gut and release from bone through mild to moderate acidification of the organism is associated with a decline of the urine pH below 7.0. Urine pH values of dry cows on a low-DCAD diet above 7.0 suggest that the degree of acidification may not be sufficient to effectively mobilize Ca through the mechanisms previously described. It is suggested that a urine pH between 6.0 and 7.0 is ideal.[3]

Anionic Salts for Acidification of Prepartum Diets for Dairy Cows

Several anionic salts are available for addition to the ration of prepartum dairy cows to prevent milk fever. Generally, acidification of the cows occurs within approximately 36 hours following addition of the anionic salts to the ration; it also takes less than 36 hours for the cow to return to an alkaline state following removal of the salts from the diet. The relative acidifying activity of anionic salts commonly used to prevent milk fever has been evaluated. Salts of chloride have about 1.6 times the acidifying activity of sulfate. Calcium and magnesium, which are usually not included in the DCAD equation, have a small but significant alkalinizing effect when accompanied by chloride or sulfate. The ranking of the anion sources tested at a dose of 2 Eq/day, from most to least potent urine acidifier, was **hydrochloric acid, ammonium chloride, calcium chloride, calcium sulfate, magnesium sulfate, and sulfur.** Magnesium sulfate is the most palatable of the anionic salts commonly supplemented, and calcium chloride is the least palatable. It is best to add the anionic salts to a total mixed ration. Because of the low incidence of milk fever in heifers, there is no need to feed anionic salts to heifers.

Anionic salts can reduce dry matter intake when more than 300 mEq of anions/kg diet DM are supplemented in the diet. The reductions in dry matter intake are commonly ascribed to decreased palatability, but they may represent a response to the metabolic acidosis induced by the salts. The duration of feeding anion salts ranges from 21 to 45 days before expected parturition. At least

5 days of consumption are necessary for maximal benefit.

Ammonium Chloride. Ammonium chloride is more effective than most other salts as an acidifier. The addition of ammonium chloride salts to prepartum diets offers considerable promise as a practical and reliable method of control of milk fever. Within the European Union, ammonium chloride is currently permitted as a pharmacologically active substance in veterinary medicinal products, but not as a zootechnical or feed additive in cattle.[14] Experimentally, the addition of ammonium chloride and ammonium sulfate, each at 100 g/head per day, to the prepartum diets 21 days before parturition decreased the incidence of milk fever from 17% in the unsupplemented group to 4% in the supplemented group.

Strategies for Supplementing Anion Sources

A systematic protocol for the addition of anions to a prepartum diet and monitoring of its effects is as follows:

1. perform macromineral analysis of all available forages for prepartum cows.
2. Select feed ingredients with a low DCAD, especially those low in potassium.
3. Calculate the DCAD of the diet without any supplemental anion sources. If the DCAD is more than +250 mEq/kg, then priority must be given to reduce this value by replacing some of the forage with a lower-DCAD forage.
4. Balance dietary magnesium at 0.40% DM by adding additional magnesium chloride or magnesium sulfate. Magnesium chloride is preferred.
5. Evaluate the feeding management of the prepartum cows. Ensure adequate feeding space and quality of feed.
6. Add supplemental chloride and/or sulfur to the prepartum cow diet to lower DCAD to about −150 mEq/kg DM.
7. Evaluate the dietary nonprotein nitrogen (NPN) and degradable intake protein (DIP) of the diet. If NPN is more than 0.50% of the diet DM or DIP is more than 70% of crude protein, then reduce the amount of ammonium salts or other NPN or DIP sources in the diet.
8. Monitor dry matter intake of the prepartum-cow group.
9. Consider more palatable anion sources or a reduced dose of anion sources if dry matter intake is depressed.
10. After 1 week of feeding anionic salts, monitor the pH of close-up dry cows. Urinary pH is an accurate indication of optimal dietary acidification. Collect urine from at least six cows at one time and average the urinary results. Adjust the dose of supplemental anions to achieve an average urinary pH of between 6.0 and 7.0.

DCAD and Acid–Base Balance of Dairy Cows on Pasture-Based Diets

The dairy industries of southern Australia and New Zealand are based largely on fresh pasture and pasture silage, and grazed pasture is the key determinant of the DCAD. The concentration of potassium is often in excess of 4%, and the DCAD greater than 500 mEq/kg DM, in pasture-based diets, yet the incidence risk of milk fever is not higher than those in other countries where dietary potassium is much lower. For a considerable part of spring and early summer, the DCAD of pasture in those countries may be in excess of +500 to +700 mEq/kg DM. The variation in the DCAD of pasture and the difficulty in accurately assessing dry matter intake make an accurate reduction in DCAD difficult to achieve practically. Pasture cation–anion difference in those conditions is not greatly influenced by stocking rate or associated management practices. The urine pH of grazing dairy cows in south eastern Australia remains relatively constant throughout the year despite changes in stage of lactation, management practices, season, weather, and large changes in DCAD. The DCAD of pasture throughout the year in south eastern Australia ranges from 0 to 800 mEq/kg DM and is often outside the levels previously recommended for optimal performance of lactating cows. For spring-calving herds on pasture, a high DCAD at the time of parturition presents practical problems in administering the large amounts of anionic salts required to lower urine pH and to decrease the incidence of hypocalcemia.

In these pasture-based systems, sulfur (S) is considered a more important dietary constituent in determining the risk of hypocalcemia than either chloride or potassium. The absorption efficiency of S is less than either Cl or K and would not be expected to incur the same change in systemic pH. Thus its importance in hypocalcemia prevention does not fit with the current understanding of how manipulation of DCAD influences calcium homeostasis. Studies indicate that precalving dietary S is more important in the control of hypocalcemia than either K or Cl concentration. Although the effects of a systemic acidosis on Ca absorption is accepted, the effect of S on periparturient Ca homeostasis when absorption of S is low in comparison to Cl, Na, or K suggest that there are mechanisms involved that are not related to acid–base balance. An increased incidence of milk fever may occur in pastured-based dairy when the diet is supplemented with Cl and S, even though calcium absorption, as indicated by urine calcium concentration, increases. The increased incidence may be a result of a greater demand for dietary calcium after calving following a reduction in the pH of body fluids precalving and the fact that pasture-based diets, as opposed to total mixed rations, are generally low in calcium. Supplementation of cows with calcium after calving increased plasma calcium concentration on the day of calving and during the subsequent 14 days. Milk production was not affected by pre- or postcalving treatments.

Experimentally, the application of potassium fertilizer on pasture resulted in a DCAD ranging from 350 to 535 mEq/kg DM, but calcium homeostasis in pasture-based dairy cows was not changed. Plasma concentrations were increased, and the risk of clinical periparturient hypocalcemia was reduced, by $MgCl_2$ and $MgSO_4$ delivered by 150 g $MgCl_2$, 200 g $MgSO_4$, and 35 g MgO/head daily for 21 days prepartum. After calving, cows were supplemented with 150 g $CaCO_3$/head per day for 4 days. Improvements in calcium homeostasis were not the result of an altered systemic pH.

The optimum DCAD for lactating cows grazing fresh pasture and the effect of deviating from the optimum on milk production have been examined under experimental manipulation of the dietary DCAD using a drench in early-lactation dairy cows in New Zealand. Dietary cation-anion differences ranged from +23 to +88 mEq/100 g of DM. As DCAD increased, there was a linear increase in blood pH and HCO_3 concentration and blood base excess. Plasma concentrations of Mg, K, and Cl declined as DCAD increased and Na increased. Urinary excretion of Ca decreased as DCAD increased. Increasing DCAD did not significantly affect milk yield or milk protein, but the concentration and yield of milk fat increased linearly. Milk production results suggest that DCAD for optimal production on pasture diets may be higher than the +20 mEq/100 g DM previously identified for total mixed rations.

Summary of Macromineral Nutritional Strategies for the Prevention of Hypocalcemia in the Soon-to-Calve or Transition Dairy Cow in Pasture-Based Systems

Circumstances and principles can be summarized as follows:

- When dairy cows are dried off, they are commonly moved onto nonirrigated pastures until calving. In the summer, dry cows would be put onto actively growing tropical pasture, whereas in autumn, winter, and spring, the pasture is most likely to be tropical pasture carried over from the previous summer. This carryover pasture is likely to be supplemented with medium-quality hay, silage, and grain or molasses 2 to 3 weeks before calving. Anionic salts have been added to these diets.
- The DCAD on a yearly basis ranges from 0 to 80 mEq/100 g DM.
- The incidence of milk fever in Australia ranges from 1.6% to 5.4%, but in some

years the incidence in individual herds may reach 20%. The incidence of subclinical hypocalcemia can range widely; up to 40% of apparently normal cows had subclinical hypocalcemia (total plasma calcium < 1.9 mmol/L during the first 12 days of lactation).

- In temperate climates, reducing dietary calcium to recommended low levels can be difficult to achieve, but in tropical pastures the levels are already low.
- Excessive levels of potassium may be the most important dietary risk factor for milk fever in Australian feeding systems. Potassium contents of pastures may be as high as 4% to 5% of DM. The use of potassium fertilizers exacerbates the problem. Potassium and consequently dietary DCAD peak in winter and are lowest in autumn. The majority of cows in Victoria, Australia, calve in winter to early spring when the potassium levels are high.
- Hypomagnesemia influences calcium homeostasis, and diets high in potassium reduce the concentration of plasma magnesium. Magnesium supplementation of the transition diet should be done to ensure that magnesium requirements are met (0.4% of DM).
- Excessive dietary phosphorus increases the concentration of phosphorus in plasma, which can induce hypocalcemia and increase the incidence of milk fever at calving. Supplements likely to increase the dietary intake of phosphorus above 40 g/day should not be fed to cows in the weeks before calving.

Supplementation of Vitamin D During the Dry Period

Parenteral Vitamin D_3 Application

In an attempt to reverse the negative Ca balance of susceptible cows at the onset of lactation, the administration of vitamin D_3 and its analogs has been used to increase intestinal Ca absorption. Vitamin D_3 is hydroxylated in the liver, and the resulting metabolite is 25-hydroxycholecalciferol. This is metabolized in the kidney to 1,25-dihydroxycholecalciferol, which has an active hypercalcemic effect but is difficult to synthesize. One of its analogs, 1-α-hydroxycholecalciferol, is as active, is easy to prepare, and is used pharmacologically. A single parenteral dose of 10 million IU per cow of intramuscular (IM) vitamin D_3 given 2 to 8 days before parturition is often recommended, although the dose recommendation based on body weight (1 million units per 45 kg BW) has given consistently better results. Two important inconveniences of the parenteral treatment with vitamin D_3 are the narrow time frame before calving during which vitamin D_3 must be administered to be effective and the narrow therapeutic range of the drug. If the cow fails to calve within 10 days of treatment, another 10 million units may need to be administered because cows treated more than 10 days before calving are at increased risk of developing clinical milk fever. Repeated treatment is associated with soft tissue calcification, particularly after repeated injections. Pregnant cows are more susceptible to calcification than nonpregnant animals. Whereas single doses below 10 million units to an adult cow were found to be considerably less effective in preventing clinical milk fever, a dose of 17 million units was lethal for 75% of treated animals.

Another disadvantage of using injectable vitamin D_3 is that although it is effective in preventing clinical milk fever, it tends to result in significantly lower plasma Ca concentrations between 3 and 14 days postpartum compared with untreated control cows. Cows treated with injectable vitamin D_3 therefore are at decreased risk of developing clinical milk fever around parturition but may be at increased risk of subclinical hypocalcemia during the first weeks of lactation. The problem appears to be that the effect of the exogenous metabolite on intestinal Ca absorption declines, whereas its inhibiting effect on the renal enzymes activating endogenous vitamin D_3 is more sustained. Treated cows therefore appear to be impaired in their ability to produce sufficient 1,25-$(OH)_2$D to maintain enhanced intestinal absorption of calcium in the first weeks of lactation.

Oral Vitamin D Administration

Oral dosing with 20 million IU of vitamin D_2/d for 5 days to cows immediately before calving can markedly reduce the expected incidence of milk fever. Because the onset of action after oral treatment is more delayed than after injection, a cow must be treated for at least 5 days before calving for the treatment to be effective. The exact date of calving is often difficult to determine, and if the administration is discontinued for up to 4 days before calving, an unusually high incidence of the disease may follow, probably because of the depression of parathyroid activity that follows the administration. Toxicity of the oral treatment is considerably lower compared with injection. A dose of 30 million IU of vitamin D administered over 7 days was without obvious signs of toxicity. The danger of causing metastatic calcification, however, also exists; this has been produced with smaller doses (20 million IU daily for 10 days).

Oral Calcium Supplementation Around Parturition

The oral administration of easily absorbed Ca salts such as calcium chloride or calcium propionate providing the equivalent of 40 to 50 g calcium per dose as a bolus, gel, paste, or liquid, given in a single dose or repeated doses beginning 12 to 24 hours before calving and continuing to 24 hours after calving, is a common practice that will effectively increase the plasma Ca concentrations for at least 6 hours. Based on clinical studies, a treatment interval of 6 to 12 hours for the period around calving has been suggested. Depending on the type of formulation, its palatability, and the required treatment frequency, oral treatment can be more or less labor intensive, demanding, and invasive. Calcium chloride is highly soluble, resulting in a rapid increase of the plasma Ca concentration within 30 minutes, but it is also caustic and may result in epithelial lesions of the mucosa of the oropharyngeal region, esophagus, forestomaches, or abomasum. In contrast, Ca-propionate requires a larger volume to provide a similar amount of Ca and has a more delayed effect on the plasma Ca concentration, but it is less injurious and thus safer to administer. The combined administration of Ca together with propionate, which is a glucose precursor in the form of calcium propionate, has been used as a further supporting argument for the use of this compound around calving. However, studies investigating the effect of Ca-propionate on feed consumption, milk yield, plasma glucose, insulin, and NEFA concentration in periparturient cows failed to identify a beneficial effect.[12]

Prophylactic treatment with oral Ca formulations in contrast to parenteral Ca administration bears the advantage that it does not disturb mechanisms regulating the Ca homeostasis, but rather supports them by providing oral Ca while intestinal Ca absorption has been upregulated.[15]

Parenteral Calcium Supplementation Around Parturition

Intravenous or subcutaneous administration of Ca-gluconate or Ca-borogluconate solutions to cattle around parturition is sometimes practiced because this approach may be perceived as a convenient and inexpensive method to control milk fever.[15] However, increasing the plasma Ca concentration to supraphysiological levels, as often occurs after parenteral administration of therapeutic doses of Ca solutions, disturbs the endocrine circuits regulating calcium homeostasis by abruptly interrupting the PTH secretion that is essential to prevent excessive declines of the plasma Ca concentration around parturition. This disruption will result in a delay of the correction of the periparturient disequilibrium of the Ca balance, which has been documented in several studies. Cows treated prophylactically with Ca solutions parenterally have pronounced but transient hypercalcemia that is followed by decline of the plasma Ca concentration below pretreatment Ca concentrations within 12 hours. A recent study comparing IV Ca administration with oral Ca administration and no treatment in periparturient cows not showing clinical signs of milk fever revealed that plasma Ca concentrations were significantly

higher than those in orally treated and control cows only for the first 4 hours posttreatment, but they were below the Ca concentrations of orally treated cows from 24 hours until at least 48 hours posttreatment and below the values of untreated cows from 36 hours until at least 48 hours posttreatment.[16] **Parenteral administration of Ca solutions should therefore be a tool reserved to rapidly correct clinical hypocalcemia and should never be a standard procedure at calving.**[8,15]

Partial Milking

Partial milking after calving has been proposed for decades as a strategy to decrease Ca losses through the mammary gland in early lactation. Although this practice evidently reduces the amount of Ca excreted through the mammary gland, studies investigating the effect of partial milk-out on the plasma Ca concentration in the first days of lactation failed to identify a beneficial effect.[6]

ACUTE HYPOKALEMIA IN CATTLE

SYNOPSIS

Etiology Sustained decrease in dry matter intake in lactating dairy cattle, abomasal disorder, alkalemia, two or more injections of isoflupredone acetate (corticosteroid/mineralocorticoid).

Epidemiology Most common in lactating dairy cattle with decreased appetite and high-milk-production potential and low muscle mass.

Clinical findings Generalized muscle weakness; depression; cardiac arrhythmias, particularly atrial fibrillation.

Clinical pathology Low serum/plasma potassium concentrations; alkalemia and hyperglycemia may be present.

Necropsy findings Multifocal myonecrosis with microphage infiltration and myofiber vacuolation, characteristic for hypokalemia myopathy.

Diagnostic confirmation Response to treatment, serum potassium concentration less than 2.5 mEq/L.

Treatment Potassium chloride administered orally, increased feed intake.

Control Maintain adequate dry matter intake, early detection and correction of abomasal disorders, no more than one treatment of isoflupredone acetate.

ETIOLOGY

Hypokalemia is most common in lactating dairy cattle and is secondary to the following:

- Anorexia resulting from clinical mastitis and retained placenta
- Upper gastrointestinal obstruction, particularly left-displaced abomasum, right-displaced abomasum, abomasal volvulus, and abomasal impaction
- Obligatory loss of potassium in milk (1.4 g potassium/L of milk)
- Hyperinsulinemia secondary to hyperglycemia and transcellular shift of extracellular potassium
- Sympathetic nervous system activation
- Aldosterone release in response to hypovolemia and the need for sodium retention
- Decreased whole-body potassium stores as a result of the relatively low muscle mass in dairy cows

In most cases, the hypokalemia is not severe enough to cause weakness and recumbency.

EPIDEMIOLOGY

Hypokalemia occurs commonly in lactating dairy cattle with prolonged inappetence (>2 days), but it is rare in adult ruminants with adequate dry matter intake and neonatal calves, lambs, and kids. Hypokalemia occurs more commonly in lactating dairy cows than beef cows or feedlot animals because of the additional loss of potassium in the milk, the lower muscle mass in dairy cows that results in decreased whole-body potassium stores, and the use of glycogen and skeletal muscle protein for energy in early lactation.

Milk typically has a potassium concentration of 36 mmol/L.[1] High-producing dairy cows are therefore at increased risk for hypokalemia, and the incidence of hypokalemia in the postparturient period increases as milk production increases. Early-lactation dairy cows are in a marked state of negative energy balance; catabolism of intracellular glycogen and protein leads to increased potassium excretion in urine and therefore whole-body potassium depletion because potassium is bound to glycogen.

Potassium excretion by the kidneys is via secretion by the distal tubular cells. Aldosterone or other steroids with mineralocorticoid activity enhance distal tubular secretion of potassium by increasing permeability of the tubular luminal membranes to potassium and increasing losses of potassium in the urine. Hypokalemia and whole-body potassium depletion is common in lactating dairy cattle receiving one or more injections of corticosteroids for ketosis that have mineralocorticoid activity, particularly isoflupredone acetate.[2,3] The hypokalemic effect occurs because the mineralocorticoid activity of isoflupredone enhances renal and gastrointestinal (saliva and colon) losses of potassium. Hypokalemia reaches its nadir of approximately 60% to 70% of the normal value by 72 hours after the first of two 10-mg injections. Exogenous or endogenous insulin release secondary to hyperglycemia following IV dextrose administration or corticosteroid administration can lead to hypokalemia associated with the intracellular movement of potassium accompanying glucose; this is a shift in potassium and not whole-body depletion.[4,5]

In general, alkalemia decreases serum potassium concentration, and acidemia increases serum potassium concentration. Hypokalemia therefore occurs commonly in ruminants with metabolic alkalosis. Experimental induction of metabolic alkalosis by oral administration of sodium bicarbonate in three Jersey cows caused marked metabolic (strong ion) alkalosis (base excess, 14 to 19 mEq/L), hypokalemia (2.6 to 3.1 mEq/L), and an increase in muscle potassium concentration of 6% to 10%, indicating an intracellular shift of potassium from the extracellular space to the intracellular space.

Whole-body depletion of potassium may be present in healthy dairy cattle immediately after calving, based on the results of potassium balance studies and studies documenting decreased skeletal muscle potassium content at calving and decreased

urinary potassium concentrations immediately after calving.[2,6]

PATHOGENESIS

Potassium homeostasis in adult cattle is determined by the balance between absorption of potassium from the gastrointestinal (GI) tract and subsequent excretion by the kidneys and salivary glands. Transport of potassium is passive in the small intestine and active in the colon under the influence of aldosterone. The most important hormone affecting renal and salivary potassium excretion is aldosterone, which is released from the zona glomerulosa of the adrenal gland in response to hyperkalemia and other factors. At least 95% of whole-body potassium is intracellular, with skeletal muscle containing 60% to 75% of the total intracellular potassium. Total potassium losses in lactating cattle are 75% in urine, 13% in feces (mainly endogenous loss), and 12% milk, with urine, fecal, and milk losses being obligatory. Marked changes in serum or plasma potassium concentrations alter the resting membrane potential of cells because the potassium gradient generated by Na-K ATPase is the main cause for the negative electric potential across cell membranes. Hypokalemia therefore alters the resting membrane potential and leads to clinically significant changes in cellular and organ function. Hypokalemia indicates whole-body depletion of potassium unless induced by hyperglycemia and hyperinsulinemia.[4,5]

The potassium content of cattle has been estimated at approximately 2.2 g/kg BW. Lactating dairy cattle should be fed a diet containing at least 0.7% potassium on a dry-weight basis, although high-producing dairy cattle need a higher dietary potassium concentration, and potassium is frequently fed at 1.3% to 1.4% on a dry-weight basis. The absorption efficiency of potassium on a typical lactating dairy cow diet ranges from 74% to 88%, with potassium being absorbed in the small intestine and forestomach, with the former predominating. Rumen fluid in cattle usually has a potassium concentration of 24 to 85 mEq/L, and rumen fluid potassium concentration and potassium absorption are strongly dependent on intake. This indicates that increasing potassium intake (specifically, increasing rumen potassium concentration) will directly lead to increased potassium absorption. Studies in fed sheep have indicated a strong linear relationship between potassium absorbed from the rumen and rumen potassium concentration; however, it should be noted that the rate of potassium absorption depends also on whether the animal is fed or fasted. Fasting in sheep for 26 hours decreased rumen potassium concentration from 50 mmol/L to 24 mmol/L and decreased plasma potassium concentration from 4.2 to 3.7 mmol/L.

Potassium homeostasis is not considered to be under direct hormonal control in sodium-replete healthy lactating cattle because there is no association between plasma aldosterone concentrations and whole-blood or urine potassium concentrations.[3] Anorexia is thought to play an important role in the development of hypokalemia in cattle because 24 to 48 hours are needed for the mammalian kidney to adjust to a reduction in dietary potassium intake.[3] Dehydration also plays an important role in hypokalemia via aldosterone activation. There appears to be a gut or hepatoportal sensor that detects potassium intake and sends a signal to the kidney to increase potassium excretion in response to increased potassium ingestion, but the anatomic location of the sensor and the molecular pathway for signal transduction remain unknown.[7] Nevertheless, activation of the gut/hepatoportal sensor means that there is increased potassium excretion by the kidneys even before there is a detectable increase in serum potassium concentration following increased potassium intake.

Relative to an in vitro potassium concentration of 5 mmol/L, decreases in tissue bath potassium concentration decrease the amplitude of contraction of the circular muscle of the cow abomasal corpus; this smooth muscle is responsible for the propulsion of abomasal chyme.[8] Small, but nonsignificant, decreases in the force developed by abomasal smooth muscle from bulls is observed when in vitro potassium concentration is decreased from 5.4 to 2.0 to 3.0 mmol/L.[9] Hypokalemia may therefore result in decreased abomasal emptying rate and consequently an increased risk of developing left-displaced abomasum, abomasal volvulus, and potentially retained placenta and metritis in dairy cattle. The relationship between potassium concentration and skeletal muscle tone has not been determined for cattle, but studies in humans suggest hypokalemia must be marked (<2.0 to 2.5 mEq/L) to decrease skeletal muscle tone.

CLINICAL FINDINGS

Affected animals have generalized muscle weakness, decreased gastrointestinal motility, and depression. Severely affected animals are unable to stand or lift their heads from the ground. Cows with severe hypokalemia (<2.0 mEq/L) are usually recumbent and profoundly weak, appear flaccid, and lie in sternal or lateral recumbency. They are unable to support the weight of their heads off the ground and commonly hold their heads in their flanks. Profound weakness of the lateral cervical muscles may occur. Anorexia is common. Cardiac arrhythmias are often detectable on auscultation, and atrial fibrillation may be present on electrocardiography.

Cardiac arrhythmias are associated with abnormal serum potassium concentrations, both hypokalemia and hyperkalemia. In an unpublished study of 110 adult cattle with atrial fibrillation, hypokalemia was commonly present before the induction of atrial fibrillation. Although there do not appear to be any large-scale studies examining the association between hypokalemia and cardiac arrhythmias in adult cattle, hypokalemia, hypocalcemia, and alkalemia are commonly present in lactating dairy cattle with left-displaced abomasum and atrial fibrillation. In a recent study, 2/15 lactating dairy cows with experimentally induced hypokalemia and alkalemia developed atrial fibrillation that resolved within 24 hours of administration of KCl, accompanied by an increase in plasma potassium concentration and a decrease in blood pH.[6] Atrial fibrillation in other studies was diagnosed in 4/10, 2/14, and 5/17 cows with naturally acquired hypokalemia, and in 1/7 lactating dairy cows with experimentally induced hypokalemia following IM administration of two 20-mg doses of isoflupredone acetate at a 48-hour interval. Taken together, these findings suggest that hypokalemia plays an important role in the development of atrial fibrillation in adult cattle.

Signs of chronic potassium depletion in cattle include anorexia; pica characterized by hair licking, floor licking, and chewing of wooden partitions; rough hair coat; muscular weakness; irritability; paralysis; and tetany.

CLINICAL PATHOLOGY

The order of sensitivity/specificity in determining whole-body potassium depletion is as follows: skeletal muscle > serum/plasma > milk > erythrocyte/whole blood > urine > saliva.

Skeletal Muscle Potassium Content

Skeletal muscle potassium concentration is considered the most sensitive and specific method for assessing whole-body potassium status and therefore provides the gold-standard test. Skeletal muscle is considered the best tissue to sample because it contains approximately 75% of the whole-body stores of potassium. A standardized muscle should be evaluated in cattle because differences in potassium content of greater than 15% are present in individual animals, and this muscle-to-muscle variation is greater than that produced by breed.

Plasma Potassium Concentration

Determination of serum/plasma potassium concentration is required to confirm a suspected diagnosis of hypokalemia. A serum potassium concentration less than 2.5 mEq/L reflects severe hypokalemia, and most animals will be weak or recumbent. A serum potassium concentration of 2.5 to 3.5 mEq/L reflects moderate hypokalemia, and some cattle will be recumbent or appear weak, with depressed gastrointestinal motility. In addition to measurement of serum potassium concentration, determination of the serum concentrations of sodium, chloride,

calcium, and phosphorus and the serum activities of creatine kinase and aspartate aminotransferase can be very helpful in guiding treatment of cattle with hypokalemia. Serum potassium concentration is usually a little higher than plasma potassium concentration because platelet activation releases potassium. In summary, a serum/plasma potassium concentration below the normal range provides unequivocal evidence of hypokalemia unless there is concurrent hyperinsulinemia or alkalemia.[4,5] However, because more than 95% to 98% of whole-body potassium stores are intracellular, it is likely that serum/plasma potassium concentration is not as sensitive as skeletal muscle potassium content in indicating whole-body potassium depletion.

Milk Potassium Concentration

Milk potassium concentration is theoretically more sensitive than serum/plasma potassium concentration in detecting whole-body potassium depletion in individual cows because the milk concentration of potassium is constant for an individual cow. Potassium depletion in lactating dairy cows caused milk potassium concentration to decrease from 1.45 g/L to 1.28 g/L; this was a greater percentage decrease than that in the plasma or whole blood of cattle with whole-body potassium depletion. However, there is marked individual variation in the milk concentration of potassium in healthy cattle, with variations of up to 50% occurring between cows. This variability appears to be a result of changes in milk fat, protein, and lactose percentage, with the highest correlation of milk potassium concentration being with milk lactose concentration ($R = -0.53$ or -0.74). The relationship between potassium and lactose is attributable to the fact that these are important contributors to milk osmolality, which is constant and isotonic. Milk potassium concentration also changes during lactation, being 42 mmol/L in early lactation, 40 mmol/L in midlactation, and 27 mmol/L in late lactation, with a mean bulk milk potassium concentration of 37 mmol/L. The large cow-to-cow variability in milk potassium concentration and dependence on milk lactose concentration make it difficult to produce a suitable cut-point for identifying whole-body potassium depletion in sick lactating dairy cows. However, milk potassium concentration has clinical utility in monitoring potassium homeostasis over time in an individual cow.

Erythrocyte Potassium Concentration

Erythrocyte potassium concentration is determined by measuring plasma potassium concentration and hematocrit, and then adding sufficient distilled water to hemolyze the erythrocytes followed by potassium measurement of the hemolyzed fluid and mathematical calculation. There is marked cow-to-cow variability in the erythrocyte potassium concentration (7 to 70 mmol/L) and sodium concentration (15 to 87 mmol/L) of healthy cattle that has a genetic basis with no breed influence. There are two main peaks of cellular potassium concentration, one at 20 mmol/L and a second at 50 mmol/L. In lactating dairy cattle with induced whole-body potassium deficiency, whole-blood potassium concentration changed similarly to plasma potassium concentration. However, in 180 cows, no relationship between plasma potassium concentration and erythrocyte potassium concentration was found. Measurement of erythrocyte or whole-blood potassium concentration is not currently recommended in evaluating whole-body potassium status.

Urine Potassium Concentration

Urine potassium concentrations are normally high (454 ± 112 mEq/L) but variable, with a mean fractional clearance of 82% and a coefficient of variation of 61%. The large variability in urine potassium concentration makes it difficult to produce a suitable cut-point for identifying whole-body potassium depletion. However, determination of urine potassium concentration has clinical utility in an individual cow ingesting a constant diet over time because it reflects potassium homeostasis. Urine pH may provide some value as a better screening test because aciduria may be present in response to a marked decrease in urine potassium concentration.[10]

Salivary Potassium Concentration

Salivary potassium concentrations are more influenced by aldosterone in the response to changes in serum sodium concentration, and salivary potassium concentration must therefore be compared with the salivary sodium concentration (one-for-one exchange), sodium homeostasis, and the ratio of serum sodium to potassium to have clinical utility. The normal saliva potassium concentration shows a large range of 4 to 70 mEq/L, with sodium homeostasis having the greatest effect. A study in cattle with left-displaced abomasum, right-displaced abomasum, or abomasal volvulus indicated no association between salivary potassium concentration and serum potassium concentration. Taken together, it appears that measurement of salivary potassium concentration provides minimal insight into whole-body potassium status.

NECROPSY FINDINGS

Necropsy of cattle with hypokalemia-induced recumbency reveals the presence of muscle necrosis in the pelvic limbs. Histologic examination of non-weight-bearing muscles reveals multifocal myonecrosis with microphage infiltration and myofiber vacuolation, which is characteristic of hypokalemic myopathy in humans and dogs. It is important to note that hypokalemic myopathy is also present in muscles not subject to ischemia of recumbency.

TREATMENT

Treatment of hypokalemia in lactating dairy cows should focus on surgical correction of abomasal displacement, increasing the potassium intake by increasing dry matter intake or the oral administration of KCl, and correction of hypochloremia, alkalemia, metabolic alkalosis, and dehydration.[2] Oral potassium administration is the method of choice for treating hypokalemia. Inappetent adult cattle should initially be treated with 120 g of KCl PO, followed by an additional oral treatment of 120 g KCl 12 hours later, for a total 24-hour treatment of 240 g KCl (0.4 g/kg BW).[6] Higher oral doses of KCl are not recommended because they can lead to diarrhea, excessive salivation, muscular tremors of the legs, and excitability.

Potassium is rarely administered intravenously; the IV route is used only for the initial treatment of recumbent ruminants with severe hypokalemia and rumen atony because it is much more dangerous and expensive than oral treatment. The most aggressive IV treatment protocol is an isotonic solution of KCl (1.15% KCl), which should be administered at less than 3.2 mL/kg/hr, equivalent to a maximal delivery rate of 0.5 mEq of potassium/kg BW per hour. Higher rates of potassium administration run the risk of inducing hemodynamically important arrhythmias, including ventricular premature complexes that can lead to ventricular fibrillation and death.

Palatable hay and propylene glycol orally are recommended. In a series of 14 cases, treatment consisted of potassium chloride given intravenously and orally at an average total daily dose of 0.42 g/kg BW (26 g orally and 16 g IV) for an average of 5 days, resulting in recovery in 11 cases after an average of 3 days. During recumbency, affected cattle require special attention to minimize ischemic necrosis of muscles of the pelvic limbs.

Glucocorticoids are often used to treat ketosis, and the most commonly used glucocorticoids are dexamethasone and isoflupredone acetate. Dexamethasone has little mineralocorticoid activity compared with prednisone and prednisolone, which are related chemically to isoflupredone. Dexamethasone is recommended for the treatment of ketosis in dairy cattle at a single dose of 10 to 20 mg IM, and repeated, if necessary, 12 to 24 hours later. Field observations indicate that repeated doses of isoflupredone acetate decrease plasma concentrations of potassium by 70% to 80%, which suggests a strong mineralocorticoid activity. It is recommended that isoflupredone acetate be used judiciously and animals be monitored for plasma potassium and any evidence of weakness and recumbency. Treatment with oral potassium chloride may be required, but treatment may be ineffective.

CONTROL

Oral administration of potassium is a mandatory component of fluid and electrolyte administration to inappetent lactating dairy cattle. Ensuring an adequate dry matter intake is the best method for preventing hypokalemia in lactating dairy cattle.

TREATMENT AND CONTROL

Treatment

KCl 120 g PO, followed by an additional oral treatment of 120 g KCl 12 hours later, for a total 24-hour treatment of 240 g KCl (0.4 g/kg BW) (R-1)

KCl 1.15% IV, less than 3.2 (mL/kg BW)/hour, equivalent to a maximal delivery rate of 0.5 mEq of potassium/kg BW per hour (R-2)

Isoflupredone acetate (R-4)

Control

Maintain adequate dry matter intake (R-1)

DOWNER-COW SYNDROME

SYNOPSIS

Etiology Ischemic myopathy of large muscles of pelvic limbs and ischemic neuropathies of obturator or sciatic nerve or its branches secondary to prolonged recumbency associated with milk fever or dystocia; injury of bones, joints, and muscles; undetermined etiologies.

Epidemiology Most common in dairy cows with previous episodes of milk fever; in beef cows after prolonged or difficult calving. Delay of more than 4 hours in treatment for recumbent milk-fever cows. Hypophosphatemia and/or hypokalemia have been discussed as potential risk factors.

Signs Alert downer cows: Unable to stand following treatment for milk fever. Sternal recumbency; normal mental status, vital signs, and alimentary tract. Appetite and thirst normal or mildly decreased. Most will stand in few days if provided good clinical care and secondary muscle necrosis is minimized.

Nonalert downer cows: Persistent recumbency with altered mentation and vital signs; frequently unable to maintain sternal recumbency; abnormal position of legs; groaning; anorexia; die in several days.

Clinical pathology Increased serum activity of creatine kinase (CK) and aspartate aminotransferase (AST); serum phosphorus and potassium concentrations may be subnormal or elevated; proteinuria, myoglobinuria.

Necropsy findings Ischemic necrosis, edema and hemorrhage of large medial thigh muscles.

Diagnostic confirmation Increased serum activities of CK, AST, proteinuria; myoglobinuria necropsy lesions in cow unable to rise with no other lesions.

Treatment Provide excellent bedding or ground surface such as sand or dirt pack. Roll animal from side to side every few hours. Antiinflammatory therapy/pain management. Fluid and electrolyte therapy as necessary. Hoist cows making attempts to stand.

Control All recently calved dairy cows that are at high risk for milk fever must be observed closely 12 to 24 hours before and after calving for evidence of milk fever and while still standing; if recumbent, do not delay treatment for more than 1 hour. Can treat all high-risk cows with calcium salts orally to prevent clinical milk fever.

The term *downer cow* first appeared in the veterinary literature in the 1950s and referred to cattle that were too injured, weak, or sick to stand or walk without assistance.[1] In most of the early publications using this terminology a case definition was not provided or was imprecise, such as "cattle unable to rise" or "unable to stand without assistance," and did not make reference to possible etiologies, duration of recumbency, or outcome.[2] More recently the term *downer cow* was used to denote nonambulatory cattle recumbent for at least 24 hours without obvious reason.[1] A further classification of downer cows into mentally alert, nonambulatory cattle that are able to maintain themselves in sternal recumbency, so-called alert downer cows, and cows with moderate to severe mental obtundation and abnormal vital signs that frequently are unable to maintain sternal recumbency, the so-called nonalert downer cows, was proposed.[3] The term *creeper cows* is sometimes used to denote alert recumbent cows that are unable to bear weight on their hindlimbs but that use the forelegs to propel themselves over short distances.

ETIOLOGY

Alert downer cows are in most cases recumbent because of musculoskeletal or neurologic injuries such as lesions of the sciatic or obturator nerve secondary to dystocia (calving paralysis), fractures of long bones or the pelvis, hip luxation, or muscle injury as a result of primary trauma or secondary to prolonged recumbency. Nonalert downer cows comprise animals with systemic disease affecting mental status and general attitude, such as periparturient hypocalcemia, septicemia, hypovolemia, diffuse peritonitis, and severe hepatic lipidosis, or neurologic diseases affecting the brainstem or cortex.[3]

In most cases, the downer-cow syndrome is a complication of milk fever. Myopathies and neuropathies develop in nonambulatory cows secondary to prolonged periods of recumbency. Ischemic myopathy affecting the large muscles of the pelvic limbs and injuries to the tissues around the hip joint and of the obturator muscles are common in cows that do not fully recover and stand. Injuries to the musculoskeletal system are also common as a result of cows "spread-eagling" their hindlimbs if they are unsteady during parturition or forced to stand or walk on a slippery floor immediately before or following parturition.

A survey conducted among dairy operations in 21 U.S. states determined that the three most common causes for persistent recumbency were periparturient hypocalcemia (19%), calving-related injuries (22%), and injuries from slipping or falling (15%). Beef cattle operations reported calving paralysis as the single most common cause for downer-cow syndrome.[1]

EPIDEMIOLOGY

Occurrence

The disease is most common in dairy cows and typically occurs within the first 2 or 3 days after calving, often immediately following an episode of milk fever. Other debilitating conditions of periparturient cows that can be associated with persistent recumbency include acute coliform mastitis, septic metritis, and acute rumen acidosis (grain overload).

In the United States an estimated 270,000 cattle became nonambulatory on-farm in 2004, of which 57.4% were dairy and 31.5% beef cattle, corresponding to 1.2% of dairy cattle and 0.2% of beef cattle becoming persistently recumbent in 1 year.[4] An older survey conducted in 1986 in Minnesota that included data from 738 dairy operations and 34,656 cow years at risk reported incidences per herd and year between 0.4% and 2.1% (case definition in this study: "sternal recumbency for at least 24 h for no obvious reason"). The overall outcome was that 33% of downer cows recovered, 23% were slaughtered, and 44% died. The owners perceived that downer cows were high producers (48%) or average producers (46%), with only 6% being low producers. Approximately 58% of cases occurred within 1 day of parturition, and 37% occurred during the first 100 days

of lactation. The incidence was highest (39%) during the three coldest months: December to February. A clinical survey conducted in New Zealand and including 433 periparturient recumbent cows reported a recovery rate of 39%, whereas 30% died, and 32% had to be destroyed. The case-fatality rate in this study was 11% higher in precalving recumbent cows than postcalving cows. A 2006 survey including dairy operations from 21 U.S. states reported that 78.6% of participating operations had at least one downer cow in 2006.[2] The case definition of a downer cow in this study was "nonambulatory cattle that were unable to stand for any length of time, including those that recovered."[2]

Because it is a syndrome lacking in clinical definition and includes all those "other cases" that cannot be otherwise classified, downer-cow incidence varies depending on the clinical acuity of the individual veterinarian and various environmental factors in different areas. In any case, the incidence seems to be increasing, particularly in intensive dairy farming areas, although this impression could arise from the increased necessity to effect a cure in valuable animals.

Risk Factors

Animal Risk Factors

Complication of Milk Fever. Prolonged recumbency after an episode of clinical milk fever either because of a delay in administration of proper treatment or delayed response to treatment is considered the most common primary cause of downer-cow syndrome. The incidences for downer-cow syndrome that is associated with milk fever reported in the literature range from 3.8% to 28.2% of all milk-fever cases.[5]

Prolonged recumbency, regardless of the primary cause, results in increased tissue pressure over a confined anatomic area, causing local ischemia and neuromuscular dysfunction. An insecure gait of a hypocalcemic periparturient cow presents an increased risk of injury from slipping or falling, such as muscle rupture, bone fractures, or hip luxation, that can result in downer-cow syndrome.

Traumatic Injuries to Pelvis and Pelvic Limbs. Traumatic injuries to bones, muscles, and nerves can be directly related to parturition (e.g. calving paralysis), be associated with muscle weakness and an insecure gait (e.g. in hypocalcemic cattle), or be the result of an inadvertent accident. **Calving paralysis** refers to a paresis or paralysis of one or both hindlimbs caused by a lesion of the obturator nerve and/or the lumbar root of the sciatic nerve inflicted during the calving process. Both nerves are vulnerable to compression between the bony birth canal and the calf at parturition; accordingly, nerve damage is most commonly diagnosed after dystocias, deliveries of large calves, or prolonged calvings. Calving paralysis is considered the most common cause for persistent recumbency in beef cattle.

Pressure injuries of the superficial nerves of the extremities may occur as secondary lesions in cows that are recumbent for an unrelated reason.

Serum Electrolyte Imbalances. Apart from hypocalcemia, hypophosphatemia, hypokalemia, and hypomagnesemia have been incriminated as potential factors contributing to downer-cow syndrome. **Hypophosphatemia** is a common finding in recumbent but also in healthy periparturient cows;[6] it is the mineral imbalance most commonly quoted as risk factor, especially in the so-called creeper cows, which are bright and alert and crawl about, but are unable to rise. The clinical relevance of hypophosphatemia in persistently recumbent animals has been debated contentiously, but an undisputed empirical observation is that hypophosphatemia is more common or more pronounced in recumbent periparturient cows that are unresponsive to intravenous calcium administration at least in very early stages of recumbency.[5,6] However, the mechanisms through which phosphate depletion may cause persistent recumbency are not well understood, and treatment response to oral or parenteral administration of phosphate salts is inconsistent.[6] Studies including cattle that were nonambulatory for longer than just a few hours, in contrast, found that low serum phosphorus levels are suggestive of a good prognosis, whereas nonsurvivors tend to have higher serum phosphorus concentrations.[3] A likely explanation for this finding is that cows recumbent for longer time periods may have developed more severe muscle damage that is associated with release of intracellular phosphorus into the circulation and thus an increase of the serum phosphorus concentration.

A long-term low-level **hypomagnesemia** has been associated with downer-cow syndrome, especially when it accompanies hypocalcemia. But it is usually manifested by a tetanic hyperesthetic state, which is not part of downer-cow syndrome.

Severe **hypokalemia** in cattle is associated with signs of depression and profound skeletal muscle weakness leading to recumbency.[7] Reports of pronounced hypokalemia in individual animals that were associated with persistent recumbency, with serum potassium concentrations below 2.0 mmol/L, have accumulated over the past decades. These cases have in most instances been traced back to the repeated use of isoflupredone, a mineral corticoid with strong kaliuretic effect that was commonly used for the treatment of ketosis in the United States.[7] Mild to moderate hypokalemia is known to occur in early lactating and anorectic cows, but the role of this mild form in the pathogenesis of downer-cow syndrome needs to be determined.[8]

The **age and stage of lactation** of a recumbent cow were found to be risk factors for nonrecovery. Recovery rates of nonambulatory cows were 10.1% for first-lactation cows, 17.7% for cows in their second to fourth lactation, and 22.2% for fifth-lactation cows.[2] Cows less than 15 days in milk had a recovery rate of 28.4%, whereas cows in later lactation had a 6.2% chance of making a full recovery.[2] Higher recovery rates in older cows and cows that were earlier in lactation have been attributed to an association between persistent recumbency and hypocalcemia. Cows that are older and earlier in lactation are more likely to be recumbent because of hypocalcemia as primary or contributing cause, which has a better prognosis than persistent recumbency for other reasons.

Duration of recumbency was also found to be associated with the likelihood of making a full recovery. Cows that were down for less than 24 hours recovered in 32% of the cases, whereas cows recumbent for longer periods had an 8.2% chance of recovery.[2]

A high **body-condition score** is a recognized risk factor for milk fever and therefore must also be considered as predisposing for downer-cow syndrome. Cows with a BCS above 4.0/5 around calving were found to be at 4.3 times higher risk to become nonambulatory than thinner cows. In contrast, cows in poor body condition, with a BCS below 2.5/5, recovered in 8.1% of all cases, whereas 16.6% of cows with a BCS of 2.75 or higher made a full recovery.[2]

Environmental and Management Risk Factors

A slippery ground surface is a major risk factor. Cattle that must walk across slippery floors, especially at the time of calving, may slip and fall and injure the large muscles of the pelvic limbs, resulting in an inability to stand.

PATHOGENESIS

In most cases downer-cow syndrome is a complication of an unrelated primary problem causing muscle weakness or persistent recumbency. Primary conditions that can lead to downer-cow syndrome have been grouped into four major categories: metabolic disorders (e.g., hypocalcemia, hypokalemia), acute systemic illness (e.g., coliform mastitis, toxic metritis), musculoskeletal disorders (e.g., fractures, joint luxation), and undetermined causes.[9]

Prolonged recumbency will result in secondary damage from excessive pressure on limbs squeezed between the body and the ground or from struggling to get up. If severe enough, these secondary lesions may prevent the affected cow from getting up, even though the primary cause of recumbency may in the meantime be resolved. Secondary damage can affect muscles, nerves, or other structural components such as bones or joints. Regardless of the initial cause,

prolonged recumbency results in varying degrees of pressure damage predominantly affecting the hindlimbs. Based on the results of experimental studies, it has been suggested that 6 hours of recumbency is the time threshold, beyond which tissue damage as a result of excessive weight bearing must be expected. This underscores the importance of handling any persistently recumbent cow as a medical emergency.

Pressure damage in recumbent cattle primarily occurs in the major muscles of the hindlimbs, particularly the semitendinous muscle, muscles caudal to the stifle, and the peripheral sciatic nerve and its branches. The local tissue damage is referred to as **compartment syndrome**; systemic effects resulting from local tissue damage are summarized in the so-called **crush syndrome**.

Compartment Syndrome

A compartment of the body is composed of muscle and nerves within an anatomically defined area that is surrounded by a rigid muscle fascia layer. In a recumbent cow, the compartments of interest are the ones of the upper part and to a lesser extent the lower part of each hindlimb. The initial pressure acting on the hindlimb located underneath the body of a recumbent cow depends on the body weight resting on this limb and the rigidity of the ground on which the cow is lying. This pressure on the limb directly translates into increased pressure within the affected compartment and will result in partial or complete occlusion of venous blood flow before the arterial blood flow of the affected region is decreased. The mismatch between blood flow into and out of the compartment leads to a further pressure increase within the compartment. Impaired blood supply to muscles and nerves and ensuing tissue hypoxia will add to the direct damage from mechanical compression. The thick muscle-fascial boundaries surrounding the compartment prevent tissue expansion that would relieve the structures within the compartment from the excessive pressure. Cell damage and inflammation are associated with swelling, causing a further increase in pressure and contributing to a detrimental cascade of events.

Experimental external compression of the pelvic limb in goats, to simulate limb compression in recumbent cows, resulted in a marked reduction in the nerve conduction velocity of the peroneal nerve, which was associated with clinically evident limb dysfunction.

Crush Syndrome

Crush syndrome refers to the sum of the systemic effects of extensive muscle tissue injury and is attributed to the massive release of muscle-tissue breakdown products into the blood circulation. Notably, a large increase in the serum activity of muscle enzymes, such as aspartate aminotransferase (AST) or creatine kinase (CK); increases in serum concentration of predominantly intracellular electrolytes, such as potassium and phosphorus; and ultimately the appearance of myoglobin in urine are indicative of crush syndrome. Myoglobinuria is a potentially life-threatening complication of downer-cow syndrome that can lead to acute renal failure.

Experimental Sternal Recumbency

Experimentally induced sternal recumbency with one hindlimb positioned under the body to simulate prolonged recumbency will result in a swollen rigid limb within 6 to 9 hours. Following injury to the muscle cells, the serum activity of CK is markedly elevated at about 12 hours after the onset of recumbency. Proteinuria and in some severe cases myoglobinuria occur between 12 and 36 hours after the onset of prolonged recumbency, as a result the release of myoglobin from damaged muscles. In cows that make efforts to stand but cannot do so, continued struggling may result in rupture of muscle fibers and hemorrhage.

Acute focal myocarditis occurs in about 10% of cases, resulting in tachycardia, arrhythmia, and the unfavorable response to IV calcium salts observed in some cases. The cause of the myocardial lesion is unknown, but repeated administration of calcium salts has been suggested. The prolonged recumbency can result in additional complications, such as acute mastitis, decubitus ulcers, and traumatic injuries of the limbs.

The pathogenesis of the nonalert downer cow is not understood. Most such cows have had an initial episode of milk fever and did not respond satisfactorily. Within 1 or 2 days, affected cows have a preference for lateral recumbency and exhibit expiratory moaning and groaning. They represent about 2% of all cases of milk fever.

CLINICAL FINDINGS

Downer-cow syndrome may occur independently or follow apparent recovery after treatment for milk fever, except for the prolonged recumbency. In the typical case, affected cows either make no effort or are unable to stand following treatment for parturient paresis. About 30% of cows treated for milk fever will not stand for up to 24 hours following treatment. Affected cows are usually bright and alert with good or only mildly depressed feed intake and are thus classified as alert downer cows. The temperature is normal and the heart rate may be normal or elevated to 80 to 100 bpm. Tachycardia and arrhythmia occur in some cows, especially immediately following the administration of IV calcium, and sudden death has occurred. Respirations are usually unaffected. Defecation and urination are normal, but proteinuria is common and may indicate extensive muscle damage if marked.

Some affected cows may make no effort to stand. Others will make frequent attempts to stand but are unable to fully extend their pelvic limbs and lift their hindquarters more than 20 to 30 cm from the ground. On a nonslippery surface (bare ground, sand pack, or deep bedding) some cows are able to stand with some assistance by lifting on the tailhead or with the use of hip slings. Those cows that do not make an effort to stand usually cannot stand even with assistance, and if supported with cow slings, they will usually make no effort to bear weight with either the hindlimbs or the forelimbs. Their limbs appear stiff, painful, or numb, and they are unable or reluctant to bear weight. Damage to the peroneal nerve is usually present when there is hyperflexion of the fetlock joints, which is evident if and when the cow is able to stand and bear weight on the hindlimbs.

In some cases, the hindlimbs are extended on each side of the cow and reach up to the elbows on each side. In this position, the cow is bearing considerable weight on the medial thigh musculature and causing ischemic myopathy. This abnormal position of the legs may also result from dislocation of one or both hip joints or be associated with traumatic injuries surrounding the hip joints with or without rupture of the ligamentum teres. Regardless of the cause, the cow prefers this leg position and invariably will shift the legs back to the abnormal position if they are placed in their normal position.

In some cows, the signs may be more marked and bizarre, including a tendency to lie in lateral recumbency with the head drawn back. When placed and propped up in sternal recumbency, these cows appear almost normal, but when they are left alone, they revert to the position of lateral recumbency within a short period of time. Still more severe cases are hyperesthetic, and the limbs may be slightly stiff, but only when the cow is lying in lateral recumbency. These severe cases do not usually eat or drink and have been described as nonalert downers.

Complications in downer-cow syndrome are common and often result in death or the need for euthanasia. Coliform mastitis, decubitus ulceration, especially over the prominences of the hock and elbow joint, and traumatic injuries around the tuber coxae caused by the hip slings are common. When these complications occur in the early stages of the disease, they commonly interfere with any progress being made and become the focus of clinical attention.

The course of the disease is variable and dependent on the nature and extent of the lesions and the quality of the care and comfort that is provided for the cow during the first few days. About 50% of downer cows will stand within 4 days or less if cared for properly. The prognosis is poor for those that are still recumbent after 7 days, although some affected cows have been down for 10 to 14 days and subsequently stood up and recovered. Death may occur in 48 to 72

hours following the onset and is usually associated with myocarditis.

Clinical Examination of the Downer Cow

Clinical examination of the downer cow can be very difficult and challenging depending on the environmental circumstances and the physical size of the animal.[9] Causes of persistent recumbency in cattle include metabolic, musculoskeletal, neurologic, neoplastic, and inflammatory disease; accordingly, obtaining an adequate history and conducting a thorough physical examination are indispensable.[10] Key aspects of the history include age and stage of lactation of the animal, duration of recumbency, any previous clinical abnormalities before the recumbent stage, any previous treatments, diet and accidental access to new feeds, sudden unaccustomed exercise, and assessment of the management provided.

The environment and the ground surface surrounding the recumbent animal may provide clues about the possibility that the animal slipped, fell, and was injured.

A systematic physical examination of all accessible body systems is necessary. The animal should be examined visually from a distance for evidence of abnormalities of the carriage of the head and neck, to observe the position of the limbs, and to observe any attempts of the animal to stand or creep along the ground surface.

The details of the clinical examination are presented elsewhere in this book. The standard close clinical examination is necessary to determine body temperature, heart rate and pulse, respiratory rate, and the state of the major body systems, such as the respiratory tract, cardiovascular system, central nervous system for mental state, gastrointestinal tract, mammary gland, and reproductive tract, any of which may indicate the presence of abnormalities associated with shock that results in recumbency.

In the recently calved cow, particular emphasis must be given to adequate examination of the udder for mastitis, the uterus for metritis, and the gastrointestinal tract for diseases associated with toxemia, dehydration, and shock (abomasal volvulus, acute diffuse peritonitis, carbohydrate engorgement) that result in recumbency. A urine sample must always be obtained and tested for ketones and the presence of myoglobinuria. Careful systematic examination of the musculoskeletal system includes palpating the muscles, bones, joints, and feet of each limb, including passive flexion and extension of each limb. The coxofemoral joints are examined for evidence of dislocation. The vertebral column is examined for evidence of fracture or dislocation of vertebrae. It is important to examine both sides of the animal, which means rolling the cow over from side to side; often the animal may have to be rolled over more than once to repeat a particular examination.

A neurologic examination includes examination of the withdrawal reflexes, patellar reflexes, and sensation of all four limbs and the reflex arcs of the spinal cord; careful examination of lumbar and sacral areas, including sensation and tone in the tail; and examination of the cranial nerves.

The examination can be extended by lifting the downer cow with appropriate lifters and observing if the animal extends its limbs and attempts to bear weight. While the animal is being assisted to stand, additional examinations of other parts of the body can be made.

CLINICAL PATHOLOGY

The serum calcium and glucose concentrations are frequently within the normal range, whereas phosphorus and potassium concentrations may be decreased in cows with depressed feed intake or increased in animals with more pronounced muscle damage and/or dehydration. Results of hematologic examinations are usually unremarkable in early stages of the recumbency. The serum activity of CK and AST are usually markedly elevated by 18 to 24 hours after the onset of recumbency. Very high levels of serum CK activity shortly after the onset of recumbency that decline markedly within the following 24 to 48 hours are indicative of an acute muscle trauma (e.g., muscle rupture) that may be the cause of recumbency. More moderate elevation of the serum activity of CK with a tendency to slightly increase or remain constant over the following days is suggestive of continuous and ongoing muscle trauma resulting from prolonged muscle-tissue compression. Muscle tissue is rich in CK. and the plasma half-life of this enzyme in cattle is only about 8 to 9 hours; this parameter is therefore a sensitive but short-lived marker of muscle damage. When interpreting the serum CK activity of a recumbent cow, it is critical to consider the time of sample collection relative to onset of recumbency.

AST, in contrast, has a considerably longer half-life and remains elevated for several days after initial trauma. In a series of 262 recumbent dairy cows, serum samples were analyzed for CK, lactate dehydrogenase (LDH), and AST to evaluate the value of serum enzyme activities for predicting a failure to recover. The optimal cutoff points maximizing the sensitivity and specificity of the tests were 2330, 2225, and 171 U/L for CK, LDH, and AST, respectively. The predictive value of AST was significantly better, with optimal cutoff points of 128 and 189 U/L, respectively. AST provided the best predictive indicator of whether a recumbent cow would not recover, the best results being obtained with serum samples taken on the first day of recumbency.

In experimentally induced recumbency in cows, the CK activity remained within normal limits for the first 6 hours. However, by 12 hours there was a marked increase to mean values of 12,000 U/L rising to 40,000 U/L by 24 hours. There may be moderate ketonuria. A marked proteinuria is usually evident by 18 to 24 hours after the onset of recumbency. The proteinuria may persist for several days or be absent within a few days. In severe cases, the urine may be brown and turbid because of severe myoglobinuria.

Elevations of serum urea, muscle enzymes, and laboratory evidence of inflammation are considered the best prognostic indicators of an unfavorable recovery. The recovery rate was lower in cows with a total protein : fibrinogen ratio less than 10 : 1, and evidence of neutropenia and/or left shift. Cows with a serum urea level above 25 mmol/L and serum creatinine levels above 130 mmol/L had a poor prognosis.

NECROPSY FINDINGS

Hemorrhages and edema of the skin of traumatic origin are common. The major pathologic changes consist of hemorrhages and degeneration of the medial thigh muscles. Hemorrhages around the hip joint with or without rupture of the ligamentum teres are also common. Local areas of ischemic necrosis of the musculature (gracilis, pectineus, and adductor muscles) occur at the anterior edge of the pelvic symphysis. Eosinophilic infiltration of ruptured necrotic thigh muscles of downer cows has been described. Hemorrhages and edema of the nerves of the limbs (obturator, sciatic, peroneal, radial) are also common and usually associated with severe muscle damage. The heart is dilated and flabby; histologically, there is focal myocarditis. There is fatty degeneration of the liver, and the adrenal glands are enlarged. Histologically, there are also degenerative changes in the glomerular and tubular epithelium of the kidneys.

DIFFERENTIAL DIAGNOSIS

The diagnosis of downer-cow syndrome is typically made by exclusion of all other known causes of recumbency in a cow persistently recumbent for at least 24 hours while having received two courses of parenteral calcium treatment.

Differential diagnoses for alert downer cows:

- Hypocalcemia
- Calving paralysis
- Fractures of bone or pelvis
- Hip luxation
- Hypokalemia
- Botulism
- Spinal lymphosarcoma (BLV)

Differential diagnoses for nonalert downer cows:

- Hypokalcemia
- Hepatic lipidosis/puerperal liver coma
- Coliform mastitis
- Toxic metritis

- Hypomagnesemia
- Hypovolemic shock
- Septic shock
- Generalized peritonitis
- Acute rumen acidosis
- Right-displaced abomasum/abomasal volvulus
- Hypokalemia
- Botulism
- Meningoencephalitis
- Polioencephalomalacia

TREATMENT

Treatment of a nonambulatory cow evidently must focus on the primary cause of recumbency whenever it has been identified, but must also address secondary damage resulting from prolonged recumbency. The reader is referred to the corresponding chapter of this book for the treatment of primary cause of recumbency whenever it is known. Intensive supportive care is required for the treatment of secondary damage and prevention of further damage. The prognosis of a downer cow not only depends on the initial cause of the recumbency but to a large part also on the quality of the care provided during the recumbent period.

Antiinflammatory Therapy

Antiinflammatory therapy as part of pain management in ruminant production medicine has received increased attention over the past years because this is increasingly recognized as an essential aspect of animal welfare by veterinarians and owners alike.[11]

Although currently not much data are available to support the use of steroidal and nonsteroidal antiinflammatory drugs in downer cows, their use seems indicated not only to alleviate pain and discomfort of the sick, nonambulatory cow, but also to contain and control inflammation secondary to recumbency that is likely to exacerbate myopathy and neuropathy. Pain in cattle, as in other species, can occur as result of tissue damage, nerve damage, and inflammation, all factors considered to greatly contribute to downer-cow syndrome.[12] Repeated doses of nonsteroidal antiinflammatory drugs (NSAIDs) may be required for adequate control of pain and inflammation, which may put the treated animal at increased risk for adverse gastrointestinal effects, such as abomasal ulceration.[12] It is therefore advisable to instruct the patient owner to regularly check the produced feces for signs of melena.

A single but high dose of dexamethasone (0.2 to 0.3 mg/kg IV) early in the recumbent period has been advocated by some clinicians, based on clinical experience, to control and contain inflammatory neuropathy resulting from trauma or pressure. Because of the abortive effect of the treatment, this therapy in pregnant cows must be discussed with the animal owner.

Fluid and Electrolyte Therapy

Fluid and electrolyte therapy orally and if necessary parenterally is indicated in patients with inadequate water and feed intake. Multiple electrolytes can be added to the drinking water if the cow is drinking normally. The supplementation of minerals such as phosphates, magnesium, or potassium has been advocated, but they have been used without consistent success.

Oral fluid therapy by drenching is an effective way to maintain hydration in an alert animal. For a recumbent cow, drenching should only be considered in alert cows with a good swallowing reflex. Because the pressure on visceral organs is increased with recumbency, the amount of fluid administered per treatment should not exceed 40 L to prevent the risk of reflux as a result of increased intraruminal pressure.

Bedding and Clinical Care

The most important aspect of treatment is to provide the most comfortable bedding possible and to roll the cow from side to side several times daily to minimize the extent of ischemic damage and para-analgesia that results from prolonged recumbency. With conscientious care and the provision of good bedding, palatable feed, and liberal quantities of water, most cows will attempt to stand with some difficulty and assistance within 24 hours, and most will stand unassisted and normally 1 or 2 days later. A sand or dirt pack is the ideal ground surface to facilitate standing when downer cows attempt to stand. If affected cows are left on a slippery ground surface, they will not make an effort to stand and will become progressively worse. Cows should be milked normally and the udder kept clean by washing with germicide soap before milking, and postmilking teat dips should be applied.

Assisted Lifting to Aid Standing

The clinician and farmer are commonly faced with the questions of whether or not to lift a recumbent cow that has not attempted to stand within a few hours after treatment for milk fever. The guiding principle should be the behavior of the cow. If the cow makes an effort to stand on her own or by some coaxing such as a gentle nudge in the ribs, she should be assisted to stand by ensuring a good nonslip ground surface, providing deep bedding, and lifting up on the tailhead when she attempts to stand. The cow should be rolled from side to side every few hours and encouraged to stand a few times daily.

Several different kinds of **cow-lifting devices** have been used to assist downer cows to stand. Hip lifters, which fit and tighten over the tuber coxae, and body slings such as harnesses are designed to fit around the abdomen and thorax of the animal. These devices can assist a downer cow to stand if she makes some effort on her own. For those cows that make some effort to stand, the hip lifters or slings can be applied and the animal lifted to the standing position. If the animal bears weight on all four legs, she should be allowed to stand with the aid of the device for 20 to 30 minutes and then lowered down. This procedure can be repeated once or twice a day, provided the cow is able to support her own weight while standing. In most cases, such downer cows will stand on their own within a few days. While the cow is in the standing position, she can be milked, and other clinical examinations can be carried out.

The hip lifters can result in traumatic injuries to the tissues surrounding the tuber coxae if not used judiciously. Cows carrying their own weight after being lifted must not under any circumstances be left unattended while hoisted with the hip lifter because they could lose strength and hang in the device, which could result in severe trauma. Animals that make no effort to stand and bear weight on their own must not be left suspended in the lifter for more than a few minutes but lowered immediately. If the hip lifters are not applied carefully, the animal may slip out of the device while it is being lifted, which commonly results in tissue injury around the tuber coxae; fractures of the coxae have even occurred. These injuries are often unnoticed clinically, but contribute to persistent recumbency. Lifting devices must be used carefully by experienced personnel.

Body slings that fit around the abdomen and thorax of the animal are more suitable to lift down cows that will not readily bear weight after being hoisted, because they distribute the weight over several sites in contrast to the hip lifters, which concentrate the weight over the tuber coxae. However, the body slings are cumbersome to apply to a recumbent animal, and they require more time and experienced personnel to ensure proper application. When the slings are applied properly, they do appear to allow the lifted animal to stand comfortably for 30 minutes or more and promote recovery.

Lifting cows that make no effort to stand on their own is usually unsuccessful. When lifted, they usually do not bear any significant weight.

More recently, water flotation tanks have been used for the management of nonambulatory cows.[3] Proposed devices consist of a watertight metal tub with inside dimensions of approximately 234 cm long, 109 cm wide, and 130 cm high. The system can be mobile, and although the use is labor intensive, it can give good results when selecting suitable patients judiciously.[3] Depending on the system used the downer cow is either pulled into the tub on a mat and the ends of the tub closed to make a water-tight container with an open top like a bathtub or is fitted with a harness and lifted into the tub already filled with warm water. With the cow's head held up by a halter, the tub is filled with water at 37°C to 38°C (100°F to 102°F) as quickly as

possible. Cows in lateral recumbency will roll into sternal recumbency when 40 to 50 cm of water are in the tub and will usually attempt to stand when the tub is one-half to two-thirds full. Cows are allowed to stand in the water for 6 to 8 hours, in some cases up to 24 hours. If the water temperature falls below 35° C (95°F), more hot water is added. When the decision is made to remove the cow, the water is drained and the end of the tub opened, or the cow is hoisted out of the tub on a sling. A recent retrospective study including 51 recumbent patients of a veterinary teaching hospital treated with flotation tank reported a success rate of this therapy of 37%.[3] The success rate could be higher if the selection of cases for flotation is more rigorous. Cows with ruptured tendons, fractures, luxated coxofemoral joints, septic polyarthritis, and other physical injuries of the musculoskeletal system are not good candidates for flotation. The most suitable case for flotation would appear to be the downer cow as a sequel to milk fever.

Handling, Transportation, and Disposition of Nonambulatory Cattle

There has been considerable controversy and disparity among veterinarians and livestock producers about the handling, transportation, and disposition of nonambulatory cattle. Economics has a major influence on decision making in these cases. There has been no common understanding of whether or not they are fit for transportation and which ones are fit for slaughter for salvage. When the owner and veterinarian are faced with a downer cow that is valuable and the cause of the recumbency is uncertain, the tendency is to either attempt to provide treatment for several days and assess the progress or consider slaughter for salvage. In the case of valuable breeding animals that are recumbent as a complication of milk fever, or a disease such as acute carbohydrate engorgement or peracute mastitis, supportive and specific therapies are commonly selected. In the case of downer cattle of commercial value, slaughter for salvage has been a common option. Cattle producers would like to obtain as much financial return as possible by slaughter for salvage. Cattle affected with complications of milk fever, traumatic injuries of the musculoskeletal system, and other diseases not associated with toxemia or septicemia are commonly submitted to slaughter for salvage. Transportation of these compromised animals has always been an animal welfare issue because of the difficulty of loading them humanely because of their size. The mere act of lifting, pulling, dragging, or by other means forcefully loading an animal weighing 500 to 800 kg onto a truck cannot be done without considerable pain and discomfort to the animal. However, beginning in the 1990s, worldwide concern emerged from the public about the handling and disposition of nonambulatory animals, particularly downer cows, regardless of the cause of their recumbency. Government animal health regulatory agencies, livestock associations, and veterinary associations began drafting regulations on the care and handling of nonambulatory recumbent animals such as the downer cow.

Downer-cow syndrome is an animal welfare issue, and the veterinarian should be proactive about the problem. Society is concerned about how downer animals are cared for and handled and the methods used for their disposition. If recovery does not occur within a few days, the prognosis is uncertain; the owner and veterinarian must decide whether to continue providing clinical care to the downer cow or whether the animal should be euthanized.

Euthanasia

The quality of care provided to a recumbent cow can easily become an issue of animal welfare, and humane euthanasia should always be considered, particularly in cases with poor prognosis or when the attending veterinarian can foresee that adequate supportive care cannot or will not be provided for whatever reason. Suggested "trigger points" for euthanasia suggested in the literature include the following:[10]

- Conditions with poor prognosis
- Pain and suffering that is unresponsive to treatment
- Anorexia over several days
- Nonalert downer cows not responding to treatment in due time
- Cows unable to maintain sternal recumbency
- Owner unable or unwilling to provide adequate care
- Complications such as pressure sore, mastitis, or other condition
- Deterioration despite adequate patient care
- Unresponsive to treatment for over 10 days

TREATMENT AND CONTROL

Treatment of primary cause as indicated

Supportive care

Move cow off concrete floor onto soft bedding (R-1)

Oral fluid therapy in dehydrated or anorectic cows (R-1)

Roll recumbent cow from one side to the other q4-8h (R-1)

NSAIDs (at label dose with label treatment interval) (R-2)

Dexamethasone (0.2 to 0.3 mg/kg IV as a single dose) (R-2)

Hoist cows that make attempts to stand (R-2)

Control

Close monitoring of periparturient cows for signs of milk fever (R-1)

Immediate and adequate treatment of cows with milk fever (R-1)

Provide comfortable calving area with soft bedding and nonslippery flooring (R-1)

Avoid moving pregnant cows too late to calving area (R-2)

Avoid moving fresh cows too early out of calving pen (R-2)

CONTROL

The early detection and treatment of milk fever will reduce the incidence and severity of downer-cow syndrome. Under ideal conditions, cows should be treated during the first stage of milk fever before they become recumbent. Once recumbent, cows should be treated as soon as possible and not delayed for more than 1 hour. Cows with milk fever should be well bedded with liberal quantities of straw or moved to a soft-ground surface. Recumbent cows should be coaxed and assisted to stand if possible after treatment for milk fever. If they are unable to stand, they should be rolled from one side to the other every few hours if possible. It is usually difficult to get owners to comply with this recommendation, but frequent rolling from side to side is necessary to minimize the ischemic necrosis. Dairy cows should be placed in a comfortable, well bedded box stall before calving and should be left in that box stall until at least 48 hours after partition in the event that milk fever develops.

HYPOMAGNESEMIC TETANIES

Tetany associated with a marked decrease in serum magnesium concentration is a common occurrence in ruminants. The syndrome associated with hypomagnesemia is relatively constant, irrespective of the cause, but the group of diseases in which it occurs has been divided into three groups:

- hypomagnesemic tetany of calves, which appears to result specifically from a deficiency of magnesium in the diet transport tetany
- a group of hypomagnesemias in ruminants characterized by lactation tetany, in which there may be a partial dietary deficiency of magnesium but in which nutritional or metabolic factors reduce the availability, or increase the body's loss, of the element so that serum magnesium levels fall below a critical point.

In general, the occurrence of hypomagnesemic tetany is related to three sets of circumstances. Most common is the occurrence in lactating cows turned out onto lush, grass-dominant pasture in the spring after wintering in closed housing—the classic lactation or grass tetany of Holland. Wheat pasture poisoning may occur when cattle or sheep are grazed on young, green cereal crops. The third occurrence is in beef or dry dairy cattle running at pasture in the winter, usually when nutrition is inadequate and where no shelter is provided in changeable weather rather than in severe, prolonged cold. Less common forms occur in housed animals on poor feed. Hypomagnesemia of sheep, although less common, occurs in the same general groups of circumstances as the disease in cattle. A chronic hypomagnesemia, without manifestations of tetany, can be a cause of suboptimal production efficiency and may predispose to hypocalcemia.

HYPOMAGNESEMIC TETANY (LACTATION TETANY, GRASS TETANY, GRASS STAGGERS, WHEAT PASTURE POISONING)

SYNOPSIS

Etiology The etiology is multifactorial, related to magnesium concentration in the diet and the presence of competing cations such as potassium and sodium that affect either herbage magnesium status or magnesium absorption.

Epidemiology Disease of all classes of ruminants, but reaches its highest incidence in older lactating cows exposed to bad weather or grazing green cereal crops or lush grass-dominant pasture.

Clinical findings Incoordination, hyperesthesia and tetany, tonic–clonic muscular spasms and convulsions. High case fatality without treatment.

Clinical pathology Serum, urine, vitreous humor, or cerebrospinal fluid (CSF) magnesium concentrations. Hypomagnesemia, and in some circumstances hypocalcemia.

Necropsy findings None specific.

Diagnostic confirmation Response to treatment, serum or urinary magnesium concentrations.

Treatment Magnesium or combined calcium/magnesium solutions administered IV or SC.

Control Magnesium supplementation, but a palatable and practical delivery method is a problem. Magnesium applied to pastures. Avoidance of movement and food deprivation at risk periods.

ETIOLOGY

Magnesium is the major **intracellular divalent cation** and is an essential element in a large number of enzymatic activities in the body. For this reason, it might be expected that hypomagnesemia would be rare. However, because of the peculiarities of absorption of magnesium in the ruminant forestomaches, and the use of animal and pasture management systems that can lead to marginal magnesium uptake, ruminants are at risk of hypomagnesemia.

Magnesium Homeostasis

There is **no feedback regulatory mechanism** to control concentrations of magnesium in the body of ruminants. As a consequence, magnesium concentrations in blood and extracellular fluid are essentially determined by the balance between dietary intake of magnesium, loss in feces and milk, and the modulating effect of magnesium **homeostasis by the kidney**.

Dietary Intake

In normal circumstances, magnesium absorbed from the diet is sufficient to meet the requirements of the body, and excess amounts are excreted in the urine.

Renal Excretion

The kidney is the major organ of homeostasis and can act to conserve magnesium. Magnesium is freely filtered across the renal glomerulus and is reabsorbed within the renal tubules, the degree of reabsorption acting in homeostasis. The endogenous daily urinary loss is typically 3 mg/kg BW, equivalent to 1.8 g/day for a 600-kg cow. When the dietary intake of magnesium is decreased, blood and interstitial fluid magnesium concentrations fall; excretion of magnesium in the urine will cease when **serum concentrations fall below 1.8 mg/dL**. The renal threshold for magnesium excretion is partially under the control of parathyroid hormone, and increased plasma concentrations of parathyroid hormone will act to conserve magnesium.

Magnesium Reserves

There are large stores of magnesium in the body, especially in bone. These are available to the young calf, but mobilization rate decreases with age, and in the adult ruminant there is little mobilization in response to short-term deficits of magnesium. In ruminants, this control mechanism for magnesium can maintain adequate concentrations of magnesium in bodily fluids in most production circumstances, but it can fail where there is a high requirement for magnesium coupled with a decreased intake. This combination leads to hypomagnesemia, and hypomagnesemic tetany is a possible outcome.

Lactation

Increased requirement for magnesium is almost always associated with the loss of magnesium in the milk during lactation. Whereas the amount of magnesium in milk is not high (14 mg/kg BW), the loss of magnesium to milk in high-producing animals (4.2 g of magnesium in 30 L of milk) represents a significant proportion of the dietary intake of magnesium. As a consequence of this drain, most instances of hypomagnesemia occur in lactating animals around the period of peak milk production, although in some circumstances the demands of late pregnancy are the cause of the increased requirement. The decreased intake of magnesium can result from an absolute deficiency of magnesium in the diet or because the availability or absorption of magnesium from the diet is impaired. These factors determine the circumstances of occurrence of the disease and are the **factors that can be manipulated for control**.

Factors Influencing Absorption of Magnesium

In the adult ruminant, magnesium absorption occurs in the forestomach with little absorption in the abomasum and small intestine. Some absorption occurs in the large intestine, particularly in sheep; however, it cannot compensate for malabsorption in the forestomach. Magnesium is absorbed from the small intestine of calves, lambs, and kids, but this ability appears to be lost when these animals become ruminants.

Na:K Ratio in Rumen

Magnesium is transported across the epithelium of the forestomaches by an active sodium-linked ATPase-dependent transport system. Absorption, and the serum magnesium concentration, is influenced by the

Na:K ratio in the rumen, which is determined by the dietary and salivary concentrations of sodium and potassium. Absorption of magnesium increases with an increasing Na:K ratio to plateau at a ratio of 5:1. Absorption is significantly impaired if the Na:K ratio is less than 3:1.

Young, rapidly growing grass that is low in sodium and high in potassium can result in **sodium deficiency** in grazing ruminants and can significantly depress the Na:K ratio in the rumen fluid, causing impaired magnesium absorption. Depression is observed at dietary potassium concentrations of greater than 22 g/kg dry matter.

Saliva normally has a high Na:K ratio, but where there is a deficit of sodium in the diet, a proportion of sodium in saliva may be replaced with potassium under the influence of aldosterone, which further negatively influences the uptake of magnesium.

Approximately 40% of the total magnesium available in extracellular fluid is secreted daily in saliva, and 20% of this is reabsorbed in the forestomach. When animals are on tetany-prone grass, forestomach absorption is impaired, which accounts for the susceptibility of ruminants to hypomagnesemia compared with monogastric animals.

Other Factors Influencing Absorption

Young grass fertilized with nitrogenous fertilizers has an increased crude protein content, which is readily fermentable and leads to increased ammonia concentrations. A sudden rise in ruminal concentrations of ammonia impairs magnesium absorption in the rumen. The uptake of magnesium is also influenced by the carbohydrate content of the diet; magnesium absorption is improved with increasing amounts of readily degradable carbohydrates. The mechanism of this action is not known, but low concentrations of readily degradable carbohydrate in tetany-prone pastures in combination with high concentrations of protein may be important to the occurrence of the syndrome. Volatile fatty acids provide the energy for the active transport of magnesium across the rumen wall and increase magnesium absorption.

Ruminal pH is thought to affect absorption efficiency by influencing magnesium solubility, which decreases markedly as ruminal pH increases above 6.5. Magnesium binders, such as fats, can form insoluble magnesium salts. Other dietary substances have been proposed to influence the absorption of magnesium, including calcium and phosphorus, organic acids such as citric acid and transaconitate, fatty acids, and aluminum, but the significance of their role is controversial.

Magnesium in Pastures and Tetany Hazard

The dietary intake of magnesium in grazing animals is directly related to the magnesium concentration in pastures, but other elements in pastures also influence magnesium absorption by the ruminant, as detailed earlier.

Required Magnesium Concentrations

Hypomagnesemia can result from the ingestion of pastures that have insufficient magnesium to meet dietary requirements. The estimated magnesium concentration in pasture required to meet the dietary requirement for pregnant or lactating cattle varies from 1.0 to 1.3 g/kg dry matter (DM) for pregnant cattle, depending on the stage of pregnancy, and from 1.8 to 2.2 g/kg DM for lactating cattle, with both estimates assuming minimal interference of absorption by other elements in the pasture.

The recommended minimal "safe" concentration of magnesium in pastures is 2 g/kg DM for lactating and pregnant cattle, with a preference for a concentration of 2.5 g/kg DM.

Magnesium Availability in Pastures and Hazard

Hypomagnesemia can also occur in animals grazing pastures with adequate concentrations of magnesium but that contain high concentrations of potassium and nitrogen, which, as detailed earlier, impair absorption of magnesium in the rumen. Pastures with concentrations of **potassium** of greater than 30 g K/kg DM and **nitrogen** greater than 40 g N/kg dry matter are considered hazardous.

An alternate method for estimating the potential **hazard of a pasture** is to calculate the **K/(Ca + Mg) ratio** using milliequivalent (mEq) values for this estimate. Pastures with ratios above 2.2 are considered a risk.

Winter Hypomagnesemia

The occurrence of hypomagnesemia is not restricted to cattle grazing lush pastures; it can also occur during winter. In **housed lactating dairy** cattle being fed conserved feeds, hypomagnesemia probably has the same genesis as that in grazing cattle, being associated with a high lactational drain of magnesium in combination with the feeding of conserved feeds prepared from pastures with marginal magnesium concentrations. Hypomagnesemia also occurs in **cattle outwintered** on poor-quality feed.

Hypomagnesemia and Hypocalcemia

In some outbreaks of hypomagnesemic tetany, there is also hypocalcemia, and although it is of less severe degree than in parturient paresis, there is increasing evidence that the actual onset of clinical tetany may be associated with a rapid fall in serum calcium levels superimposed on a preexisting hypomagnesemia. This is particularly true for wheat pasture poisoning but can also apply to outbreaks with different predisposing factors.

Chronic hypomagnesemia can have a profound effect on calcium homeostasis. Hypomagnesemia reduces the production and secretion of parathyroid hormone, reduces hydroxylation of vitamin D in the liver, and also causes target-organ insensitivity to the physiologic effects of parathyroid hormone and 1,25-dihydroxyvitamin D_3. Chronic subclinical hypomagnesemia can increase susceptibility to milk fever and can predispose to episodes of **milk fever and downer cows in lactating dairy cows** during the period of peak lactation.

Summary of Etiology

In summary, it appears that a number of factors are capable of causing hypomagnesemia in ruminants and that under particular circumstances one or other of them may be of major importance.

In lactation tetany of cows and ewes turned out onto lush pasture in the spring, a primary dietary deficiency of magnesium or the presence of high relative concentrations of potassium and nitrogen in the diet reduces the absorption of magnesium and possibly calcium.

In wheat (cereal) pasture poisoning, the ingestion of abnormally large amounts of potassium and low levels of calcium in the diet leads to hypomagnesemia and also hypocalcemia.

Hypomagnesemic tetany in cattle wintered at pasture and exposed to inclement weather is associated with low magnesium intake and inadequate caloric intake, and possibly to the resultant hyperactivity of the thyroid gland.

Although the suggestions as to the most important etiologic factors in each set of circumstances in which lactation tetany occurs may be valid, undoubtedly **combinations** of these and other factors have etiologic significance in individual outbreaks of the disease. The **worst combination** of causative factors, and the most common circumstances in which the disease occurs, is inadequate energy intake with a low dietary content of magnesium (grass pasture) in recently calved cows during a spell of cold, wet, and especially windy weather.

One other important factor is the **variation between individual animals in susceptibility** to hypomagnesemia and to the clinical disease. These variations are quite marked in cattle, and in intensively managed, high-producing herds it is probably worthwhile to identify susceptible animals and give them special treatment.

EPIDEMIOLOGY

Occurrence and Risk Factors for Lactation Tetany

Lactation tetany in dairy and beef cattle turned out to graze on lush, grass-dominant pasture after winter housing is common in northern Europe, the United Kingdom, and the northern parts of North America. Grass tetany also occurs in Australia and New Zealand, where the cows are not housed in winter but have access to a phenomenal flush

of pasture growth in the spring. This also commonly occurs in beef cattle in all countries.

With housed cattle, or cattle fed conserved feed during the winter, most cases occur during the first 2 weeks after the cattle are turned out to **spring pasture**. Pasture that has been heavily top dressed with fertilizers rich in nitrogen and potash is potentially the most dangerous. The disease may also occur on this type of pasture even when the cattle have wintered on pasture in temperate regions. In regions where there is an autumn flush of pasture, a high incidence of hypomagnesemic tetany may occur in the **autumn** or early winter.

Cattle in the **first 2 months of lactation** and **4 to 7 years of age** are most susceptible, which probably reflects an increased risk because of a higher loss of magnesium in milk. **Friesian** cows have lower magnesium concentrations than Jerseys grazed under the same conditions.

In the northern parts of the United States, outbreaks commonly occur during periods of **low barometric pressure** when the **ambient temperature** ranges between 7°C (45°F) and 16°C (60°F) and **soil temperatures** are below 7°C (45°F). Outbreaks may be precipitated by inclement weather. In beef cattle there is commonly a history of poor nutrition and falling body condition in the past few weeks as a result of diminishing hay supplies.

Occurrence and Risk Factors for Wheat (Cereal) Pasture Poisoning

Wheat pasture poisoning is a misnomer because it can occur with grazing of any small-grain cereal pasture. It has been recorded in many countries, but it is most prevalent where **young cereal crops** are utilized for winter grazing. The southwestern United States has experienced heavy losses of cattle caused by this disease. This pasture can induce hypomagnesemia in **pregnant and lactating cattle and sheep**. The risk is with young, rapidly growing pasture, either in the **spring** or in the **autumn and winter** with pastures planted in late summer. The pasture is usually dangerous for only a few weeks, but heavy losses may occur in all classes of sheep and cattle. *Bos taurus* breeds are more susceptible to the development of hypomagnesemia than *Bos indicus*.

Occurrence and Risk Factors for Winter Hypomagnesemia

Hypomagnesemic tetany in cattle wintered in the open causes some losses in the United Kingdom, New Zealand, southern Australia, and the east-central states and Pacific slope of the United States. It occurs in cattle grazed on pasture in the winter with **minimal supplemental hay** and in cattle grazed on **aftermath crops** and corn stover. The disease occurs in regions with temperate climates, and risk is increased by **exposure to bad weather**, which is exacerbated by absence of trees or other **shelter** in fields and by failure to supply supplementary feed during these cold spells. The disease does not seem to occur in cattle kept outside in prolonged winters where environmental temperature is consistently very low and there is adequate feed. Hypomagnesemia, commonly presenting as chronic hypomagnesemia and sudden death, has been recognized as occurring in housed cattle in the winter in Europe for many years and recently has also been reported in the United States.

Morbidity and Mortality

In all of these forms of the disease, the morbidity rate is highly variable, reaching as high as 12% in individual herds and up to 2% in particular areas. The incidence varies from year to year depending largely on climatic conditions and management practices, and the disease is often limited in its occurrence to particular farms and even to individual fields.

Although an effective treatment is available, the **case-fatality rate is high** because of the short course. Because animals die before they are observed to be ill, there are not accurate figures on case fatality, but it is probably of the order of 30% in dairy cattle and considerably higher in beef cattle.

There have been few epidemiologic studies specifically addressing the importance of the syndrome. In Finland, a **lactational incidence** varying between 0.1% and 0.3% has been recorded, with an **increase in parity** to at least six for lactation tetany occurring on pasture but not for indoor tetany. No association with other diseases was found other than for milk fever. In Northern Ireland, approximately 10% of dairy cows and 30% of beef cows have subnormal or deficient blood magnesium concentrations during the grazing season, and hypomagnesemia is considered the cause of 20% of the sudden-death mortality in beef cattle. Surveys of beef cattle owners of the relative importance of different diseases invariably rate hypomagnesemia high in importance.

Pasture Risk Factors

In most areas of the world, there is a strong association between risk for hypomagnesemia and systems of pasture improvement and pasture fertilization to increase forage yield. There are a number of influences on the concentration of magnesium and other elements in pasture.

Pasture Species

Hypomagnesemia is a problem on grass-dominant pastures. Concentrations of calcium and magnesium are higher in legumes and forbs than in grasses. Within the grasses, different genotypes of the same species can differ markedly in calcium and magnesium concentrations, and most **cool-season grasses** have the potential to produce hypomagnesemia. However, there are some differences, and grasses with a high ratio of potassium to calcium and magnesium (e.g., *Dactylis glomerata*, *Lolium perenne*, *Phalaris arundinacea*) are more likely to cause grass tetany than those with low ratios (e.g., *Bromus inermis*, *Poa pratensis*, *Agrostis* spp.). On soil types where the disease is common, cool-season grass pastures top dressed with **nitrogenous fertilizers** are dangerous, and their toxicity may be increased by the **application of potash**. **Warm-season grasses** do not have the same risk, and grass tetany is not a problem in cattle grazing tropical grasses.

Cereal Pastures

The greater tendency of cereal grazing to cause hypomagnesemia is related to a high content of potassium and a low content of magnesium. The tetany hazard, in order of decreasing hazard, is wheat, oats, barley, rye.

Season

High concentrations of potassium and nitrogen and low concentrations of sodium and soluble carbohydrates occur in pastures during the early growing season and during rapid growth following cold, wet periods. Pasture magnesium concentrations may not be depressed, but the K/(Ca + Mg) ratio is increased.

Fertilization

Application of potash and nitrogenous fertilizers to pastures will decrease the concentration of calcium and magnesium in plants and will also increase the concentration of potassium and nitrogen. There is some evidence that nitrate sources of nitrogen depress magnesium less than ammonium sources of nitrogen.

Soil Type

The availability of magnesium to the plant is influenced by soil type, and some deficiencies in plant magnesium can be corrected by soil fertilization with magnesium. There is no strong association with any one soil type, but high potassium concentrations are consistently associated with increased risk for tetany.

Highly leached, acid, sandy soils are particularly magnesium deficient and the most likely to respond to liming and magnesium fertilization. In very acidic soils, high aluminum concentrations may depress magnesium uptake by plants.

A local knowledge of soil type and its influence on magnesium, potassium, calcium, and nitrogen uptake by pastures can allow the judicious selection or avoidance of the use of pastures for at-risk groups during periods of risk for hypomagnesemia.

Animal and Management Risk Factors

Dry Matter Intake

The dry matter and energy intake of ruminants can influence susceptibility to

hypomagnesemia. A reduction in dry matter intake must reduce the magnesium intake; in situations where hypomagnesemia is already present, a further depression of serum magnesium levels can be anticipated when complete or partial starvation occurs. An insufficient intake of **fiber** in the winter months can precipitate hypomagnesemia in pastured cows and ewes, and lipolysis is accompanied by a fall in serum magnesium.

Period of Food Deprivation

Many outbreaks of hypomagnesemia are preceded by an episode of stress or temporary starvation. Whether chronic hypomagnesemia preexists or not, a period of starvation in lactating cows and ewes is sufficient to produce a marked hypomagnesemia, and the fall may be sufficiently great to cause clinical tetany. A period of **bad weather, yarding, transport, or movement** to new pastures or the introduction to **unpalatable pastures** may provide such a period of partial starvation.

Alimentary Sojourn

Diarrhea is commonly associated with lactation tetany on spring pasture and, by decreasing the alimentary sojourn, may also reduce magnesium absorption.

Climate

A close association between climatic conditions and serum magnesium levels has also been observed. Reduced levels occur in adult cattle and sheep exposed to cold, wet, windy weather with little sunshine and no access to shelter or supplementary feed. Supplementary feeding appears to reduce the effect of inclement weather on serum magnesium levels, and it is possible that failure to eat, or depression of appetite, and a negative energy balance during bad weather may be a basic contributing cause to hypomagnesemia in these circumstances.

Animal Movement

Epinephrine release will result in a precipitous fall in serum magnesium, and this may explain the common observation that clinical cases are often precipitated by excitement or movement of the herd.

Intensive Dairies

Intensive dairies that apply effluent on a limited land base can build soil potassium to high concentrations. Silage from these grounds can have a high risk for inducing hypomagnesemia.

Hypomagnesemia in Sheep

Hypomagnesemia occurs in sheep, particularly in Australia and the United Kingdom. The disease is not common, but it appears to be increasingly associated with pasture improvement practices, and it can cause heavy losses in individual flocks. It is more common in ewes bred for milk and lamb production. In outbreaks, **ewes with twins** are more liable to develop clinical disease than those with singles, and the main occurrence is in ewes **1 to 4 weeks after lambing,** with cases up to 8 weeks after lambing.

Disease is often precipitated by a **management procedure** involving movement and temporary food deprivation, and cases will occur within the first 24 hours following this and for a few days afterward. As in cattle, disease occurs when ewes are placed on lush grass pastures, but it is especially common where ewes in early lactation are placed on young cereal pastures. Losses usually cease when the flock is moved onto rough, unimproved pasture.

Cases also occur in sheep that are exposed to inclement weather when on low nutritive intake. Simultaneous hypomagnesemia and ketosis can occur in ewes after lambing if they are exposed to low feed availability. These cases do not respond well to treatment. Hypomagnesemia in ewes is predisposed by **prior pregnancy toxemia** in the flock.

PATHOGENESIS

Most evidence points to hypomagnesemia as the cause of the tetanic signs observed, but the concurrent hypocalcemia may have a contributory effect and in many instances may even be the dominant factor. Most clinical cases of the disease have serum magnesium concentrations below 1 mg/dL (0.4 mmol/L) compared with the reference range in cattle of 1.7 to 3.0 mg/dL (0.7 to 1.2 mmol/L), and there is a striking relationship between the incidence of the clinical disease and the occurrence of a seasonal hypomagnesemia.

The reduction in serum concentrations of magnesium is concurrent with a marked fall in the excretion of magnesium in the urine. In affected herds and flocks, many clinically normal cows and sheep have low serum magnesium concentrations. In some of these circumstances a concurrent hypocalcemia may be the precipitating cause.

Magnesium has many influences on impulse transmission in the neuromuscular system, including effects on the release of acetylcholine, on the sensitivity of the motor end plate, on the threshold of the muscle membrane, and on activation of the cholinesterase system. These offer an attractive hypothesis for the muscular irritability seen with the disease. However, it has also been established that magnesium concentrations in the cerebrospinal fluid (CSF) are more predictive of clinical disease than those in serum, which would indicate that alterations in central nervous system (CNS) function are more important than alterations in peripheral nerve function. It is also evident that CSF concentrations of magnesium in hypomagnesemic animals rise significantly after treatment with a magnesium salt. The need for this to happen would explain the delay of about 30 minutes after an IV injection before recovery occurs, because CSF volume turns over at approximately 1% per minute.

CLINICAL FINDINGS

For convenience, lactation tetany is described in acute, subacute, and chronic forms.

Acute Lactation Tetany

In acute lactation tetany, the animal may be grazing at the time and suddenly cease to graze, adopt a posture of **unusual alertness,** and appear uncomfortable; twitching of the muscles and ears is also evident. There is severe **hyperesthesia,** and slight disturbances precipitate attacks of continuous bellowing, frenzied galloping, and occasionally aggression. The gait becomes **staggering,** and the animal falls, with obvious tetany of the limbs, which is rapidly followed by **clonic convulsions** lasting for about a minute. During the convulsive episodes the following characteristics are common:

- Opisthotonos
- Nystagmus
- Champing of the jaws
- Frothing at the mouth
- Pricking of the ears
- Retraction of the eyelids

Between episodes, the animal lies quietly, but a sudden noise or touch may precipitate another attack.

The temperature rises to 40.0 to 40.5°C (104 to 105°F) after severe muscle exertion; the pulse and respiratory rates are also high. The absolute intensity of the heart sounds is increased so that they can be heard some distance away from the cow. Death usually occurs within 5 to 60 minutes, and the mortality rate is high because many die before treatment can be provided. The response to treatment is generally good if the animal is treated early.

Subacute Lactation Tetany

In subacute lactation tetany, the onset is more gradual. Over a period of 3 to 4 days, there is slight inappetence, **wildness of the facial expression,** and **exaggerated limb movements**. The cow often resists being driven and throws her head about as though expecting a blow. **Spasmodic urination** and frequent defecation are characteristic. The appetite and milk yield are diminished, and ruminal movements decrease. **Muscle tremor** and mild tetany of the hindlegs and tail with an unsteady, straddling gait may be accompanied by retraction of the head and trismus. Sudden movement or noise, the application of restraint, or the insertion of a needle may precipitate a violent convulsion.

Animals with this form of the disease may recover spontaneously within a few days or progress to a stage of recumbency with a similar but rather milder syndrome than in the acute form. Treatment is usually effective, but there is a marked tendency to relapse.

Chronic Hypomagnesemia

Many animals in affected herds have low serum magnesium levels but do not show clinical signs. There may be sudden death. A few animals exhibit a rather vague syndrome that includes dullness, unthriftiness, and indifferent appetite and may subsequently develop one of the more obvious syndromes. In lactating cows, this may be the development of paresis and a milk-fever-like syndrome that is poorly responsive to calcium treatment. Depressed milk production has also been attributed to chronic hypomagnesemia in dairy herds in New Zealand. The chronic type may also occur in animals that recover from the subacute form of the disease.

Parturient Paresis With Hypomagnesemia

This syndrome is described in the discussion of parturient paresis and consists of paresis and circulatory collapse in an adult cow that has calved within the preceding 48 hours but in which dullness and flaccidity are replaced by hyperesthesia and tetany.

CLINICAL PATHOLOGY

Serum or urinary magnesium concentrations can be used for clinical cases. Where an animal is dead and hypomagnesemia is suspect, a presumptive diagnosis can be made from samples taken from other at-risk animals in the group or from the **vitreous humor** of the dead animal. An acute-phase inflammatory response with leukocytosis and increased numbers of neutrophils and monocytes has been recorded in ruminants and laboratory animals fed magnesium-deficient diets.

Serum Magnesium Concentrations

Normal serum magnesium concentrations are 1.7 to 3.0 mg/dL (0.70 to 1.23 mmol/L). These levels in cattle are often reduced in seasonal subclinical hypomagnesemia to between 1 and 2 mg/dL (0.41 and 0.82 mmol/L), but risk for tetany is not present until the level falls to below 1.2 mg/dL (0.49 mmol/L).

The average concentration at which signs occur is approximately 0.5 mg/dL (0.21 mmol/L), and in sheep it is suggested that clinical tetany does not occur until the serum magnesium concentration is below 0.5 mg/dL (0.21 mmol/L).

Serum magnesium concentration in some animals may fall to as low as 0.4 mg/dL (0.16 mmol/L) without clinical illness. This may be a result of individual animal variation in the degree of ionization of the serum magnesium and in the difference between serum and CSF concentrations. A transitory elevation of serum magnesium concentration occurs after violent muscular exercise in cattle with clinical signs of hypomagnesemia.

Total serum calcium concentrations are often reduced to 5 to 8 mg/dL (1.25 to 2.00 mmol/L), and this may have an important bearing on the development of clinical signs. Serum inorganic phosphate concentrations may or may not be low.

In wheat pasture poisoning of cattle there is hypomagnesemia, hypocalcemia, and hyperkalemia. In acute tetany, serum potassium concentrations are usually dangerously high and may contribute to the high death rate.

Magnesium Concentrations in Cerebrospinal Fluid

Magnesium concentrations in CSF can be used as a diagnostic procedure, but CSF is not easily or safely collected in tetany cases. CSF collected up to 12 hours after death can be used diagnostically.

Magnesium concentrations in CSF of 1.25 mg/dL (0.51 mmol/L) were found in tetanic cows with hypomagnesemia (serum magnesium concentrations of 0.54 ± 0.41 mg/dL; 0.22 ± 0.17 mmol/L). In clinically normal cows with hypomagnesemia, comparable concentrations in CSF were 1.84 mg/dL (0.74 mmol/L) and 0.4 mg/dL (0.16 mmol/L) in serum. In normal animals CSF concentrations are the same as in plasma, that is, 2.0 mg/dL (0.82 mmol/L) and up. The magnesium content of ventricular CSF may be quite different from that of lumbar CSF. Ventricular CSF is also more responsive to changes in serum magnesium concentrations and is preferred for diagnosis at necropsy.

Vitreous Humor

Magnesium concentrations in vitreous humor (but not aqueous humor) can be measured because vitreous humor magnesium concentration remains stable for a longer period of time than magnesium concentrations in serum or CSF. In general, vitreous humor magnesium concentrations less than 0.55 mmol/L for cattle and less than 0.65 mmol/L for sheep up to 48 hours after death indicate the presence of hypomagnesemia, particularly at ambient temperatures of 4° C or 20° C.[1]

Vitreous humor is viscous and must be collected using a 14-gauge (preferably) or 16-gauge needle attached to a syringe. With the deceased animal placed in sternal recumbency, the needle is introduced vertically from a position caudal to the dorsal limbus of the eye parallel and caudal to the lens before aspiration (Fig. 17-5). The needle position should be altered to facilitate aspiration.[1] The aspirated sample should be placed in a plain tube and centrifuged, and the supernatant should be submitted for determination of the magnesium concentration. Aqueous humor should not be collected for analysis because it is readily contaminated by degenerating iris tissue and evaporation of free water across the cornea.

Urine Magnesium Concentrations

The occurrence of low urine magnesium levels is good presumptive evidence of hypomagnesemia; however, it is not the most sensitive test. Normalization of urine magnesium to simultaneously determine urine creatinine concentration will adjust urine magnesium concentration for animal-to-animal variability in urine concentration.[2] Further adjustment by calculating the fraction clearance of magnesium (requiring simultaneous determination of plasma/serum magnesium and creatinine concentrations) has not been shown to provide additional information beyond that provided by the concentration of urinary magnesium to creatinine alone.

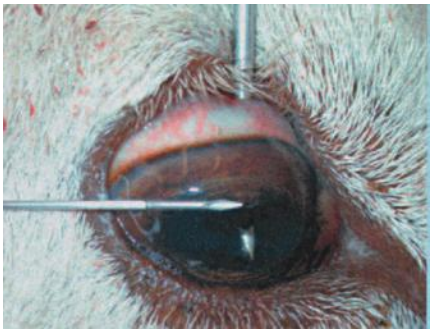

Fig. 17-5 Vitreous humor is sampled from a recently deceased animal by inserting a 14-gauge needle perpendicular and caudal to the limbus. The needle tip can be observed through the pupil. Aqueous humor is obtained by inserting a 21-gauge needle horizontally rostral to the limbus and into the anterior chamber. Vitreous humor is required to evaluate magnesium concentrations. (Reproduced, with permission, from Edwards G, Foster A, and Livesey C. *In Practice* 2009; 31:22-25.)

Herd Diagnosis

The kidney is the major organ of homeostasis, and it has been argued that analysis of urine magnesium status is a more accurate method of assessing herd magnesium status than serum magnesium concentrations. The magnesium status of a herd, and the need to supplement the diet to prevent lactation tetany, can be established from the following values:

- serum magnesium concentrations
- urine magnesium concentrations
- urinary magnesium fractional clearance[2]
- creatinine-corrected urinary magnesium concentrations

Laboratory charges for urinary magnesium fractional clearance ratios are expensive. The determination of the **creatinine-corrected urinary magnesium concentration** from 10 cows in a herd has been found to be a more sensitive indicator of magnesium status of the herd than estimates from serum, and it is a better predictor of response to supplementation. Values of less than 1.0 mmol/L indicate that a positive response to supplementation is likely. **Urine**

magnesium concentrations below 1.0 mg/dL (0.4 mmol/L) indicate a danger for tetany.

NECROPSY FINDINGS

There are **no specific necropsy findings**. Extravasations of blood may be observed in subcutaneous tissues and under the pericardium, endocardium, pleura, peritoneum, and intestinal mucosa. Agonal emphysema may also be present.

The magnesium content of the bovine vitreous humor is considered to be an accurate estimate of magnesium status for 72 hours after death, provided the environmental temperature does not exceed 23° C (73° F) and there is not growth of bacterial contamination after sampling, which can result in a false low magnesium concentration. The addition of a small amount of 4% formaldehyde (3% of the vitreous humor volume) will allow accurate analysis for periods up to 72 hours after sampling.

Concentrations in the aqueous humor are not stable after death.

DIFFERENTIAL DIAGNOSIS

Cattle
- Acute lead poisoning
- Rabies
- Nervous ketosis
- Bovine spongiform encephalopathy

Sheep
- Hypocalcemia
- Phalaris poisoning
- "Stagger" syndromes

TREATMENT

IV administration of preparations containing magnesium or, more commonly, magnesium and calcium are used. The efficiency of the various treatments appears to vary from area to area, and even within areas under different conditions of management and climate. Response rates and recovery rates are much higher in cases treated early in the clinical course. IV chloral hydrate may be administered to reduce the severity of convulsions during treatment with magnesium. Case fatality, even with therapy, can be high, especially in advanced cases.

Combined Calcium/Magnesium Therapy

The safest general recommendation is to use a combined calcium–magnesium preparation (e.g., 500 mL of a solution containing 25% calcium borogluconate and 5% magnesium hypophosphite for cattle, 50 mL for sheep and goats) IV followed by an SC injection of a concentrated solution of a magnesium salt. The details and risks of administration of the type of solution are described in the section on parturient paresis. A combination of 12% magnesium adipate and 5% calcium gluconate at a dose rate of 500 mL is also used.

Magnesium Therapy

When magnesium solutions are used, 200 to 300mL of a 20% solution of magnesium sulfate may be injected **IV**; this is followed by a very rapid rise in serum magnesium concentration, which returns to preinjection levels within 3 to 6 hours. A much slower rise and fall occurs after **SC injection,** and for optimum results the SC injection of 200 mL of a 50% solution of magnesium sulfate has been recommended. A rise in serum magnesium of 0.5 mg/dL (0.21 mmol/L) occurs within a few minutes, and subsequent serum concentrations do not go above 5 mg/dL (2.06 mmol/L). In cases where serum magnesium concentrations are low because of seasonal hypomagnesemia, the injection of magnesium salts is followed by a rise and then a return to the subnormal preinjection levels.

The IV injection of magnesium salts is not without danger. It may induce cardiac dysrhythmia, or medullary depression may be severe enough to cause respiratory failure. If signs of respiratory distress or excessive slowing or increase in heart rate are noticed, the injection should be stopped immediately and, if necessary, a calcium solution injected.

The substitution of magnesium lactate for magnesium sulfate has been recommended to provide a more prolonged elevation of serum magnesium levels. A dilute solution (3.3%) causes minimal tissue injury and can be administered IV or SC. Magnesium gluconate has also been used as a 15% solution at dose rates of 200 to 400 mL. High serum magnesium concentrations are obtained more slowly and are maintained longer with magnesium gluconate than with magnesium sulfate. The feeding of magnesium-rich supplements, as described in the following section on control, is recommended after parenteral treatment.

Provision for Further Cases

The predisposing factors that lead to a case of hypomagnesemia apply to the herd as a whole, and it is probable that further clinical cases will occur before the effects of corrective strategies are observed. In extensive range situations, it is advisable to instruct the owner on how to treat cases because a delay in treatment can markedly increase the rate of treatment failures. SC treatment is within the realm of most, but successful therapy is also recorded by the rectal infusion of 30 g of magnesium chloride in a 100-mL solution; serum concentrations of magnesium return to normal levels within 10 minutes of administration.

CONTROL

Where possible, animals at high risk should be moved to low-risk pastures during the grass tetany season. High-risk pastures can be grazed by low-risk animals, steers, or yearling heifers, for example, during this period.

The occurrence of hypomagnesemia can be corrected by the provision of adequate or increased amounts of magnesium in the diet. A requirement as high as 3.0 g/kg DM diet may be required for lactating cows on spring pasture. The problem is in determining an **adequate delivery system,** and this will vary according to the management system. Thus blocked minerals containing magnesium or foliar dressing of magnesium may be adequate delivery systems where there is a high stocking density of cattle, but they are totally inadequate or economically unfeasible on range with one cow per 20 acres.

Magnesium oxide is commonly used for supplementation, but other magnesium salts can be used, and they have an approximate equivalent availability. The biological **availability** of magnesium from magnesium carbonate, magnesium oxide, and magnesium sulfate for sheep is influenced by particle size, but it has been determined as 43.8%, 50.9%, and 57.6%, respectively.

Feeding of Magnesium Supplements

The preventive measure that is now universally adopted is the feeding of magnesium supplements to cows during the danger period. The feeding of magnesite (containing not less than 87% magnesium oxide), or other sources of **magnesium oxide**, prevents the seasonal fall in serum magnesium concentrations. Daily administration by drenching, or in the feed, of at least 60 g of magnesium oxide per day is recommended to prevent the disease. This is not always completely effective, and in some circumstances large doses may be necessary. Daily feeding of 120 g is safe and effective, but 180 g daily may cause diarrhea. The dose for sheep and goats is 7 g daily or 14 g every second day. Magnesium phosphate (53 g/d) is also a safe and effective way of ensuring a good intake of magnesium. The protection afforded develops within several days of commencing administration and terminates abruptly after administration ceases.

Problems With Palatability

The problem with magnesium supplements is getting the stock to eat the required amount because they are unpalatable. This can be partially countered by mixing the supplement with molasses in equal parts and allowing free access to the mixture or feeding it in ball feeders, but uniform intake by all animals does not occur, and at-risk animals may still develop hypomagnesemic tetany. Similarly, magnesium blocks may have limited efficacy in preventing hypomagnesemia. **Salt blocks** can help repair the sodium deficiency associated with young spring grasses and improve the Na:K ratio in the rumen. If they also contain Mg they can be

an aid in prevention, but usually, by themselves, they do not guarantee freedom from risk for tetany.

Spraying on Hay

One method of attempting to ensure an adequate intake of magnesium is to spray it on hay and to feed this hay as a supplement during periods of grass tetany risk. The common practice is as follows:

1. Mix magnesite with molasses.
2. Dilute mixture with water.
3. Spray mixture onto hay in the windrows when it is being made.
4. Inject mixture into the bales before feeding or spray onto the hay at feeding.
5. Tip bale of hay so that the cut side is uppermost and pour the mixture evenly over the entire surface area.
6. Determine the level of application by the amount of hay intended to be fed.

Depending on local circumstances, this method may or may not be effective because cattle and sheep will frequently not eat hay when on spring pasture unless they are confined for that purpose.

Pellets

Magnesium-rich pellets suggest themselves as a means of supplementation when the additional cost can be borne. Palatability is again a problem, and care needs to be taken to include palatable material in the pellets; alternatively, they may be mixed with other grain or molasses for feeding. Calves should be restricted from access because magnesium oxide at high levels of intake (2% and 4% of the ration) is toxic to calves and causes diarrhea with much mucus in the feces.

In some high-risk situations it may be advisable to provide magnesium in several forms to ensure adequate intake.

Routine Daily Drenching

A once-daily oral administration of magnesium oxide or magnesium chloride to lactating dairy cows (to provide 10 g magnesium per cow), administered with a drenching gun just before the cows leave the milking parlor, is used in New Zealand to ensure adequate supplemental magnesium during periods of high risk. The cows become used to the procedure (and the farmers adept at carrying it out), and it causes minimal disruption of management.

Heavy Magnesium "Bullets"

The use of heavy "bullets" of magnesium to prevent hypomagnesemia has been effective in laboratory trials, and they are available commercially in some countries. The objective is to place a heavy bullet of magnesium in the reticulum, from which it constantly liberates small amounts of magnesium—about 1 g/d. This objective is achieved, and the occurrence of the clinical disease is usually greatly reduced but not eliminated. In dangerous situations, it is customary to administer up to four bullets at a time. As with all bullets, there is a proportion lost by regurgitation and by passage through the gut. A special sheep-sized bullet is used in ewes, with similar results.

Top Dressing of Pasture

Top dressing of pasture, together with magnesium-rich fertilizers, raises the level of magnesium in the pasture and decreases the susceptibility of cattle to hypomagnesemia. For top dressing, calcined magnesite (1125 kg/ha) or magnesic limestone (5600 kg/ha) are satisfactory, with the former resulting in a greater increase in pasture magnesium.

Other magnesium-containing fertilizers can be used depending on cost. The duration of the improved magnesium status varies with the type of soil: it is greatest on light sandy loams, on which a dressing of 560 kg/ha of calcined magnesium can provide protection for 3 years. On heavy soils protection for only 1 year is to be expected. To avoid unnecessary expense, it may be possible to top dress one field with the magnesium fertilizer and keep this field in reserve for spring grazing. Fertilization with magnesium is expensive, and the response of pastures varies markedly with the soil type. It is advisable to seek agronomic advice.

Foliar Dusting and Spraying

The magnesium content of pastures can be raised much more quickly by spraying with a 2% solution of magnesium sulfate at fortnightly intervals or by application of very finely ground magnesium oxide to the pasture (30 kg/ha) before grazing commences. The technique is referred to as foliar dusting or spraying and has the advantage over feed supplementation that the intake is standard. It is very effective in cattle in maintaining serum magnesium concentrations and preventing the occurrence of the clinical disease.

Dusting with 20 to 50 kg MgO/ha can provide protection for up to 3 weeks, but the duration is adversely influenced by wind and rain. A MgO-bentonite-water slurry sprayed onto pastures (26 kg MgO and 2.6 kg bentonite/ha) is effective in providing protection in high-rainfall periods.

Provision in Drinking Water

The problem with water medication is that the water intake of the group to be treated is not known and may be minimal on rapidly growing pastures. However, water medication may provide a delivery system for magnesium on management systems such as extensive range pastures where other methods may have limited success. Water sources other than the medicated supply need to be fenced off or otherwise restricted. The addition of magnesium sulfate (500 g/100 L) or magnesium chloride hexahydrate (420 g/100 L) to the water supply during the risk period for hypomagnesemia has proved effective.

Management of Pasture Fields

The economics of dairy farming make it necessary to produce maximum pasture growth, and the development of tetany-prone pastures is unavoidable in many circumstances. In some areas it may be possible to reduce the danger of such pastures by encouraging the development of legumes. In other areas the period of legume growth does not coincide with the period of maximum risk for grass tetany.

Restricting the amount of potash added to pastures, especially in the period immediately preceding the risk period for tetany, or using potash fertilizers in the autumn or late spring after the period of risk can reduce risk of the disease. The grazing of low-risk animals on high-risk pastures is another strategy. Ensuring that ample salt is available during the danger period to counteract the high intake of potassium can also reduce risk of the disease.

Plant geneticists are developing cultivars of cool-season grasses with high magnesium content that could be used for grazing during the tetany season. Lactating sheep grazing a **high-magnesium cultivar** of perennial rye grass (*Lolium perenne* cv *Radmore*) in the spring have shown higher serum magnesium concentrations than sheep grazing control cultivar, and cultivars of tall fescue (*Festuca arundinacea*) with high magnesium and calcium concentrations and low tetany potential are also available.

Provision of Shelter

In areas where winter pasturing is practiced, the observation that serum magnesium levels fall during the winter and in association with inclement weather suggests that cattle and sheep should be provided with shelter at such times. If complete housing is impractical, it may be advisable to erect open-access shelters in those fields that have no tree cover or protection from prevailing winds. Fields in which lactating cows are kept should receive special attention in this regard. Unfortunately, the disease is most common on highly improved farms, where most natural shelter has been removed, and it is desired to keep the cows on the highly improved pasture to maintain milk production or fatten calves rapidly.

Time of Calving

In areas where the incidence of the disease is high, it may be advisable to avoid having the cows calve during the cold winter months when seasonal hypomagnesemia is most likely to develop. Unfortunately, it is often important to have cows calve in late winter to take advantage of the flush of spring growth when the cows are at the peak of their lactation.

Feeding on Hay and Unimproved Pasture

Because of the probable importance of lush, improved, grass pasture in producing the disease, the provision of some grain, hay, or rough grazing may reduce its incidence. It is most important that the periods of fasting, such as occur when cattle or sheep are yarded or moved or during bad weather, should be avoided, especially in lactating animals and when seasonal hypomagnesemia is likely to be present.

TREATMENT AND CONTROL

Treatment

IV administration of a solution containing 25% calcium borogluconate and 5% magnesium hypophosphite (500 mL for cattle, 50 mL for sheep and goats) (R-1)

SC administration of a 50% solution of magnesium sulfate (200 mL for cattle) (R-1)

IV administration of a 15% solution of magnesium gluconate (200 to 400 mL for cattle) or a 20% solution of magnesium sulfate (200 to 300 mL for cattle) (R-2)

Control

Magnesium oxide—daily administration by drenching or in the feed of 60 g (cattle) or 7 g (sheep and goats) (R-1)

Increase dietary magnesium intake at times of increased risk for hypomagnesemia (R-2)

Monitor urine magnesium-to-creatinine ratio of animals at increased for hypomagnesemia (R-2)

HYPOMAGNESEMIC TETANY OF CALVES

SYNOPSIS

Etiology Hypomagnesemia, resulting from inadequate magnesium in the diet.

Epidemiology Most commonly calves 2 to 4 months of age, on whole milk or milk-replacer diets and poor or no roughage. Diarrhea and chewing of bedding or other coarse fiber may exacerbate the deficiency.

Clinical findings Apprehension, agitation, hypersensitivity to all external stimuli, fine muscle tremors progressing to spasticity and violent convulsions. Rapid course and high case-fatality rate.

Clinical pathology Serum magnesium concentrations below 0.8 mg/dL, bone calcium:magnesium ratio above 90:1.

Necropsy findings Calcification of the spleen, diaphragm, and endothelium of the aorta and endocardium. Enzootic muscular dystrophy is often concurrent.

Diagnostic confirmation Blood magnesium and response to treatment. Bone calcium:magnesium ratios.

Treatment and control Magnesium injection and dietary supplementation with magnesium compounds.

ETIOLOGY

The disease results when the dietary intake of magnesium is inadequate for the requirements of the calf. Affected animals may have concurrent hypocalcemia.

Magnesium Homeostasis in the Calf

Milk has low concentrations of magnesium. A milk diet provides adequate magnesium for the requirements of a growing calf up to a body weight of approximately 50 kg, but if milk is the sole diet, the intake of magnesium will be inadequate for requirements once this body weight is reached. The deficit will perpetuate if the other feeds that are fed are also low in magnesium.

In the young calf, magnesium is absorbed in the intestine; however, the efficiency of magnesium absorption decreases from 87% to approximately 30% at 3 months of age, when maximum susceptibility to the disease occurs. The efficiency of absorption is also decreased by a reduction in intestinal transit time caused by diarrhea.

In contrast to adult cattle, young calves can mobilize body stores of magnesium, which are principally located in the skeleton. Approximately 40% of the magnesium stored in the skeleton can be mobilized, which will protect against a short-term deficit.

Hypomagnesemic tetany in calves is often complicated in field cases by the coexistence of other diseases, especially enzootic muscular dystrophy.

EPIDEMIOLOGY

Occurrence

The disease is not common. Cases may occur sporadically, or a number of deaths may occur on one farm within a short period of time.

Risk Factors

The disease can occur under a number of different circumstances. Most commonly, hypomagnesemic tetany occurs in calves 2 to 4 months of age or older that are fed solely on a diet of whole milk, and calves receiving the greatest quantity of milk and growing most rapidly are more likely to be affected because of their greater need for magnesium for incorporation into developing soft tissues. It is most likely to occur in calves being fattened for veal. Those cases that occur in calves on milk replacer appear to be related to chronic scours and the low magnesium content of the replacer. This problem is less common than it once was because most modern commercial milk replacers have added adequate magnesium.

A significant loss of magnesium in the feces also occurs in calves allowed to chew fibrous material, such as bedding; the chewing stimulates profuse salivation and creates greater loss of endogenous magnesium. Peat and wood shavings are bedding materials known to have this effect.

Cases have also been reported in calves fed milk-replacer diets or milk, concentrates, and hay, and in calves running at pasture with their dams. Deaths resulting from hypomagnesemic tetany have also occurred in 3- to 4-month-old calves whose hay and silage rations were low in magnesium content.

Hypomagnesemia also occurs in young cattle, about 6 months of age, that are being fattened intensively indoors for the baby beef market. The phosphorus content of their diet is high, and a lack of vitamin D is probable. The situation is exacerbated by a shortage of roughage. The hypomagnesemia is accompanied by hypocalcemia.

Experimental Reproduction

A condition closely resembling the field syndrome has been produced experimentally by feeding an artificial diet with a very low content of magnesium and a high calcium content, and biochemical hypomagnesemia is readily produced in calves with a diet based on skim milk and barley straw. Hypomagnesemia has also been produced experimentally in very young foals by feeding a diet with a very low magnesium content. The clinical signs are similar to those in calves, and the calcification found in the walls of vessels of calves also occurs in foals.

PATHOGENESIS

On affected farms, calves are born with normal serum magnesium concentrations of 2 to 2.5 mg/dL (0.82 to 1.03 mmol/L), but the concentrations fall gradually in the succeeding 2 to 3 months, often to below 0.8 mg/dL (0.33 mmol/L). Tetany does not occur until the serum magnesium falls below this concentration and is most severe at concentrations below 0.6 mg/dL (0.25 mmol/L), although some calves in a group may have

concentrations even lower than this and show few clinical signs.

Magnesium deficiency inhibits the release and action of parathyroid hormone, and this is thought to be the genesis of the concurrent hypocalcemia. It is probable that depression of the serum calcium level precipitates tetany in animals rendered tetany prone by low serum magnesium levels. Tetanic convulsions can occur in hypocalcemic calves in the absence of hypomagnesemia.

Hypomagnesemic tetany is not related in any way to enzootic muscular dystrophy, although the diseases may occur concurrently.

CLINICAL FINDINGS

The first sign in the experimental disease is constant movement of the ears. The temperature is normal and the pulse rate accelerated. Hyperesthesia to touch and grossly exaggerated tendon reflexes with clonus are present. Shaking of the head, opisthotonos, ataxia without circling, and a droopy, backward carriage of the ears are constant. There is difficulty in drinking because of the animal's inability to get to the bucket.

Initially, the calves are apprehensive, show agitation and retraction of the eyelids when approached, and are hypersensitive to all external stimuli, but they show no tetany. Later, fine muscle tremors appear, followed by kicking at the belly, frothing at the mouth, and spasticity of the limbs. Convulsions follow, beginning with stamping of the feet, head retraction, chomping of the jaws, and falling.

During the convulsions the following signs are present:

- Jaws are clenched.
- Respiratory movements cease.
- There are tonic and clonic movements of the limbs.
- There is involuntary passage of urine and feces.
- There are cycles of protrusion and retraction of the eyeballs.

The pulse rate rises to 200 to 250/min, and the convulsions disappear terminally. The pulse becomes impalpable, and cyanosis appears before death.

In field cases the signs are almost identical, but they are rarely observed until the terminal tetanic stage. Older calves usually die within 20 to 30 minutes of the onset of convulsions, but young calves may recover temporarily only to succumb to subsequent attacks. Cases that occur in young calves with scours, usually at about 2 to 4 weeks of age, show ataxia, hyperesthesia, opisthotonos, and convulsions as the presenting signs. The convulsions are usually continuous, and the calves die within 1 hour.

CLINICAL PATHOLOGY

Serum magnesium concentrations below 0.8 mg/dL (0.33 mmol/L) indicate severe hypomagnesemia, and clinical signs occur with levels of 0.3 to 0.7 mg/dL (0.12 to 0.29 mmol/L). Normal values are 2.2 to –2.7 mg/dL (0.9 to 1.11 mmol/L). Erythrocyte magnesium concentrations are also low, indicating a chronic deficiency. Serum calcium concentrations tend to fall when serum magnesium levels become very low and are below normal in most clinical cases.

The estimation of the magnesium in bone (particularly ribs and vertebrae) is a reliable confirmatory test at necropsy. Values below a ratio of 70 : 1 for calcium : magnesium may be regarded as normal, and those above 90 : 1 are indicative of severe magnesium depletion. In the normal calf the ratio is about 55 : 1.[1] Absolute bone calcium values are not decreased and are often slightly elevated. An incidental change is the marked increase in serum creatinine kinase activity in calves after an acute attack of hypomagnesemic tetany.

NECROPSY FINDINGS

There is a marked difference between the necropsy lesions of some natural cases and those in the experimental disease. In field cases, there is often calcification of the spleen and diaphragm, and calcified plaques are present in the aorta and endocardium, together with hyaline degeneration and musculature. In other cases necropsy lesions similar to those in enzootic muscular dystrophy occur.

In experimentally produced cases these lesions are not evident, but there is extensive congestion in all organs, and hemorrhages are present in unsupported organs, including the following:

- Gallbladder
- Ventricular epicardium
- Pericardial fat
- Aorta
- Mesentery wall
- Intestinal wall

The lesions are obviously terminal and are associated with a terminal venous necrosis. Some field cases present a picture identical to this.

DIFFERENTIAL DIAGNOSIS

- Acute lead poisoning
- Enterotoxemia caused by *Clostridium perfringens* type D
- Polioencephalomalacia
- Tetanus
- Vitamin A deficiency
- Meningitis

TREATMENT

Response to magnesium injections (100 mL of a 10% solution of magnesium sulfate) is only transitory because of the severe depletion of bone reserves of magnesium. This dose provides only a single day's requirements. A magnesium sulfate enema in warm water (containing 15 g of magnesium sulfate) was associated with a rapid response in hypomagnesemic 3-month-old calves.[2] Follow-up supplementation of the diet with magnesium oxide or carbonate as described later is advisable. Chloral narcosis or tranquilization with an ataractic drug may be essential to avoid death as a result of respiratory paralysis during convulsions.

CONTROL

The provision of hay that is high in magnesium, such as alfalfa, helps to prevent the disease, as will well-formulated concentrates.

Supplementary Feeding of Magnesium

If begun during the first 10 days of life, supplementary magnesium feeding will prevent excessive drops in serum magnesium, but if begun after the calf is 7 weeks old, it may not prevent further depression of the levels. Supplementation should continue until at least 10 weeks of age. Daily feeding of the magnesium compound and fairly accurate dosing are necessary to avoid scouring or inefficient protection. For calves of average growth rate, appropriate dose rates are 1 g/d for calves to 5 weeks of age, 2 g/d for calves 5 to 10 weeks of age, and 3 g/d for calves 10 to 15 weeks of age of magnesium oxide or twice this dose of carbonate. Supplementation of the diet with magnesium restores serum calcium levels to normal and corrects the hypomagnesemia.

Magnesium Alloy Bullets

Two bullets of the sheep size (together releasing approximately 1 g/d of magnesium) per calf have shown high efficiency in preventing the clinical disease and also the hypomagnesemia that precedes it. Calves kept indoors and fed largely on milk should get adequate mineral supplement and vitamin D (70,000 IU vitamin D_3/d). Magnesium utilization will not be affected, but calcium absorption, which is often sufficiently reduced to cause a concurrent hypocalcemia, will be improved.

TRANSPORT RECUMBENCY OF RUMINANTS

Transport recumbency (tetany) occurs after prolonged transport, usually in cows and ewes in late pregnancy. It is also recorded in lambs transported to feedlots and in cows and sheep delivered to abattoirs. It is characterized by recumbency, alimentary tract stasis, and coma, and it is highly fatal. It occurs in most countries. Large losses can be encountered when cows and ewes in late pregnancy are moved long distances by rail, by truck, or on foot.

Although cows of any age in late pregnancy are most commonly affected, the disease has also been recorded in cows

recently calved, bullocks, steers, dry cows, and lambs. Risk factors include the following:

- Heavy feeding before shipment
- Deprivation of feed and water for more than 24 hours during transit
- Unrestricted access to water
- Exercise immediately after unloading

There is an increased incidence of the disease during hot weather. The cause is unknown, although physical stress is an obvious factor. Lambs show the following characteristics:

- Restlessness
- Staggering
- Partial paralysis of hindlegs
- Early assumption of lateral recumbency

Death may occur quickly, or after 2 to 3 days of recumbency. There is mild hypocalcemia (7 to 7.5 mg/dL; 1.75 to 1.87 mmol/L). The recovery rate even with treatment is only fair.

Clinical signs may occur while the cattle are still on the transportation vehicle or up to 48 hours after unloading. In the early stages, animals may exhibit excitement and restlessness, trismus, and grinding of the teeth. A staggering gait with paddling of the hindlegs and recumbency occur, accompanied by stasis of the alimentary tract and complete anorexia. Animals that do not recover gradually become comatose and die in 3 to 4 days. There may be moderate hypocalcemia and hypophosphatemia in cattle. In sheep of various ages, some are hypocalcemic and hypomagnesemic, some are hypoglycemic, and some have no detectable biochemical abnormality. There are no lesions at necropsy other than those related to prolonged recumbency. Ischemic muscle necrosis is the most obvious of these lesions. The relationship of the disease to transport or forced exercise is diagnostic.

Some cases respond to treatment with combined calcium, magnesium, and glucose injections. Repeated parenteral injections of large volumes of electrolyte solutions are recommended. In lambs, the SC injection of a solution of calcium and magnesium salts is recommended, but the response is usually only 50%, due probably because of an intercurrent myonecrosis.

If prolonged transport of cows or ewes in advanced pregnancy is unavoidable, they should be provided with adequate food, water, and rest periods during the trip. The incidence of this condition after transportation appears to have been markedly reduced with increased monitoring and awareness of transportation-related morbidity and mortality.

KETOSIS AND SUBCLINICAL KETOSIS (HYPERKETONEMIA) IN CATTLE

SYNOPSIS

Etiology A multifactorial disorder of energy metabolism. Negative energy balance results in hypoglycemia, ketonemia (the accumulation in blood of acetoacetate, β-hydroxybutyrate [BHB] and their decarboxylation products acetone and isopropanol), and ketonuria.

Epidemiology Primary ketosis and subclinical ketosis occurs predominantly in well-conditioned cows with high lactation potential, principally in the first month of lactation, with a higher prevalence in cows with a higher lactation number. Loss of body condition in the dry period and immediately postpartum. Secondary ketosis occurs where other disease reduces feed intake.

Clinical findings Cattle show wasting with decrease in appetite, body condition, and milk production. Some have short periods of bizarre neurologic and behavioral abnormality (nervous ketosis). Response to treatment is good. Subclinical ketosis (hyperketonemia) is detected by tests for ketones, usually BHB in blood, plasma, or serum, and acetoacetate in urine.

Clinical pathology Hypoglycemia, ketonemia, ketonuria, or elevated ketones in milk.

Necropsy findings None specific. Varying degrees of hepatic lipidosis.

Diagnostic confirmation Ketonemia, ketonuria, or, less commonly, elevated ketone concentration in milk.

Treatment Intravenous glucose, parenteral corticosteroid, and oral glucose precursors such as propylene glycol. The disease responds readily to treatment in cattle with mild hepatic lipidosis and is self-limiting.

Control Correction of energy imbalance. Herd biochemical monitoring coupled with condition scoring. Daily monensin administration to late-gestation and early-lactation dairy cows.

ETIOLOGY

Glucose Metabolism in Cattle

The maintenance of adequate concentrations of glucose in the plasma is critical to the regulation of energy metabolism. The ruminant absorbs very little dietary carbohydrate as hexose sugar because dietary carbohydrates are fermented in the rumen to short-chain fatty acids, principally acetate (70%), propionate (20%), and butyrate (10%). Consequently, glucose needs in cattle must largely be met by gluconeogenesis. **Propionate and amino acids are the major precursors** for gluconeogenesis, with glycerol and lactate being of lesser importance.

Propionate is produced in the rumen from starch, fiber, and proteins. It enters the portal circulation and is efficiently removed by the liver, which is the primary glucose-producing organ. Propionate is the **most important glucose precursor**; an increased availability of propionate can spare the hepatic utilization of other glucose precursors, and production of propionate is favored by a high grain inclusion in the diet. The gluconeogenic effect of propionate should be contrasted to **acetate,** which is transported to peripheral tissues and to the mammary gland and metabolized to long-chain fatty acids for storage as lipids or secretion as milk fat.

Amino acids. The majority of amino acids are glucogenic and are also important precursors for gluconeogenesis. Dietary protein is the most important quantitative source, but the labile pool of body protein (particularly skeletal muscle) is also an important source; together they contribute to energy synthesis , milk lactose synthesis, and milk protein synthesis.

Energy Balance

In high-producing dairy cows there is always a negative energy balance in the first few weeks of lactation. The highest dry matter intake does not occur until 8 to 10 weeks after calving, but peak milk production is at 4 to 6 weeks, and energy intake may not keep up with demand. In response to a negative energy balance and low serum concentrations of glucose (and consequently low serum concentrations of insulin), cows will mobilize adipose tissue, with consequent increases in serum concentrations of **nonesterified fatty acids** (**NEFA**) and subsequent increases in serum concentrations of **β-hydroxybutyrate** (**BHB**), **acetoacetate,** and **acetone**. The hepatic mitochondrial metabolism of fatty acids promotes both gluconeogenesis and ketogenesis. Cows partition nutrients during pregnancy and lactation and are in a lipolytic stage in early lactation and at risk for ketosis during this period.

Hepatic Insufficiency in Ketosis

Hepatic insufficiency has been shown to occur in bovine ketosis, but it does not occur in all cases. Ketosis is defined as an increased plasma or serum concentration of ketoacids and is divided into three types. In **type I**, or "spontaneous" ketosis, the gluconeogenic pathways are maximally stimulated, and ketosis occurs when the demand for glucose outstrips the capacity of the liver for gluconeogenesis because of an insufficient supply of glucose precursors. Rapid entry of NEFAs into hepatic mitochondria occurs and results in high rates of ketogenesis and high plasma/serum ketone concentration. There is little conversion of NEFAs to triglycerides, resulting in little fat accumulation in the liver. In **type II** ketosis, manifest with **fatty liver**, gluconeogenic pathways are not maximally stimulated, and consequently mitochondrial uptake of NEFAs is not as active, and NEFAs become esterified in the cytosol, forming triglyceride. The capacity of cattle to transport triglyceride from the liver is low, resulting in accumulation and fatty liver. The occurrence of a fatty liver can further suppress hepatic gluconeogenic capacity. Hepatic insufficiency may occur more commonly in those cows predisposed to ketosis by overfeeding in the dry period. In **type III** ketosis, cattle

are fed a diet (typically a high-maize ration) that results in a higher ruminal production of butyrate, which is directly metabolized by ruminal epithelial cells to butyrate.

Ketone Formation

Ketones arise from two major sources: butyrate in the rumen and mobilization of fat. A large proportion of butyrate produced by rumen fermentation of the diet is converted to BHB in the rumen epithelium and is absorbed as such. Free fatty acids produced from the mobilization of fat are transported to the liver and oxidized to produce acetyl-CoA and NADH.

Acetyl-CoA may be oxidized via the tricarboxylic acid (TCA) cycle or metabolized to acetoacetyl-CoA. Complete oxidation of acetyl-CoA via the TCA cycle depends on an adequate supply of oxaloacetate from the precursor propionate. If propionate, and consequently oxaloacetate, is deficient, oxidation of acetyl-CoA via the TCA cycle is limited, and acetyl-CoA is metabolized to acetoacetyl CoA and subsequently to acetoacetate and BHB.

The ketones BHB and acetoacetate can be utilized as energy sources. They are normally present in the plasma/serum of cattle, and their concentration is a result of the balance between production in the liver and utilization by the peripheral tissues. Acetoacetate can spontaneously convert to **acetone,** which is volatile and therefore exhaled in the breath; diffusion of acetone across the rumen epithelium into the rumen means that some acetone is eructated. Ruminal flora (most likely bacteria) can metabolize acetone to isopropanol, which can then be absorbed to increase plasma concentrations of **isopropanol**, a 3-carbon alcohol.[1]

Role of Insulin and Glucagon

The regulation of energy metabolism in ruminants is primarily governed by insulin and glucagon. Insulin acts as a glucoregulatory hormone stimulating glucose use by tissues and decreasing hepatic gluconeogenesis. Plasma insulin concentrations decrease with decreasing plasma concentrations of glucose and propionate. Insulin also acts as a liporegulatory hormone stimulating lipogenesis and inhibiting lipolysis. Glucagon is the primary counterregulatory hormone to insulin. The counteracting effects of insulin and glucagon therefore play a central role in the homeostatic control of glucose. A low **insulin : glucagon ratio** stimulates lipolysis in adipose tissue and ketogenesis in the liver. Cows in early lactation have low insulin : glucagon ratios because of low plasma glucose concentrations and are in a catabolic state. Regulation is also indirectly governed by **somatotropin**, which is the most important determinant of milk yield in cattle and is also lipolytic. Factors that decrease the energy supply, increase the demand for glucose, or increase the utilization of peripheral fat reserves as an energy source are likely to increase ketone production and ketonemia. There is, however, considerable cow-to-cow variation in the risk for developing clinical ketosis.

ETIOLOGY OF BOVINE KETOSIS

It is not unreasonable to view clinical ketosis as one end of a spectrum of a metabolic state that is **common in heavily producing cows** in the **postcalving period**. This is because high-yielding cows in early lactation are in negative energy balance and are subclinically ketotic as a result.

Cattle are particularly vulnerable to ketosis because, although very little carbohydrate is absorbed as such, a direct supply of glucose is essential for tissue metabolism, particularly the formation of lactose associated with milk production. The utilization of volatile fatty acids for energy purposes is also dependent on a supply of available glucose. This vulnerability is further exacerbated in the lactating dairy cow by the tremendous rate of turnover of glucose.

In the period between calving and peak lactation, the demand for glucose is increased and cannot be completely restrained. Cows will reduce milk production in response to a reduction of energy intake, but this does not follow automatically nor proportionately in early lactation because hormonal stimuli for milk production overcome the effects of reduced food intake. Under these circumstances, lowered plasma glucose concentrations result in lowered plasma insulin concentrations. Long-chain fatty acids are released from fat stores under the influence of both a low plasma insulin : glucagon ratio and the influence of high somatotropin concentration, and this leads to increased ketogenesis.

Individual Cow Variation

The rate of occurrence of negative energy status, and therefore the frequency of clinical ketosis cases, has increased markedly over the last 4 decades because of the increase in the lactation potential of the modern dairy cow. Because of the mammary gland's metabolic precedence in the partitioning of nutrients, especially glucose, milk production continues at a high rate, causing an energy drain. In many individual cows, the need for energy is beyond their capacity for dry matter intake, but there is between-cow variation in risk under similar nutritional stress. Clinical ketosis is easily produced in early-lactation dairy cows by reducing the daily feed intake.[2] Subclinical ketosis (hyperketonemia) in early-lactation dairy cows is associated with decreased dry matter intake and feeding time during the week before calving.[6]

Types of Bovine Ketosis

There are many theories on the cause and biochemical and hormonal pathogenesis of ketosis, in addition to the importance of predisposing factors. Reviews of these studies are cited at the end of this disease section. In general, it can be stated that clinical ketosis occurs in cattle when they are subjected to demands on their resources of glucose and glycogen that cannot be met by their digestive and metabolic activity.

A common classification of the disease based on its natural presentation in intensively and extensively managed dairy herds, and one that accounts for the early lactational demand for glucose, a limited supply of propionate precursors, and preformed ketones or mobilized lipids in the pathogenesis, has been developed. Such a classification scheme includes the following mechanisms for ketosis, which will be discussed in turn:

- Primary ketosis (production ketosis)
- Secondary ketosis
- Alimentary ketosis
- Starvation ketosis
- Ketosis resulting from a specific nutritional deficiency

Primary Ketosis (Production Ketosis)

This is the ketosis of most herds, the so-called estate acetonemia. Primary ketosis occurs in cows in good to excessive body condition that have high lactation potential and are being fed good-quality rations but that are in a negative energy balance. There is a tendency for the disease to recur in individual animals, which is probably a reflection of variation between cows in digestive capacity or metabolic efficiency. A proportion of primary ketosis cases appear as **clinical ketosis,** but a much greater proportion occurs as cases of **subclinical ketosis** in which there are increased concentrations of circulating ketone bodies but no overt clinical signs. Affected cattle recover with correct feeding and ancillary treatment.

Secondary Ketosis

Secondary ketosis occurs where the presence of **other disease** results in a **decreased food intake**. The cause of the reduction in food intake is commonly the result of abomasal displacement, traumatic reticulitis, metritis, mastitis, or other diseases common to the postparturient period. A high incidence of ketosis has also been observed in herds affected with fluorosis. An unusual occurrence reported was an outbreak of acetonemia in a dairy herd fed on a ration contaminated by a low level (9.5 ppm) of lincomycin, which caused ruminal microbial dysfunction. The proportion of cases of ketosis that are secondary and their diagnosis as such are both matters of great interest because a significant proportion of all cases of ketosis in lactating dairy cattle are secondary to other disease.

Alimentary Ketosis

Alimentary ketosis (also called type III in some classification systems) is a result of

excessive amounts of **butyrate in silage** and possibly also a result of decreased food intake resulting from the poor palatability of high-butyrate silage. Silage made from succulent material may be more highly ketogenic than other types of ensilage because of its higher content of preformed butyric acid. Spoiled silage is also a cause, and toxic biogenic amines in silage, such as putrescine, may also contribute. This type of ketosis is commonly subclinical, but it may predispose to the development of production or primary ketosis.

Starvation Ketosis

Starvation ketosis occurs in cattle that are in poor body condition and that are fed poor-quality feedstuffs. There is a deficiency of propionate and protein from the diet and a limited capacity of gluconeogenesis from body reserves. Affected cattle recover with correct feeding.

Ketosis Resulting From Specific Nutritional Deficiency

Specific dietary deficiencies of **cobalt** and possibly phosphorus may also lead to a high incidence of ketosis. This may be in part a result of a reduction in the intake of total digestible nutrients, but in cobalt deficiency, the essential defect is a failure to metabolize propionic acid in the TCA cycle. The problem is restricted to the cobalt-deficient areas of the world, although the occurrence of cobalt deficiency in high-producing dairy cows in nondeficient areas has been described.

There is a marked nadir in food intake around calving, followed by a gradual increase. This increase is quite variable between cows, but in the great majority of cases does not keep pace with milk yield. The net result is that high-yielding dairy cows are almost certain to be in negative energy balance for the first 2 months of lactation.

EPIDEMIOLOGY

Occurrence

Ketosis is a very common disease of lactating dairy cattle and is prevalent in most countries where intensive farming is practiced. Ketosis occurs mainly in animals housed during the winter and spring months and is rare in cows that calve on pasture. In housed or free-stalled cattle, ketosis occurs year around. The occurrence of the disease is very much dependent on management and nutrition and varies between herds. As might be expected, **lactational incidence rates** vary between herds, and a review of 11 epidemiologic studies showed a lactation incidence rate for ketosis that varied from 0.2% to 10.0%.

The incidence of **subclinical ketosis** (more correctly called hyperketonemia) is influenced by the cut-point of plasma BHB used for definition, but it is much higher than the incidence of clinical ketosis, especially in undernourished herds, and can approach 40%. Incidence can be challenging and expensive to estimate because prevalence information is usually measured. In general, the incidence of subclinical ketosis is 1.8 times the prevalence.

Animal and Management Risk Factors

There are conflicting reports on the significance of risk factors for ketosis and subclinical ketosis, which probably reflect that the disease can be a cause or effect of a number of interacting factors. The disease occurs in the immediate postparturient period, with 90% of cases occurring in the first 60 days of lactation. Regardless of the specific etiology, ketosis occurs most commonly during the **first month** of lactation, less commonly in the second month, and only occasionally in late pregnancy. In different studies, the median **time to onset following calving** has varied from 10 to 28 days, with some recent studies showing a peak prevalence of subclinical ketosis in the first 2 weeks postcalving. A prolonged previous intercalving interval increases risk.

Age. Cows of any age may be affected, but the disease increases from a low prevalence at the first calving to a peak at the fourth calving, associated with the level of milk production. Lactational incidence rates of clinical ketosis of 1.5% and 9%, respectively, were found in a study of 2415 primiparous and 4360 multiparous cows. Clinical ketosis can also recur in the same lactation.

Herd differences in prevalence are very evident in clinical practice and in the literature, with some herds having negligible occurrence. Although apparent differences in breed incidence are reported, evidence for a heritable predisposition within breeds is minimal. Feeding frequency has an effect, with the prevalence of ketosis being much lower in herds that feed a **total mixed ration** (TMR) ad libitum compared with herds that feed roughage and concentrate separately fed twice a day (**component fed**).

Body-Condition Score. There are conflicting reports on the relation between BCS at calving and ketosis, but it is very likely that studies that have found no relationship have not had many fat cows in the herds examined. Fat body condition postpartum was observed to be associated with a higher first-test-day milk yield, milk-fat-to-protein ratio of greater than 1.5, increased body-condition loss, and a higher risk for ketosis. In another study, cows with a BCS greater than 3.25 at parturition and that lost 0.75 points in BCS in the first 2 months of lactation developed subclinical ketosis. Body-condition loss during the dry period also increases risk for ketosis in the following lactation.

Season. There is no clear association with season. In some but not all summer grazing areas, a higher risk is generally observed in cattle during the winter housing period. Higher prevalence has been observed in the late summer and early winter in Scandinavian countries.

Other Interactions. There is a **greater risk** for the development of ketosis in cows that have an extended long dry period;[3] those that develop milk fever, retained placenta, lameness, or hypomagnesemia; or those that have high milk production and high first milking colostrum volume.[3] Cows with twins are also at risk for ketosis in the terminal stages of pregnancy. There is a bidirectional relation between risk for displaced abomasum and risk for ketosis, but in a field study of 1000 cows in 25 herds, cows that had a serum BHB concentration greater than 1.4 mmol/L in the first 2 weeks of lactation had odds of 4:1 that a displaced abomasum would be diagnosed 1 to 3 weeks later. In another study of 1010 cows, a serum BHB concentration of 1.5 mmol/L or greater in the first 2 weeks of lactation was found to be associated with a threefold increase in ketosis or displaced abomasum. Interestingly, cows with increased blood BHB concentration immediately before surgical correction of left-displaced abomasum have increased longevity within the herd, compared with cattle with BHB concentrations within the reference interval.[7,8]

Economic Significance

Clinical and subclinical ketosis are major causes of loss to the dairy farmer. In rare instances the disease is irreversible and the affected animal dies, but the main economic loss results from the loss of production while the disease is present, the possible failure to return to full production after recovery, and the increased occurrence of periparturient disease. Both clinical and subclinical ketosis are accompanied by **decreased milk yields**; lower milk protein and milk lactose; **increased risk** for delayed estrus and lower first-service conception rates; lower pregnancy rates; increased intercalving intervals; increased risk of cystic ovarian disease, metritis, and mastitis; and increased involuntary culling.[4] The estimated economic loss from a single case of subclinical ketosis was US$117 in 2015, and the estimated average total cost per case of subclinical ketosis was $289 after considering the costs of displaced abomasum and metritis attributed to hyperketonemia.[5]

PATHOGENESIS

Bovine Ketosis

The principal metabolic disturbances observed, hypoglycemia and ketonemia, may both exert an effect on the clinical syndrome. However, in the experimental disease in cattle, it is not always clear what determines the development of the clinical signs in cases that convert from subclinical to clinical

ketosis. In many cases, the severity of the clinical syndrome is proportional to the degree of hypoglycemia, and this, together with the rapid response to parenterally administered glucose in cattle, suggests **hypoglycemia as the predominant factor**. This hypothesis is supported by the development of prolonged hypoglycemia and a similar clinical syndrome to that of ketosis, after the experimental IV or SC injection of insulin (2 U/kg BW).

However, in most field cases the severity of the clinical syndrome is also roughly proportional to the degree of ketonemia. This is an understandable relationship because ketone bodies are produced in larger quantities as the deficiency of glucose increases. However, the ketone bodies are thought to exert an additional influence on the clinical signs observed; for instance, acetoacetic acid is known to be toxic and probably contributes to the terminal coma in diabetes mellitus in humans.

The **nervous signs** that occur in some cases of bovine ketosis are thought to be caused by the production of isopropanol, a breakdown product of acetone in the rumen,[1] although the requirement of nervous tissue for glucose to maintain normal function may also be a factor in these cases. A reasonable explanation for the development of nervous ketosis is that a rapid increase in plasma acetone concentration in an animal that has an active rumen flora leads to a rapid increase in ruminal acetone concentration. The acetone is metabolized by rumen microflora to isopropanol, which is then absorbed into the bloodstream, potentially leading to neurologic abnormalities. This mechanism is consistent with observations that nervous signs of ketosis are more common in cattle with severe ketosis that is rapidly induced.

Spontaneous ketosis in cattle is usually **readily reversible** by treatment; incomplete or temporary response is usually a result of the existence of a primary disease, with ketosis present only as a secondary development, although fatty degeneration of the liver in protracted cases may prolong the recovery period. Changes in ruminal flora after a long period of anorexia may also cause continued impairment of digestion.

Immunosuppression has been demonstrated with energy deficiency and ketosis. The higher susceptibility of ketotic postpartum cows to local and systemic infections may be related to impairment of the respiratory burst of neutrophils that occurs with elevated plasma concentrations of BHB.

CLINICAL FINDINGS

Two major clinical forms of bovine ketosis are described—wasting and nervous—but these are the two extremes of a range of syndromes in which wasting and nervous signs are present in varying degrees of prominence.

The **wasting form** is the most common of the two and is manifest with a gradual but moderate decrease in appetite and milk yield over 2 to 4 days. In component-fed herds, the pattern of appetite loss is often very specific in that the cow first refuses to eat grain, then ensilage, but may continue to eat hay. The appetite may also be depraved.

Body weight is lost rapidly, usually at a greater rate than one would expect from the decrease in appetite. Farmers usually describe affected cows as having a "woody" appearance because of the apparent wasting and loss of cutaneous elasticity presumably resulting from disappearance of subcutaneous fat. The feces are firm and dry, but serious constipation does not occur. The cow is moderately depressed and is quieter than usual. The disinclination to move and to eat may suggest the presence of mild abdominal pain, but localized pain cannot be detected via abdominal palpation.

The temperature and the pulse and respiratory rates are normal, and although the ruminal movements may be decreased in amplitude and number, they are within the normal range unless the course is of long duration, in which case they may virtually disappear. The characteristic sweet odor of ketones is detectable on the breath and often in the milk, but people vary in their ability to detect ketones on the breath (specifically the volatile ketone, acetone).

Very few affected animals die, but without treatment the milk yield falls; although spontaneous recovery usually occurs over about a month, as equilibrium between the drain of lactation and food intake is established, the milk yield is never fully regained. The fall in milk yield in the wasting form may be as much as 25%, and there is an accompanying sharp drop in the solids-not-fat content of the milk. In the wasting form, nervous signs may occur in a few cases, but they rarely comprise more than transient bouts of staggering and partial blindness.

In the **nervous form (nervous ketosis),** signs are usually bizarre and begin quite suddenly. The syndrome is suggestive of delirium rather than of frenzy, and the characteristic signs include the following:

- Walking in circles
- Straddling or crossing of the legs
- Head pushing or leaning into the stanchion
- Apparent blindness
- Aimless movements and wandering
- Vigorous licking of the skin and inanimate objects (Fig. 17-6)
- Depraved appetite
- Chewing movements with salivation

Hyperesthesia may be evident, with the animal bellowing on being pinched or stroked. Moderate tremor and tetany may be present, and there is usually an incoordinate gait. The nervous signs usually occur in **short episodes** that last for 1 or 2 hours and may recur at intervals of about 8 to 12 hours. Affected cows may injure themselves during the nervous episodes. Surgical correction of displaced abomasum in cows exhibiting some signs consistent with nervous ketosis should be delayed until their energy status has been evaluated and treatment instituted, if indicated.

Subclinical Ketosis (Hyperketonemia)

Subclinical ketosis is defined as an increase in blood/plasma/serum BHB above the normal reference range or ketonuria in a cow without detectable clinical signs of disease. Many cows that are in negative energy balance in early pregnancy will have ketonuria without showing clinical signs, but they

Fig. 17-6 Holstein–Friesian cow with nervous ketosis, manifest as excessive and sustained licking behavior.

will have diminished productivity, including depression of milk yield and a reduction in fertility. Clinical diagnosis is not effective, and in one study, diagnosis by routine urine testing at 5 to 12 days postpartum was considerably more efficient (15.6% detected) than diagnosis by the herdsman (4.4% detected). In a British study of 219 herds the annual mean rate of reported clinical ketosis was 0.5 per 100 adult cows, but the rate of subclinical ketosis, as defined by increased plasma concentrations of BHB and nonesterified fatty acids, was substantially higher. There is debate about whether subclinical ketosis is the correct term, with some support for replacing the term with *hyperketonemia*.

Potential milk production in cows with subclinical ketosis is reduced by 1% to 9%. Surveys of large populations show a declining prevalence of ketosis-positive cows after a peak in the period immediately after calving and a positive relationship between hyperketonemia and high milk yield. **Infertility** may appear as an ovarian abnormality, delayed onset of estrus, or endometritis resulting in an increase in the calving-to-conception interval and reduced conception rate at first insemination.[4]

CLINICAL PATHOLOGY

Hypoglycemia, ketonemia, and ketonuria are characteristic of the disease.

Glucose

Plasma glucose concentrations are reduced from the normal of approximately 50 to 65 mg/dL to 20 to 40 mg/dL. Ketosis secondary to other diseases is usually accompanied by plasma glucose concentrations above 50 mg/dL, and many cattle have much higher concentrations. Conversion factors are shown in Table 17-7.

Ketones

Most commonly, plasma or serum β-hydroxybutyrate (BHB) measured in SI units (mmol/L) is used for analysis of ketonemia. BHB is the quantitatively highest circulating ketone body in cattle. Plasma concentrations of BHB significantly correlate with plasma concentrations of acetoacetate, but acetoacetate is unstable in blood samples, whereas BHB is stable, particularly when samples are refrigerated or frozen. Normal cows have plasma BHB concentrations less than 1.0 mmol/L; cows with subclinical ketosis have blood or plasma/serum concentrations greater than 1.0, 1.2, or 1.4 mmol/L (the cut-point varies depending on the study, analytical method, and whether blood or plasma is analyzed).[9,10] Different cut-points have been proposed for serum BHB concentration in the first week postpartum (1.0 mmol/L) and the second week postpartum (1.4 mmol/L);[11] this may be attributable to blood BHB concentrations being highest at 8 days in milk.[12] In general, because the cut-point for the diagnosis of subclinical ketosis should be based on a detectable effect on decreasing milk production or an increased risk of adverse health events,[10] a consensus is developing around the use of serum/plasma BHB concentration greater than 1.0 mmol/L as the cut-point for subclinical ketosis based on the association with impaired reproductive performance[11] and increased risk of developing a displaced abomasum, puerperal metritis, or clinical ketosis.[13]

Cows with clinical ketosis usually have serum/plasma BHB concentrations in excess of 2.5 mmol/L, with values rarely reaching 10.0 mmol/L. Plasma BHB shows some diurnal variation in cows fed twice daily, with peak concentrations occurring approximately 4 hours after feeding and higher concentrations in the morning than in the afternoon. This diurnal variation is not as prominent in cows fed a total mixed ration ad libitum.

Measurement of blood or plasma/serum BHB concentration has recently become a cost-effective and convenient method for routine analysis and cow-side monitoring, with the introduction of low-cost point-of-care devices for measurement (US$2/test). The concentration of acetoacetate or BHB in urine and milk is also used for diagnostic purposes.[14] Concentrations of BHB and acetoacetate in urine and milk are less than those in plasma/serum, but the correlation coefficients for plasma/serum and milk BHB and plasma/serum and milk acetoacetate are 0.66 and 0.62, respectively. For cow-side use, urine acetoacetate concentration using the nitroprusside test and blood BHB concentration using a point-of-care device are currently the preferred tests for detecting subclinical or clinical ketosis in cattle.

Table 17-7 To convert from the SI unit to the conventional unit, divide by the conversion factor; to convert from the conventional unit to the SI unit, multiply by the conversion factor

Substrate	Conventional unit	Conversion factor	SI unit
β-hydroxybutyrate	mg/dL	0.0961	mmol/L
Acetoacetate	mg/dL	0.0980	mmol/L
Acetone	mg/dL	0.1722	mmol/L

Milk and Urine Cow-Side Tests

Cow-side tests have the advantage of being inexpensive and giving immediate results, and they can be used as frequently as necessary. A minor source of error is that the concentration of ketone bodies in these fluids will depend not only on the ketone concentration of the plasma, but also on the amount of urine excreted or on the milk yield. Milk concentration of ketones is less variable, easier to collect, and may give fewer false negatives in cows with subclinical ketosis.

Milk and urine ketone concentrations have been traditionally detected by the reaction of acetoacetate with **sodium nitroprusside** and can be interpreted in a semiquantitative manner based on the intensity of the reaction. The nitroprusside reaction detects both acetoacetate and acetone, but it is much more sensitive to acetoacetate than acetone; the latter is only detected when acetone concentrations are greater than 600 mmol/L, which represents a supraphysiologic concentration.[15] As a consequence, the nitroprusside test functions as a semiquantitative test of acetoacetate concentration and should be clinically regarded as a test of acetoacetate and not acetone. Several products are available commercially as strips or test powders and are commonly accompanied by a color chart that allows a classification of acetoacetate concentration in grades such as negative, trace (5 mg/dL; 0.5 mmol/L), small (15 mg/dL; 1.0 mmol/L), moderate (40 mg/dL; 2.0 mmol/L), or large (>80 mg/dL; 5 mmol/L), based on the intensity of the color of the reaction.[15] Milk powder tests are not sufficiently sensitive for detection of subclinical ketosis (report too many false negatives), and urine tests are not sufficiently specific (report too many false positives).

Milk Testing. The sensitivity and specificity of the nitroprusside powder test with milk in various studies is reported as 28% to 90% and 96% to 100%, respectively. Currently, a milk strip test detecting the concentration of BHB in milk is available and is graded on the concentration of BHB. In different studies, milk BHB has a reported sensitivity and specificity of 58% to 96% and 69% to 99%, respectively. These variations are in part a result of the use of different plasma BHB reference values (1.2 and 1.4 mmol/L) for designation of subclinical ketosis and different statistical methods for analysis. Somatic cell counts in milk greater than 1 million cells/mL will cause an elevation in reading of both the BHBA strip test and the nitroprusside tests.

Urine Testing. A nitroprusside tablet has a reported sensitivity and specificity of 100% and 59%, respectively, compared with serum BHB concentrations above 1.4 mmol/L; a nitroprusside strip test has a reported

sensitivity and specificity of 78% and 96%, respectively, with a urine cut-point corresponding to "small" on the color chart or 49% and 99%, respectively, with a urine cut-point corresponding to "moderate" on the color chart. BHB test strips when used with urine have a reported sensitivity and specificity of 73% and 96%, respectively, at a urine cut-point of 0.1 mmol/L BHB and 27% and 99%, respectively, at a urine cut-point of 0.2 mmol/L BHB. Urinary ketone concentrations are more closely related to plasma ketone concentrations than are milk BHB and acetoacetate concentrations.[16,17] Moreover, urine acetoacetate concentration appears superior to milk BHB concentration in diagnosing ketosis.[17]

Milk-Fat-to-Protein Ratio. Milk-fat concentration tends to increase, and milk protein concentration tends to decrease, during postpartum negative energy balance. A **fat-to-protein ratio greater than 1.5** in first-day test milk is indicative of a lack of energy supply in the feed and of risk for ketosis and provides a similar test sensitivity (Se = 0.63) for detecting subclinical ketosis as does milk BHB concentration (Se = 0.58).[17] Milk production in multiparous animals is also separately associated with postpartum negative energy balance.[18]

Clinical Chemistry and Hematology. White and differential cell counts are variable and not of diagnostic value for ketosis. There are usually elevations of liver enzyme activity in plasma/serum, but liver function tests are within the normal range. Liver biopsy is the only accurate method to determine the degree of liver damage.

Plasma concentrations of NEFAs and total bilirubin are elevated in ketosis, with mean NEFA concentrations increasing above 0.3 mmol/L from 3 days before parturition to approximately 0.7 mmol/L from 0 to 9 days in milk, after which time plasma NEFA concentration gradually decreases.[12] The increase in bilirubin is attributed, in part, to hepatic dysfunction; however, bilirubin is not a sufficiently sensitive indicator to assess the extent of fat mobilization and liver function in cows with ketosis. Plasma cholesterol concentration is typically decreased for the stage of lactation; the decrease in cholesterol is a result of decreased hepatocyte secretion of very-low-density lipoproteins (VLDLs), which are cholesterol rich, or increased mammary uptake of cholesterol relative to cholesterol availability. After secretion, VLDLs are processed in plasma to intermediate-density lipoproteins by hydrolysis of triglycerides.[19] Intermediate-density lipoproteins are then metabolized in plasma to cholesterol-rich low-density lipoproteins that carry cholesterol to peripheral tissues, including the mammary gland.[19,20] A clinically significant proportion of lactating dairy cattle with ketosis have low plasma cortisol concentrations;[21] although the mechanism has not been determined, it is possible that decreased cholesterol availability negatively affects cortisol synthesis.

Liver glycogen levels are low, and the glucose tolerance curve may be normal. Volatile fatty acid levels in the rumen are much higher in ketotic than in normal cows, and the ruminal concentrations of butyrate are markedly increased relative to acetate and propionate acids. There is a small but significant drop in serum calcium concentrations (down to about 9 mg/dL [2.25 mmol/L]), probably as a result of decreased dry matter intake in lactating dairy cattle relative to the level of milk production.

Plasma and urine metabolic profiling shows promise as a means of differentiating cattle with clinical ketosis and subclinical ketosis from healthy cattle at the same stage of lactation. Twenty-five plasma metabolites[22,23] and 11 urine proteins[24] have been identified to differ between these three groups. Differences include changes in plasma amino acid concentrations that may reflect differences in feed intake relative to milk production or altered metabolic pathways and changes in urine polypeptide concentrations that may reflect decreased immune responsiveness.

NECROPSY FINDINGS

The disease is not usually fatal in cattle, but fatty degeneration of the liver and secondary changes in the anterior pituitary gland and adrenal cortex may be present.

DIFFERENTIAL DIAGNOSIS

Cattle

The clinical picture is usually too indefinite, especially in cattle, to enable a diagnosis to be made solely on clinical grounds. General consideration of the history, with particular reference to the time of calving, and the feeding program, and biochemical examination to detect the presence of hypoglycemia, ketonemia, and ketonuria are necessary to establish a diagnosis.

Wasting form:

- Abomasal displacement
- Traumatic reticulitis
- Primary indigestion
- Cystitis and pyelonephritis

Nervous form:

- Rabies
- Hypomagnesemia
- Bovine spongiform encephalopathy

TREATMENT

In cattle, a number of effective treatments are available for ketosis, but in some affected animals, the response is only transient; in rare cases, the disease may persist and cause death or necessitate slaughter of the animals. Most of these cases are secondary, and failure to respond satisfactorily to treatment is a result of the primary disease. Specific treatment for subclinical ketosis is usually not applied on an individual basis, but nutrition and management issues should be investigated whenever a large proportion of early-lactation cows are diagnosed with subclinical ketosis.

The rational treatment in ketosis is to relieve the need for glucose formation from tissues and allow ketone-body utilization to continue normally. Theoretically, the simplest means of doing this is by the administration of glucose replacement therapy. The effect of the administration of glucose is complex, but it allows the reversal of ketogenesis and the establishment of normal patterns of energy metabolism. Ideally, treatment should be at an early stage of the disease to minimize loss, and with subclinical ketosis this requires biochemical testing.

Replacement Therapy

Glucose (Dextrose)

The IV injection of 500 mL of a 50% solution of glucose results in transient hyperglycemia, increased insulin and decreased glucagon secretion, and reduced plasma concentration of NEFAs. Glucose administration effects a marked improvement in most cows, but relapses occur commonly unless repeated treatments are used. This is probably a result of the transience of the hyperglycemia (3 to 4 hours) or insufficient dosing—the dose required varies directly with the amount of lactose being lost in the milk. Contrary to widespread belief, **very little of the administered glucose is lost to urinary excretion** (<10%).[25,26] SC injections of hypertonic glucose prolong the response, but they are not recommended because they cause discomfort, and large unsightly swellings, which often become infected, may result. Intraperitoneal injections of 20% solution of dextrose have also been used, but they are not recommended because of the risk of infection.

Other Sugars

Other sugars, especially fructose, either alone or as a mixture of glucose and fructose (invert sugar), and xylitol, have been used in an effort to prolong the response, but idiosyncratic responses to some preparations, in the form of polypnea, muscle tremor, weakness, and collapse, can occur while the injection is being given.

Propylene Glycol and Glycerine/Glycerol

To overcome the necessity for repeated injections, propylene glycol can be administered as a drench. The traditional dose is 225 ml twice daily for 2 days, followed by 110 ml daily for 2 days to cattle, but higher volumes are also used for larger cattle (a typical treatment protocol in North America is 300 ml PO daily for 5 days). Some of the administered propylene glycol is metabolized to propionate in the rumen and absorbed, whereas some of the propylene glycol is absorbed

directly across ruminal epithelium and metabolized by the liver. Propylene glycol (200 to 700 g daily), or **salts of propionate**, can be administered in the feed and give good results. Administration in feed is preferred by some because this method avoids dangers of aspiration with drenching; however, cows not used to its inclusion in the feed may show feed refusal. Studies also suggest that drenching of propylene glycol provides a more beneficial response than including the same amount in a total mixed ration; the bolus effect of propionate production appears to be more beneficial than a steady-state increase as a result of a bolus increase in plasma insulin concentration. It is recommended that for best results, dosing with propylene glycol should be preceded by an IV injection of glucose.

Parenteral infusions of glucose solutions and the feeding of glycerol depress the fat content of milk, and the net saving in energy may favorably influence response to these drugs. Glycerol and propylene glycol are not as efficient as glucose because conversion to glucose utilizes oxaloacetate. Propylene glycol is absorbed directly from the rumen and acts to reduce ketogenesis by increasing mitochondrial citrate concentrations; its metabolism to glucose occurs via conversion to pyruvate, with subsequent production of oxaloacetate via pyruvate carboxylase.

Other Glucose Precursors

Because of its glucogenic effect, sodium propionate is theoretically a suitable treatment, but when administered in 110- to 225-g doses daily, the response in cattle is often very slow. Lactates are also highly glucogenic, but both calcium and sodium lactate (1 kg initially, followed by 0.5 kg for 7 days) and sodium acetate (110 to 500 g/d) have given less satisfactory results than those obtained with sodium propionate. Ammonium lactate (200 g for 5 days) has, however, been used extensively, with reported good results. Lactose, in whey or in granular form in the diet, can increase dry matter intake, but it also increases ruminal butyrate concentration and plasma BHB concentrations.

Hormonal Therapy

Glucocorticoids. The efficiency of glucocorticoids in the treatment of bovine ketosis has been demonstrated in both experimental and field cases. The observation that a clinically significant proportion of lactating dairy cattle with ketosis have low plasma cortisol concentrations[21] provides support for glucocorticoid administration. Hyperglycemia occurs within 24 hours of glucocorticoid administration and appears to result from a repartitioning of glucose in the body rather than from gluconeogenesis.

Historically, many glucocorticoid preparations have been used successfully, but current drugs are more potent, require lower dosage, and have fewer side effects. A hyperglycemic state is produced for 4 to 6 days in ketotic cows given 10 mg of dexamethasone 21-isonicotinate, and other preparations that have a shorter duration of action, such as dexamethasone sodium phosphate (40 mg) and flumethasone (5 mg), are also used. Dexamethasone 21-isonicotinate (20 to 25 mg IM) decreases whole-body insulin sensitivity and affects glucose and lipid metabolism; it decreases liver fat content in early-lactating dairy cows with surgically corrected left-displaced abomasum.[27] Label regulations vary between countries; in general, the recommendations of the manufacturer with regard to glucorticoid use and dosage should be followed. Profound hypokalemia with high case fatality is a potential sequel to prolonged repeated therapy of ketosis with isoflupredone acetate, which has both glucocorticoid and mineralocorticoid activity. For this reason, only one treatment of isoflupredone acetate is recommended for cows with ketosis. Response of cows with primary ketosis to treatment with **corticosteroids and IV glucose is superior** to therapy with corticosteroids or IV glucose alone, with fewer relapses.

Insulin facilitates cellular uptake of glucose, suppresses fatty acid metabolism, and stimulates hepatic gluconeogenesis. Insulin is administered in conjunction with either glucose or a glucocorticoid and may be of particular value in early-onset cases of ketosis that are unresponsive to glucose or corticosteroid therapy, but it is not commonly used. The dose of protamine zinc insulin is 200 to 300 IU per animal (depending on body weight) administered SC every 24 to 48 hours as required. It should be recognized that endogenous insulin is released in all lactating dairy cattle administered 500 mL of 50% dextrose, although to a lower extent in ketotic cattle because they have a lower peak plasma glucose concentration following IV infusion of glucose or propionate;[28] consequently, IV dextrose administration should always be considered as a dual treatment of glucose and insulin.

Anabolic steroids have also been used for treatment of lactational ketosis and ketosis in late pregnant cows that are overfat, stressed, or have twin fetuses. Experimentally, 60 mg and 120 mg of trenbolone acetate are effective as single injections, but no extensive field trials are recorded, and the drug is banned for use in food animals in most countries.

Miscellaneous Treatments. Vitamin B_{12} and cobalt are indicated in regions where cobalt deficiency is a risk factor for ketosis. Cobalt is sometimes administered to cattle with ketosis in regions where cobalt deficiency does not occur, but the therapeutic value is not proven. Cyanocobalamin (vitamin B_{12}, 1 to 4 mg daily IV) in a combined formulation with butaphosphan has strong evidence supporting its role in normalizing energy status in early-lactation dairy cows when administered to dairy cattle before or around parturition.[29,30] Cyanocobalamin is essential for gluconeogenesis from propionate, and a theoretical argument can be made for the administration of cyanocobalamin for ketotic dairy cattle being treated for ketosis. It is also thought that high-producing dairy cows in early lactation have a relative or actual deficiency of cyanocobalamin.[30] Cysteamine (a biological precursor of coenzyme A) and also sodium fumarate have been used to treat cases of the disease. Reported results were initially good, but the treatment has not been generally adopted. The recommended dose rate of cysteamine is 750 mg IV for three doses at 1- to 3-day intervals.

Glucagon, although ketogenic, is strongly gluconeogenic and glycogenolytic, and glucagon concentrations are decreased in the plasma of fat cows at calving and cows with ketonemia. Glucagon could be of value in prevention and therapy, but it would require a prolonged delivery system because it has a very short physiologic half-life and its effects following a single injection are short-lived.

TREATMENT AND CONTROL

Treatment

Propylene glycol (300 to 500 mL daily for 5 days, PO) (R-1)

Dextrose (500 mL of 50% dextrose once, IV) (R-1)

Dexamethasone, dexamethasone-21-isonicotinate or flumethasone, IM (R-1)

Cyanocobalamin (vitamin B_{12}, 1 to 4 mg IV, daily for 2 to 6 treatments) (R-2)

Isoflupredone (20 mg, IM, multiple injections) (R-3)

Insulin (lente formulation, 200 IU SC daily for 3 days) (R-3)

Control

Monensin (11 to 22 g/ton of total mixed ration on a 100% dry matter basis; oral administration of a controlled-release capsule delivers 335 mg/day for 95 days) (R-1)

Propylene glycol (300 to 500 mL daily, PO) (R-1)

Rumen-protected choline (15g daily, PO, from 25 days precalving to 80 days postcalving) (R-2)

Cyanocobalamin (vitamin B_{12}, 1 to 4 mg IV, daily for 2 to 6 treatments before or at calving) (R-2)

Isoflupredone (20 mg, IM, once), with or without insulin (100 U, SC) (R-3)

CONTROL

The control of clinical ketosis is integrally related to the adequate nutrition of the cow in the dry and lactating periods. This encompasses details such as the following:

- Dry matter intake
- Fiber digestibility
- Particle size distribution
- Energy density
- Fat incorporation in early lactation rations
- Protein content
- Feeding systems
- Rumen size
- Other factors better covered in texts on nutrition

It is difficult to make general recommendations for the control of the ketosis because of the many conditions under which it occurs, its probable multiple etiology, and feeding systems that vary from those that feed components separately to those that feed total mixed rations. Cows neither should have been starved nor be overfat at calving. Careful estimation of diets by reference to feed value tables is recommended, and detailed recommendations on diet and management are available, with the caveat that planned rations can deviate from feed bunk rations, and feed bunk dry matter and actual dry matter intake may not be the same. Too low a feeding frequency and the feeding of concentrates separate from roughage rather than as a total mixed ration can lead to an increase in rates of ketosis.

In the United States, dry cows are typically divided into two groups: far-off and close-up cows. Far off cows are generally fed to National Research Council (NRC) dry-cow feeding guidelines, and close-up cows are given an acidogenic ration that decreases the incidence of clinical milk fever (periparturient hypocalcemia) starting 3 weeks before the estimated calving date. Practical recommendations based on British feeding standards and units are also available.

In high-producing cows being fed stored feeds, poor-quality roughage commonly leads to ketosis. Wet ensilage containing much butyrate, and moldy or old and dusty hay, are the main offenders. In concentrates, it is the change of source that creates off-feed effects and precipitates attacks of ketosis.

Cows that are housed should get some exercise each day, and in herds where the disease is a particular problem during the stabling period, the cattle should be turned out to pasture as soon as possible in the spring.

The ration should contain adequate amounts of cobalt, phosphorus, and iodine.

If there is a high incidence of ketosis in a herd receiving large quantities of ensilage, reduction of the amount fed for a trial period is indicated.

Energy Supplements

Propylene glycol is used for the prevention of clinical and subclinical ketosis. Traditionally, propylene glycol has been drenched to cattle in early lactation at doses varying from 350 to 1000 mL daily for 10 days after calving. There is a linear effect of dose on plasma glucose. Propylene glycol can also be added to feed and is frequently present in commercial feed products, but a bolus dose of propylene glycol is more effective in raising blood glucose than incorporation in feed. A dose of 1 L per day given as an oral drench for 9 days before parturition has also been shown efficacious; however, it is important to note that at doses above 500 mL administered by drench or present in feed, some cows may develop rapid and shallow respiration, ataxia, salivation, and somnolence. For this reason, a maximum daily dose of 500 mL as a drench should considered.

Glycerol can be substituted for propylene glycol at equivalent dose rates, although most studies indicate that glycerol is inferior to propylene glycol. A preliminary report of a small experimental study with larger doses of glycerol showed that glycerol given orally at a dose of 1 L, 2 L, or 3 L elevated blood glucose concentrations to 16%, 20%, and 25%, respectively, of pretreatment values at 0.5 hours after treatment and that these concentrations remained elevated for 8 hours. Staggering, depression, and diuresis were observed in some cows given the 2-L or 3-L dose, but this could be prevented by administering the glycerol in a large (37-L) volume of water. It concluded that a dose of 1 L was effective in increasing milk production and reducing urinary ketones. Glycerol fed as a constant component in the transition dairy cow diet is not effective and possibly may be ketogenic when fed continually. Glycerol should only be used as drench in hypoglycemic cows and not fed as a component of the diet.

Propionic Acid and Its Salts

Propionic acid absorbed across the rumen wall is transported to the liver, where it is converted to glucose via gluconeogenesis to result in an increase in serum blood glucose levels. Older literature reports that 110 g/d fed daily for 6 weeks, commencing at calving, has given good results in reducing the incidence of clinical bovine ketosis and improving production, but is not palatable and has the risk of reducing feed intake. In controlled trials, feeding energy supplements containing propionic acid and/or its salts for 3 weeks prepartum and 3 weeks postpartum had a beneficial effect on milk production, but a variable effect on reducing subclinical ketosis.

Ionophores

Ionophores alter bacterial flora of the rumen, leading to decreases in gram-positive bacteria, protozoa, and fungi and increases in gram-negative bacteria. The net effect of these changes in bacterial flora is increased propionate production and a decrease in acetate and butyrate production providing increased gluconeogenic precursors. Field trials with monensin have consistently demonstrated a reduction in serum or blood BHB, acetoacetate, and HEFA concentrations. In addition, monensin increased serum or blood glucose, urea, and cholesterol concentrations, and decreased the prevalence of clinical ketosis, clinical mastitis, and displaced abomasum in dairy cattle.[31-33] Monensin also decreases methane production by cattle; methane production by ruminants has been considered as contributing to global warming. Although approved for administration to lactating dairy cows in more than 20 countries, ionophores are not labeled for inclusion in lactating-cow rations in a number of countries.

Monensin is approved for continuous administration (>14 days) to dairy cattle in the United States at 185 to 660 (mg/head)/day monensin to lactating cows or 115 to 410 (mg/head)/day monensin to dry cows. To accomplish this, monensin is approved to be fed at 11 to 22 g/ton of total mixed ration on a 100% dry matter basis, at a daily per-cow cost of about 2 to 4 cents. Monensin is also approved for use in the United States as part of a component feeding system at 11 to 400 g/ton (as is basis); this includes application as a "top dress," where a small amount of feed is added to a ration.

In some countries, monensin can be administered orally as a controlled-release capsule to cattle 2 to 4 weeks before calving. The capsule contains 32 g of monensin and releases approximately 335 mg monensin a day for 95 days. This product is effective and practical for a variety of feeding systems, and approximately 18% of dairy herds in Canada are administering monensin by controlled-release capsule.

Corticosteroids

Isoflupredone acetate (20 mg, IM, once) was not effective in preventing subclinical ketosis in early-lactation dairy cows, and it actually increased the likelihood of subclinical ketosis.[34]

Ancillary Agents

A commercially available injectable product containing **cyanocobalamin** (vitamin B_{12}, 1 to 4 mg daily IV) in a combined formulation with **butaphosphan** is effective in normalizing energy status when administered to dairy cattle 2 to 6 times before or around parturition.[29,30] The administration of cyanocobalamin and butaphosphan may be most beneficial in cows at increased risk of developing ketosis, such as older cows, overconditioned cows, or those experiencing dystocia or metritis.[29] Phosphorus may be limiting in early lactation, based on low liver phosphorus content in dairy cattle.[35] It is not clear whether additional phosphorus mitigates the reduction in hepatic phosphorus content.

Rumen protected choline (15 g/day) fed daily starting 25 days before calving and continuing to 80 days after calving decreased the incidence of clinical ketosis and improved the health of lactating dairy cows.[36] Choline

is a precursor for phosphatidylcholine, which is thought to be rate limiting in early lactation; phosphatidylcholine deficiency is associated with impaired lipid metabolism.

Niacin is antilipolytic and induces increases in blood glucose and insulin, but there is conflicting evidence that **niacin** given in the feed has a beneficial effect on subclinical ketosis in cattle. It has been suggested that niacin should be supplemented from 2 weeks before parturition to 12 weeks postpartum.

General Control

Herd Monitoring. There is currently no consensus as to the optimal monitoring program for ketosis and subclinical ketosis in lactating dairy cattle, and consequently a variety of monitoring programs have been proposed. Challenges with developing optimal monitoring programs are the herd size (through the influence on the eligible numbers of animals available to be tested), ease of testing, cost of the test, and test sensitivity and specificity. In addition, the goals of the monitoring program need to be defined; typically they are either to monitor the adequacy of the diet relative to the level of milk production (i.e., the magnitude of negative energy balance in early lactation) or to identify animals to receive a standard treatment protocol, such as daily oral propylene glycol drenching. The optimal time for testing appears to be cows 3 to 9 days in milk because cows that are hyperketonemic at this stage of lactation are at highest risk for subsequent negative production and health effects, with the incidence and prevalence of subclinical ketosis occurring on day 5 of lactation.[37] A recent modeling approach utilizing 13,000 cows from 833 dairy farms in North America and Europe suggested that testing cows twice weekly from 3 to 9 days in milk was the most cost effective strategy when the subclinical ketosis incidence was between 15% and 50%; below an incidence of 15% it was not economical to test, and above 50% all cows should be treated without testing.[38] In addition, whenever the subclinical ketosis incidence increased to above 15%, a variety of testing and treatment protocols are economically beneficial.[38]

The six most valuable and practical indices for monitoring negative energy balance are urine acetoacetate concentration, blood BHB concentration, blood glucose concentration, body-condition score, back-fat thickness determined ultrasonographically, and milk-fat-to-protein ratio. The first five indices can be obtained cow side and at no cost or relatively low cost, although determining the blood BHB concentration costs approximately 5 to 10 times that of the first two tests and requires a blood sample. The milk-fat-to-protein ratio is readily obtained from individual monthly test data and is more highly correlated with energy balance than plasma BHB or glucose concentration.[39] This should be coupled with body-condition scoring or back-fat thickness to monitor the efficacy of the nutritional program. Plasma NEFA concentration is an excellent monitoring test of negative energy balance, but it is currently too expensive for routine herd monitoring, and an easy-to-use cow-side test is not available.

Urine testing using the nitroprusside test for acetoacetate is the simplest of the cow-side tests, and despite some reports that urine samples are difficult to obtain from all cattle, urine is easily obtained from more than 90% of cattle using the following standardized technique. First, stimulation of the perineum to obtain a urine sample must be the first part of the examination of the cow and ideally should be performed without the cow being aware that the veterinarian is present. Second, never hold the tail while stimulating the perineum because tail holding alerts the cow to the presence of the veterinarian, and it is not needed because cattle never urinate on their tails when posturing to urinate. Third, obtain urine samples in the normal environment of the animal; because cattle urinate on average five times per day, urine samples are easily obtained on recumbent cattle that are gently encouraged to stand.

Blood BHB testing has become very popular because of the availability of low-cost point-of-care meters. Despite this, it must be recognized that obtaining a blood sample is more complicated than obtaining a urine sample, and that the cost, although low, is much higher than that for urine acetoacetate or blood glucose testing. Moreover, serum BHB concentration is correlated with energy balance in a similar manner to plasma glucose concentration.[40] Automated monitoring by in-line measurements of ketone bodies in milk has been studied and may be of particular value in large dairies. BHB is proposed as the candidate because it is the more robust in milk, and where cows are fed a total mixed ration, it is not subject to significant diurnal variation. Milk BHB concentration can be measured in real-time with a fluorometric method that requires no pretreatment of the milk.

Biochemical monitoring of herds for subclinical ketosis and adequacy of periparturient feeding can be conducted using blood glucose estimations on a sample of cows in their second week of lactation. Plasma glucose concentrations below 45 mg/dL (2.4 mmol/L) suggest subclinical ketosis. For individual cows, blood glucose estimations should be done at about 14 days after calving. This method of monitoring is inexpensive using widely available point-of-care devices.

FATTY LIVER IN CATTLE (FAT-MOBILIZATION SYNDROME, FAT-COW SYNDROME, HEPATIC LIPIDOSIS, PREGNANCY TOXEMIA IN CATTLE)

Fatty liver (hepatic lipidosis) is an important metabolic disease of dairy cows in early lactation and is associated with decreased health status and reproductive performance.

SYNOPSIS

Etiology Mobilization of excessive body fat to liver during periods of negative energy balance at time of parturition or in early lactation of dairy cows and late pregnancy of beef cows.

Epidemiology High-producing dairy cows overfed during dry period may develop fatty liver syndrome just before or after calving precipitated by any factor or disease that interferes with feed intake. Occurs in well-conditioned beef cattle in late pregnancy when energy intake is suddenly decreased. Moderate and subclinical degrees of fatty infiltration may adversely affect reproductive performance of dairy cows.

Signs Inappetence to anorexia, ruminal atony, lethargic, inactivity, ketonuria, fat body condition, weakness and recumbency if worsens. Recover if continue to eat and appetite improves.

Clinical pathology Increase in plasma/serum nonesterified fatty acid, acetoacetate, β-hydroxybutyrate, and total bilirubin concentrations; increase in plasma/serum hepatic enzyme activity (particularly aspartate aminotransferase and ornithine carbamoyl transferase activity); increased fat content in liver biopsy.

Necropsy findings Fatty infiltration of liver, liver may appear yellow.

Diagnostic confirmation Liver biopsy.

Differential diagnosis list
- Left-sided or right-sided displacement of abomasum
- Milk fever
- Abomasal impaction
- Vagus indigestion
- Peritonitis

Treatment Fluid and electrolyte therapy including glucose IV (bolus infusion). Propylene glycol orally. Dexamethasone IM. Provision of palatable feed.

Control Avoid overfeeding during late lactation and dry period. Avoid situations that reduce feed intake at time of parturition.

ETIOLOGY

Fatty liver is caused by the mobilization of excessive quantities of fat from body deposits to the liver. It develops when the hepatic uptake of lipids exceeds the oxidation and secretion of lipids by the liver. Excess lipids are stored as triacylglycerol in the liver, and excessive lipid in hepatocytes is associated with decreased metabolic function of the liver. Fatty liver occurs because of a sudden demand of energy in the immediate postpartum period in well-conditioned lactating dairy cows. Fatty liver also occurs because of a sudden deprivation of feed in fat pregnant beef cattle, and is especially severe in those bearing twins. The disease is an exaggeration of what is a common occurrence in high-producing dairy cows that are in a state of negative energy balance in early lactation. A substantial drop in voluntary dry matter intake is initiated in late pregnancy and continues into early lactation. This decrease has traditionally been interpreted as caused by physical constraints in the abdomen as a result of the enlarging gravid uterus, but this purported mechanism appears to have been overemphasized. The decline in dry matter intake coincides with changes in reproduction status, changes in fat mass, and metabolic changes in support of lactation, and the associated metabolic signals are likely to play an important role in intake regulation. These signals include nutrients, metabolites, reproductive hormones, stress hormones, leptin, insulin, gut peptides, cytokines, and neuropeptides. Body fat, especially subcutaneous fat, is mobilized and deposited primarily in liver but also in muscle and the kidneys. Whether or not the cow is truly fat at parturition may not be important in determining the degree of fat mobilization, but the degree of negative energy balance in early lactation is critical.

EPIDEMIOLOGY

Occurrence and Incidence

Fatty infiltration of the liver is common in high-producing dairy cattle from a few weeks before and after parturition[1] and is associated with several periparturient diseases and an increase in the calving-to-conception interval. In dairy cows, fatty liver occurs primarily in the first 4 weeks after calving when up to 50% of all cows have some accumulation of triacylglycerol in the liver. A severe form of fatty infiltration of the liver immediately before or after parturition is known as the **fat-mobilization syndrome**, **fat-cow syndrome,** or **pregnancy toxemia** of cattle, and it can be highly fatal. In beef cattle, the disease occurs most commonly in late pregnancy when the nutrient intake is decreased in cattle that were previously well fed and in good body condition. In a field study, the percentage of cattle dying or being culled because of disease was affected by the amount of hepatic triglyceride: 15%, 31%, and 42% for cattle with mild, moderate, and severe hepatic lipidosis, respectively. **Outbreaks of the disease have occurred in dairy herds** in which up to 25% of all cows were affected, with a case-fatality rate of 90%.

Cattle have been classified into three groups on the basis of liver fat content determined histologically 1 week after parturition. Less than 20% lipid corresponds to less than 50 mg/g liver by weight; 20% to 40% lipid, 50 to 100 mg/g liver; and greater than 40% represents more than 100 mg/g liver. These concentrations correspond to mild, moderate, and severe cases of fatty infiltration, respectively. Cows with less than 20% lipid in the liver at 1 week after calving are considered normal, and those with more than 20% are considered to have a fatty liver. About 30% of high-yielding dairy cows in the United Kingdom are considered to have a fatty liver 1 week after calving. Clinical evidence of hepatic disease may not occur consistently until liver lipid concentrations are in the range of 35% to 45% or more.

Risk Factors

Host Factors

Fatty infiltration of the liver is part of a generalized fat-mobilization syndrome that occurs in early lactation, particularly in high-yielding dairy cows, as milk production outstrips appetite and body reserves are used to meet the energy deficit. In about 30% of high-producing cows, fatty infiltration in the liver is severe and is associated with reversible but significant effects on liver structure and function. In some populations of cows, the incidence of fatty liver is much lower and insignificant.

Diseases that occur commonly in early lactation predispose to fatty liver include **ketosis, left-side displacement of the abomasum, mastitis, retained fetal membranes, milk fever**, and **downer-cow syndrome.** Any disease of early lactation that affects appetite and voluntary intake can contribute to fatty liver.

The deficit occurs because dietary intake cannot meet the energy requirements for the high yield. Peak yields of milk are reached 4 to 7 weeks after calving, but the highest levels of voluntary feed intake are not reached until 8 to 10 weeks after calving. As a result of the energy deficit, the cow mobilizes body reserves for milk production and may lose a large amount of body weight.

The BCS at calving can have a direct effect on the health, milk yield, and fertility of cows. It represents the cumulative effects of the dry period, the BCS at drying off, and the loss of body condition during the dry period. The risk of retained placenta may be greater for cows underconditioned at drying, whereas cows that lost more body condition during the dry period may be more affected by both retained placenta and metritis; the two effects are independent of each other. The risk of ketosis is increased in cows overconditioned at calving, which may be a result of a long dry period. Cows calving at a higher BCS produced more milk, fat, and protein in the first 90 days of lactation, and the effect was most pronounced for milk-fat content. Cows with a higher BCS at calving were less prone to anestrus, but they did not conceive more successfully to first service. A reduction of 6 open days in primiparous cows was estimated for each additional unit of BCS at calving. Multiparous cows that lose more body condition during the dry period are more prone to inactive ovaries and are more likely to be open 150 days after calving in the next lactation.

Dairy cows with abnormally long dry periods also have a tendency to become

obese and develop the fatty liver syndrome of parturition. The feeding of dairy cows in large groups, as in loose housing systems, has been associated with an increase in the incidence of the disease. The disease has occurred in pregnant heifers within 31 days after being turned out onto grass.

The disease can occur in **nonlactating dairy cows** by the imposition of a partial-starvation diet in late pregnancy in an attempt to reduce the body weight of cows that are considered to be too fat. Changing the diet of pregnant beef cows from silage to straw in an attempt to reduce their body weight and the incidence of dystocia has resulted in outbreaks of the disease.

In beef cattle in North America, the severe form of the disease, pregnancy toxemia, is seen most commonly in the last 6 weeks of pregnancy in cows that are fat and pregnant with twins. The affected cows are usually well fed until late pregnancy, when an unexpected shortage of feed occurs, or the cows are too fat and cannot consume sufficient low-energy feed to meet the demands of pregnancy. Under usual circumstances, the disease in beef cattle occurs sporadically: the morbidity is about 1%, but the mortality is usually 100%.

Pregnancy toxemia of cattle has occurred in pregnant beef cattle in Australia and the United Kingdom. First-calf heifers were more commonly affected than older cows, and most were in late pregnancy (7 to 9 months) or had just recently calved. Cows pregnant with twins are particularly susceptible.

Genetics of Lipid Mobilization

Cows generally mobilize body lipid reserves in early lactation and regain these reserves during subsequent pregnancy. Lipid mobilized from body reserves makes a substantial contribution to the energetic cost of milk production in early lactation. It is usually assumed that this mobilization of body energy reserves is entirely a response to a deficit in feed energy intake relative to milk energy output. This implies that increasing the energy content of the feed being offered would decrease body energy mobilization in early lactation. A number of studies indicate that this is not always the case. It has been proposed that mobilization of body reserves in early lactation and the subsequent gain in body reserves during pregnancy are to a large extent genetically driven. Genetically driven body-lipid change is defined as that which would occur in cows kept in an environment that was in no way constraining. It then follows that environmentally driven body-lipid change is defined as that which occurs in response to an environment that is constraining. The rationale and evidence for genetically driven body-lipid change have their basis in evolutionary considerations and in the changes in lipid metabolism throughout the reproductive cycle.

Environmental and Dietary Factors

In North America, the introduction of the system of **challenge feeding** of dairy cows was associated with an increased incidence of fatty liver. The overall effect of the system is to provide excess energy in the diet during late pregnancy or during the dry period generally. The diets fed may contain a high percentage of the cereal grains, corn ensilage, or brewer's grains. In this system, high-energy rations are fed beginning a few weeks before parturition. The total daily amount of feed is increased by regular increments to reach a high level at parturition and peak levels to coincide with the peak in the lactation curve several weeks after parturition. This resulted in some excessively fat cows at the time of parturition, when energy demands are high. The disease has also occurred in dairy cows that were fed excessive amounts of high-energy rations throughout the dry period. In dairy herds, fatty liver syndrome has also been associated with an increase in the incidence of milk fever, ketosis, and left-sided displacement of the abomasum, all of which are much more difficult to treat successfully because of the fatty liver.

Overfeeding during the dry period predisposes cows to accumulate fat in adipose tissue during the prepartum period. Before parturition, adipose tissue from overfed cows has higher rates of esterification than the adipose tissue of cows fed a restricted energy intake. In the fatty livers of these overfed cows, the rate of gluconeogenesis is not optimal, which results prolongation of lipolysis, particularly during the first few weeks after parturition. The increased lipolysis after parturition leads to a major increase in the hepatic triacylglycerol concentration and to a shift in hepatic fatty acid composition. Unrestricted feed intake during the dry period impairs postpartum oxidation and synthesis of fatty acids in the liver of dairy cows.

In Australia, only beef cattle have been involved in pregnancy toxemia; the fat and the obese are most commonly affected. The disease occurred most notably when there was a shift to autumn calving (February to April) when feed supplies were low because of low late-summer rainfall. The cows were in good to fat body condition because of lush pastures in the spring and early summer, but by autumn when the calving season approached, the feed supplies were low and the nutritive value of the pasture inadequate. The lack of feed combined with the expensive nature of supplementary feeding resulted in an inadequate level of nutrition during late pregnancy. The morbidity is usually from 1% to 3%, but may be as high as 10%, and the disease is usually fatal.

PATHOGENESIS

Fatty liver is associated with a negative energy balance that is essentially universal in dairy cows in the first few weeks of lactation. Most cows adapt to the negative energy balance through an intricate mechanism of metabolic adaptation. Fatty liver develops because of failure of these adaptive mechanisms. Under normal physiologic conditions, the total amount of fat increases in the liver beginning a few weeks before calving, rises to an average of about 20% (of wet-weight basis) 1 week after calving, and declines slowly to the normal level of less than 5% by 26 weeks after calving. However, the fat content varies from almost none to 70% among cows 1 week after calving. Fat mobilization begins about 2 to 3 weeks before calving and is probably induced by a changing hormonal environment before calving rather than an energy deficit. After calving, there is a larger increase in fat accumulation. The changes in the liver in dairy cows are functional and reversible and related to the metabolic demands of late pregnancy and early lactation.

The heavy demands for energy in the high-producing dairy cow immediately after parturition, or in the pregnant beef cow that may be bearing twins, result in an increased rate of mobilization of fat from body reserves, usually subcutaneous fat, to the blood that transports it to body tissues, particularly the liver but also muscle and the kidneys. Any decrease in energy intake caused by a shortage of feed or an inability of the cow to consume an adequate amount of feed during the critical periods of late pregnancy or early lactation results in the mobilization of an excessive amount of **nonesterified fatty acids** (**NEFAs**). This results in increased hepatic lipogenesis with accumulation of lipid in enlarged hepatocytes, depletion of liver glycogen, and inadequate transport of lipoprotein from the liver. Most of the lipid infiltration of the liver in dairy cows after calving is in the form of triacylglycerols because of the increased uptake of NEFAs and a simultaneous increase in diacylglycerol acyltransferase; the activity of this enzyme is activated by fatty acids. The gradual increase in plasma NEFA concentration during the final prepartum days may explain the gradual depression in dry matter intake and a contributing factor to triglyceride accumulation in the liver. During this period there is also an elevated concentration of plasma glucose and a lowered plasma BHB concentration. The serum lecithin : cholesterol acyltransferase activity in spontaneous cases of fatty liver in cows is also decreased, which may be associated with reproductive performance because cholesteryl esters are utilized for the synthesis of steroid hormones.

Cattle are prone to fatty liver because their hepatocytes have limited capacity to export VLDLs and therefore a limited ability to export accumulated fat in the hepatocytes. NEFAs transported to the liver are usually oxidized in the mitochondria and peroxisomes or secreted as VLDL particles into the blood. Fatty liver develops when the

uptake of NEFAs by the liver exceeds the oxidation of NEFAs by the liver to CO_2, partial oxidation of NEFAs to form ketones, and export of phospholipids, cholesterol, and apoproteins from the liver as lipoproteins. For unknown reasons, the capacity for VLDL formation is low in cattle and further impaired in early-lactating cows a result of very low apoliprotein B100 (apoB100) availability, the main apolipoprotein of VLDL particles. Production of ketones in moderate levels is beneficial in that energy is exported from the liver to other tissues that can utilize ketones as an energy source. Excess lipids that cannot be exported are stored as triacylglycerol in the liver and are associated with decreased metabolic functions of the liver. Also, a prepartum surge of estrogen may contribute to the development of fatty liver in ruminants by increased fatty acid esterification along with limited export of triglyceride.

During fat mobilization, there is a concurrent loss of body condition and adipose tissue. The degree of mobilization will be dependent on the fatness of the cow and extent of the energy deficit. Fat and thin cows respond differently to the metabolic demands of early lactation. Fat cows appear less able to utilize mobilized fatty acids, and as a result they accumulate esterified fat in tissues. This can adversely influence susceptibility to disease, and the response of the cow to that disease imposes further metabolic demands, particularly on muscle and protein metabolism. Both fat and skeletal muscle mass are decreased after calving, and fat cows lose 2.5 times more muscle fiber area than thin cows. Thus the loss of body condition is a result of total tissue mobilization (protein and fat) rather than fat alone. There appears to be a higher rate of protein mobilization in fat cows than in thin cows.

Cows that are not fat initially do not develop fatty liver syndrome. Pregnant beef cows in thin body condition on pasture can become extremely emaciated and eventually recumbent and die of starvation, but they do not develop pregnancy toxemia.

CLINICAL FINDINGS

In dairy cattle, fat-cow syndrome occurs usually within the first few days following parturition and is commonly precipitated by any condition that interferes with the animal's appetite temporarily, such as the following:

- Parturient hypocalcemia
- Left-sided displacement of the abomasum
- Indigestion
- Retained fetal membranes
- Dystocia

Affected cows are usually excessively fat, with a BCS of 4/5 or higher. Excessive quantities of subcutaneous fat are palpable over the flanks, the shoulder areas, and around the tailhead. The affected cow usually does not respond to treatment for some of these diseases and becomes anorexic. The temperature, heart rate, and respiration are within normal ranges. Rumen contractions are weak or absent, and the feces are usually scant. Periods of prolonged recumbency are common, and affected cows may have difficulty in standing when they are coaxed to stand. A severe ketosis that does not respond to the usual treatment may occur. There is marked ketonuria. Affected cows will not eat and gradually become weaker and progress to totally recumbent, and they die in 7 to 10 days. Some cattle exhibit nervous signs consisting of a staring gaze, holding the head high, and muscular tremors of the head and neck. Some severe cases appear to develop hepatic failure, do not respond to therapy, and become weak and recumbent and die. Terminally there is coma, tachycardia, and marked hyperglycemia. The case-fatality rate in severe cases may reach 50% or more.

In fat beef cattle shortly before calving, affected cows are aggressive, restless, excited, and uncoordinated with a stumbling gait; sometimes have difficulty in rising; and they fall easily. The feces are scant and firm, and there is tachycardia. When the disease occurs 2 months before calving, the cows are depressed for 10 to 14 days and do not eat. Eventually they become sternally recumbent. The respirations are rapid, there may be an expiratory grunt, and the nasal discharge is clear, but there may be flaking of the epithelium of the muzzle. The feces are usually scant; terminally, there is often a fetid yellow diarrhea. The disease is highly fatal; the course is 10 to 14 days, and terminally there may be coma, with cows dying quietly.

In dairy cattle with moderately severe fatty liver, the clinical findings are much less severe, and most will recover within several days if they continue to eat even small amounts of hay. In dairy cattle, there is a relationship between the occurrence of a subclinical fatty liver within the first few weeks after parturition and inferior reproductive performance as a result of a delay in the onset of normal estrus cycles and a reduction in the conception rate that results in an increase in the average days between calving and conception. There may be differences in reproductive performance between cows with mild and moderate fatty livers early after calving. However, an examination of the postpartum hormone profiles of cows with fatty liver did not reveal the pathogenic mechanism of the reduced fertility. Fat-cow syndrome may also be associated with an increased incidence of parturient paresis and unresponsive treatment for ketosis in early lactation.

CLINICAL PATHOLOGY

Serum Biochemistry

The biochemical changes associated with fatty liver syndrome in cows depend on the severity of the fatty liver. There is a significant association between increasing serum biochemical abnormalities with increasing amounts of liver fat, although there may be considerable overlap in the distribution of individual test values in a population of animals with suspected fatty liver.

Increased plasma/serum nonesterified fatty acid, acetoacetate, BHB, and total bilirubin concentrations, and decreased serum fructosamine concentration,[2] are associated with increased liver fat percentage. Likewise, increased plasma/serum hepatic enzyme activity (particularly aspartate aminotransferase and ornithine carbamoyl transferase activity) is also associated with increased liver fat percentage. Other hepatic enzyme activities in plasma, such as alanine aminotransferase, sorbitol dehydrogenase, glutamate dehydrogenase, alkaline phosphatase, and gamma-glutamyl transferase activities, are poorly associated with liver fat percentage.[1] Possibly the most relevant biochemical index of the liver fat percentage is the **plasma NEFA : cholesterol** ratio. The rationale for using this ratio is that the plasma NEFA concentration reflects a metabolite that has not been cleared by the liver, whereas the plasma cholesterol concentration reflects the rate of hepatic reesterification and export as a VLDL. A high plasma NEFA : cholesterol concentration therefore is thought to indicate a high liver fat percentage. An increased concentration of plasma total bilirubin is also associated with increased liver fat percentage; competition between bilirubin and NEFA for the same binding site on hepatocytes decreases the hepatic uptake of bilirubin and therefore results in hyperbilirubinemia.[2] Serum fructosamine concentration provides a retrospective record of serum/plasma glucose concentrations over the previous 1 to 3 weeks and therefore provides a useful longer-term index of glucose availability. Serum fructosamine concentrations less than 213 µmol/L are predictive of hepatic lipidosis in dairy cattle.[2]

The plasma ammonia concentration in arterial or venous samples is poorly associated with liver fat percentage, but it is an excellent indicator of hepatic failure in severely affected cattle with hepatic lipidosis.[3] In cattle, ammonia in plasma is derived mainly from bacterial activity in the rumen and metabolism of tissue amino acids and is converted to urea by the liver or glutamine by the liver and other tissues. Consequently, severe liver dysfunction results in elevated plasma ammonia concentrations (>29 µmol/L), with higher ammonia concentrations in arterial samples than venous samples because of nonhepatic metabolism of ammonia.

Several cow-side blood, urine, and milk ketone tests are available for the detection of subclinical ketosis in postpartum dairy cows (see previous section on ketosis and subclinical ketosis). Metabolomic biomarkers show promise in identifying a typically pattern

of changes in cattle with hepatic lipidosis; for example, plasma fibrinogen decreases inversely with the severity of hepatic lipidosis, presumably because of intracellular lipid accumulation interferes with fibrinogen synthesis.[4]

Hemogram

In cattle with subclinical fatty liver, there may be a leukopenia, neutropenia, and lymphopenia. Leukopenia has been observed in dairy cows with more than 20% liver fat in the second week after calving. This may be related to the increased incidence of postparturient diseases, such as mastitis and endometritis, observed in cows with subclinical fatty liver. In cows with fatty liver, there is decreased functional capacity of the polymorphonuclear cells. However, this is not necessarily a cause-and-effect relationship.

Liver Biopsy and Analysis

The severity of fatty liver has been arbitrarily classified into severe, moderate, and mild, based on the amount of triglyceride present in the hepatocytes.[1] In severe hepatic lipidosis, the accumulation of triglyceride in the cytoplasm is accompanied by disturbances in hepatic structure and function that may result in hypoglycemia and ketonemia; these signs are manifested as anorexia and depression, and there may be clinical evidence of nervous signs. A liver biopsy can be used to determine the severity of the fatty liver and the concentration of triglyceride and is the most reliable method of accurately estimating the degree of fatty infiltration of the liver.

The triglyceride concentration of liver in normal cows ranges from 10% to 15% on a wet-weight basis. Estimation of the lipid content of bovine liver samples obtained by biopsy may be made by biochemical or histologic methods. Both methods provide reasonable estimates of liver fat content over a wide range of values. The lipid content of bovine liver is highly correlated with its specific gravity and the submersion of needle biopsy specimens into water, and copper sulfate solutions with specific gravities of 1.025 and 1.055 can be used as a test to estimate lipid content. For routine clinical diagnosis, three solutions of specific gravities of 1, 1.025, and 1.055 can be used. Liver samples that float in all three solutions contain greater than 34% lipid, those that sink in water but float in solutions of 1.025 and 1.055 specific gravity contain less than 34% but greater than 25% lipid, whereas those that float only in solutions of 1.055 specific gravity contain less than 25% but greater than 13% lipid. Samples that sink in all three solutions contain less than 13% lipid. Some limited evidence indicates that cows with liver lipid concentrations above 34% are severely affected and can be expected to have clinical manifestations of hepatic insufficiency. Those with liver lipid levels between 34% and 25% are moderately affected and might have some clinical evidence of hepatic insufficiency. Those between 25% and 13% are mildly affected, which is the range of most postpartum dairy cows without any evidence of disease. Liver lipid concentrations below 13% are inconsequential.

Ultrasonography of the Liver

Ultrasonography of the liver has been used to evaluate fatty infiltration in dairy cattle with mixed results.[5,6] Two strategies have been employed: identification of hepatic enlargement by comparing liver position with published reference range relative to the ribs, and the echogenicity or brightness of the liver. In the normal cow, the hepatic ultrasonogram consists of numerous weak echoes distributed homogeneously over the entire area of the liver. The echo beam gradually attenuates as it passes through the normal liver tissue. The portal and hepatic veins can be seen within the normal echotexture, and the parenchymal edges are normally visible. In the fatty liver, there is a diffuse nature and echogenicity that are roughly proportional to the volume of fat vacuoles and the amount of triglyceride in the liver. Assessment of echogenicity is subjective and varies with equipment and settings on the ultrasonographic unit. Consequently, objective ultrasonographic indices of hepatic lipidosis are under investigation, such as spectral analysis and analysis of brightness (B)-mode image statistics and texture characteristics.[6] Technological challenges associated with digital processing of ultrasonographic images of the liver need to be resolved before the noninvasive measurement of liver fat percentage becomes a widely available diagnostic tool.

NECROPSY FINDINGS

In severe fatal cases, the liver is grossly enlarged, pale yellow, friable, and greasy. Mild and moderate cases are usually not fatal unless accompanied by another fatal disease, such as peracute mastitis. The degree of fatty infiltration in these instances is much less obvious. The histologic changes include the occurrence of fatty cysts or lipogranulomas, enlarged hepatocytes, compression of hepatic sinusoids, a decreased volume of rough endoplasmic reticulum, and evidence of mitochondrial damage. The latter two changes are reflected in reduced albumin levels and increased activities of liver enzymes in the blood. The proportions of the various fatty acids in the liver are altered considerably. Palmitic and oleic acid proportions are higher in fatty-liver cows than in normal cows, whereas stearic acid is lower.

DIFFERENTIAL DIAGNOSIS

In **dairy cows, fatty liver** must be differentiated from those diseases that occur commonly immediately following parturition.
Left-sided displacement of the abomasum results in a secondary ketosis, inappetence, and pings over the left abdomen.

Retained placenta and **metritis** may be accompanied by fever, inappetence to anorexia, ruminal atony, and a foul-smelling vaginal discharge. A degree of fatty liver may occur in these cows, making it indistinguishable from the effects of the retained placenta and metritis.

Primary ketosis may occur immediately after parturition or within several days rather than at the most common time, at 6 to 8 weeks of lactation. Inappetence, ruminal hypotonicity, marked ketonuria, and a good response to glucose and propylene glycol are characteristic.

In **beef cattle, pregnancy toxemia** before parturition must be differentiated from abomasal impaction, vagus indigestion, and chronic peritonitis.

TREATMENT

The prognosis for severe fatty liver is unfavorable. In general, cows with the severe fat-cow syndrome that are totally anorexic for 3 days or more usually die in spite of intensive therapy. The prognosis for cases with nervous signs is very poor. Liberal quantities of highly palatable good-quality hay and an ample supply of water should be provided. Cattle that continue to eat in increasing daily amounts will recover with supportive therapy and palatable feeds. The major prognostic factor is whether the cow will eat; failure of the appetite to return is usually a very poor prognostic sign.

Three treatment strategies for fatty liver are available. The most effective strategy is to decrease the rate of fat mobilization and therefore the plasma NEFA concentration; propylene glycol appears to act partly by this mechanism. The second strategy is to facilitate the complete oxidation of NEFAs in the liver. The third strategy is to increase the rate of export of VLDLs from the liver; choline is thought to act by this method. Because they address different mechanisms, combined treatment using propylene glycol and rumen-protected choline offers theoretical advantages. Several different therapeutic approaches have been tried and are discussed in detail in the previous section on ketosis and subclinical ketosis

Additional treatments that have been tried in cattle with fatty liver include intravenous fluids, ruminal transfaunation, and glucagon.

Fluid and Electrolyte Therapy. Intensive therapy directed at correcting the effects of the ketosis and the fatty liver is required. The recommended treatment includes continuous IV infusion of 5% **glucose and multiple electrolyte solutions** and the intraruminal administration of rumen juice (5 to 10 L) from normal cows in an attempt to stimulate

the appetite of affected cows. Water and multiple electrolytes (10 to 30 L) can be administered intraruminally.

Glucagon. The subcutaneous injection of 15 mg/d of glucagon for 14 days beginning at day 8 postpartum decreases liver triglyceride concentrations in cows older than 3.5 years. Glucagon, containing 29 amino acids, is a pancreatic hormone that improves the carbohydrate status of cows by stimulating hepatic gluconeogenesis, glycogenolysis, amino acid uptake, and ureagenesis. The effect of glucagon on lipid metabolism is both direct and indirect because it directly increases lipolysis in adipose tissue but indirectly decreases lipolysis by increasing concentrations of plasma glucose and insulin. IV infusions of glucagon are not practical for on-farm use.

Glucocorticoids. Dexamethasone-21-isonicotinate (20 to 25 mg, IM) decreases hepatic total lipid and triglyceride content in cattle after surgical correction of left-displaced abomasum, which is a beneficial effect.[7]

Propylene glycol given orally at 300 mL/day for 5 days promotes gluconeogenesis and is used for the treatment of ketosis.

Insulin as zinc protamine at 200 to 300 SC twice daily promotes the peripheral utilization of glucose, but clinical results have been mixed. It is important to recognize that IV administration of glucose is always accompanied by insulin release, no matter the metabolic state of the cow. Consequently, IV glucose administration should be considered as a combined treatment with glucose and insulin.

Outbreaks in a Herd. When outbreaks of fat-cow syndrome occur in pregnant beef cattle, all remaining cows should be sorted into groups according to body condition and fed accordingly. Excessively fat cows should be fed the best-quality hay that is available along with a supplement. Fat cows should be exercised by feeding them on the ground and forcing them to walk.

TREATMENT AND CONTROL

Treatment

Propylene glycol (300 mL daily for 5 days, PO) (R-1)

Dextrose (500 mL of 50% dextrose once, IV) (R-1)

Dexamethasone, dexamethasone-21-isonicotinate, or flumethasone, IM (R-1)

Cyanocobalamin (vitamin B_{12}, 1 to 4 mg IV, daily for 2 to 3 treatments) (R-2)

Isoflupredone (20 mg, IM, multiple injections) (R-3)

Control

Monensin (controlled-release capsule, 335 mg/day) (R-1)

Propylene glycol (300 to 500 mL daily for 5 days, PO) (R-1)

Cyanocobalamin (vitamin B_{12}, 1 to 4 mg IV, daily for 2 to 6 treatments before or at calving) (R-2)

CONTROL

Control and prevention of fatty liver in cattle will depend on decreasing or eliminating most of the potential risk factors for the disease. Early recognition and treatment of diseases that affect the voluntary dietary intake in late pregnancy and immediately after parturition are necessary to minimize the mobilization of body-fat stores to meet the overall energetic requirements of the cow during the period of negative energy balance and to maintain or increase hepatic gluconeogenesis. Diseases such as ketosis, displaced abomasum, retained placenta, acute mastitis, milk fever, and downer-cow syndrome must be treated as early as possible to avoid varying degrees of hepatic lipidosis.

Dry Matter Intake and Energy Balance in the Transition Period

The literature on dry matter intake and energy balance in the transition period of the dairy cow has been reviewed.

The transition from late gestation to early lactation in the dairy cow is a critical period in the lactation–gestation cycle. During this period, feed intake is at the lowest level in the production cycle. In addition to the drop in feed intake, there is a concurrent transition from late gestation to lactation, with huge increases in energy demands. This leads to a negative energy balance that can result in ketosis or fatty liver. Voluntary dry matter intake (DMI) may decrease 25% and 52% during the final 14 days of gestation for first- and second-parity animals and aged (third and fourth or greater) cows, respectively. A negative energy balance can occur before parturition and is more likely to occur in heifers than cows because heifers have a lower DMI and an additional need for energy requirement for growth. The fall in DMI is the usual cause of a negative energy balance rather than an increase in energy requirements for fetal growth.

Metabolic Adaptations During the Transition Period

The primary goal of nutritional management strategies of dairy cows during the transition period should be to support the metabolic adaptations that occur. The hallmark of the transition period of dairy cattle is the dramatic change in nutrient demands that necessitates exquisite coordination of metabolism to meet requirements for energy, amino acids, and calcium by the mammary gland after calving. Estimates of the demand for glucose, amino acids, fatty acids, and net energy by the gravid uterus at 250 days of gestation and the lactating mammary gland at 4 days postpartum indicate approximately a tripling of demand for glucose, a doubling of demand for amino acids, and approximately a fivefold increase in demand for fatty acids during this period. In addition, the requirement for calcium increases approximately fourfold on the day of parturition. The literature on the integration of metabolism and intake regulation in periparturient animals has been reviewed.

Glucose Metabolism

The primary homeorhetic adaptation of glucose metabolism to lactation is the concurrent increase in hepatic gluconeogenesis and decrease in oxidation of glucose by peripheral tissues to direct glucose to the mammary gland for lactose synthesis. The major substrates for hepatic gluconeogenesis are propionate from ruminal fermentation, lactate from Cori cycling, amino acids from protein catabolism or net portal-drained visceral absorption, and glycerol released during lipolysis in adipose tissue.

Lipid Metabolism

The primary homeorhetic adaptation of lipid metabolism to lactation is the mobilization of body fat stores to meet the overall energetic requirements of the cow during a period of negative energy balance in early lactation. Body fat is mobilized into the bloodstream in the form of NEFAs that are used to make upward of 40% of milk fat during the first days of lactation. Skeletal muscle uses some NEFA for fuel, particularly as it decreases its reliance on glucose as a fuel during early lactation. Given that NEFA concentrations increase in response to increased energy needs accompanied by inadequate feed intake, and plasma NEFA concentrations usually are inversely related. The liver takes up NEFAs in proportion to their supply, but the liver typically does not have sufficient capacity to completely dispose of NEFAs through export into blood or catabolism for energy. Therefore cows are predisposed to accumulate NEFAs as triglycerides within liver when large amounts of NEFA are released from adipose tissue into the circulation.

Nutritional Management to Support Metabolic Adaptations During the Transition Period

Grouping Strategies

The primary goal of nutritional management strategies of dairy cows during the transition period should be to support the metabolic adaptations just described. Industry-standard nutritional management of dairy cows during the dry period consists of a two-group nutritional scheme. The National

Research Council (NRC) Nutrient Requirements of Dairy Cattle recommends that a diet containing approximately 1.25 Mcal/kg of NE_L should be fed from dry-off until approximately 21 days before calving, and that a diet containing 1.54 to 1.62 Mcal/kg of NE_L should be fed during the last 3 weeks before calving. The primary rationale for feeding a lower-energy diet during the early part of the dry period is to minimize BCS gain during the dry period. During the last 3 to 4 weeks prepartum, a diet higher in energy and protein concentration than current NRC recommendations should be fed so that adequate nutrient intake occurs within the limits of the reduced voluntary dry matter intake. Supplying excessive energy to dairy cows during the early dry period may have detrimental carryover effects during the subsequent early lactation. Managing cows to achieve a BCS of approximately 3.0 at drying off rather than the traditional 3.5 is now recommended.

Strategies to Meet Glucose Demands and Decrease NEFA Supply During the Transition Period

Carbohydrate Formulation of the Prepartum Diet. Feeding diets containing higher proportions of nonfiber carbohydrate (NCF) promotes ruminal microbial adaptation to NFC levels typical of diets fed during lactation and provides increased amounts of propionate to support hepatic gluconeogenesis and microbial protein (providing the diet contains sufficient ruminally degradable protein) to support protein requirements for maintenance, pregnancy, and mammogenesis.

Direct Supplementation With Glucogenic Precursors. Propylene glycol is a glucogenic precursor that has been used as an oral drench in the treatment of ketosis. Decreased concentrations of plasma NEFA and BHB follow oral administration of propylene glycol. The administration of an oral drench of propylene glycol for 2 days beginning at calving decreased concentrations of NEFA in plasma and increased milk yield during early lactation. However, in general, the lack of consistent production responses does not support a recommendation for routine use. Propionate supplements added to the diet to supply substrate for hepatic gluconeogenesis have also been used, but with inconsistent results.

Glycerol given orally is an effective treatment for lactational ketosis in dairy cattle. Feeding glycerol to dairy cows from 14 days prepartum to 21 days in milk did not have the glucogenic effect attributed to it when given orally as a drench to individual cows.

Monensin provided in controlled-release capsules (CRCs) administered 2 to 4 weeks prepartum has been shown to decrease the incidence of energy-associated diseases, subclinical ketosis, and left-side displaced abomasum by 40%, and a 25% reduction in retained placenta was found. The capsule delivers 335 mg/d of monensin for 95 days. The common mechanism for reduction of the incidences of these energy-associated diseases is likely to be improved energy metabolism during the transition period. The net effect of monensin within the rumen is to increase ruminal propionate production at the expense of ruminal acetate and methane production so that propionate supply is increased and the overall energetic efficiency of ruminal fermentation is increased.

Added Fat in Transition Diets. It has been proposed that dietary fat may partially decrease concentrations of NEFA and prevent the occurrence of ketosis. Dietary long-chain fatty acids are absorbed into the lymphatic system and do not pass first through the liver. The fat can provide energy for peripheral tissues and the mammary gland, and the increased energy availability would in turn decrease mobilization of body fat and decrease plasma NEFA concentrations. However, available evidence indicates that added fat fed to cows during the prepartum period does not decrease plasma NEFA concentrations.

Effects of Specific Fatty Acids on NEFA Supply. A substantial amount of research has examined the metabolic roles of individual fatty acids in transition-cow nutrition and metabolism. Feeding *trans*-10, *cis*-12 conjugated linoleic acid or transoctadecanoic acid experimentally may decrease the negative energy balance, but the ultimate metabolic effects in transition cows are as yet uncertain.

Because of the large economic losses associated with pregnancy toxemia in cattle, every economic effort must be made to prevent the disease. The principal method of control is to prevent pregnant cattle from becoming fat during the last trimester of pregnancy, particularly during the dry period in dairy cattle. During pregnancy, mature cattle should receive sufficient feed to meet the needs for maintenance and pregnancy, and the total daily nutrient intake must increase throughout the last trimester to meet the needs of the fetus. However, this increase is usually difficult to control without some cows getting fat and others losing weight. Sorting cows into groups on the basis of size and condition and feeding accordingly is recommended. Metabolic profiles may be used as a means of assessing energy status and, correspondingly, the likelihood of occurrence hyperketonemia or pregnancy toxemia. Both plasma glucose and BHB concentrations can be used.

Body-condition scoring of dairy cows at strategic times can be used to monitor the nutritional status of the herd and minimize the incidence and severity of fatty liver syndrome. The scoring should be done throughout the production cycle as part of a herd health program. Scoring done at calving, at 21 to 40 days, and 90 to 110 days postpartum can be used to monitor the nutritional status of the herd. Scoring done at 100 to 60 days before drying off provides an opportunity for management to make appropriate adjustments in the feeding program so that optimal body-condition goals are achieved. The optimum BCS of a cow at calving that will result in the most economical amount of milk has not yet been determined. On a scale of 5, the suggested optimum score at calving has ranged from 3 to 4. The optimum score will probably depend on the characteristics of the individual herd, which include type of cow, type of feedstuffs available, season of the year, environmental temperature, and the people doing the actual body-condition scoring.

PREGNANCY TOXEMIA (TWIN LAMB DISEASE) IN SHEEP

SYNOPSIS

Etiology A multifactorial disorder of energy metabolism, with hypoglycemia and ketonemia (the accumulation in blood of acetoacetate, β-hydroxybutyrate, and their decarboxylation products acetone and isopropanol).

Epidemiology The disease in sheep is associated with a falling plane of nutrition, principally in the last month of pregnancy in ewes bearing twins and triplets, but can be induced by other stress at this time.

Clinical findings Encephalopathy with blindness, muscle tremor, convulsions, metabolic acidosis, and a clinical course of 2 to 8 days, usually terminating fatally unless treated early.

Clinical pathology Hypoglycemia, ketonemia, ketonuria.

Necropsy findings None specific. Twin lambs and fatty liver.

Diagnostic confirmation Ketonemia, ketonuria, or elevated ketones in milk. Elevated β-hydroxybutyrate (BHBA) in aqueous humor of dead sheep.

Treatment Parenteral glucose with corticosteroid and oral glucose precursors such as propylene glycol, occasionally insulin, or oral glucose and electrolyte therapy. Cesarean section or induction of parturition. Case fatality high.

Control Monitoring of condition score, pasture availability, feeding, and biochemical indicators of ketosis. Correction of energy imbalance if detected.

ETIOLOGY

Hypoglycemia and hyperketonemia are the primary metabolic disturbances in pregnancy toxemia. The precipitating cause is the energy demand of the conceptus in the latter part of pregnancy. However, there is a great deal of variation between sheep flocks in the prevalence of the naturally occurring disease under conditions that appear conducive to its development. The most important factor in pregnancy toxemia is a decline in the plane of nutrition during the last 4 to 6 weeks of pregnancy. This is the period when fetal growth is rapid and the demands for energy are markedly increased, particularly in ewes carrying twins or triplets. For example, the energy requirement for a 70-kg ewe carrying twins increases 36% in the last weeks of pregnancy, from 13.5 MJ (3.2 Mcal)/d midgestation to 18.3 MJ (4.4 Mcal)/d at term. The disease in goats during late pregnancy has the same initiating causes.

Pregnancy toxemia can be classified according to the underlying management cause that is critical to its control and prevention:

- Primary pregnancy toxemia
- Fat-ewe pregnancy toxemia
- Starvation pregnancy toxemia
- Secondary pregnancy toxemia
- Stress-induced pregnancy toxemia

EPIDEMIOLOGY

Primary Pregnancy Toxemia

Primary pregnancy toxemia is the most common. In most flocks it is a result of a declining plane of nutrition in the latter half of pregnancy, often exacerbated by a short period of food deprivation associated with a management procedure in late pregnancy, such as crutching, shearing, a change of environment, or drenching. In sheep grazing pastures the decreased plane of nutrition is often associated with inadequate pasture availability and/or overstocking. In sheep at pasture it occurs more frequently in early-lambing flocks, where there is insufficient supplement provided during autumn or winter. In some outbreaks ewes have been moved onto better pasture during late pregnancy specifically to prevent the occurrence of ketosis, but if ewes are unaccustomed to the new feed, their intake of metabolizable energy will be reduced.

For sheep that are housed in late pregnancy, the provision of poor-quality hay may predispose pregnancy toxemia. A change in feed type, feeding of moldy feed, or feed contaminated with manure can also lead to decreased intake, especially with goats. Competition for inadequate trough space can also be important. Goats exhibit greater dominant/submissive behavior than sheep, and this can result in lower food intake in submissive goats in groups that are being fed a partial supplement or total ration.

In all management systems, failing to identify and separate ewes bearing twins and triplets, and to feed them accordingly, or failing to increase the nutritional plane of mixed mobs of pregnant sheep during the last 6 weeks of pregnancy are important predisposing factors.

Fat-Ewe Pregnancy Toxemia

Fat-ewe pregnancy toxemia occurs without a specific stressor in ewes that are very well fed and are in an overfat condition in late pregnancy (a condition score of 4 or 5 on a scale of 1 [emaciated] to 5 [fat]). Fat ewes have a decreased food intake in late pregnancy when the volume of the rumen is reduced by the pressure of intraabdominal fat and the developing fetus. This can occur especially when feeds with high water content are being fed, such as silage or root crops. A lack of exercise is thought to predispose this type of pregnancy toxemia, and there is often concurrent hypocalcemia.

Starvation Pregnancy Toxemia

Starvation pregnancy toxemia occurs in ewes that are excessively thin. It is relatively uncommon, but it occurs in extensive grazing systems where there is prolonged drought and an inadequate alternative feed supply. It can occur in any production system where there is mismanagement and undernutrition.

Secondary Pregnancy Toxemia

Secondary pregnancy toxemia usually occurs as a sporadic disease as the result of the effect of an intercurrent disease, such as foot rot or foot abscess, that affects food intake. Heavy worm infestation, such as mixed infections of *Teladorsagia, Haemonchus*, or *Trichostrongylus* species, would add a similar drain on glucose metabolism and increase the chances of development of this condition.

Stress-Induced Pregnancy Toxemia

Stress-induced pregnancy toxemia is the least common variant of this condition, in which stress is the initiator. Examples are the close shepherding or housing of late-pregnant sheep of breeds not used to being housed, the transport of late pregnant sheep, and outbreaks following attack by dogs.

Occurrence

Pregnancy toxemia is seen primarily in ewes carrying triplet or twin lambs in the last 6 weeks of pregnancy, with the peak incidence in the last 2 weeks of pregnancy. It occurs wherever sheep are raised, but it is primarily a disease of sheep raised in intensive farming systems, either grazing or when housed during the winter. In part this is because the breeds of sheep used in intensive farming a re more likely to bear twins or triplets. In contrast, sheep breeds in extensive grazing systems commonly bear single lambs, and significant outbreaks of pregnancy toxemia are uncommon except where there is drought or insufficient pasture as a result of poor management. The attack rate in a flock varies with the nature and severity of the nutritional deprivation and the proportion of the flock at risk. It can be very high in starvation pregnancy toxemia, whereas fat-ewe pregnancy toxemia is generally sporadic. In outbreaks that follow management procedures or other stressors, clinical disease is not seen until 48 hours afterward, and new cases will develop over several days. Intercurrent disease in late-pregnant ewes, such as foot rot or foot abscess, may predispose pregnancy toxemia.

The natural incidence in intensively farmed sheep is approximately 2% of pregnant ewes, but where there are severe management deficiencies it may affect the majority of late-pregnant ewes. The proportion of flocks with cases varies by year, but in a study of sheep diseases in Canada, 19% of flocks reported cases of pregnancy toxemia. The case fatality is high unless treatment is initiated early in the clinical course, but even with early treatment many ewes will die.

Experimental Reproduction

Hypoglycemia and ketosis can be experimentally produced in pregnant sheep by undernourishment, but the resultant syndrome has biochemical and clinical differences from spontaneously occurring pregnancy toxemia. For example, loss of appetite is an early sign in the spontaneous disease, whereas starved experimental animals, even though hypoglycemic and ketotic, will eat feed when offered. Consequently, there is debate about whether hypoglycemia is the primary precipitating cause of the clinical signs in the naturally occurring disease.

There is a great deal of variation between sheep in the ease with which the hypoglycemia and ketosis can be produced experimentally and in the variation in incidence of the naturally occurring disease in conditions that appear to be conducive to it developing. It is likely that the difference between sheep

depends on the metabolic efficiency of the liver.

Animal Risk Factors

Pregnancy

The disease occurs only in ewes in the last 6 weeks of pregnancy, with the peak incidence in the last 2 weeks. It occurs primarily in ewes carrying triplet or twin lambs, although ewes bearing a single, large lamb may also be affected.

Parity

The disease is uncommon in maiden ewes because of their lower fecundity, and then increases in prevalence up until 5 to 6 years of age.

Breed

Breed differences largely reflect differences in fecundity and differences in management systems. Thus the disease is more common in British lowland breeds and their crosses than the Merino. British hill-breeds are traditionally thought to be more resistant to the development of pregnancy toxemia in the face of nutritional deprivation of the ewe, but resistance is achieved at the expense of lamb birth weight and has the penalty of higher neonatal mortality. Differences in the susceptibility of individual sheep appear to be related to differences in rates of hepatic gluconeogenesis.

Economic Significance

The disease has considerable effect. Without treatment, the case-fatality rate can approach 100%, and in individual flocks the prevalence can be high enough to be classed as an outbreak. Treated ewes that recover may have dystocia and die during parturition or develop retained placenta and metritis. Flocks that experience pregnancy toxemia also have a significantly higher-than-normal mortality in neonatal lambs and often a severe decrease in wool quality. Often these flocks are also predisposed to hypomagnesemia during lactation.

PATHOGENESIS

Approximately 60% of fetal growth takes place in the last 6 weeks of pregnancy, and pregnancy toxemia results from inadequate energy intake during this time, usually in ewes with more than one fetus. Ewes that are predisposed to the disease have an ineffective gluconeogenic response to the continued preferential demands for glucose by the growing fetuses, resulting in hypoglycemia, lipid mobilization, and the accumulation of ketone bodies and cortisol. The reason for this predisposition is not precisely known, but the subsequent disease and metabolic changes are associated with excessive lipid mobilization. Elevated concentrations of BHB further suppress endogenous glucose production and exaggerate the development of ketosis. Thus the negative feedback of hyperketonemia on glucose production produces a self-perpetuating cycle.

An encephalopathy develops, thought to be a hypoglycemic encephalopathy from hypoglycemia in the early stages of the disease. The encephalopathy and the disease are frequently not reversible unless treated in the early stages. The onset of clinical signs is always preceded by hypoglycemia and hyperketonemia, although it is not related to the minimum blood glucose or maximum ketone levels, and thus hypoglycemia may not be the initial or precipitating cause of the syndrome. In affected ewes, there is an abnormally high level of cortisol in plasma, and adrenal steroid diabetes ("insulin resistance") may either contribute to or be a predisposing factor. For example, a comparison of ewes with a high risk of pregnancy toxemia (German Blackheaded Mutton) with a breed of lower risk (Finnish Landrace) found that the glucose elimination rate and glucose stimulated first-phase insulin secretion was lower and the basal rate of lipolysis significantly higher in the high-risk ewes. However, further investigation of insulin resistance and impaired insulin sensitivity, and the underlying cause of pregnancy toxemia, is needed.[1]

The increase in plasma concentrations of nonesterified fatty acids depresses cellular and humoral immune responses in the experimentally produced disease, but the clinical significance of this to naturally occurring disease is not clear.[2] Renal dysfunction is also apparent in the terminal stages of ovine ketosis and contributes to the development of clinical signs and the fatal outcome.

Those ewes that are carrying only one lamb and have been well fed before a short period of undernutrition may develop a subacute syndrome, both clinically and biochemically. In lines of ewe selected for increased fecundity, ewes bearing more than three fetuses have an increased susceptibility to pregnancy toxemia.[3]

CLINICAL FINDINGS

The earliest signs of ovine ketosis are separation from the group, altered mental state, and apparent blindness, manifested by an alert bearing but a disinclination to move. Sheep at pasture may fail to come up for supplementary feeding, and housed sheep may stand near the feed trough with other sheep but not eat. The ewe will stand still when approached by attendants or dogs and will turn and face them, but it will make no attempt to escape. If it is forced to move, it blunders into objects; when an obstacle is encountered, it presses against it with its head. Many affected ewes stand in water troughs all day and lap the water. Constipation with dry, scanty feces is common, and there is grinding of the teeth.

In later stages, marked drowsiness develops, and episodes of more severe nervous signs occur, but they may be infrequent and easily missed. In these episodes, tremors of the muscles of the head cause twitching of the lips, champing of the jaws, and salivation, and these are accompanied by a cog-wheel type of clonic contraction of the cervical muscles causing dorsiflexion or lateral deviation of the head, followed by circling. The muscle tremor usually spreads to involve the whole body, and the ewe falls with tonic-clonic convulsions. The ewe lies quietly after each convulsion and rises normally afterward, but is still blind.

Between the convulsions there is marked drowsiness that may be accompanied by head pressing; assumption of abnormal postures, including unusual positions of the limbs and elevation of the chin (the "stargazing" posture); and incoordination and falling when attempting to walk. A smell of ketones may be detectable on the breath.

Affected ewes usually become recumbent in 3 to 4 days and remain in a state of profound depression or coma for a further 3 to 4 days, although the clinical course is shorter in fat ewes. Terminally there may be a fetid diarrhea.

Fetal death often occurs and is followed by transient recovery of the ewe, but the toxemia caused by the decomposing fetus soon causes a relapse.

Affected ewes commonly have difficulty in lambing. Recovery may occur after the ewe lambs or if the lambs are removed by cesarean section in the early stages of the disease. In an affected flock, the disease usually takes the form of a slow, prolonged outbreak, with a few ewes affected each day over a period of several weeks. Recovered ewes may subsequently show a break in the wool.

CLINICAL PATHOLOGY

Hypoglycemia, ketonemia, and ketonuria are characteristic of the disease. The initial changes are similar to ketosis in cattle but the sequel is not. Hypoglycemia can be used as a diagnostic aid in the early stages of the disease, but is of limited value later on when the ewe becomes recumbent, when blood glucose levels may be normal or grossly elevated. This may follow fetal death, which has been shown to remove the suppressing effect of the fetus on hepatic gluconeogenesis.

Ketonemia and ketonuria are constant, with serum BHB concentrations greater than 3.0 mmol/L. Sheep develop a severe metabolic acidosis, develop renal failure with a terminal uremia, and become dehydrated. Liver function tests show liver dysfunction. Elevated plasma cortisol concentrations occur, with greater than 10 ng/mL indicative of pregnancy toxemia. However, elevated plasma cortisol can occur with other conditions, such as hypocalcemia.

NECROPSY FINDINGS

Without treatment, pregnancy toxemia in ewes is almost always fatal. At necropsy, there is severe fatty degeneration of the liver and usually constipation, although some

cases have fetid, light-colored diarrhea. A large single or, more commonly. twin or greater number of fetuses are present. These may have died before the ewe and be in varying stages of decomposition.

Histopathologically there is hepatic lipidosis and a poorly defined renal lesion, and there may be evidence of neuronal necrosis. Hepatic glycogen concentrations are usually very low. Concentrations of BHB in the aqueous humor or the CSF greater than 2.5 mmol/L or 5.0 mmol/L respectively, are supportive of a diagnosis of pregnancy toxemia.

DIFFERENTIAL DIAGNOSIS

Pregnancy toxemia is usually suspected in late-pregnant ewes that show nervous signs and die within 2 to 7 days. There may be a history of exertion, stress, or sudden deprivation of food. **Hypocalcemia** can occur under similar circumstances, but the following help in differentiation:

1. The onset is within 12 hours of the stress.
2. A considerable proportion of the flock will be affected at the same time.
3. There is obvious myasthenia.
4. It has a much shorter course, 12 to 24 hours.
5. Affected animals respond well to treatment with solutions of calcium salts.

Differential diagnoses include

- Listeriosis
- Cerebral abscess
- Acidosis
- Uterine torsion or impending abortion
- Rabies

TREATMENT

Sheep treated very early in the course of the disease generally respond favorably,[4] but response to therapy is poor once sheep have become recumbent, and the IV administration of 50% dextrose at this time may hasten death. Optimum therapy requires the correction of fluid, electrolyte, and acid–base disturbances in addition to treating with glucose.

Parenteral Therapy

Ideally, individual sheep should be examined biochemically and the corrective therapy based on these results, with fluids, electrolytes, and glucose (dextrose) given over a prolonged period. A recommendation for glucose therapy is the administration of 5 to 7 g of glucose IV 6 to 8 times a day in conjunction with 20 to 40 units of zinc protamine insulin given IM every other day for 3 days. However, in many sheep-raising areas intensive laboratory monitoring and such intensive therapy is not possible because of lack of access, expense, or the number of sheep involved in an outbreak. In the absence of biochemical monitoring, therapy with glucose should be accompanied by the IV injection of isotonic sodium bicarbonate or lactated Ringer's solution, with additional fluids given by a stomach tube.

Standard doses of corticosteroids have little therapeutic effect in sheep, and thus treatment with these drugs is not recommended, although they are often used. Very large doses are effective in ewes still able to stand, but the success probably rests in the removal of the glucose drain by the induction of premature parturition.

Oral Therapy

Oral propylene glycol or glycerin (100 mL once daily) can be used to support parenteral glucose therapy. Less intensive therapy with propylene glycol or glycerin alone can give excellent results, especially with early treatment,[4] but is less successful with longer-standing cases. Oral drenching every 4 to 8 hours with 160 mL of a commercial calf scours concentrate (containing 28% glucose, 3.9% glycine, 5.3% sodium chloride, and other electrolytes) induces higher blood concentrations of glucose compared with drenching with glycerol or propylene glycol. Reported recovery rates are 90% in early and 55% in advanced cases. For the more intensive treatment of valuable ewes, insulin ([0.4 IU/kg]/d SC), combined with oral glucose precursors and electrolytes, may improve survival compared with treatment with oral glucose precursors and electrolytes alone.

Induction of parturition is an option, but it should only be used if the ewe is in the early stage of the disease because there is a delay in the delivery of the lambs (24 hours or more). If the ewe is unlikely to survive this period, cesarean section may be a better option. Induction can be achieved with dexamethasone 21-isonicotinate or the sodium phosphate form, at a dose rate of 16 to 25 mg per ewe, but dexamethasone trimethylacetate appears to be ineffective. Lambs will be born 24 to 72 hours after injection, with most born within 36 hours. Induction of parturition in normal sheep can be achieved with 10 mg of betamethasone or 2.5 mg of flumethasone, but there are no reports of their efficacy in sheep with pregnancy toxemia.

Cesarean Section

Cesarean section can be used as an alternate to glucose replacement, and provided that ewes are in the early stages of the disease, removal of the lambs by cesarean section probably has the greatest success. The demand for glucose by the lambs is immediately removed, and both the ewe and the lambs have a high chance of survival, provided that the cesarean section is conducted before there is irreversible brain damage in the ewe and the lambs are close to term. If the ewe is recumbent, then chances of survival, for both the ewe and the lamb, are reduced. The lamb may already be dead, and thus ultrasound examination will inform fetal age and condition and hence whether to undertake a cesarean section.

TREATMENT AND CONTROL

Treatment

Oral electrolyte and glucose (calf scours) concentrate solution (160 mL qid) (R-1)

OR Oral propylene glycol (60 mL bid or 100 mL/d for 3 days) (R-1)

For more intensive treatment, include: oral calcium (calcium lactate 12.5 g/d for 3 days); oral potassium (7.5 g KCl/d for 3 days); insulin 0.4 ([IU/kg]/d SC for 3 days) (R-2)

If hypoglycemia: Dextrose (60 to 100 mL IV) (R-2)

Abort fetus

Ewe: Dexamethasone (20 mg IV or IM) (R-2)

Doe: Dexamethasone plus prostaglandin F2α (10 mg IM) or synthetic analog (cloprostenol; 75 g/45 kg IM) (R-2)

Cesarean section if late-term fetus and valuable ewe/doe (R-2)

Control

Correct the contributing factors (e.g., insufficient feed or inadequate trough space, intercurrent disease such as foot rot or foot abscess) (R-1)

CONTROL

When clinical cases occur, the rest of the flock should be examined daily for evidence of ketosis, and affected animals should be treated immediately with oral glucose/glycine/electrolyte or propylene glycol/glycerol. Supplementary feeding of the flock should immediately be increased or started, with particular attention given to increasing in the intake of energy (carbohydrate). However, care is needed with cereal grains because rapid introduction can cause ruminal acidosis, and ewes may need from 0.25 to 1 kg/head per day (0.5 to 2.0 lb/head per day). Consequently, good-quality lucerne hay or legume grains, such as lupins or field peas, may be a safer option if ewes are not currently being fed a grain-based supplement, even though ewes do not need the higher protein content of these feeds.

Prevention

Ensure that the plane of nutrition is rising in the second half of pregnancy, even if it means restricting the diet in the early stages. An ideal condition score for ewes at 90 days of gestation is 2.75 to 3.0 on a scale of 1 to 5. If necessary, ewes with higher condition scores at the end of the first month of pregnancy can be fed to slowly lose 0.5 in condition score during the period to the third month of pregnancy without any detrimental effect on the ewe or the size or viability of the lamb. In many smaller flocks ewes tend to be in

excessively high condition score early in pregnancy.

The last 2 months are important in the prevention of pregnancy toxemia because 70% of the lamb's birth weight is gained during the last 6 weeks of pregnancy. In intensively managed flocks the provision of cereal grain or a concentrate containing 10% protein during this period, at the rate of 0.25 kg/d, increasing to 1 kg/d in the last 2 weeks, provides adequate energy. During this period, there should be an increase in body weight of 10% for ewes with single lambs and 18% in those carrying twins, but the average condition score should remain around 3.0. Higher body-condition scores can result in higher birth weight of lambs, but this is usually not a financially viable strategy, and it increases the risk of fat-ewe pregnancy toxemia and dystocia. At the beginning of the fourth month of pregnancy, the flock can be divided into three groups by condition score, suboptimal, acceptable, and excess (overfat), and the groups are then fed accordingly. These can be monitored by condition scoring every 2 to 3 weeks during the fourth and fifth months of pregnancy. Maiden ewes should be fed as a separate group to provide for their growth in addition to pregnancy. Attention should also be given to broken-mouthed or older ewes to ensure that they maintain adequate body condition.

There are too many variations in flock structure and husbandry systems to discuss nutritional management in great detail here; readers should consult specialist texts appropriate to the system they work in.[5] However, in more intensive systems, especially prime lamb production, ewes can be pregnancy tested by ultrasound and divided into groups depending on whether they are barren or are carrying single or multiple fetuses. Account needs to be taken of those ewes (and does) that are timid and are thus, or for other reasons, slow feeders. If there is insufficient trough space or if the supplement is fed in small amounts and highly edible, a proportion may get little or no feed. The cost-effectiveness of a feeding program should be evaluated. In breeds with low twinning rates that are well managed, it is often more profitable to simply observe the flock and treat the occasional case.

Flock monitoring for latent pregnancy toxemia during the last 6 weeks of pregnancy can be conducted using serum BHB; concentrations of 0.8 mmol/L indicate adequate energy intake, 0.8 to 1.6 mmol/L indicate inadequate energy intake, and greater than 1.6 mmol/L indicate severe undernourishment. Pooled samples can reduce the cost of analysis, but serum glucose and BHB concentrations do vary significantly between flocks.

Ionophores are used in transition rations for dairy cows to prevent subclinical ketosis. There is some evidence that feeding monensin may have benefits for the energy metabolism of late pregnant ewes. Lower serum BHB, lowered feed intake, and improved feed efficiency have been observed, and thus further investigation of this strategy is warranted.[6]

STEATITIS, PANNICULITIS, AND FAT NECROSIS

Steatitis is inflammation of adipose tissue and can affect any fatty tissue. Clinical expression is usually because of inflammation of intraabdominal or subcutaneous fat (panniculitis). The disease can be relatively innocuous or fulminant and is reported for cattle, in which it is referred to as fat necrosis or bovine lipomatosis, and horses. The colloquial name is "yellow-fat disease" because of the color of affected tissues—a result of accumulation of lipofuscin and products of fat oxidation.[1-4] The disease is not neoplastic.

The **disease in cattle** is characterized by inflammation and necrosis of fat in the abdominal cavity. It can be clinically silent with lesions detected during rectal examination for pregnancy diagnosis or other reason. Clinical signs of the disease in cattle are usually attributable to space-occupying lesions (such as compression of the rectum) or intestinal obstruction as a result of constriction of the intestine by mesenteric accumulations of fat or fibrotic constriction of the lumen.[3] The lesions are firm masses present in any portion of the omental, mesenteric, or retroperitoneal fat or as mobile, free-floating structures in the abdomen.[2] The free-floating masses do not appear to originate from necrosis of fat.[2] The masses range from small nodules to large, solid, and irregularly shaped tumors. Unlike in horses, in which intraabdominal lipomas are often pedunculated (see Chapter 7) and cause acute intestinal obstruction when the peduncular stalk wraps and constricts the small intestine, the lesions in cattle are seldom pedunculated.[2]

The clinical disease in cattle can be variable and range from silent through inappetence, decreased milk production, persistent diarrhea, mild recurrent colic, acute colic, dystocia, urinary retention of feces, and decreased passage of feces. Masses can be detected on rectal examination or laparotomy. Ultrasonography (transcutaneous or transrectal) can be useful in detecting and characterizing the lesions.[3] The lesions are present as heterogenous hyperechoic masses in the retroperitoneal, omental, or mesenteric fat. A hyperechoic ring around the kidney is common.[3] Affected tissues can be biopsied with ultrasonographic guidance.

Abnormalities in the hemogram and serum biochemistry are confined to indicators of inflammation (neutrophilia), hypergammaglobulinemia, decreased concentrations of phospholipids and cholesterol, and an increase in concentration of free fatty acids.[3]

The disease must be differentiated from lymphosarcoma, adenocarcinoma, intraabdominal abscess, or dry fecal balls in the descending colon. The lesions are composed of necrotic fat embedded in normal adipose tissue with mild inflammatory infiltrates of neutrophils, lymphocytes, plasma cells, macrophages and giant cells, and fibrosis.[2] There is rarely evidence of pancreatitis in the disease in cattle.[2]

The cause of the disease is unknown, although a prevalence of 67% is reported in steers grazing tall fescue, in which serum cholesterol concentrations were abnormally low.

The **disease in horses** affects mostly foals and young animals and ponies. Older animals are less frequently affected.[1] Generalized steatitis can be a fulminant disease in horses, ponies, and foals.[1,4] Panniculitis, an unusual form of steatitis limited to the subcutaneous tissues, has been reported in an aged pony mare[5] and in perivaginal tissues after dystocia.[6] Perivaginal steatitis included involvement of the bladder ligament and subsequent rupture of the bladder.[6]

The clinical signs of generalized steatitis consist of anorexia and depression, fever, tachycardia, and subcutaneous edema.[1,4] Painful subcutaneous swellings can occur in the nuchal crest and inguinal and axillary regions. Affected horses often have mild to moderate colic and signs of abdominal tenderness. Rectal examination reveals painful masses in the mesentery of some horses.

Hematology and serum biochemical examination reveal mild to moderate leukocytosis, with occasional horses having leucopenia, hypoproteinemia, hypoalbuminemia, and increases in activity in serum of lactate dehydrogenase (LDH), aspartate aminotransferase (AST), GGT, and lipase and amylase.[1,4] Serum vitamin E concentrations are sometimes abnormally low.

Biopsy of some of the SC swelling reveals histopathological evidence of fat necrosis with mineralization. At necropsy, the fat is hard, dry, and yellow-white, with areas of necrosis forming abscess-like lesions up to 3 cm deep and 10 cm in diameter. The fat lining the abdominal wall may contain firm yellow-white and red tissue nodules up to 3 cm in diameter. Pancreatitis is evident in equids with systemic disease, and there is necrosis and inflammation in most fatty

tissues (subcutaneous, retroperitoneal, mesenteric, and omental).[1]

Generalized steatitis with fat necrosis ("yellow-fat disease") has been recognized in many species at various ages and is thought to be related to a dietary deficiency of vitamin E and selenium and intake of unsaturated fatty acids.[1,5]

Inherited Metabolic Diseases of Ruminants

DEFICIENCY OF UMP SYNTHASE (DUMPS)

This is a partial deficiency of an enzyme that is involved in the conversion of orotate to uridine 5'-monophosphate (UMP) as a step in the synthesis of pyrimidine nucleotides. It is recorded at a high prevalence in Holstein–Friesian cattle in the United States and Japanese Black cattle and is characterized by an autosomal-recessive form of inheritance and the secretion of high levels of orotate in the milk.[1] Heterozygous animals have a partial deficiency of UMP synthase, but they have no individual or herd clinical abnormalities. Heterozygous animals can be detected biochemically by their half-normal levels of erythrocyte UMP synthase or by nested polymerase chain reaction (PCR) testing.[2,3] Bovine homozygotes die at about the 40th day of pregnancy. Embryonic mortality is the only form of loss.

HEPATIC LIPODYSTROPHY IN GALLOWAY CALVES

Hepatic lipodystrophy has been reported in Galloway calves on five farms in the United Kingdom over a 10-year period. Calves appear normal after birth but die by 5 months of age. Clinically there is tremor, opisthotonus, and dyspnea before affected calves become recumbent and die. At necropsy the liver is enlarged, pale, and mottled. Histologically there is evidence of hepatic encephalopathy. The cause is unknown, but limited evidence suggests a storage disease is possible.

Metabolic Diseases of Horses

EQUINE PITUITARY PARS INTERMEDIA DYSFUNCTION (FORMERLY EQUINE CUSHING DISEASE)

Equine pituitary pars intermedia dysfunction (PPID) is a slowly progressive neurodegenerative disease of older equids caused by nonmalignant hypertrophy and hyperplasia of melanotropes of the pars intermedia of the pituitary gland. It is characterized in its most severe form by hirsutism, laminitis, polyuria, and polydipsia.

ETIOLOGY

The pars intermedia of equids is composed of a single cell type—melanotropes—which are innervated by dopaminergic neurons of the periventricular nucleus. Innervation by these neurons is inhibitory on secretion by the melanotropes of proopiomelanocortin (POMC)-derived peptides. Thyrotropin-releasing hormone stimulates melanotropes.[1] The pars distalis of the pituitary of healthy horses releases adrenocorticotropic hormone (ACTH) in response to, among other stimuli, declines in plasma cortisol concentration. Cortisol exerts negative feedback on secretion of ACTH by the pars distalis, but not by the pars intermedia.[2]

The disease is attributable to degeneration of the periventricular hypophyseal dopaminergic neurons with subsequent development of a nonmalignant functional tumor comprised of melanotropes of the pars intermedia of the pituitary gland.

Cushing syndrome caused by adrenocortical tumors is exceedingly rare in equids.

EPIDEMIOLOGY

The disease is being diagnosed with increasing frequency.[3] The prevalence of the disease is not well documented, but surveys of owners indicate hair-coat abnormalities consistent with the disease in 15% to 39% of aged equids. Of 200 randomly selected equids 15 years of age or older in the United Kingdom, 22% had hair-coat abnormalities suggestive of PPID detected on clinical examination,[4] and owners of 12% of approximately ~980 aged equids in the United Kingdom reported hair-coat abnormalities and abnormal moulting.[5] Similarly, owners of 17% of 974 horses 15 years of age or older in Queensland, Australia, reported hirsutism.[6] Given that changes in hair coat are specific (95%) but of unknown sensitivity for the diagnosis of PPID,[7] these estimates likely provide the lower range for prevalence of the disease. Accordingly, 21% of 325 randomly selected horses 15 years of age or older in Queensland had PPID diagnosed based on measurement of plasma ACTH concentrations and using seasonally adjusted cutoff values.[8] This likely provides the best current estimate of the prevalence of PPID in mature and aged horses. Reports of prevalence of the disease provided in early studies likely were unreliable as indicators of disease frequency in the overall population of horses because of selective or nonrandom sampling of horses.

The disease occurs worldwide in all breeds of horses and ponies. Differences in geographic distribution are not reported.

The only well-recognized animal risk factor for the disease is increasing age (adjusted OR of 1.18 [95% CI, 1.1 to 1.25]) per year of age, and there is no apparent sex or breed predisposition.[8]

PATHOGENESIS

PPID is a neurodegenerative disease in which there is a loss of the inhibitory effect of dopamine with subsequent hypertrophy and hyperplasia of **melanotropes** of the pars intermedia of the pituitary gland with unchecked secretion of **proopiomelanocortin** and compression of the neurohypophysis, hypothalamus, and optic chiasma.[9] Production of proopiomelanocortin by melanotropes in the pars intermedia is not under the negative feedback control of glucocorticoids, and as a result, affected equids produce large quantities of POMC, melanocyte-stimulating hormone (α-MSH), β-endorphin, and smaller but still excessive quantities of ACTH. Production of ACTH results in loss of the normal circadian rhythm in serum cortisol concentration.[10] The space-occupying effects of the tumor can cause blindness because of compression of the optic chiasm. Polyuria and polydipsia are common and are probably related to neurohypophyseal dysfunction and compression of the pars nervosa, the source of antidiuretic hormone.[11]

Not all equids with PPID have **impaired glucose metabolism.**[12,13] A proportion of horses, estimated as ~40%, with PPID have evidence of abnormal glucose metabolism, including hyperinsulinemia, hyperglycemia, or both, although only 20% have evidence based on results of an IV glucose and insulin test.[12] Furthermore, horses with PPID do not have abnormalities in glucose metabolism detected during an isoglycemic clamp procedure.[13] It is unclear if the abnormal glucose metabolism and hyperinsulinemia are attributable to PPID or concurrent equine metabolic syndrome, but it is apparent that there should not be an assumption of abnormalities in glucose metabolism in all equids with PPID.

CLINICAL FINDINGS

Affected equids exhibit one or more findings of hirsutism, hyperhidrosis, polyuria, polydipsia, polyphagia, muscle atrophy (sarcopenia), laminitis, and docile demeanor.

Hirsutism is a clinical sign with high specificity (95%) for the disease,[7] meaning that aged equids with hirsutism are likely to

have the disease and that there will be few false-positive diagnoses when hirsute aged equids are considered to have PPID. Equids with an owner-reported history of hirsutism are 7.8 times (95% CI, 3.7 to 16.6) more likely to have PPID than are nonhirsute equids of similar age.[8] Hirsutism is characterized by delayed or absent seasonal moulting resulting in a long, shaggy hair coat. There can be some lightening of the coat color. The changes in hair coat are a result of equids with PPID having a greater proportion of hair follicles in the anagen phase (95% of hair follicles on the neck) than healthy equids (15%).[14] Abnormalities of hair follicles resolve and resumption of moulting occurs with administration of pergolide.[14]

Polyuria and polydipsia are common clinical signs in equids with PPID and are likely secondary to diabetes insipidus and not to hyperglycemia.[11] Administration of desmopressin reduces polyuria and polydipsia.[11]

Hyperhidrosis is reported in affected equids, although it does not appear to have been quantified. Equids with PPID in hot environments can be anhidrotic, and this resolves with treatment of the PPID.[15]

Myopathy associated with PPID is characterized by atrophy of type 2 (slow-twitch) fiber types consistent with sarcopenia.[16] Plasma activity of muscle-derived enzymes is not greater in equids with PPID than in healthy aged-matched equids.[16] The molecular basis for muscle atrophy in equids with PPID has been investigated, but the mechanism remains unclear.[17]

There is often central obesity, characterized by excessive fat deposition in the crest of the neck and in the supraorbital fossae, but this is likely a reflection of comorbidity with equine metabolic syndrome rather than a characteristic of PPID. One report demonstrates insulin resistance in equids with PPID using the euglycemic-hyperinsulinemic clamp technique, but this is not a consistent finding.[13,18] However, equids were not screened for hyperinsulinemia before admission to the study and were selected from a population of equids referred for treatment of laminitis, among other diseases. These equids might well have had both equine metabolic syndrome (EMS) and PPID. Further evidence to support this comorbidity is that plasma fructosamine concentrations are not different between nonlaminitic equids with PPID and healthy controls (reference interval of 195.5 to 301.9).[19] Equids with PPID and laminitis have plasma fructosamine concentrations that are higher than those of animals with PPID but not laminitis.[19] Fructosamine is a reflection of average blood glucose concentrations over a period of weeks, and higher values are indicative of hyperglycemia.

Laminitis is common in equids with PPID (see "Laminitis of Horses," Chapter 15).[8] However, it is unclear if this is a result of PPID or comorbidity with EMS.

Rarely, affected equids are blind or have seizures. Affected equids are often infertile and heal poorly. Equids with PPID are considered immunosuppressed and susceptible to development of opportunistic infections and parasitism.[20,21]

Computed tomography allows measurement of the size of the pituitary gland of equids that correlates well with that measured postmortem.[22] The size of the pituitary gland can be evaluated antemortem.

The outcome is favorable in that 50% of equids are alive 4.6 years after diagnosis, most owners are satisfied with the equid's quality of life, and most (28/29; 97%) would treat a second equid with the disease.[3] In a study of cases diagnosed between 1993 and 2002, the cause of death among equids (15/20; 85%) was euthanasia, and 11/15 (73%) were euthanized because of conditions associated with PPID.[3]

CLINICAL PATHOLOGY

There are no characteristic findings on serum biochemical testing or hematology.[8] Resting serum cortisol concentrations of affected and healthy equids are similar and not useful in diagnosis.

DIAGNOSTIC CONFIRMATION

Antemortem diagnosis of PPID is not simple and is achieved on the basis of clinical signs and results of one or more of several diagnostic tests. It is important that testing be based on the presence of clinical signs compatible with the disease to minimize the frequency of false-positive diagnoses. Laboratory tests for the disease are not infallible, and the results of these tests should be viewed only in the context of the equid's clinical signs. Further complicating diagnosis of equine pars intermedia dysfunction is the slow and progressive onset of the disorder. It is therefore likely that attempting a definitive dichotomous answer (disease present or disease absent) based on laboratory testing is unreasonable—some mildly affected equids will test normal, and, less commonly, some apparently healthy equids with histologically normal pituitary glands will test positive. Repeated testing is warranted when test results are ambiguous or not consistent with clinical signs (primarily hirsutism).

Assessment of the utility of the various diagnostic tests is prevented by the lack of a gold-standard diagnosis, except for postmortem examination. Determination of sensitivity and specificity of laboratory tests, or clinical signs, is therefore difficult. Furthermore, antemortem testing is complicated by the seasonal and circadian variations in pituitary function with consequent changes in "resting" or basal serum or plasma concentrations of many analytes. Furthermore, plasma concentrations of some analytes, including ACTH, are affected by feeding.[23] The changes in pituitary function with season are a recognized physiologic phenomenon related to preparing or adapting physiologic functions to colder conditions and shorter days.[10,24-30] This phenomenon was not generally recognized before about 2005, and reports of the characteristics of diagnostics tests before that date should be interpreted with caution.

Laboratory tests used to diagnose pars intermedia dysfunction include measurement of serum or plasma cortisol, ACTH, glucose, or insulin concentrations; the ACTH stimulation test; the thyrotropin-releasing hormone stimulation test; administration of domperidone with subsequent measurement of plasma ACTH; measurement of urinary and salivary corticoid concentrations; and combinations of these tests (Table 17-8). The most widely accepted laboratory tests are the overnight dexamethasone suppression test and measurement of serum ACTH concentration. Other tests have been suggested, but either their sensitivity and specificity have not been determined or they involve measurement of multiple variables or of hormones for which assays are not readily commercially available. Measurement of basal serum insulin concentration is not a useful diagnostic test for equine pars intermedia dysfunction. Measurement of urine or salivary cortisol concentrations has been suggested as a means of diagnosing equine pars intermedia dysfunction, but neither has been validated in a sufficient number of equids to permit assessment of their clinical utility.[31]

One of the first diagnostic tests developed was the **overnight dexamethasone suppression test**.[31] After collection of a serum sample for measurement of cortisol, dexamethasone (40 µg/kg IM) is administered at about 5 p.m. A second blood sample is collected 15 hours later, with the option to collect a third sample 19 hours after dexamethasone administration. Normal horses will have a serum cortisol concentration of less than 1 µg/dL (28 nmol/L) in the second and third blood samples, whereas affected horses will not show a significant reduction in serum cortisol concentration from that of the initial sample. The sensitivity and specificity of this test are apparently high, with both reported in earlier studies to be approximately 100%.[31] However, recent studies of healthy horses demonstrate that there is considerable seasonal variation in the dexamethasone suppression test, with all of 39 healthy aged ponies and horses having normal tests in January (winter) but 10 of the same 39 (26%) having abnormal tests in September (autumn),[31] and that the test is specific but not sensitive.[32] These results suggest that these diagnostic tests should be interpreted with caution when conducted in the autumn.

Measurement of **plasma adrenocorticotropin (ACTH)** concentration has been widely accepted as a useful laboratory indicator of equine pars intermedia dysfunction. The plasma ACTH concentration varies with the age of the horse and with the season

Table 17-8 Diagnostic Testing Methods for Equine pituitary pars intermedia dysfunction (PPID)

Diagnostic test	Procedure	Sample	Interpretation	Comments (also see text)
Overnight DEX suppression	Collect serum between 4 and 6 p.m. Administer DEX at 40 μg/kg BW IM. Collect serum 19–20 hours later.	2 serum samples, 1 mL each; 1 pre-DEX administration and 1 post-DEX administration	Serum control of > μg/dL at 19 hours post-DEX administration suggests PPID.	A mildly decreased resting cortisol (pre-DEX administration) is typical of a PPID-affected horse. A resting cortisol of < 1.8 μg/dL is suggestive of iatrogenic adrenal insufficiency.
Endogenous plasma ACTH concentration	Collect EDTA plasma, preferably in plastic blood-collection tube. Separate plasma by centrifugation, and freeze for submission to laboratory. Avoid hemolysis and heat. Process sample within 8 hours of collection.	EDTA plasma sample, 1 mL	Normal reference range depends on methodology and laboratory. Typically an ACTH concentration < 35 pg/mL (chemiluminescent immunoassay) or < 45–50 pg/mL (radioimmunoassay) is considered normal.	ACTH is likely affected by many biologic events, all of which are not well documented at present. Seasons can have a profound effect, with higher concentrations seen in autumn.
Endogenous plasma α-MSH concentration	Collect EDTA plasma, preferably in plastic blood-collection tube. Separate plasma by centrifugation, and free for submission to laboratory. Avoid hemolysis and heat. Process sample within 8 hours of collection.	1 EDTA plasma sample, 1 mL	Nonautumn reference range: > 35 pmol/L suggests PPID.	Plasma α-MSH concentration is extremely seasonal. High concentrations are observed in autumn.
TRH stimulation assay	Collect serum. Administer TRH, 1 mg IV. Collect serum 30–60 minutes after TRH.	2 serum samples, 1 mL each: pre-TRH administration, 30 minutes post-TRH administration, and 24 hours post-DEX administration	30%–50% increase in serum cortisol 30 minutes after TRH administration suggests PPID.	Pharmaceutical TRH is expensive; TRH compounded for this use may be difficult to obtain. False-positive results may be common.
Combined DEX suppression/ TRH stimulation test	Collect plasma between 8 and 10 a.m. Administer DEX at 40 μg/kg BW IM. Administer TRH, 1 mg IV, 3 hours after DEX administration. Collect serum 30 minutes after TRH and 24 hours after DEX administration.	3 plasma samples, 1 mL each: pre-DEX administration, 30 minutes post-TRH administration, and 24 hours post-DEX administration	Plasma cortisol > 1 μg/dL at 24 hours post-DEX administration or ≥ 66% increase in cortisol levels 3 hours after TRH administration suggests PPID.	Some diagnostic laboratories prefer to use serum for measurement of cortisol levels. The effect of season on the combined test has not been assessed but would likely result in false-positive results as each of the component tests do.
Domperidone response test	Collect EDTA plasma at 8 a.m. Administer domperidone at 3.3 mg/kg BW po. Collect EDTA plasma at 2 and 4 hours after domperidone administration.	3 EDTA plasma samples, 1 mL each	A twofold increase in plasma ACTH concentration suggests PPID.	Higher doses (5 mg/kg po) may improve response. The 2-hour sample is more diagnostic in the summer and autumn, and the 4-hour sample is best in the winter and spring.

Abbreviations: ACTH, adrenocorticotropic hormone; BW, bodyweight; DEX, dexamethasone; IM, intramuscularly; IV, intravenously; THR, thyroid-releasing hormone. of the year in both the northern and southern hemispheres, but not between ponies and horses.[33] The upper reference intervals of plasma ACTH for healthy horses in the United Kingdom in one report were 29 pg/mL between November and July and 47 pg/mL between August and October.[25] The reference intervals were obtained by sampling a convenience sample of hospitalised horses. A similar pattern is detected in the eastern and southern United States, with the autumnal peak in ACTH occurring earlier in horses in more northern locations.[1,24,29,30] This circannual variation in plasma ACTH occurs in both non-PPID and PPID horses, with PPID horses having higher concentrations than non-PPID horses at all times.[10,23,25,26,33,34] Furthermore, the increase in plasma ACTH concentrations stimulated by administration of thyrotropin-releasing hormone (1 mg, IV) to healthy horses is greater in autumn and summer than in late winter.[23,27] These results demonstrate the need for including consideration of season (photoperiod) and latitude when assessing the diagnostic importance of plasma ACTH concentrations in aged horses. It is prudent to use reference intervals developed in local laboratories or in distant laboratories with knowledge of the reference interval for the particular geographic location (latitude) and season of the horse.[30]

There is no circadian rhythm to ACTH concentrations in horses with PPID, but there is conflicting evidence of a circadian rhythm in healthy horses.[10,35,36] It appears that ACTH concentrations of horses are highest at 0800 hours and then decline over the day, although the changes are small and not likely to affect clinical interpretation of plasma ACTH concentrations.[35] There is not an ultradial rhythm (periodic changes during a 24-hour period) in plasma ACTH

concentration, although measured concentrations do vary over brief periods of time (minutes) and to a greater extent in horses with PPID.[35]

Fasting and feeding affect plasma ACTH concentrations in healthy horses, with higher concentrations found 2 hours after feeding than after a 12-hour fast (46 vs. 17 pg/mL, respectively).[23]

Measurement of **plasma ACTH** combined with use of seasonally adjusted cutoffs provides good **sensitivity and specificity** for diagnosis of PPID, defined using the presence of hirsutism plus three or more clinical signs as the gold standard.[33] The referenced study was of 325 randomly selected horses 15 years of age or older in Queensland, Australia (approximate latitude 27.5°S). Cutoff values for diagnosis of PPID were 30 pg/mL (sensitivity and specificity of 80% and 82%, respectively) for nonautumn months and 77 pg/mL (sensitivity and specificity of 100% and 95%, respectively) during the autumn. It is important to note that the gold standard for determining the characteristics of the test was a clinical examination. Therefore the sensitivity and specificity reported for measurement of plasma ACTH concentration apply only for horses with characteristic clinical signs of the disease. The usefulness of measuring plasma ACTH concentration in horses that have milder, or nonexistent, clinical signs is unknown. Similarly, the clinical importance of elevated ACTH concentrations in younger horses is unclear, and such results should be considered cautiously and carefully before decisions regarding treatment are made.

Plasma concentrations of α-melanocyte-stimulating hormone (α-MSH) correlate well with plasma ACTH concentrations, and comments about seasonal and horse-related factors affecting ACTH concentrations also apply for α-MSH.[1,10,24,27,33,37]

Plasma ACTH concentrations can be measured before and after administration of **thyrotropin-releasing hormone** or **domperidone**.[37,38] The thyrotropin-releasing hormone test appears to have greater utility than administration of domperidone, with the latter having greater variation. These tests have not been adequately evaluated to recommend at this time.

The combined **dexamethasone suppression/thyroid-releasing hormone (TRH) stimulation** test has reported sensitivity and specificity of 88% and 76%, respectively.[7] The test is performed by administering 40 µg/kg of dexamethasone phosphate (or similar dexamethasone salt) intravenously between 8 a.m. and 10 a.m. Cortisol concentration in serum is then measured 3 hours later, and TRH (1 mg) is administered intravenously. Serum cortisol concentration is measured 30 minutes after TRH administration. Serum cortisol concentrations of healthy horses 30 minutes after TRH administration are unchanged from those at the time of TRH administration, whereas serum cortisol concentrations in horses with equine pars intermedia dysfunction increase by more than 66% of the baseline value.

Plasma **fructosamine** concentrations do not differ between healthy horses (range 195.5 to 301.9 mu mol/L) and horses with PPID.[39] **Plasma insulin** concentrations are increased in a proportion of horses with PPID and are suggested to be indicative of the risk of laminitis in these horses (see discussion of equine laminitis, Chapter 15).[40,41]

NECROPSY FINDINGS

The pituitary gland is usually enlarged as a result of the increased numbers of melanocortin cells comprising an adenoma of the pars intermedia. The adrenal cortices are usually of normal width, but they may be thickened in some cases. With the appropriate clinical history, the observation of a well-defined nodule within the pituitary gland is usually sufficient for confirmation of the diagnosis, but histology and immunohistochemical testing of the mass can be performed. There is only fair (kappa = 34%) agreement among pathologists for histologic diagnosis of the disease.

DIFFERENTIAL DIAGNOSIS

- Insulin resistance
- Diabetes insipidus (nephrogenic)
- Both of these diseases are exceedingly rare in horses
- Obesity
- Psychogenic polydipsia or salt eating
- Chronic renal failure

TREATMENT

Treatment is palliative and not curative in that clinical signs can be controlled by administration of pergolide, but the underlying neurodegenerative disease is not cured. The aim of treatment is to reduce secretion of the products of the melanotropes through the use of dopamine agonists or serotonin antagonists. Treatment must be continued for the life of the horse or pony.

The **treatment of choice** is administration of **pergolide mesylate**, a dopamine agonist, at 1.7 to 5.5 µg/kg orally every 24 hours. The recommended starting dose is 2.0 to 3.0 µg/kg once daily for 2 months, at which time clinical (hirsutism) and laboratory (plasma ACTH concentration) signs of the disease should be evaluated. The dose can be escalated by 1-µg/kg increments until control of clinical signs is achieved.

Pergolide mesylate is rapidly absorbed after oral administration to fasted mares with a time to maximum drug concentration in plasma of 0.4 hours, maximum concentration of 4 ± 2 ng/mL, and terminal elimination half-life estimated to be 5.9 ± 3.4 hours.[43]

Care should be exercised in the storage of pergolide mesylate compounded in an aqueous vehicle because it is susceptible to degradation if exposed to heat, light, or both.[44] Compounded pergolide formulations in aqueous vehicles should be stored in a dark container, protected from light, and refrigerated, and it should not be used more than 30 days after production. Formulations that have undergone a color change should be considered degraded and discarded.[44] A commercial form of pergolide mesylate formulated for use with horses and ponies (Prascend®, Boehringer Ingelheim) is available in some countries.

Cyproheptadine, a serotonin antagonist, is administered at 0.25 mg/kg orally every 24 hours for 1 month. If an acceptable response is achieved, then this dose is continued; if not, then the dose is increased to 0.25 mg/kg every 12 hours. This drug is now rarely used in the treatment of PPID.

Symptomatic treatment should include clipping of the hair coat in spring, treatment of laminitis and wounds, prevention of injuries and infection, and dietary management to reduce hyperglycemia in those animals with this abnormality documented (see "Equine Metabolic Syndrome"), in addition to maintenance of optimal body weight. Some equids with PPID lose weight and require careful nutritional management.

CONTROL

None.

EQUINE METABOLIC SYNDROME

SYNOPSIS

Etiology Unknown, but likely involves genetic predisposition for insulin resistance with phenotypic expression permitted or induced by environmental factors that favor obesity.

Epidemiology Associated with obesity and particular breeds, especially ponies. Standardbreds appear to be at reduced risk. No sex predilection. Increasing incidence with age.

Clinical signs Obesity, regional adiposity including cresty neck, predisposition to laminitis.

Clinical pathology Hyperinsulinemia, hypertriglyceridemia, normal blood glucose concentration.

Diagnostic confirmation Demonstration of insulin resistance in presence of clinical signs of equine metabolic syndrome. Measurement of serum insulin and plasma or blood glucose concentrations. Requires validated insulin assay.

Treatment Weight loss, which can be difficult to achieve. Exercise. Potentially administration of insulin sensitizing drugs (metformin).

Control Maintenance of optimal body condition and prevention of obesity.

Equine metabolic syndrome (EMS) is a recently recognized condition of equids characterized by increased regional adiposity (localized deposition of fat) or generalized obesity, hyperinsulinemia, hypertriglyceridemia, insulin resistance, and a predisposition to laminitis that develops in the absence of other known inciting factors (such as colic, metritis, or acute carbohydrate overload).[1] Insulin resistance is defined as abnormally depressed insulin-mediated glucose transport into insulin-sensitive cells (adipose tissue, skeletal muscle). EMS is the clinical syndrome, whereas insulin resistance in an underlying metabolic abnormality.

ETIOLOGY

EMS likely has important genetic determinants, with manifestation of the syndrome when susceptible animals, by virtue of their genetic composition, are exposed to environmental conditions that favor or enable development of the disease. This is thought to be similar to the situation with human metabolic syndrome or type 2 diabetes. It is speculated that breeds of equids that evolved under conditions of frequent restriction of energy intake, such as during long winters, are genetically predisposed to have efficient energy metabolism that under modern management systems can result in obesity and development of insulin resistance.[1,2]

EPIDEMIOLOGY

The epidemiology of EMS is not well described, and there are few studies that have identified the frequency of the condition, using established case definitions, in large numbers of horses or ponies. Consequently, there is little evidence on outcome (morbidity, case-fatality rates, all-cause morbidity, specific-cause mortality) in horses and only anecdotal information on breed, age, and sex as risk factors. Twenty seven percent (51/188) of ponies of various breeds examined in Australia were hyperinsulinemic (>20 mu/mL) after ponies with documented PPID (see previous section) were excluded.[3] There is somewhat more information regarding the epidemiology of obesity in horses, but it should be recognized that not all obese horses are insulin resistant (and therefore do not fit the definition of EMS).[4,5] Similarly, there is information on the epidemiology of pasture-associated (endocrinopathic) laminitis (see "Laminitis of Horses," Chapter 15), and from this one can infer risk factors for insulin resistance and EMS.

Horses or ponies of different breeds but similar body weight differ in their insulin resistance, and there is consensus that particular **breeds** are at increased risk of EMS; these include ponies (of any of the common breeds), Morgan Horses, Paso Fino, Andalusian, Arabian, Saddlebred, Quarter Horses, Tennessee Walking Horses, and Warmblood Horses.[1,2] It appears that some light breeds such as Standardbreds and perhaps Thoroughbreds are at reduced risk. The frequency of the condition increases with age in ponies,[3] and sex does not appear to be a risk factor.

There is a **seasonality** to the occurrence of pasture-associated laminitis,[6] and this might represent seasonal changes in energy intake (from pasture) of susceptible animals rather than seasonal variations in severity of insulin resistance. However, there is evidence that measures of insulin resistance in horses and/or ponies vary depending on season, with declines in insulin sensitivity of ponies in summer.[7] Insulin sensitivity, defined using the combined insulin and glucose intravenous test, and serum insulin concentrations are not related to season in healthy, mature horses.[8,9]

Obesity is common in domestic horses, with studies in Scotland and the eastern United States finding that 45% and 19%, respectively, of horses were considered obese.[10,11] Although interpretation of both studies is limited by the localized nature of the sampling and restrictions on the types of horses included, these studies do support a wider consensus that obesity is common in horses. Chronic intake of energy in excess of maintenance needs (overeating) and insufficient exercise are thought to be risk factors, or inciting factors, for obesity.

PATHOGENESIS

EMS is primarily a manifestation of insulin resistance, and insulin resistance is often, but not always, associated with obesity. The syndrome likely includes abnormalities in energy metabolism, adipocyte function, hemostasis (thrombosis), inflammation, response to lipopolysaccharide (endotoxin) exposure, and oxidant stress.[1,12] The pathogenesis of laminitis associated with EMS ("endocrinopathic laminitis") is discussed elsewhere.

Insulin resistance is the decreased rate of transport of glucose into cells of glucose-sensitive tissues in response to exposure to insulin. Horses with insulin resistance have lesser reductions in blood glucose concentration in response to administration of insulin than do insulin-sensitive horses.[13,14] Insulin-stimulated glucose transport is achieved by GLUT-4 (glucose transporter protein 4, which is one of at least 12 glucose transporter proteins) when it is present on the surface of adipose or muscle tissue. Insulin causes the relocation of GLUT-4 within the cell to the cell plasma membrane and subsequent increases in rate of glucose transport into the cell. Horses with insulin resistance have abnormal glycemic and insulinemic responses to oral or IV administration of glucose or oral administration of sugar (see following discussion) and have reduced concentrations of GLUT-4 on the surface of skeletal muscle and adipose tissue.[15-17] Insulin resistance in horses is associated with an exaggerated response in plasma/serum insulin concentration after administration of glucose. This exaggerated response allows maintenance of resting blood glucose concentrations in the reference range in affected horses—so-called compensated insulin resistance.[1]

Insulin resistance in humans is currently thought linked to inflammation induced by macrophage activation in adipose tissue, and there is increasing evidence of a similar mechanism in equids.[18] The BCS of horses is also correlated with both plasma insulin concentration and serum amyloid A

concentration (an acute-phase protein indicative of inflammation).[19] There are only minimal effects of insulin infusion (6-hour duration) on tumor necrosis factor alpha and interleukin(IL)-6 concentrations in the plasma of healthy horses,[20] and no association has been found between BCS or insulin concentration and plasma concentrations of tumor necrosis factor and IL-6.[19] Horses with EMS have prolonged inflammatory responses (evidenced by plasma IL-8, IL-10 and tumor necrosis factor concentrations) to infusion of endotoxin compared with healthy horses,[12] although the clinical importance of this observation is unclear. Horses with EMS have a marked increase in neutrophil reactive oxygen species production induced by phagocytosis that is strongly correlated to the blood insulin concentration.[21] In contrast, peripheral blood cells of obese hyperinsulinemic horses showed decreased endogenous proinflammatory cytokine gene expression (IL-1 and IL-6) and similar cytokine response following immune stimulation compared with that of control horses. The authors conclude that this could suggest that, unlike in people, cytokine-mediated inflammation does not increase in direct response to obesity or insulin resistance in horses.[21]

Mechanisms underlying obesity and regional adiposity are unclear, but at the most fundamental level involve an excess of energy intake over energy expenditure, with deposition of the net excess energy as fat. As discussed previously, some horses and ponies appear to be much more efficient at converting feed into energy, or at regulating energy use, with the result that it is challenging to achieve a reduction in the weight of these animals even with strict control of food intake.[22] The genetic or hormonal causes of this resistance to weight loss are unclear, although it is apparent that some horses and ponies have an exaggerated insulinemic response to ingestion of soluble carbohydrate.[2,17,23] This exaggerated response could be the underlying mechanism for hyperinsulinemia, obesity or regional adiposity, and endocrinopathic laminitis.[24]

Adipose tissue is an important source of hormones regulating energy metabolism and of inflammatory cytokines. Obesity, or "overconditioning," in horses (as assessed by BCS) is associated with higher plasma insulin and leptin concentrations than in optimally conditioned horses.[25,26] Obese horses also have higher triglyceride concentrations and lower red blood cell glutathione peroxidase activities (an indication of antioxidant capacity) than optimally conditioned horses.[27]

Regional obesity is an important risk factor in humans for metabolic syndrome and might be similarly so in horses and ponies. Visceral fat is important in humans, but it appears to be less so in horses, with nuchal ligament fat (which contributes to the cresty neck characteristic of affected horses and ponies) having greater proinflammatory gene expression (IL-1β and IL-6) in affected horses,[28] although others, using measurement of other markers of inflammation, find that the omental and retroperitoneal (visceral) fat of insulin-resistant horses have greater expression of markers of inflammation (Toll-like receptor 4 and suppressor of cytokine signaling 3 [SOCS-3]) than do insulin-sensitive horses.[18] Finally, there is evidence of regional differences in glucose transport by adipose tissue, with omental adipose tissue having the highest total GLUT content compared with subcutaneous and nuchal ligament fat in healthy horses, but having a reduced total GLUT4 content and cell surface expression in insulin-resistant horses.[16]

CLINICAL SIGNS

Equine metabolic syndrome is defined by obesity (with or without regional adiposity), insulin resistance, and increased susceptibility to laminitis. As such, only obesity and regional adiposity and clinical signs of active or past laminitis are physical evidence of the presence of metabolic syndrome. Affected ponies can be hypertensive.[5,7]

Clinical assessment of obesity/adiposity is achieved by use of body-condition scoring, measurement of subcutaneous or retroperitoneal fat by ultrasound, and grading of regional adiposity. Methods used for research studies include slaughter and dissection with proximate analysis of body constituents or measurement of the deuterium dilution space (volume of distribution) in living animals.[29,30] Bioelectrical impedance can be used to measure body-water content, but it has not achieved widespread clinical acceptance.[31] Measurement of body weight is not useful for assessment of obesity or adiposity because body weight is highly correlated with height and girth and does not provide an accurate indication of body fat.[32]

A number of body-condition scoring systems have been developed, and the two most commonly used are those of Henneke (later modified by various authors), which uses a 1-to-9 grading system (Table 17-9 and Fig. 17-7), and Carroll and Huntington, which uses a 1-to-5 grading system.[33,34] These grading systems were not developed to assess the fat content (proportion) of horses, but rather to assess "flesh" or the general body condition. Both systems have limitations, including their subjective nature and the fact that they have not been validated in all breeds and body types of horses (validation determines the relationship between BCS and a gold-standard measure of body fat, such as deuterium dilution space or carcass analysis), nor has their reliability (intrarater and interrater agreement/repeatability expressed as an intraclass correlation coefficient or, less optimally, a kappa or weighted-kappa statistic) been demonstrated over large numbers of raters. There are reports of an intraclass correlation coefficient (ICC) of 0.74 for four raters of 21 mares and 75 ponies, but details are not provided.[35] Another reports an ICC of 0.92, but without details to allow assessment of the methodology.[25] Additionally, body-condition scoring systems do not provide an assessment of regional adiposity, which might have greater clinical relevance.

BCS (1-to-9 scale) correlates well with percent body fat (TBF) when both are log transformed ($e^{TBF} = 0.006 + e^{1.56*BCS}$).[32] In practical terms, this means that the accuracy of this body-condition scoring system to predict the proportion of body fat declines as BCS increases—for example, the proportion of body fat varies from ~13% to 36% in horses with a BCS of 7 to 8/9.[32] The log-log BCS model correctly predicted body fat greater than 20% (BCS = 6.83) in 76% of horses and with sensitivity of 83% and specificity of 71%.[32] However, the need to use log-log transforms decreases the general utility of this technique.

Body-condition scoring is a demonstrably insensitive measure of changes in body fat—ponies subject to 11% reduction in body weight and a 45% reduction in body fat did not have a change in BCS.[36,37] This indicates that the BCS system (1-to-9 scale) has some utility in assessment of body-fat proportion in horses and ponies, but it should be used with a full awareness of its limitations.

The BCS correlates well with plasma concentrations of glucose tolerance, insulin sensitivity, and insulin, leptin, and triglyceride concentrations in horses or ponies,[5,19,35] all of which could be clinically important.

A grading system for assessment of regional adiposity evident as a "cresty neck" has been developed for use with ponies and horses.[35] The ICC (a measure of reliability between raters) is 0.70 for four raters of 21 mares and 75 ponies.[35] The "cresty neck score" correlates well with plasma insulin and glucose concentrations in pooled horse and pony data, and with insulin, leptin, glucose, and triglyceride concentrations when horses and ponies are considered separately. Additionally, ponies with a cresty neck score of 4 or greater are at increased risk of developing pasture-associated laminitis.[39] This scoring system therefore appears to be both reliable (good interrater agreement) and indicative of clinically meaningful variables and outcomes (Table 17-10).

Acute laminitis and residual signs of laminitis (sometimes call chronic laminitis) are common in animals with insulin resistance and provide the physical confirmation of EMS in these animals. Clinical signs of laminitis are described under that topic (Chapter 15).

Diagnosis

Definitive diagnosis of EMS of horses in the field is achieved by demonstration of insulin resistance in equids with appropriate clinical signs (obesity, regional adiposity, laminitis) and is confirmed by measurement of plasma concentrations of glucose and insulin.[1]

Table 17-9 Criteria for estimating body condition in light-breed horses

Score	Condition	Description
1	Poor	Animal is extremely emaciated. Spinous processes (parts of vertebrae that project upward), ribs, tailhead, hooks (tuber coxae; hip joints), and pins (tuber ischia; lower pelvic bones) projecting prominently. Bone structure of withers, shoulders, and neck easily noticeable. No fatty tissue can be felt.
2	Very thin	Animal is emaciated. Slight fat covering over base of the spinous processes, transverse processes (portions of vertebrae that project outward) of lumbar (loin area) vertebrae feel rounded. Spinous processes, ribs, tailhead, hooks, and pins are prominent. Withers, shoulders, and neck structures are faintly discernible.
3	Thin	Fat is built up about halfway on spinous processes; transverse processes cannot be felt. Slight fat cover over ribs. Spinous processes and ribs are easily discernible. Tailhead is prominent, but individual vertebrae cannot be visually identified. Hook bones appear rounded, but are easily discernible. Fat can be felt around tailhead (prominence depends on conformation). Hook bones are not discernible. Withers, shoulders, and neck are not obviously thin.
4	Moderately thin	Negative crease along back (spinous processes of vertebrae protrude slightly above surrounding tissue). Faint outline of ribs is discernible. Fat can be felt around tailhead (prominence depends on conformation). Hook bones are not discernible. Withers, shoulders, and neck are not obviously thin.
5	Moderate	Back is level. Ribs cannot be visually distinguished, but can be easily felt. Fat around tailhead begins to feel spongy. Withers appear rounded over spinous processes. Shoulders and neck blend smoothly into body.
6	Moderately fleshy	May have slight crease down back. Fat over ribs feels spongy. Fat around tailhead feels soft. Fat begins to be deposited along at sides of the withers, behind shoulders, and along neck.
7	Fleshy	May have crease down back. Individual ribs can be felt, but with noticeable filling of fat between ribs. Fat around tailhead is soft. Fat is deposited along withers, behind shoulders, and along neck.
8	Fat	Crease down back. Difficult to feel ribs. Fat around tailhead is very soft. Area along withers is filled with fat. Area behind shoulder is filled with fat and flush with rest of the body. Noticeable thickening of neck. Fat is deposited along inner thighs.
9	Extremely fat	Obvious crease down back. Patchy fat appears over ribs. Bulging fat around tailhead, along withers, behind shoulders, and along neck. Fat along inner thighs may rub together. Flank is filled with fat and flush with rest of the body.

Based on Henneke et al. (1983) Henneke DR, et al. Equine Vet J. *1983;15:371 and reproduced with permission. Carter RA, et al. In: Geor RJ, et al., eds.* Equine Applied and Clinical Nutrition. *W.B. Saunders; 2013:393.*

Table 17-10 Grading system for assessing regional adiposity in the neck of ponies and horses

Score	Description
0	No visual appearance of a crest (tissue apparent above the ligamentum nuchae). No palpable crest.
1	No visual appearance of a crest, but slight filling felt with palpation.
2	Noticeable appearance of a crest, but fat deposited fairly evenly from poll to withers. Crest easily cupped in one hand and bent from side to side.
3	Crest enlarged and thickened, so fat is deposited more heavily in middle of the neck than toward poll and withers, giving a mounded appearance. Crest fills cupped hand and begins losing side-to-side flexibility.
4	Crest grossly enlarged and thickened and can no longer be cupped in one hand or easily bent from side to side. Crest may have wrinkles/creases perpendicular to topline.
5	Crest is so large it permanently droops to one side.

Insulin resistance can be detected by use of measurement of insulin and glucose concentrations in a single blood sample (point testing) or by more sophisticated testing using measurement of these analytes on multiple occasions after administration of glucose and insulin to equids (dynamic testing)—either as the euglycemic clamp technique or the frequently sampled intravenous glucose and insulin test (minimal model).[40-42] The former has greater utility in clinical and field settings, although with the potential for reduced sensitivity and/or specificity, whereas the latter is useful for research or referral settings and is regarded as the gold standard for diagnosis.

Hyperglycemia is rarely detected in equids with insulin resistance, and measurement of blood glucose concentrations alone is not a useful test for detection of insulin resistance.[1] Detection of persistent, inappropriate hyperglycemia (i.e., that not associated with stress or ingestion of food) should prompt consideration of diabetes mellitus.[43]

Hyperinsulinemia in the absence of conditions that increase insulin secretion (stress, pain, feeding) is strong evidence of the presence of insulin resistance.[1] Interpretation of plasma or serum insulin concentration must include consideration of a number of factors that could affect the actual concentration reported by the laboratory. Physiologic factors that can increase serum insulin concentration include feeding, stress and pain, and administration of alpha-2 adrenergic agonists (xylazine, detomidine, romifidine, etc.). Feeding increases plasma insulin concentration in both healthy and insulin-resistant horses and confounds interpretation of the results of testing. Pain and stress increase both plasma glucose and insulin concentrations through increases in cortisol and epinephrine concentrations in blood, which decrease insulin sensitivity.[44] This could be important when testing equids with active laminitis or other causes of pain—evaluation should be delayed until the pain is resolved.[1]

Point testing of plasma glucose and insulin concentrations should be performed under controlled conditions and ideally after 6 hours of feed withholding and preferably with sampling between 8 and 10 a.m.[1] Horses can be fed a small amount of hay with a low content of nonstructural carbohydrates the night before testing (approximately 2 kg of hay per 500-kg horse) and then nothing immediately before testing.[1]

Laboratory factors can influence the insulin concentration reported for a blood sample. This is primarily a result of differences in testing methodology returning different concentrations for the same blood sample.[45] Until recently, most testing for equine insulin involved use of kits or testing methodology designed for use with human samples, taking advantage of the

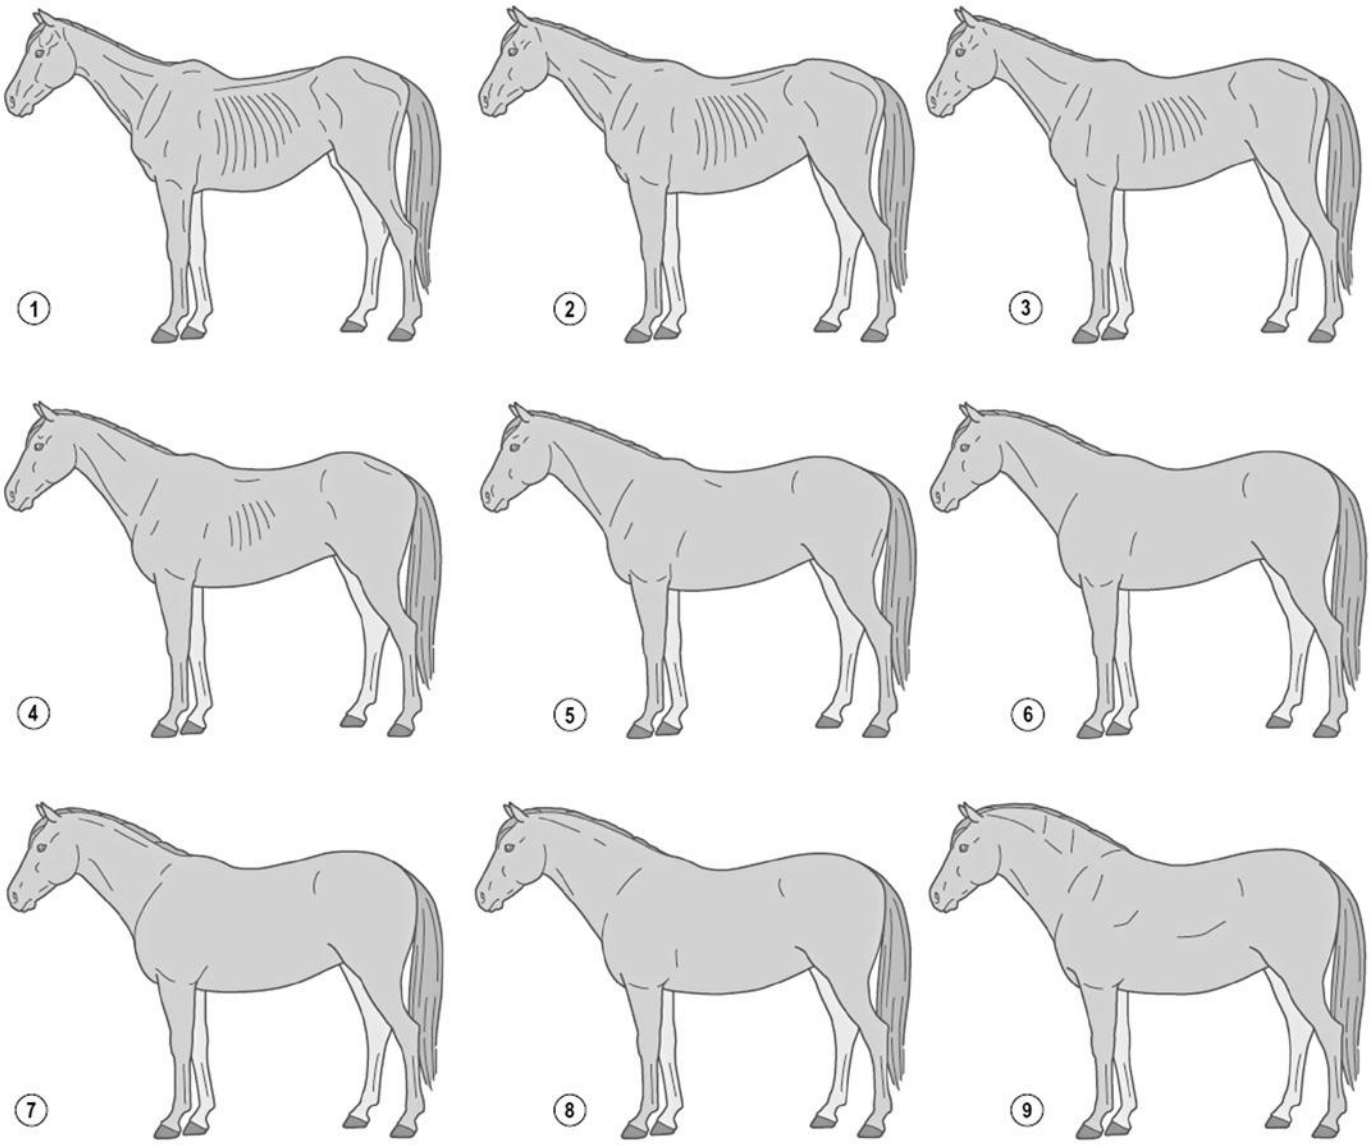

Fig. 17-7 Appearance of light-breed horses at each of the body-condition scores described by Henneke et al. (1983). Henneke DR, et al. *Equine Vet J*. 1983;15:371. (Reproduced with permission from Carter RA, et al. In: Geor RJ, et al., eds. *Equine Applied and Clinical Nutrition*. W.B. Saunders; 2013:393.)

considerable cross-reactivity between human and equine insulin. Equine-specific tests are now available, and their precision, accuracy, and specificity have been reported.[45] The gold-standard methodology is liquid chromatography–mass spectrometry (LC-MX), but this is expensive and has limited accessibility in laboratories processing large numbers of clinical samples. Analysis of six commonly used or available test kits for measuring plasma or serum concentrations of insulin demonstrated that none reflected concentrations measured by LC-MS and that only one provided reliable (valid) results—the Siemens Coat-a-Count Insulin Radioimmunoassay (RIA)—and only if samples with concentrations exceeding the highest standard were diluted with charcoal-stripped plasma and not the provided diluents.[45]

The effect of use of differing methods of measuring serum insulin concentration is that use of "cutoff" values for detecting insulin resistance provided by different laboratories is problematic. A value of 20 μU/mL is recommended as a cutoff, measured using the Siemens Coat-a-Count Insulin RIA, for defining insulin resistance.[1] However, this value should be interpreted with caution because the sensitivity (proportion of false negatives) and specificity (proportion of false positives) are not reported, and the test as a way of defining insulin resistance has not been well validated. It can be a useful screening test.[1] Local laboratories should be contacted before testing to determine the test used and whether the laboratory has determined reference ranges for its testing methodology.

Proxy indicators of insulin resistance, derived from measurement of plasma glucose and insulin concentrations, have been proposed and used to define insulin resistance and predict predisposition to laminitis in ponies.[7,40,41,46] A commonly used proxy is the RISQI:

$$RISQI = insulin\ concentration^{-0.5}$$

where lower values of the RISQI indicate lower insulin sensitivity.

Dynamic testing is usually achieved using combined glucose and insulin challenge tests of varying complexity.[1,41] One of these tests measures the insulin and glucose responses to IVs administration of glucose (150 mg/kg BW) and insulin (0.10 U/kg) with frequent sampling of blood (immediately before and at 1, 5, 15, 25, 35, 45, 60, 75,

90, 105, 120, 135, and 150 minutes after infusion).[1,5] Blood glucose concentrations of insulin-sensitive horses return to baseline values within 45 minutes of infusion of glucose. Insulin-resistant horses have a delayed decline of blood glucose concentrations and an exaggerated increase in plasma/serum insulin concentrations.[1,5] A more complex test, involving the frequent sampling of blood and delayed administration of insulin, is analyzed using the "minimal model" and yields four measures of insulin sensitivity, glucose disposal, and insulin secretion (pancreatic response).[41]

Dynamic testing can also involve the administration of insulin and monitoring of blood (plasma) glucose concentrations.[13,14] More complex testing involves the IV administration of increasing doses of insulin (either bovine or human recombinant) and measurement of blood glucose concentrations at defined times. The dose of insulin required to achieve a 50% reduction in blood glucose concentration is then used as the diagnostic index. This test is cumbersome and has a high risk of inducing hypoglycemia and is therefore of limited clinical utility.[13] A modified test involves administration of 0.1 U/kg IV of recombinant human insulin and measurement of blood glucose concentrations immediately before and 30 minutes after.[14] Insulin-sensitive horses ($n = 6$ in the study) all had a 50% or greater reduction in blood glucose concentrations 30 minutes after insulin administration, whereas none of the insulin-resistant horses ($n = 6$) had this response. The sensitivity and specificity of this test need to be determined in larger numbers of healthy and insulin-resistant horses for it to be clinically useful.

An oral sugar test (OST) provides results as reliable as the IV glucose tolerance test for detection of insulin resistance and hyperinsulinemia. The test involves oral administration of 0.15 mL/kg of corn syrup (approximately 150 mg/kg BW of dextrose-derived digestible sugars) to equids after an overnight fast. Plasma insulin and glucose concentrations are measured immediately before and 30, 60, and 90 minutes after administration of corn syrup. Equids with EMS have higher glucose and insulin concentrations than do unaffected horses.[17]

CLINICAL PATHOLOGY

Clinical pathology includes detection of hyperinsulinemia (as noted in the previous discussion), hyperleptinemia, hypertriglyceridemia, and normoglycemia. Plasma ACTH concentrations of horses with EMS are within the reference range for healthy horses, noting that horses with EMS might also have PPID.

NECROPSY

Affected horses are usually examined postmortem because of laminitis. Other than signs of laminitis and obesity/regional adiposity, there are no other characteristic lesions. The pancreas is normal.

DIFFERENTIAL DIAGNOSIS

- Obesity without insulin resistance
- Pituitary pars intermedia dysfunction
- Laminitis of cause other than EMS (systemic septic disease such as colitis or metritis)

TREATMENT

The objective of treatment is to improve the insulin sensitivity of affected equids. This can be achieved by reducing the proportion of the body made up of fat through careful dietary control. Administration of insulin-sensitizing drugs is attracting interest, but has yet to be of clearly demonstrated clinical utility.

Dietary Management

The fundamental aims of dietary management are as follows:

- Achieve and maintain an ideal BCS (body weight, noting earlier comments that body weight does not indicate body composition).
- Minimize intake of nonstructural carbohydrates because these induce an insulinemic and hyperglycemic response in EMS-affected equids and at-risk animals.[1]
- Ensure an adequate and balanced intake of essential nutrients.

The ideal BCS of ponies has been much mentioned, but little or seldom defined. The ideal body condition for a pony or horse would be one at which it has insulin sensitivity within the reference range (i.e., is not insulin resistant), has plasma triglyceride concentrations within the reference range, and is not at increased risk of laminitis. There is likely no one BCS that meets all of these criteria for all equids, and each animal must be considered in light of its own circumstances and physiology. Monitoring of measures of insulin resistance and plasma triglyceride concentration would provide guidance in achieving the animal's ideal, or acceptable, body weight.

Achieving and maintaining an acceptable BCS (as a proxy for proportion of body fat) is not easy.[47] Animals at most risk of obesity and regional adiposity are often metabolically equipped to maintain this body condition, and reducing body weight or BCS might not be as simple as just reducing feed intake.[22]

Recommendations for reduction in feed intake suggest that feeding 1.25% of body weight daily as hay is adequate to achieve a gradual reduction in body weight. However, planning a diet to provide a reduction in body weight while ensuring an adequate intake of essential nutrients and providing for the digestive and psychological health of the horse or pony can be challenging.

An initial step must be to eliminate or severely reduce access to pasture. Pasture provides unregulated access to fodder, and ponies can consume 2% to 5% of their body weight in pasture each day. This will result in weight gain. Additionally, pasture, and especially green pasture, has a high content of nonstructural carbohydrates (glucose, starch) that induces a glycemic and hyperinsulinemia response in ponies and susceptible horses. Access to pasture can be eliminated by housing animals on a dry lot or by fitting a grazing muzzle.

Hay can be fed as 1.25% to 1.5% of body mass as dry matter per day. The nonstructural carbohydrate content of the hay should be reduced by soaking it in cold water for 12 to 16 hours before feeding. The water used to soak the hay should not be provided to the horse or pony. Feeding this diet will induce a reduction in body weight and improvement in indices of insulin sensitivity.[22,37,48,49] Individual horses and ponies can be resistant to weight loss, and a reduction in daily dry matter intake to 1% of body weight might be needed to achieve loss of body weight. However, restriction of intake to this level can cause behavioral changes, such as eating bedding, chewing tails of companions, and other allotriophagia. An early example of dietary restriction inducing allotriophagia was that of Robert Falcon Scott's use of ponies in an expedition to reach the South Pole. The ponies displayed profound appetite for roughage as a consequence of their highly concentrated ration.

Supplements including chromium have been promoted as improving insulin sensitivity in horses. There is evidence that they are not effective, and there is no evidence of efficacy.[50]

Exercise

Exercise increases the insulin sensitivity of horses,[51] and it appears sensible to recommend an increase in the amount of exercise of obese ponies and horses.[1] However, moderate exercise training does not improve the insulin sensitivity of horses.[52] Moderate exercise by nonobese ponies previously affected with laminitis reduced serum amyloid A concentrations, heptoglobin concentrations, and postexercise serum insulin concentrations.[53] These results suggest a beneficial role for relatively low-intensity exercise (10 minutes enforced walking followed by 5 minutes of trotting) in reducing inflammation in ponies at risk of laminitis.

Medications

Administration of levothyroxine or metformin has been advocated for treatment of EMS.[1,54,55] Levothyroxine (0.1 mg/kg orally q24 h) causes weight loss and improves insulin sensitivity in obese horses and is recommended as an adjunct to dietary management.[55]

Metformin, which is used for treatment of type 2 diabetes in people, has been administered to horses in an attempt to improve insulin sensitivity. Although initial reports were favorable,[56] more recent pharmacologic investigation has not demonstrated its efficacy at a dosage of 15 mg/kg orally q12h in improving insulin sensitivity.[54,57-59] However, administration of metformin at 30 mg/kg q12h reduced glycemic and insulinemic responses of healthy horses and horses with dexamethasone-induced insulin resistance to administration of dextrose.[60] Whether this dosage will be effective in horses or ponies with naturally occurring insulin resistance remains to be determined.

Pioglitazone has been investigated in healthy horses, in which it does not improve insulin sensitivity (at 1 mg/kg q24h for 12 days) or attenuate the effects of endotoxin infusion on indicators of systemic inflammation.[61,62] The pharmacokinetics of pioglitazone in horses have been reported.[63]

PHEOCHROMOCYTOMA (PARAGANGLIOMA)

Pheochromocytomas are unusual tumors of domestic animals and occur in cattle, sheep, and horses.[1-5] A pheochromocytomas is a neuroendocrine tumor of chromaffin cells of the adrenal medulla or extraadrenal chromaffin tissue. The tumor secretes catecholamines; in humans, clinical signs are related to elevated concentrations of circulating epinephrine or norepinephrine. The clinical presentation in horses usually involves intermittent or acute colic or hemoabdomen. Horses can die acutely of exsanguination into the abdomen from ruptured tumor.[2] Affected horses can be persistently or intermittently tachycardic with excessive or untimely sweating. The mass can be palpable near the left kidney or imaged by transrectal ultrasonography.[2,6] The normal right adrenal gland cannot be imaged transrectally in a horse.[6] The disease in cattle and sheep is usually detected at postmortem examination and has no real economic impact, with the exception of the rare valuable bull affected.[5] The disease can occur as part of multiple endocrine neoplasia, but is usually solitary, although gangliomas can metastasise.[7] Antemortem diagnosis can be confirmed by measuring high concentrations of metanephrine and vanillylmandelic acid, both of which are metabolites of catecholamines, in blood or urine. There is no effective treatment, nor are there control measures.

GLYCOGEN BRANCHING ENZYME DEFICIENCY IN HORSES

Glycogen branching enzyme deficiency (GBED) is a fatal condition of fetuses and neonatal foals of the Quarter Horse, Paint Horse, and associated breeds.[1] The disease is caused by a nonsense mutation in codon 34 of the *GBE1* gene, which prevents the synthesis of a functional GBE protein and severely disrupts glycogen metabolism.[1] The mutant GBE1 allele frequency in registered Quarter Horse, Paint Horse, and Thoroughbred horses is reported as 0.041, 0.036, and 0.000, respectively.[2] Among 651 elite-performance American Quarter Horses, 200 control American Quarter Horses, and 180 control American Paint Horses, the GBED allele was detected with an overall frequency of 0.054.[3] GBED is inherited as a simple recessive trait from a single founder.[2] The disease is reported in North America and Germany.[4]

Affected foals are aborted, born dead, or affected at birth. It is estimated that up to 2.5% of fetal and early neonatal deaths in Quarter Horses and related breeds are associated with this defect.[2] Foals that are born alive are weak and hypothermic, some have flexural limb deformities, and all die usually within hours to days of birth.[5] Affected foals have refractory hypoglycaemia and minor elevations in serum activity of creatine kinase.

The disease is confirmed by detection of periodic acid–Schiff (PAS)-positive inclusions in the cardiac or skeletal muscle and genotype analysis. There is no effective treatment, and control is by selective and prudent breeding.

LACTATION TETANY OF MARES (ECLAMPSIA, TRANSPORT TETANY)

Lactation tetany of mares is caused by hypocalcemia and is characterized by abnormal behavior progressing to incoordination and tetany. The precise cause of the hypocalcemia has not been determined, but the cause of the clinical signs is a marked reduction in serum concentration of ionized calcium. The effect of feeding diets high in calcium, such as alfalfa hay, during late pregnancy, and of abrupt changes in diet after parturition, have not been investigated in horses

as they have in cattle (see discussion of milk fever).

The disease was most common when draft-horse breeding was widely practiced, but it is uncommon now.[1] The case fatality rate is high in untreated animals. Most cases occur in lactating mares, either at about the 10th day after foaling or 1 to 2 days after weaning. High-producing mares grazing on lush pasture are most susceptible and in many instances are engaged in hard physical work. The housing of wild ponies or prolonged transport can precipitate an episode. The latter has been a particularly important factor in the etiology of the disease in Britain and has been credited with precipitating it even in stallions and dry mares. Occasional cases occur without there being any apparent cause. The disease has occurred in a 20-year-old gelding pony. Hypocalcemia with clinical signs also occurs in horses used for prolonged exercise, such as endurance racing or 3-day events.

Hypocalcemia occurs in other diseases of horses, including colic and colitis, and as a result of hypoparathryoidism.[2,3]

Many mild cases of lactation tetany that recover spontaneously occur after transport, but the case fatality rate in some shipments can be greater than 60%. Mares that develop the disease at the foal heat or at weaning are usually more seriously affected, and the case fatality rate is high if mares are not treated in a timely fashion.

Severely affected animals sweat profusely and have difficulty moving because of tetany of the limbs and incoordination. The gait is stiff, and the tail is slightly raised. Rapid, labored respirations and wide dilatation of the nostrils are often accompanied by synchronous diaphragmatic flutter ("thumps") evident as a distinct thumping sound from the thorax. Muscular fibrillation, particularly of the masseter and shoulder region, and trismus are evident, but there is no prolapse of the membrana nictitans. Affected animals are not hypersensitive to sound, but handling can precipitate increased tetany. The temperature is normal or slightly elevated, and although the pulse is normal in the early stages, it later becomes rapid and irregular. The mare might make many attempts to eat and drink but appears to be unable to swallow, and passage of a stomach tube can be difficult. Urination and defecation are in abeyance, and peristalsis is reduced.

Within about 24 hours the untreated mare becomes recumbent; tetanic convulsions develop and become more or less continuous. The mare dies about 48 hours after the onset of illness. The tetany and excitement in the early stages suggest tetanus, but there is no prolapse of the third eyelid, and there is the usual relationship to recent foaling or weaning and physical exertion. The anxiety and muscle tremor of laminitis can be confused with those of lactation tetany, especially when it occurs in mares that have foaled and retained the placenta. Pain in the feet and bounding digital pulses are diagnostic features of this latter disease.

Hypocalcemia occurs with serum concentrations in the range of 4 to 6 mg/dL (1 to 1.50 mmol/L), and the degree of hypocalcemia has been related to the clinical signs. When serum calcium levels are higher than 8 mg/dL (2 mmol/L), the only sign is increased excitability. At levels of 5 to 8 mg/dL (1.25 to 2 mmol/L), there are tetanic spasms and slight incoordination. At levels of less than 5 mg/dL (1.25 mmol/L), there is recumbency and stupor. It is the concentration of ionized calcium that is important, and some animals, such as horses used for 3-day events, can have normal total calcium concentrations but abnormally low ionized calcium concentrations as a result of changes in acid:base status. If possible, serum concentrations of ionized calcium should be measured in horses with clinical signs suggestive of hypocalcemia. Hypomagnesemia with serum magnesium levels of 0.9 mg/dL (0.37 mmol/L) has been observed in some cases, but only in association with recent transport. Hypermagnesemia has been reported in other cases.

Treatment by IV administration of calcium borogluconate as recommended in the treatment of parturient paresis in cattle results in rapid, complete recovery. The dose for a 500-kg mare is 300 to 500 mL of a 25% solution of calcium borogluconate or gluconate administered slowly (over 15 to 30 min) intravenously. One of the earliest signs of recovery is the voiding of a large volume of urine. Occasional cases that persist for some days have been recorded.

EQUINE HYPERLIPEMIA

SYNOPSIS

Etiology Abnormal energy metabolism secondary to inadequate caloric intake.

Epidemiology Pregnant or lactating middle-aged, overweight ponies, donkeys, and American miniature horses. Worldwide. Sporadic.

Clinical signs Depression, anorexia, weight loss, ventral edema, muscle fasciculation, mania, recumbency.

Clinical pathology Hypertriglyceridemia (triglyceride > 500 mg/dL, 5 mmol/L).

Necropsy findings Widespread lipidosis, swollen liver, hepatic rupture.

Treatment Increase energy intake through enteral or parenteral feeding. Treat underlying disease.

Control Maintain optimal body condition. Prevent disease and nutritional stress, including changes in diet and prolonged transportation.

ETIOLOGY

The potentially life-threatening disease hyperlipemia is associated with hyperlipidemia (an abnormal concentration of lipids in blood) in equids. The disease is a result of a derangement in fat metabolism secondary to nutritional stress and, in particular, inadequate energy intake.[1]

Hyperlipemia is the clinical syndrome of depression, weakness, and ventral edema with high blood concentrations of triglycerides and hepatic lipidosis. It carries a high case-fatality rate. A related condition is the detection of hypertriglyceridemia associated with an overt, severe, primary disease (colic, neoplasia, endocrine disease) in which the triglyceridemia likely has minimal clinical importance. Hyperlipemia has its greatest importance as a disease of ponies and donkeys in field situations and related to relatively minor inciting causes.

EPIDEMIOLOGY

Occurrence

Hyperlipemia occurs worldwide. Although its occurrence is sporadic, multiple cases can occur on a farm when there are a number of at-risk animals exposed to the same inciting factor, such as lack of adequate grazing or supplementary feeding. The annual incidence of the disease in ponies in southeastern Australia is 5%, and it is 2% to 10% in donkeys in the United Kingdom.[2] The case-fatality rate is 40% to 80%, although it appears to be less in hospitalized equids provided more focused care.[2,3] Incidence varies with season and locality; the disease in ponies in Europe occurs most commonly during late gestation (January–March), whereas in southern Australia, the disease is more common in ponies during early lactation (November–January).

Animal Risk Factors

Hyperlipemia can occur in any breed of horse or pony and in donkeys, but it is more common in ponies and donkeys.[2,3] Any breed of equid can develop hypertriglyceridemia as a result of a primary disease, but development to the clinical condition lipemia is most common in ponies, miniature horses, miniature donkeys, and donkeys. The disease is considered most common in females, uncommon in pony stallions and geldings, and rare in foals. Most affected ponies are more than 4 years old, and the peak incidence occurs in 9-year-olds. Hypertriglyceridemia occurs in foals secondary to other diseases.[3-5]

Risk factors for hyperlipemia (triglyceride concentration ≥ 4.4 mmol/L) in 449 donkeys with the disease from a population of 3829 donkeys included concurrent disease (odds ratio [OR] 77, 95% confidence interval [CI], 45 to 129), weight loss in previous month (OR = 6.4, 3.6 to 11.3), relocation to a new site (farm) (OR = 3.9, 1.3 to 12), dental disease (OR = 1.7, 1.1 to 2.8), history of inappetence (OR = 3.2, 1.3 to 7.9), and increasing age (OR = 1.26, 1.1 to 1.45).[2]

Horses and ponies with primary endocrine disease, including pituitary pars intermedia dysfunction (PPID) or suspected diabetes mellitus and conditions associated with insulin resistance, can have marked elevations in serum triglyceride concentrations (10.5 to 60.3 mmol/l) without evident clinical signs attributable to hypertriglyceridemia. The hypertriglyceridemia resolves with successful treatment of the underlying endocrine disease.[6]

Pregnancy and lactation increase the risk of the disease in ponies, but not in donkeys. The disease in miniature horses is always associated with underlying disease, such as colic, which is apparently an important risk factor. Underlying disease is identified in 50% of cases in ponies and 72% of affected donkeys;[2] however, many cases occur in pregnant or lactating pony mares without evidence of other disease.

Overweight ponies and donkeys are at increased risk, and insulin resistance is likely a risk factor for the disease.[7] Onset of disease is often preceded by some sort of stress, typically transport, lactation, food deprivation, or a combination of these factors. Characteristically the disease occurs in fat, middle-aged, pregnant, or lactating ponies that experience a decrease in feed intake. However, the disease is not restricted to this demographic, and horses or thin ponies can develop the disease.

Hypertriglyceridemia is detected in horses with evidence of systemic inflammatory response syndrome (severe illness associated with decreased feed intake). There is no opacity of the plasma or serum, and the hypertriglyceridemia has not been demonstrated to worsen the outcome of the underlying disease.

PATHOGENESIS

The combination of the innate insulin resistance of ponies and a nutritional stressor, such as disease, pregnancy, lactation, or food deprivation, results in excessive mobilization of fatty acids from adipose tissue at a rate that exceeds the gluconeogenic and ketogenic capacity of the liver.[1] Adipocytes of ponies, in response to norepinephrine, release fatty acids at a rate 6.5 times greater than those of horses, possibly providing at least a partial explanation for the difference in likelihood of differing breeds developing the disease. Lipolysis is mediated by β_2-adrenergic receptors in ponies and horses. The induction of excessive fat mobilization in ponies is likely associated with the well-characterized insulin resistance of this breed, especially in obese individuals. There is no difference between ponies and horses in the extent to which lipolysis is inhibited by insulin. The effect of insulin resistance on glucose uptake from the blood might be exacerbated in sick ponies by the increase in serum cortisol concentrations associated with stress or disease.

Equids have little propensity to produce ketones, and thus the excess fatty acids are reesterified in the liver to triglycerides and released into the circulation as very low-density lipoproteins (VLDLs). The **fundamental defect** in the disease is in the regulation of free fatty acid release from fat stores as a result of a defect in control of hormone-sensitive lipase, the enzyme responsible for hydrolysis of triglycerides to free fatty acids and glycerol in adipose tissue. Unchecked activity of this enzyme results in mobilization of fatty acids in hyperlipemic ponies that is 40 times the rate in normal ponies. There is no dysfunction of lipoprotein lipase, the enzyme mediating uptake of plasma free fatty acids by extrahepatic tissues, and its activity can be 300% of that of unaffected ponies.

Hyperlipidemia causes widespread lipidosis and organ dysfunction. Hepatic lipidosis compromises liver function, resulting in accumulation of toxic metabolites and derangement in coagulation.

CLINICAL FINDINGS

The clinical course varies between 3 and 22 days but is generally 6 to 8 days. The unchecked disease progresses from mild depression and inappetence; through profound depression, weakness, and jaundice; to convulsions or acute death in 4 to 7 days. Depression, weight loss, and inappetence are the initial signs in 90% of cases. Approximately 50% of cases have fasciculation of muscles of the limb, trunk, or neck. Ventral edema unrelated to parturition occurs in approximately 50% of cases. Inappetence progresses to anorexia and depression, which is followed by somnolence and hepatic coma. Compulsive walking or mania develops in 30% of cases. Signs of mild colic, including flank watching, stretching, and rolling, are evident in 60% of cases. The incidence of jaundice is variable. Many animals show a willingness to drink, but they are unable to draw water into the mouth and swallow. Others continually lap at water. The temperature is normal or moderately elevated, and heart rate and respiratory rates are increased above normal. Diarrhea is an almost constant feature in the terminal stages.

Visual examination of the plasma or serum phase of a blood sample collected from an affected animal reveals cloudy, milky, mildly opalescent plasma.

CLINICAL PATHOLOGY

There is usually leukocytosis with neutrophilia. Hyperlipidemia is a consistent feature of the disease. Serum triglyceride concentrations will be at least 5 mmol/L (500 mg/dL) and can be much higher. Serum cholesterol and free fatty acid concentrations are also increased, although less so than triglycerides. The plasma triglyceride concentration is of minimal prognostic use in ponies, but most American miniature horses with triglyceride concentrations above 1200 mg/dL (12 mmol/L) die.

Plasma glucose concentration is usually low. Ketonemia and ketonuria do not occur. Biochemical evidence of liver disease is characteristic of the advanced disease. Serum activity of gamma-glutamyltransferase (GGT) can be elevated before clinical signs of disease are apparent. Serum creatinine and urea nitrogen concentrations increase as renal function declines. Blood clotting time increases. Metabolic acidosis develops terminally. Hematologic and biochemical variables can also be affected by any underlying disease.

Diagnostic confirmation of hyperlipemia is achieved by demonstration of hyperlipidemia (plasma triglyceride concentrations above 5 mmol/L [500 mg/dL]) in a horse with appropriate clinical signs.

The utility of point-of-care (stall-side) analyzers has been investigated, and both units performed adequately, although not perfectly.[8,9] The upper operating range of both units (~6.0 mmol/L) was lower than values for triglycerides in severely affected animals, which limits their usefulness, although it does allow identification of equids with very high concentrations. The instruments have coefficients of variation for measurement of the same sample of 10% to 16%, which limits their usefulness in monitoring responses to treatment. These analyzers are useful for field measurement of triglyceride concentrations in equids, but care should be taken in evaluating values that exceed the range of the instrument.

NECROPSY FINDINGS

Extensive fatty change is present in most internal organs, but especially in the liver, which is yellow to orange, swollen, and friable. Liver rupture with intraabdominal hemorrhage may be present. Tissue pallor as a result of lipid accumulation is also prominent in the kidney, heart, skeletal muscle, and adrenal cortex. Serosal hemorrhages of the viscera reflect disseminated intravascular coagulation. The necropsy should also include an examination for lesions that might predispose the animal to hyperlipidemia, such as pancreatic damage or laminitis. Histologically, widespread microvascular thrombosis and intracellular lipid in various tissues are evident.

Samples for Postmortem Confirmation of Diagnosis

Samples for postmortem diagnosis include formalin-fixed liver, kidney, heart, adrenal, skeletal muscle, and pancreas for light microscopic examination.

DIFFERENTIAL DIAGNOSIS

- Parasitism
- Anemia
- Liver disease, including pyrrolizidine toxicosis
- Serum hepatitis
- Aflatoxicosis

Hyperlipemia should be considered in any pony with a history of weight loss, inappetence, and progressive somnolence, especially in late pregnancy or early lactation.

TREATMENT

- The principles of treatment are as follows:
- Treatment of the underlying or inciting disease
- Restoration and maintenance of a positive energy balance
- Correction of any defects in hydration, acid–base, and electrolyte status
- Reduction of the hyperlipidemia

Every effort should be made to determine whether there is an underlying disease, and if so, it should be treated aggressively. Parasitism is a common inciting disease, as are equine Cushing's disease and neoplasia (lymphosarcoma, gastric squamous cell carcinoma) in older ponies.

The negative energy balance must be corrected. A mature, nonpregnant, and nonlactating 200-kg (440-lb) pony has energy requirements (digestible energy intake) of 9.3 Mcal/d (38 mJ/d), whereas a lactating pony has energy requirements of 13.7 Mcal/d (57.2 mJ/d). Affected animals should be encouraged to eat and must be supplemented either orally or intravenously if they will not eat a sufficient quantity. Supplements, either oral or IV, are unlikely to meet all the animal's energy requirements, but normalization and stabilization of blood glucose concentrations, and the apparent consequent changes in hormonal milieu, inhibit lipolysis and enhance clearance of triglycerides from plasma and hepatic and renal tissues.

Oral supplementation using commercial equine or human enteral nutrition preparations has been successful for treatment of the disease in American miniature horses and donkeys. If these products are not available, a homemade gruel consisting of alfalfa pellets and cottage cheese can be used. These preparations are administered every 6 hours through a nasogastric tube. Alternatively, glucose can be given orally (1 g/kg, as 5% solution every 6 hours, about 5 L to a 250-kg pony) or intravenously (5% solution, 100 mL/kg per day as a continuous IV infusion). As noted earlier, this dose of glucose will not meet the energy needs of the pony, but it might be sufficient, along with treatment of the underlying disease and supportive care, to restore normal fat metabolism. Provision of parenteral nutrition is feasible and apparently effective, but expensive and technically demanding, thereby restricting its use to veterinary hospitals.[10,11]

Mares in late pregnancy can be aborted, and lactating mares should have the foal removed.

Dehydration and abnormalities in electrolyte and acid–base status should be corrected by oral or IV administration of isotonic fluids (lactated Ringer's solution) and, if necessary, sodium bicarbonate.

Encephalopathy associated with liver failure should be treated with oral neomycin (20 mg/kg, every 6 hours) or lactulose (1 mL/kg, every 6 hours).

Hyperlipidemia should be reduced by minimizing free fatty acid production by adipose tissue and enhancing triglyceride removal from plasma. Free fatty acid production is minimized by ensuring adequate energy intake and normal plasma glucose concentrations. Use of insulin and heparin has been recommended for reduction of plasma free fatty acid concentration. However, the efficacy of these treatments is not clear, and the emphasis should be placed on provision of adequate energy intake rather than administration of these hormones. Insulin (protamine zinc insulin) is administered at 0.1 to 0.3 IU/kg SC every 12 to 24 hours. Blood glucose concentrations should be monitored, and the insulin dose may need to be adjusted. Heparin (40 to 100 IU/kg SC every 6 to 12 hours) can be given to increase lipoprotein lipase activity and promote the clearance of triglycerides from plasma. It should be noted that lipoprotein lipase activity is not deficient in affected ponies, and therefore the administration of heparin to ponies with hyperlipemia is not recommended. Severely affected ponies may have an increase in clotting time that could be exacerbated by heparin.

Corticosteroids and adrenocorticotropic hormone are contraindicated in treatment of this disease.

CONTROL

A mature, nonpregnant, and nonlactating 200-kg (440-lb) pony has energy requirements of 9.3 Mcal/d (38 mJ/d), whereas a lactating pony has energy requirements of 13.7 Mcal/d (57.2 mJ/d), and every effort should be made to meet these requirements. This might require dietary supplementation during periods of nutritional stress, such as drought, late pregnancy, peak lactation, or transportation. Ponies should be maintained in optimal body condition, and nutritional stress should be avoided. A parasite and disease control program should be instituted. Transport of pregnant and lactating ponies should be avoided.

Disorders of Thyroid Function (Hypothyroidism, Hyperthyroidism, Congenital Hypothyroidism, Thyroid Adenoma)

Disorders of thyroid function as a result of abnormalities in the thyroid gland, pituitary gland, or hypothalamus are uncommon in the domestic species and are best documented for the horse. Thyroid disorders secondary to excessive or inadequate intake of iodine or selenium deficiency are discussed under those headings. Animals with low concentrations of thyroid hormones, usually total T3 and total T4, in blood could have nonthyroidal illness syndrome, which is well described in humans and dogs.[1] Furthermore, neonates have lower concentrations of thyroid hormones in blood than do adults, and premature neonates have even lower concentrations.[2]

ETIOLOGY

Disorders of thyroid function result in hypothyroidism or hyperthyroidism.[3] Hypothyroidism can result from diseases of the thyroid gland (primary hypothyroidism), pituitary gland (secondary hypothyroidism as a result of reduced secretion of thyroid-stimulating hormone), or hypothalamus (tertiary hypothyroidism, decreased thyrotropin [thyroid-releasing hormone] secretion). Autoimmune thyroiditis has not been described in horses. Lymphocytic thyroiditis occurs in goats. Consumption of propylthiouracil (4 mg/kg body weight orally once daily for 4 to 6 weeks) induces hypothyroidism in adult horses. Administration of trimethoprim-sulfadiazine (30 mg/kg orally q24 h for 8 weeks), which can induce

hypothyroidism in humans and dogs, does not impair thyroid function of most horses. Systemic illness, such as sepsis, or starvation can alter function of the hypothalamic–pituitary–thyroid axis, resulting in euthyroid sick syndrome, more recently termed nonthyroidal illness syndrome. The syndrome has been documented in adult horses[1] and in foals with septic and nonseptic illnesses.[2,4,5]

Hereditary congenital hypothyroidism secondary to defects in thyroglobulin production occurs in sheep, goats, and Afrikander cattle. The disease is inherited as an autosomal-recessive trait. The cause of congenital hypothyroidism in foals is uncertain, although ingestion of nitrates by the pregnant dam is strongly suspected. Partial thyroidectomy of equine fetuses results in birth of foals with clinical and pathologic characteristics similar to those in the spontaneous disease.

Hyperthyroidism in horses is attributable to functional adenocarcinoma or adenoma of the thyroid gland, but most thyroid tumors are not functional.[6-8]

EPIDEMIOLOGY

The frequency with which hypothyroidism occurs in adult horses is unknown. It is relatively common practice to administer thyroid hormone or iodinated casein to fat horses; to those with laminitis, rhabdomyolysis, or anhidrosis; or to enhance fertility, but documentation of abnormal thyroid function in these animals is rare. None of 79 clinically normal brood mares had an abnormal response to thyroid-stimulating hormone administration, indicating that hypothyroidism is uncommon in this type of animal. Importantly, horses with nonthyroid-related illness often have low concentrations of thyroid hormones in the blood without evidence of thyroid dysfunction—this is referred to as the euthyroid sick or nonthyroidal illness syndrome and is not indicative of thyroid disease.

Abnormalities of the thyroid gland were detected in 12% of 1972 **goats** examined in India. Of thyroid glands examined from 1000 goats in India, 2.4% had colloid goiter, 39% had parenchymatous goiter, 1.8% had lymphocytic thyroiditis, and 2.1% were fibrotic.

Congenital hypothyroidism in foals occurs in western Canada and the western and northern United States. One survey of necropsy records of almost 3000 equine fetuses and neonatal foals in western Canada found that 2.7% had histologic evidence of thyroid and musculoskeletal abnormalities consistent with congenital hypothyroidism. Congenital hypothyroidism occurs in Dutch goats, Merino sheep, and Afrikander cattle. Hypothyroidism is reported in an East Friesian ram.

Hyperthyroidism is a sporadic disease of older horses for which other risk factors are not identified.

Exercise and participation in endurance racing or competitive show jumping usually, but not always, influences serum concentrations of thyroid hormones, but is not considered a pathologic process.[9,10] The response depends on the type and intensity of exercise—endurance exercise (40 to 420 km) reduces plasma concentrations of T3 and T4 at the end of the race, with return to basal concentrations by 24 hours.[11] Serum T4 concentrations are lower in overtrained or malconditioned young Standardbred horses.[12]

Thyroid tumors are common in older horses, with ~50% having adenomas evident on histologic examination of the thyroid gland. The clinical course of such tumors is benign, although their size can be quite impressive. Thyroid adenocarcinoma is much less common but has a malignant course.[6-8]

Fetal undernutrition of lambs during late gestation adversely affects postnatal thyroid function and causes hyperthyroidism as adult sheep.[13]

CLINICAL FINDINGS

Clinical characteristics of hypothyroidism in adult horses are poorly defined, largely because of the difficulty of confirming the diagnosis and the pharmacologic effect of exogenous thyroid hormones. Clinical abnormalities anecdotally attributed to hypothyroidism include exercise intolerance, infertility, weight gain, maldistribution of body fat, agalactia, anhidrosis, and laminitis, among others. Peripheral neuropathy and keratitis sicca (secondary to facial nerve dysfunction) responsive to levothyroxine administration has been reported in a horse.[14] Definitive association of these clinical syndromes with abnormalities of thyroid function is lacking.

Thyroidectomy of horses causes a reduction in resting heart rate and body temperature, docility, decreased food intake, increased cold sensitivity, dull hair coat, and delayed shedding of hair. Blood and plasma volumes of horses increased after removal of the thyroid glands. Effects of thyroidectomy were reversed by administration of thyroxine, with the exception of blood and plasma volume that did not return to euthyroid values. Thyroidectomized horses did not become obese or develop laminitis.

Induced hypothyroidism in goats is evident as a loss of body weight, facial edema, weakness, profound depression, and loss of libido.

Congenitally hypothyroid foals have a prolonged gestation but are born with a short and silky hair coat, soft and pliable ears, difficulty in standing, lax joints, and poorly ossified bones. The foals are referred to as dysmature. Characteristic musculoskeletal abnormalities include inferior (mandibular) prognathism, flexural deformities, ruptured common and lateral extensor tendons, and poorly ossified cuboidal bones.

Horses with **hyperthyroidism** are tachycardic, display cachexia, and have hyperactive behavior. There is usually detectable enlargement of the thyroid gland both on physical examination and on scintigraphic imaging.

Thyroid adenomas are evident as a unilateral nonpainful enlargement of the thyroid gland of older (>15 years) horses and are detectable on scintigraphic examination.[15] Ultrasonographic and scintigraphic imaging of the thyroid gland of healthy horses is described.[16] Thyroid adenocarcinoma presents as metastatic disease with both local and distant spread. Some affected horses have signs of hyperthyroidism, although this is unusual.[6]

Anhidrosis in horses is not associated with abnormal thyroid function.[17]

CLINICAL PATHOLOGY

Hematologic abnormalities in hypothyroid horses are not well documented. Induced hypothyroidism in horses causes increases in serum concentrations of VLDLs, triglycerides, and cholesterol, and decreased concentrations of NEFAs. Induced hypothyroidism in goats caused hypoglycemia, hypercholesterolemia, and anemia. Hypothyroidism in a ram caused hypercholesterolemia.

Thyroid Hormone Assays

Assays are available for measurement of serum concentrations of T3, T4, free T4 (fT4), free T3 (fT3; radioimmunoassay or equilibrium dialysis), and/or TSH in various species.[18-20] Values of each of these analytes vary depending on the method of analysis, physiologic status of the animal, and administration of other compounds (Table 17-11). Serum concentrations of thyroid hormones are high at birth and decline with age in ruminants and nonruminants.[5,21,22] For example, serum T3 concentrations of weaned Thoroughbred foals declined from 2.89 to 0.29 nmol/L at 7 and 9 months of age, serum T4 concentrations from 100.17 to 21.77 nmoL at 1 month and at 10 months, serum fT3 concentrations were 6.96 and 1.50 pmol/L at 1 month and 4 months of age, and serum fT4 concentrations were 31.40 and 4.93 pmol/L at 1 month and 9 months of age.[22]

There are statistically significant **diurnal variations** in serum concentrations of T3 and T4 in adult horses, with the lowest concentrations observed during the early morning hours, likely coincident with the time at which metabolic rate is lowest (Table 17-8). There is not a seasonal variation in thyroid hormone concentrations in horses.[23] **Feed restriction** for 3 to 5 days lowers serum concentrations of T3, T4, and fT4 in horses by 24% to 42%. Administration of **phenylbutazone** decreases concentrations of fT4 (measured by equilibrium dialysis) and T4 by 4 days of treatment, which can persist for up to 10 days after discontinuation of phenylbutazone. The decrease in T4 is suggested

Table 17-11 Serum or plasma concentrations of thyroid hormones and thyroid-stimulating hormone in foals, horses, donkeys, and cattle

Physiologic status	Serum or plasma tT3	Serum or plasma tT4	fT4	TSH
Age				
Birth (<10 hours)	991 ng/dL 12.8 ± 7.4 mmol 366 ± 222 ng/L	28.8 µg/dL 493 ± 58 nmol/L 13.3 ± 5.1 µg/dL	12.1 ng/dL

fT4 determined by RIA or ED. PTU, propylthiouracil

to be attributable to displacement of T4 from protein binding sites by phenylbutazone, but this does not explain the decrease in fT4. Topical application twice daily of 50 g of an ointment containing 17 mg/100g of **dexamethasone-21-acetate** (daily application of 17 mg dexamethasone) suppressed serum T3 and T4 concentrations during 10 days of treatment and for at least 20 days after cessation of treatment.[24] The clinical significance of phenylbutazone-induced decreases in thyroid hormones is uncertain, but should be considered when assessing thyroid function in horses.

Plasma concentrations of fT3, tT3, rT3, fT4, and tT4 of **donkeys** differs with the age of the donkey and from that of adult horses (Table 17-11).[25] Donkeys less than 5 years of age have higher serum fT3, tT3, rT3, fT4, and tT4 than older donkeys.[25]

Because of the number of analytical and physiologic factors that affect serum thyroid hormone concentrations, values considered normal vary considerably, as illustrated by

the finding that 44 of 79 clinically normal nonpregnant broodmares had serum T4 concentrations below the reference range, although responses to TRH were normal. This example illustrates the need to determine reference ranges based on the methodology used and with well-defined definition of the physiologic state of the animals being tested.

Diagnosis of hypothyroidism is aided by demonstration of inappropriate responses of the thyroid gland to administration of TSH or TRH,[17,26] although the use of these tests depends on determining the increase in serum T3 and/or T4 that is expected in normal horses and in horses with thyroid disease. Of 79 clinically normal mares, all had some increase in T3, and 77 had an increase in T4, 2 hours after IV administration of 1 mg of TRH intravenously. The mean increase in serum T3 concentration was 4.5 times that of resting values (from 0.62 ng/mL to 2.44 ng/mL), whereas serum T4 concentration increased to a mean of 2.1 times that of resting value (from 14.7 ng/mL to 28.6 ng/mL). Although responses to administration of TSH have been reported, responses indicative of abnormal thyroid function—other than complete lack of response—have not been determined, and the utility of the test has been questioned.

The TSH response test involves administration of 5 IU of TSH intravenously. Blood samples are collected before administration and 30 minutes after, 2 hours after, and 4 hours after administration. Serum concentrations of T3 and T4 in healthy horses double after administration of TSH. An alternative involves administration of 5 IU IM and collection of blood before and 3 and 6 hours after TSH administration. TSH is often unavailable.

The TRH response test requires administration of 0.5 to 1 mg of TRH IV. Serum concentrations of T3 and T4 at 2 and 4 hours are double those before TRH administration in horses with normal thyroid function.

Measurement of fT4 in serum is useful for assessment of thyroid function. fT4 concentrations can be normal in horses with low concentrations of T3 and T4, and in this situation are likely indicative of normal thyroid function.

Measurement of serum concentrations of TSH is useful in determining thyroid responsiveness to endogenous TSH. Elevated TSH concentrations in horses with low serum concentrations of T3, T4, or fT4 is indicative of thyroid dysfunction.

Diagnosis of hypothyroidism in horses should be based on the presence of compatible clinical signs, low serum concentrations of thyroid hormones (T3, T4, fT4), elevated concentrations of TSH, lack of an increase in serum concentrations of thyroid hormones in response to administration of TRH, and increased TSH concentration in serum in response to TRH administration. Diagnosis of hypothyroidism should not be based solely on clinical signs or on the measurement of resting (unstimulated) serum T3 or T4 concentrations. At a minimum, appropriate clinical signs and documentation of an abnormal response to stimulation testing (TSH or TRH) are essential for diagnosis of hypothyroidism in horses. Measurements of fT4 concentrations determined by equilibrium dialysis are useful in determining thyroid function in sick horses in which T3 and T4 concentrations are low because fT4 concentrations will be normal in horses without thyroid disease.

Foals with congenital hypothyroidism have abnormally low concentrations of T3 and T4 and less-than-expected increases in serum concentrations of these hormones in response to TSH administration.

Horses with hyperthyroidism have markedly elevated concentrations of T3 and T4. Concentrations of T4 do not decline in response to administration of T3. T3 (2.5 mg) is administered intramuscularly twice daily for 3 days and serum concentrations of T3 and T4 measured. T4 concentrations in the serum of healthy horses decline by approximately 80%, whereas those of horses with hyperthyroidism do not decline.

NECROPSY FINDINGS

Findings on necropsy examination of hypothyroid horses have not been reported. Foals with congenital hypothyroidism have histologic evidence of thyroid hyperplasia, but no gross signs of goiter.

TREATMENT

Treatment of confirmed hypothyroidism in horses is achieved by administration of levothyroxine (20 µg/kg PO q24h). Serum T3 concentrations peak in 1 hour and then decline, whereas concentrations of T4 peak in 2 hours and persist for 24 hours. Administration of levothyroxine to healthy (euthyroid) horses resulted in 3.7- to 5.4-fold increases in pretreatment total T4 concentrations in serum.[27] The clinical status of horses treated for hypothyroidism should be monitored during treatment and serum concentrations of T3 and T4 measured every several months. Iodinated casein, which is no longer readily available in the United States, is administered at 5 g/450 kg body weight orally once daily. Administration of thyroxine or iodinated casein for treatment of low serum thyroid hormone concentrations in horses with nonthyroidal illness syndrome (euthyroid sick syndrome) should be done judiciously, if at all.

A response to thyroxine administration is not necessarily confirmation of hypothyroidism because thyroxine can have marked effects in horses with normal thyroid function.[27] Administration of thyroxine (up to 96 mg/470-kg horse, orally once daily) increases serum concentrations of T4 and, to a lesser extent, fT4, and decreases concentrations of TSH. The increases in T4 are associated with a loss of body weight; decreases in serum concentrations of triglycerides, cholesterol, and VLDLs; and an increase in whole-body insulin sensitivity. Thyroxine should be administered with caution to horses with normal thyroid function.

CONTROL

There are no recognized control measures for hypothyroidism in adult horses. Minimizing intake of nitrates by pregnant mares appears warranted, but definitive proof of the efficacy of this practice is lacking. Pregnant mares should not be fed fodder or supplements that interfere with thyroid function.

The inherited disorder in sheep, cattle, and goats can be prevented by selective breeding.

IODINE DEFICIENCY

SYNOPSIS

Etiology Primary dietary deficiency of iodine or secondary to conditioning factors such as calcium, *Brassica* plants, or bacterial pollution of water.

Epidemiology In all species, most common in continental landmasses. Neonatal animals. Diets of dams deficient in iodine as a result

of abundant pasture growth or leaching of iodine from soil in years of unusually high rainfall, or diets containing conditioning factors such as certain plants.

Signs Goiter as palpable enlargement of thyroid gland. Neonatal mortality as a result of stillbirths or weak neonates not able to suck that die in few days, alopecia at birth, myxedema.

Clinical pathology Serum total iodine concentration.

Necropsy findings Thyroid enlargement, alopecia, myxedema.

Diagnostic confirmation Goiter and iodine deficiency.

Differential diagnosis list
- Weak-calf syndrome
- Abortion
- Congenital defects
- Hypothyroidism

Treatment During an outbreak, oral administration of 280 mg/head potassium iodide to pregnant ewes and provision of iodized salt licks. Lambs with goiter can be administered 20 mg potassium iodide per os, once.

Control Ensure adequate dietary intake of iodine in pregnant animals.

Iodine metabolism is influenced by physiologic and environmental factors, making assessment of thyroid status, and the need for supplementation, challenging. See previous section for a discussion of hypothyroidism.

ETIOLOGY

Iodine deficiency can be a result of deficient iodine intake or secondarily conditioned by a high intake of calcium, diets consisting largely of *Brassica* spp., or gross bacterial pollution of feedstuffs or drinking water. A continued intake of a low level of cyanogenetic glycosides (e.g., in white clover) is commonly associated with a high incidence of goitrous offspring. Linamarin, a glycoside in linseed meal, is the agent producing goiter in newborn lambs born from ewes fed the meal during pregnancy. A continued intake of the grass *Cynodon aethiopicus*, which has low-iodine and high–cyanogenetic glucoside content, can cause goiter in lambs. Rapeseed and rapeseed meal are also goitrogenic. Presence of abundant pasture after unusually high rainfall and a "seasonal break" (marked increase in pasture growth in the weeks after end of summer) is associated with clinical iodine deficiency in newborn lambs.[1]

Goiter or hypothyroidism in newborn lambs occurs when pregnant ewes have a low iodine intake or ingest goitrogens.

EPIDEMIOLOGY

Occurrence

Goiter caused by iodine deficiency occurs in all of the continental landmasses. It is not of major economic importance because of the ease of recognition and correction, but if neglected it can cause heavy mortalities in newborn animals. Stillbirth or death of newborns reduced a pregnancy rate at midterm (number of fetuses detected by ultrasonographic examination/number of ewes) of 130% to a marking rate at ~2 weeks of age to 70%.[1] The most common cause of iodine deficiency in farm animals is the failure to provide iodine in the diet. The sporadic occurrence of the disease in marginal areas attracts most attention. An epidemiologic survey in Germany found that up to 10% of cattle and sheep farms and 15% of swine herds were affected with iodine deficiency, which included both primary and secondary conditions as a result of the presence of nitrates, thiocyanates, or glucosinolates in the diet.

The importance of subclinical iodine deficiency as a cause of neonatal mortality could be much greater than that of clinical disease. For example, in southern Australia, ewes supplemented with iodine by a single injection of iodine in oil have shown lower mortality in the lambs, have grown larger lambs, or performed the same as controls. In New Zealand, subclinical iodine deficiency has been recognized in a sheep flock in which fertility and lamb perinatal mortality occurred and was corrected by supplementation of the ewes with iodine. The annual cost associated with iodine deficiency in one Manawata Romney flock was conservatively estimated at $6.00 per ewe. Iodine supplementation reduces perinatal mortality and increases lambing percentage by 14% to 21% in pasture-fed ewes. Thus subclinical iodine deficiency can affect reproductive performance and perinatal lamb mortality.

Young animals are more likely to bear goitrous offspring than older ones, and this may account for the apparent breed susceptibility of Dorset Horn sheep, which mate at an earlier age than other breeds.

A survey of crossbred cows in the Punjab of India found that 36% of cows were iodine deficient, with considerable geographic variation from 0% to 86% within Punjab. The cardinal clinical signs of iodine deficiency were absent, and basal plasma T3 (triiodothyronine) and T4 (plasma thyroxine) concentrations and their ratios did not differ between deficient and control cows. The response to injection of 1 mL of 78% ethiodized oil can prevent the deficiency for more than 70 days.

Risk Factors

Dietary and Environmental Factors

A simple deficiency of iodine in the diet and drinking water can occur and is related to geographic circumstances. Areas where the soil iodine is not replenished by cyclical accessions of oceanic iodine include large continental landmasses and coastal areas where prevailing winds are offshore. In such areas, iodine deficiency is most likely to occur where rainfall is heavy and soil iodine is continually depleted by leaching. Iodine ingested in the diet comes largely from ingestion of soil, either directly or on pasture. Consequently, abundant pasture growth can reduce intake of soil and lead to iodine deficiency in sheep.[1]

Soil formations rich in **calcium** or lacking in humus are also likely to be relatively deficient in iodine. The ability of soils to retain iodine under conditions of heavy rainfall is directly related to their humus content, and limestone soils are, in general, low in organic matter. A high dietary intake of calcium also decreases intestinal absorption of iodine, and in some areas, heavy applications of lime to pasture are followed by the development of goiter in lambs. This factor can also be important in areas where drinking water is heavily mineralized.

There are several situations in which the relationship between iodine intake and the occurrence of goiter is not readily apparent. Goiter may occur on pastures containing adequate iodine; it is then usually ascribed to a secondary or conditioned iodine deficiency. A diet rich in plants of the ***Brassica* spp.**, including cabbages and brussels sprouts, may cause simple goiter and hypothyroidism in rabbits, which is preventable by administered iodine. Severe iodine deficiency can occur when ewes are fed *Brassica* crops for long periods. Brassicas such as swedes, turnips, and kale have low iodine content and contain goitrogens, and they may result in weak newborn lambs with enlarged thyroid glands. Goiter occurred in 85% of lambs examined at necropsy that born from ewes fed on the *Brassica* crop and not supplemented with iodine.

Diffuse hyperplastic goiter has occurred in calves in beef cows in Japan that were on pasture or being fed feed containing *Rorippa indica,* Hiern, genus *Brassica*, family Crucifera, Inugarash, which contains thiocyanate. The iodine content of the waters on affected farms was low at 0.361 μg/L and 0.811 μg/L and that of the pastures, 87 μg/kg and 121 μg/kg, on two different farms.

Hypothyroidism has also been produced in rats by feeding rapeseed and in mice by feeding rapeseed oil meal. Feeding large quantities of kale to pregnant ewes causes a high incidence of goiter and hypothyroidism, also preventable by administering iodine in the newborn lambs. The goitrogenic substance in these plants is probably a glucosinolate capable of producing thiocyanate in the rumen. The thiocyanate content, or potential content, varies between varieties of kale, being much less in rape-kale, which also does not show the twofold increase in thiocyanate content other varieties show in autumn. Small young leaves contain up to five times as much thiocyanate as large, fully formed leaves. Some of these plants are excellent sources of feed, and in some areas, it is

probably economical to continue feeding them, provided suitable measures are taken to prevent goiter in the newborn. Although kale also causes mild goiter in weaned lambs, this does not appear to reduce their rate of gain.

A diet high in linseed meal (20% of ration) given to **pregnant ewes** may result in a high incidence of goitrous lambs, which is preventable with iodine or thyroxine. Under experimental conditions, groundnuts are goitrogenic for rats, the goitrogenic substance being a glycoside-arachidoside. The goitrogenic effect is inhibited by supplementation of the diet with small amounts of iodine. **Soybean by-products** are also considered to be goitrogenic. **Gross bacterial contamination of drinking water** by sewage is a cause of goiter in humans in countries where hygiene is poor. There is a record of a severe outbreak of goitrous calves from cattle running on pasture heavily dressed with crude sewage. Prophylactic dosing of the cows with potassium iodide prevented further cases. Feeding sewage sludge is also linked to the occurrence of goiter.

Goiter in lambs may occur when permanent pasture is plowed and re-sown. This may be a result of the sudden loss of decomposition and leaching of iodine-binding humus in soils of marginal iodine content. In subsequent years the disease may not appear. There may be some relation between this occurrence of goiter and the known variation in the iodine content of particular plant species, especially if new pasture species are sown when the pasture is plowed. The maximum iodine content of some plants is controlled by a strongly inherited factor and is independent of soil type or season. Thus in the same pasture, perennial rye grass may contain 146 µg iodine per 100 g dry matter (DM) and Yorkshire grass only 7 µg/100 g DM. Because goiter has occurred in lambs when the ewes are on a diet containing less than 30 µg iodine per 100 g DM, the importance of particular plant species becomes apparent. A high incidence of goiter associated with heavy mortality has been observed in the newborn lambs of ewes grazing on pasture dominated by white clover and by subterranean clover and perennial rye-grass.

Thyroid-weight : birth-weight ratios greater than 0.8 g/kg in lambs are indicative of iodine deficiency and should be considered a risk factor for iodine deficiency in lambs. Ratios less than 0.4 g/kg rarely occur among deficient flocks.[2]

Congenital goiter has been observed in foals born to mares on low iodine intake, but also to mares fed an excessive amount of iodine during pregnancy.

PATHOGENESIS

Iodine deficiency results in a decreased production of thyroxine and stimulation of the secretion of thyrotropic hormone by the pituitary gland. This commonly results in hyperplasia of thyroid tissue and a considerable enlargement of the gland. Most cases of goiter of the newborn are of this type. The primary deficiency of thyroxine is responsible for the severe weakness and hair abnormality of the affected animals. Although the defect is described as hairlessness, it is truly hypoplasia of the hairs, with many very slender hairs present and a concurrent absence and diminution in the size of hair follicles. A hyperplastic goiter is highly vascular, and the gland can be felt to pulsate with the arterial pulse; a loud murmur may be audible over the gland. Colloid goiter is less common in animals and probably represents an involutional stage after primary hyperplasia.

Other factors, particularly the ingestion of low levels of cyanide, exert their effects by inhibiting the metabolic activity of the thyroid epithelium and restricting the uptake of iodine. Thiocyanates and sulfocyanates are formed during the process of detoxication of cyanide in the liver, and these substances have a pronounced depressing effect on iodine uptake by the thyroid. Some pasture and fodder plants, including white clover, rape, and kale, are known to have a moderate content of cyanogenetic glucosides. These goitrogenic substances may appear in the milk and provide a toxic hazard to both animals and humans. The inherited form in cattle is a result of the increased activity of an enzyme that deiodinates iodotyrosines so rapidly that the formation of thyroxine is inhibited.

Iodine is an essential element for normal fetal brain and physical development in sheep. A severe iodine deficiency in pregnant ewes causes reduction in fetal brain and body weight from 70 days of gestation to parturition. The effects are mediated by a combination of maternal and fetal hypothyroidism, the effect of maternal hypothyroidism being earlier than the onset of fetal thyroid secretion. There is also evidence of fetal hypothyroidisms and absence of wool growth and delayed skeletal maturation near parturition.

CLINICAL FINDINGS

Goiter is an unambiguous indicator of iodine deficiency in lambs and calves,[2] but clinically important increases in thyroid size might be easily missed unless careful attention is paid to assessment of the thyroid gland in newborns.[3] Thyroid volume can be estimated in calves by ultrasonographic examination.[4] It is important to recognize that ingestion of excessive iodine also can result in goiter in neonates and adults.[5]

A high incidence of **stillbirths and weak, newborn animals** is the most common manifestation of iodine deficiency.[3] Partial or complete **alopecia** and palpable enlargement of the thyroid gland are other signs that occur with varying frequency in the different species. Affected foals have a normal hair coat and little thyroid enlargement, but they are very weak at birth. In most cases, they are unable to stand without support, and many are too weak to suck. Excessive flexion of the lower forelegs and extension of lower parts of the hindlegs has also been observed in affected foals. Defective ossification occurs in foals and lambs (Fig. 17-8), and in foals the manifestation is collapse of the central and third tarsal bones, leading to lameness and deformity of the hock. Enlargement of the thyroid also occurs commonly in adult horses in affected areas, with Thoroughbreds and light horses being more susceptible than draft animals.

In **cattle**, the incidence of thyroid enlargement in adults is much lower than in horses, and the cardinal manifestations are gross **enlargement of the thyroid gland and weakness in newborn calves**. If they are assisted to suck for a few days, recovery is usual, but if they are born on the range during inclement weather, many will die. In some instances, the thyroid gland is sufficiently large to cause obstruction to respiration. Affected calves have a thick neck and appear to be suffocating. Lethargy, weakness, and difficulty in consuming colostrum are common. Partial alopecia is a rare accompaniment.

In **pigs**, the characteristic findings are birth of **hairless, stillborn, or weak piglets, often with myxedema** of the skin of the neck. The hairlessness is most marked on the limbs. Most affected piglets die within a few hours of birth. Thyroid enlargement may be present, but it is never sufficiently great to cause visible swelling in the live pig. Survivors are lethargic, do not grow well, and have a waddling gait and leg weaknesses as a result of weakness of ligaments and joints.

Adult **sheep** in iodine-deficient areas can show a high incidence of thyroid enlargement, but are clinically normal in other respects. Newborn lambs manifest weakness, extensive alopecia, and palpable, if not visible, enlargement of the thyroid glands (Fig. 17-9). The gestation length of ewes may be increased, and there is increased perinatal mortality, especially in inclement weather. Marginal iodine deficiency can result in nonspecific production losses from embryonic mortality or high perinatal lamb death and reduced lamb growth rates and is difficult to diagnose.[3]

Goats present a similar clinical picture, except that all abnormalities are more severe than in lambs. Goat kids are goitrous and alopecic. The degree of alopecia varies from complete absence of hair, through very fine hair, to hair that is almost normal.

Animals surviving the initial danger period after birth may recover, except for partial persistence of the goiter. The glands may pulsate with the normal arterial pulse and may extend down a greater part of the neck and cause some local edema. Auscultation and palpation of the jugular furrow may reveal the presence of a murmur and thrill,

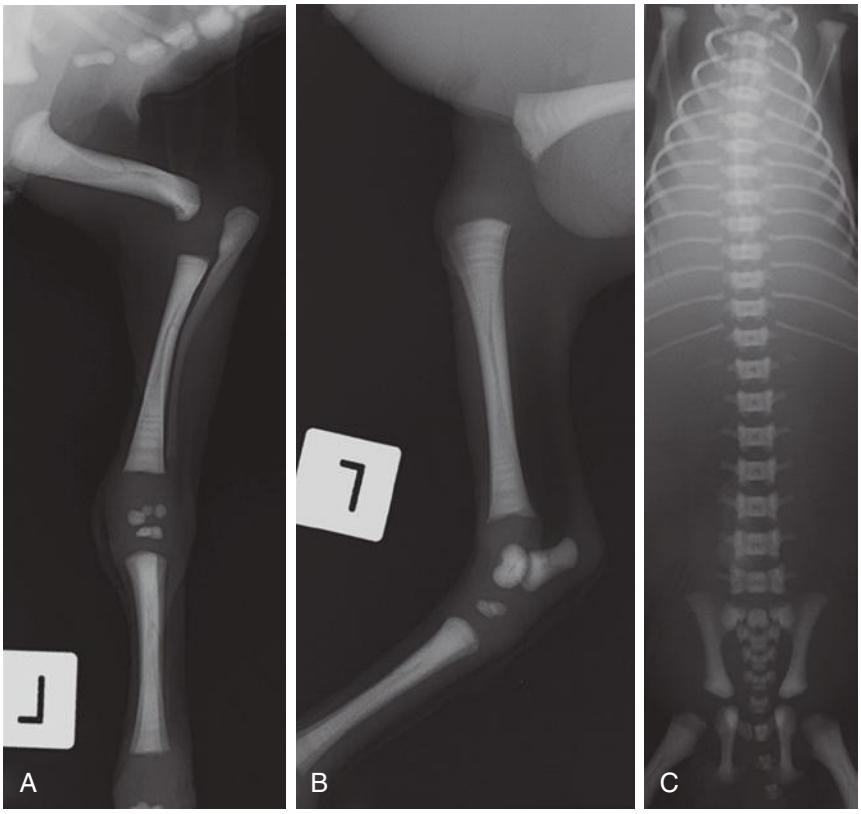

Fig. 17-8 Radiographs of a stillborn lamb from a flock with severe iodine deficiency revealing lack of mineralization of the epiphyses of long bones and vertebral bodies and presence of incompletely ossified cuboidal bones of the carpus and tarsus. (Reproduced with permission from Campbell AJD, et al. *Aust Vet J.* 2012;90:235.)

Fig. 17-9 Marked goiter in a neonatal lamb as a result of in utero iodine deficiency. A palpable thrill was present in the ventral cervical region.

the "thyroid thrill," as a result of the increased arterial blood supply of the glands. Calves that had larger goiter and were hairless (n = 8) died within the first day of life, whereas four others with moderate goiter and normal hair lived.[6]

Although loss of condition, decreased milk production, and weakness might be anticipated, these signs are not usually observed in adults. Loss of libido in the bull, failure to express estrus in the cow, and a high incidence of aborted, stillborn, or weak calves have been suggested as manifestations of hypothyroidism in cattle, whereas prolonged gestation is reported in mares, ewes, and sows. As noted previously, pathognomonic changes in production indices are not available for diagnosis of iodine deficiency.[2]

Goiter has occurred in newborn foals whose mares were supplemented with excess iodine during the last 24 hours of pregnancy.

CLINICAL PATHOLOGY

There are no wholly satisfactory indices of the severity of iodine deficiency, and biochemical markers of iodine metabolism, such as serum iodine or thyroxine (T4) and triiodothyronine (T3) concentrations, have not been shown to accurately and reliably reflect an animal's iodine status, identify marginal deficiency, or predict the production response of a flock to iodine supplementation.[2] Thyroid-related hormones often do not discriminate between adequate and marginal iodine status in pasture-fed livestock during supplementation trials, probably a result of the complex, adaptive systems maintaining homeostasis of these important regulators of cell growth and metabolic rate.[7] Knowles and Grace (2007) think that data are inadequate to quantify the relationship between iodine status and an economically relevant measure of animal performance, and this has hindered the setting of laboratory reference ranges for biomarkers.[2] However, measurement of serum total iodine concentration, which is an elemental determination that comprises the iodinated hormones plus various chemical forms of serum inorganic iodine, might be more effective in diagnosing iodine deficiency than measurement of serum iodine concentration or biochemical markers (see following "Control" section).[7]

Several criteria have been used for the laboratory diagnosis of iodine deficiency in sheep, including T3 and T4 and related hormones. They include thyroid weight, lamb thyroid-to-body-weight ratio, and comparison of serum T4 (serum thyroxine) concentrations in lamb and dam. However, concentrations of biochemical and hormonal markers are variable and difficult to compare among reports because of, among other factors, differing assay methodologies.[8]

Measurement of thyroid-stimulating hormone concentrations (TSH, thyrotropin) appears to be useful in detection of hypothyroidism attributed to iodine deficiency in calves.[6] TSH is significantly higher in goitrous calves compared with healthy calves, whereas plasma iodine concentrations do not differ. Concentrations, and ratios, of T4, T4/T3 ratio, T4/TSH ratio, rT3, and T3 are higher in healthy calves than in calves with goiter. Calves with goiter that die have higher TSH values; lower T4, T3, T4/TSH, and rT3; but similar T4/T3 ratio ($P > 0.1$) than calves with goiter that live. In the absence of TSH assay, the T4/T3 ratio can be used to diagnose hypothyroidism in newborn calves.[6] Feed iodine concentration was 175 mg/kg DM (reference range > 1200 mg/kg DM) in a herd of cattle with 10% incidence of stillbirth and death of newborns as a result of iodine deficiency.[9]

Thyroid-weight : birth-weight ratios greater than 0.8 g/kg in newborn lambs are indicative of iodine deficiency. Ratios less than 0.4 g/kg rarely occur in lambs of flocks deficient in iodine. Intermediate ratios are ambiguous.[2] The relationship between thyroid and body weight is not linear and is best defined by a probit plot (Fig. 17-10), and this nonlinear relationship should be considered when interpreting these ratios for diagnosis of iodine deficiency and need for supplementation.[2]

Other tests are concentrations of iodine in plasma, milk, and urine, all of which reflect current iodine status rather than revealing a profile or providing indications of previous iodine status.

Estimations of iodine levels in the blood and milk are reliable indicators of the iodine status of the animal. There may be between-breed differences in blood iodine levels, but levels of 2.4 to 14 µg of protein-bound iodine per 100 mL of plasma appear to be in the normal range. In ewes, an iodine concentration in milk of below 8 µg/L indicates a state of iodine deficiency. Bulk-tank milk iodine content should be greater than 300 µg/L.

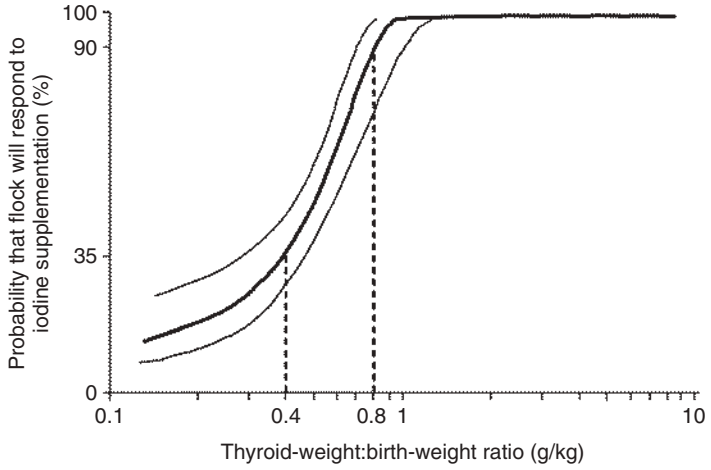

Fig. 17-10 Plot of probability that a flock of ewes will respond to iodine supplementation based on lamb thyroid-weight:body-weight ratios. A ratio of 0.40 g/kg (95% confidence interval [CI] = 0.29 to 0.47) predicted with 35% probability, and a ratio of 0.80 g/kg (95% CI = 0.70 to 0.99) predicted with 90% probability, that a lamb came from an unsupplemented (i.e., iodine-deficient) flock. (Reproduced with permission from Knowles SO, et al. *N Z Vet J*. 2007;55:314.)

Changes in serum thyroid hormone levels in newborn calves have been used as a diagnostic index in endemic goiter, but their high variation has been unreliable. The T4/T3 ratio of calves with goiter was lower than in healthy calves and adult cows, and it may be a useful diagnostic aid.

In determining the iodine status of an area, iodine levels in soil and pasture should be obtained, but the relationship between these levels, and between them and the status of the grazing animal, may be complicated by conditioning factors.

NECROPSY FINDINGS

Macroscopic thyroid enlargement, alopecia, and myxedema may be evident. The weights of thyroid glands have diagnostic value. In full-term normal calves the average fresh weight is 6.5 g; in lambs 2 g is average. Newborn lambs from ewes unsupplemented with iodine had a mean ratio of thyroid weight (g) to body weight (kg) of 0.40 g/kg or greater. In calves with severe thyroid hypertrophy, the gland may be heavier than 20 g.

The iodine content of the thyroid will also give some indication of the iodine status of the animal. At birth, a level of 0.03% of iodine on a wet-weight basis (0.1% on dry weight) can be considered to be the critical level in cattle and sheep. On histologic examination, hyperplasia of the glandular epithelium may be seen. Follicles depleted of colloid, infolded, and lined by columnar epithelium are indicative of hypothyroidism in lambs born from ewes unsupplemented with iodine.

The hair follicles will be found to be hypoplastic. Delayed osseous maturation, manifested by absence of centers of ossification, is also apparent in goitrous newborn lambs.

Samples for Confirmation of Diagnosis

- **Toxicology**—1 thyroid gland (assay [iodine])
- **Histology**—skin, thyroid (LM)

DIFFERENTIAL DIAGNOSIS

Iodine deficiency is easily diagnosed if goiter is present, but the occurrence of stillbirths without obvious goiter may be confusing. Abortion as a result of infectious agents in cattle and sheep must be considered in these circumstances. In stillbirths resulting from iodine deficiency, gestation is usually prolonged beyond the normal period, although this may be difficult to determine in animals bred at pasture. Inherited defects of thyroid hormone synthesis are listed under the heading of inherited diseases. Hyperplastic goiter without gland enlargement has been observed in newborn foals in which rupture of the common digital extensor tendons, forelimb contracture, and mandibular prognathism also occur. The cause of the combination of defects in unknown.

TREATMENT

When outbreaks of iodine deficiency occur in neonates, the emphasis is usually on providing additional iodine to the pregnant dams. The recommendations for control can be adapted to the treatment of affected animals. During an outbreak, oral administration of 280 mg/head potassium iodide to pregnant ewes and provision of iodized salt licks is advisable.[1] Lambs with goiter can be administered 20 mg potassium iodide per os, once.[1]

CONTROL

The recommended dietary intake of iodine for cattle is 0.8 to 1.2 mg/kg DM of feed for lactating and pregnant cows and 0.1 to 0.3 mg/kg DM of feed for nonpregnant cows and calves. Monitoring of lamb thyroid:body-weight ratios in areas at risk for iodine deficiency can be useful in determining the need for supplementation before and/or during pregnancy.[2] Thyroid-weight:birth-weight ratios greater than 0.8 g/kg are indicative of iodine deficiency, and ewes should be supplemented premating or during pregnancy to prevent goiter the following year. Ratios less than 0.4 g/kg rarely occurred among deficient flocks, so the probability of benefit from supplementation is low. Intermediate ratios are ambiguous, and individual-farm supplementation trials might be required to detect and manage the risks of marginal deficiency.

Pastures in New Zealand that contain 0.24 mg iodine/kg DM provide an adequate intake for dairy cows. The injection of iodine (iodized oil) IM three times at a dose of 2370 mg iodine/dose at the start of lactation and at 100-day intervals increased iodine concentrations in milk to 58 µg/L for at least 98 days after each treatment. Two iodine injections at 100-day intervals increased milk iodine concentrations to 160 µg/L and 211 µg/L at least 55 days after each treatment, but had no effect on serum thyroid hormone concentrations. Iodine supplementation had no effect on milk, milk fat, or milk protein yield. Increasing iodine concentration in milk by IM injection of iodine could provide a method for increasing iodine intakes of humans, especially children.

Iodine can be provided in salt or a mineral mixture. The loss of iodine from salt blocks may be appreciable, and an iodine preparation that is stable but contains sufficient available iodine is required. Potassium iodate satisfies these requirements and should be provided as 200 mg of potassium iodate per kilogram of salt. Potassium iodide alone is unsuitable, but when mixed with calcium stearate (8% of the stearate in potassium iodide) it is suitable for addition to salt—200 mg/kg of salt.

Individual dosing of pregnant ewes, on two occasions during the fourth and fifth months of pregnancy, with 280 mg potassium iodide or 370 mg potassium iodate has been found to be effective in the prevention of goiter in lambs when the ewes are on a heavy diet of kale. For individual animals, weekly application of tincture of iodine (4 mL for cattle; 2 mL for pigs and sheep) to the inside of the flank is also an effective preventive. The iodine can also be administered as an injection in poppy seed oil (containing 40% bound iodine): 1 mL given IM 7 to 9 weeks before lambing is sufficient to prevent severe goiter and neonatal mortality in the lambs. Control of goiter can be achieved for up to 2 years. The gestation period is also

reduced to normal. A similar injection 3 to 5 weeks before lambing is less efficient.

The administration of long-acting injectable iodine (iodized oil) at a dose of 390 mg iodine to ewes, 5 weeks premating, prevented goiter in newborn lambs from ewes fed swedes or swedes/turnips/kale as winter supplement. Administration of ~400 mg iodine per ewe increased serum iodine concentrations from 41 (standard deviation [SD] 12.2) µg iodine/L ($n = 54$) to 109 (SD 18.5) µg/L (n = 20; $p < 0.001$) at lambing ~99 days later, regardless of forage fed. High serum iodine concentrations persisted for 127 to 206 days after supplementation.[2] Diet did not affect iodine concentrations in ewe serum or milk. Responses of serum total iodine concentration (an elemental determination that comprises the iodinated hormones plus various chemical forms of serum inorganic iodine[7]) to injection of iodized oil to sheep are proportional to dose level increasing from 42 µg/L to approximately 150 and 240 mu g/L for sheep administered either 300 mg or 400 mg of iodine, remaining elevated for 161 days.[2] Milk concentrations of iodine were 26, 271, and 425 µg/L for sheep administered no supplemental iodine or 300 mg or 400 mg, respectively. Mean serum iodine concentrations of lambs from supplemented ewes with 300 mg or 400 mg iodine were 237 and 287 mu g I/L at birth, and by weaning were similar (62 ± 3 mu g/L). Concentrations in lambs born of ewes that were not supplemented were less than ~140 µg/L and were markedly affected by the diet of the ewe.[7]

Administration of 0.45 mg or 0.90 mg of potassium iodide orally daily to crossbred dairy goats increased mean milk iodine concentrations from 60.1 ± 50.5 (unsupplemented goats) to 78.8 ± 55.4 and 130.2 ± 62.0 mu g/L (mean ± SD), respectively. Milk production was not affected.[10]

A device to release iodine slowly into the forestomaches, while still retaining its position there, has given good results in preventing congenital goiter in lambs when fed to ewes during late pregnancy.

A recommended approach for iodine supplementation in sheep is as follows:[2]

1. If feeding *Brassica* crops, then supplement ewes.
2. If any lamb thyroid-weight : birth-weight ratio is greater than 0.8 g/kg, then supplement ewes. The relationship between thyroid weight and body weight is not linear and is best defined by a probit plot (Fig. 17-10), and this nonlinear relationship should be considered when interpreting these ratios for diagnosis of iodine deficiency and need for supplementation.[2]
3. If all or most thyroid-weight : birth-weight ratios are less than 0.4 g/kg, there is probably no need to supplement ewes because the probability of benefit is low.
4. If many thyroid-weight : birth-weight ratios fall between 0.4 and 0.8 g/kg, then the iodine status of the flock is unclear and can be impossible to determine from biomarkers.
   Supplement the ewes if other evidence is persuasive, such as occurrence of iodine deficiency in the district. An on-farm supplementation trial might be required to detect marginal deficiency on these properties.

INHERITED GOITER

Inherited goiter is recorded in Merino sheep, Afrikaner cattle, crossbred Saanen dwarf goats, Boer goats, possibly Poll Dorset sheep, and pigs, and it appears to be inherited as a recessive character. The essential defect is in the synthesis of abnormal thyroid hormone, leading to increased production of thyrotropic factor in the pituitary gland, causing in turn a hyperplasia of the thyroid gland. In Afrikaner cattle the defect stems from an abnormality of the basic RNA, and heterozygotes can be identified by blot hybridization analysis.

Clinically in **sheep,** there is a high level of mortality, enlargement of the thyroid above the normal 2.8 g (but varying greatly up to 222 g), and the appearance of lustrous or silky wool in the fleeces of some lambs. Other defects that occur concurrently are edema and floppiness of ears, enlargement and outward or inward bowing of the front legs at the knees, and dorsoventral flattening of the nasal area. The thyroglobulin deficiency in the neonatal lamb may result in defective fetal lung development and the appearance of neonatal respiratory distress syndrome; there is dyspnea at birth.

The clinical picture in **goats** is the same as for lambs. It includes retardation of growth, sluggish behavior, rough and sparse hair coat that worsens as the goats get older, and thick and scaly skin.

In Afrikaner **cattle,** most of the losses are from stillbirths or from early neonatal deaths. Some are caused by tracheal compression from the enlarged gland. It is the calves with the largest glands that have the greatest mortality. In these cattle there may be a concurrent inherited gray coat color, a defect in a red breed.

In **pigs,** hairless and swollen piglets with enlarged thyroid glands occur, in the proportions with normal piglets consistent with an autosomal-recessive mode of inheritance.

Diseases Caused by Nutritional Deficiencies

INTRODUCTION

Three criteria are suggested for the assessment of the importance of nutrition in the etiology of a disease state in a single animal or in a group of animals:

- Is there evidence from an examination of the diet that a deficiency of a specific nutrient or nutrients may be occurring?
- Is there evidence from an examination of the animals that a deficiency of the suspected essential nutrient or nutrients could cause the observed disease?
- Does supplementation of the diet with the essential nutrient or nutrients prevent or cure the condition?

The difficulties encountered in satisfying these criteria, and making an accurate and reliable diagnosis of a nutritional deficiency, increase as investigations progress into the area of trace element and vitamin nutrition. The concentration of these micronutrients in feedstuffs and body tissues are exceedingly small, and assays are often difficult and expensive. Because of these difficulties it is becoming more acceptable to describe individual syndromes as "responsive diseases"—that is, the investigation satisfies only the third of the previously listed three criteria. This practice is not ideal, but has advantages in that it is more a more cost-effective approach, and relevant control measures are directly assessed.

EVIDENCE OF A DEFICIENCY AS THE CAUSE OF THE DISEASE

Evidence of a deficiency as the cause of the disease will include evidence of a deficiency in the diet or an abnormal absorption, utilization, or requirement of the nutrient under consideration. Additional evidence may be obtained by chemical or biological examination of the feed.

Diet

The diet for a considerable period before the occurrence of the disease must be considered because body stores of most dietary factors may delay the appearance of clinical signs. Specific deficiencies are likely to be associated with particular soil types, and in many instances national or local soil and geological maps may predict the likely occurrence of a nutritional disease. Diseases of plants may also indicate specific soil deficiencies, such as "reclamation disease" of oats, which indicates copper deficiency. The predominant

plant species in the pasture sward may also be important; subterranean clover selectively absorbs copper, legumes selectively absorb molybdenum, and *Astragalus* spp. accumulate selenium.

Farming practices can have a strong influence on the concentration of specific nutrients in livestock feed. For example, heavy applications of nitrogen fertilizer can reduce the copper, cobalt, molybdenum, and manganese content of pasture. On the other hand, many applications of lime will reduce the concentration of copper, cobalt, zinc, and manganese in plants, but increase molybdenum. These effects are significant enough to influence the trace-element nutrition of grazing livestock. Modern hay-making methods, with their emphasis on the artificial drying of immature forage, tend to conserve vitamin A, but may result in a gross deficiency of vitamin D. Improved pasture species and increased applications of fertilizer can exaggerate the depletion of trace elements from marginally deficient soil, giving rise to overt deficiency disease in previously marginal or unaffected areas. Thus local knowledge of farming and feeding practices in a particular area is of primary importance in the diagnosis of nutritional deficiency states.

Abnormal Absorption

Although a diet may contain adequate amounts of a particular nutrient, some other factor, by decreasing its absorption, may induce a deficiency. For example, excess phosphate reduces calcium absorption, excess calcium reduces the absorption of iodine, and the absence of bile salts prevents proper absorption of the fat-soluble vitamins. Chronic enteritis reduces the absorption of most essential nutrients. The list of antagonisms that exist between elements continues to grow, most being an interference with absorption. For example, excess calcium in the diet interferes with the absorption of fluorine, lead, zinc, and cadmium, such that it may cause nutritional deficiencies of these elements, but it also reduces their toxic effects when they are present in the diet in excessive amounts.

Abnormal Utilization of Ingested Nutrients

Abnormal utilization of ingested nutrients may also have an effect on the development of conditioned deficiency diseases. For example, molybdenum and sulfate reduce copper storage, vitamin E has a sparing effect on vitamin A, and thiamine reduces the dietary requirement for essential fatty acids.

Abnormal Requirement

An enhanced growth rate of animals, either by improved nutrition or genetic selection, may increase their requirement for specific nutrients to the point where deficiency disease occurs. There seems to be little doubt that there is a genetic variation in mineral metabolism, and it has been suggested that it may be possible to breed sheep to "fit" deficiency conditions. The significance of the inherited component of an animal's nutritional requirement is unknown, but should not be overlooked when policies to upgrade livestock in deficient areas are being planned.

EVIDENCE OF A DEFICIENCY ASSOCIATED WITH THE DISEASE

Evidence of a deficiency associated with the disease is usually available from experimental work that demonstrates the clinical signs and necropsy findings produced by each deficiency. Several modifying factors may confuse the issue. Under natural circumstances, nutritional deficiencies may not be a single entity, and thus clinical and necropsy findings will often be complicated by deficiencies of other factors and intercurrent infections. Most syndromes are variable and insidious in their onset, and clinical signs and gross necropsy lesions in many nutritional deficiency diseases are either minimal or nonspecific. This increases the challenge of making a definitive diagnosis.

Consequently, laboratory examination of blood and animal tissues is an essential diagnostic aid in many instances. However, the normal range of blood or tissue concentrations of minerals and vitamins, or their biochemical markers, and those values that indicate deficiency, are often not well established. Experimentally induced and naturally occurring nutritional deficiencies provide an indication of the changes that occur in the concentrations of a particular nutrient, but variations resulting from age, genotype, production cycle, length of time on the inadequate diet, previous body stores of the element, and intercurrent disease and stressors can complicate the results, making them difficult to interpret.

In most cases, nutritional deficiencies affect a proportion of the herd or the flock at the same time. The clinicopathological examination should include a selection of both normal and clinically affected animals because the comparison of results from these groups allows a more accurate and reliable interpretation of laboratory tests, facilitating a diagnosis.

EVIDENCE BASED ON CURE OR PREVENTION BY CORRECTION OF THE DEFICIENCY

The best test of the diagnosis of a suspected nutritional deficiency is to observe the effect of supplementing that nutrient, either directly to the animal or via the ration. Confounding factors can occur, such as spontaneous recovery; hence, adequate controls and a sufficient sample size are essential. Curative responses may be poor because of an inadequate dose or advanced tissue damage. Alternatively, the abnormality may have only been a predisposing or secondary factor to another factor that is still present. A common cause of confounding in therapeutic trials is the impurity or bioactivity of the preparations used, particularly with trace elements and vitamins. The preparations used may also have some intrinsic pharmacologic activity and hence partially or temporarily ameliorate the condition without a deficiency actually having been present.

Monitoring of Nutritional Status

On breeding farms, there are several different age groups of animals at different levels of growth and production. This requires close surveillance to avoid either a deficiency or overnutrition in each class of animal. Scoring of the body condition of dairy and beef cattle, sheep, and pigs is commonly used as an indicator of the adequacy of the diet leading to the present time (termed *prior nutrition*).

The feeds and feeding program have a major influence on reproductive performance, and hence growth and milk production and must be monitored regularly. The veterinarian must be aware of any changes in the feeding program that have occurred since the last farm visit or that are intended in the near future. Veterinary clinical nutrition is now a specialty that should provide new and useful information for the practitioner working with a particular species or class of food animals. An experienced and competent nutritionist should be consulted to assist with complex nutritional problems.

Nutritional Management in Dairy Herds

Advising farms about nutrition is a key activity for dairy cattle practitioners. Feed costs are approximately 60% of the total cost of producing milk, so even minor improvements in feeding efficiency can be profitable.

Some dairy practitioners function as the nutritional specialist for the dairy farms they serve, collecting feed samples for nutrient analysis, formulating rations, and advising on crop and harvesting conditions. These veterinarians often devote a considerable amount of their professional time to nutritional management. Nevertheless, it is common for farms to employ a professional nutritionist or to use a nutritionist employed by a feed company or local cooperative. These professionals generally formulate the rations and submit feed samples for nutrient analysis. For these herds, the veterinarian can have an important role in ensuring that the diet described on paper is adequately formulated and delivered to the cows. Routine scheduled activities, such as measuring the dry matter of forages, hand-mixing of total mixed ration (TMR) for one cow and comparing it with the machine-mixed TMR (termed the TMR test mix), and scoring the feed bunk to assess feed sorting and dry matter intake are important procedures that

help to ensure the successful delivery of a nutritional program. Assessing pasture conditions by periodic inspection of pasture is an important component of managing the nutritional program of herds that use management-intensive grazing. These quality control activities should be conducted routinely as part of the health and production management program.

There is probably no aspect of a dairy enterprise that has a wider impact than the feeding program, which has direct effects on production and growth. Many health problems on a dairy farm relate in some way to the feeding program, and a significant portion of the farm's labor is spent planting, growing, harvesting, mixing, and feeding rations. Investment in equipment used in feeding programs is also an important capital cost. Small changes in feeding programs may bring about large changes in productivity, health, income, feed costs, labor allocation, cash flow, and debt. Thus the total savings from these small changes can be substantial, with one study showing that routine nutritional consultation by a veterinarian can save 14% of total feed costs even without accounting for improved production or health effects.

For these reasons, veterinarians who wish to serve their dairy clients on a whole-farm basis must become actively involved in the herd's feeding program. Dairy herds are often fed unbalanced, expensive rations, but as a consultant independent from the feed company, a veterinarian can provide unbiased advice about the feed program. For example, a recumbent, hypocalcemic cow raises questions about dry-cow feeding, whereas an anestrous, thin cow with smooth ovaries raises questions about energy and dry matter intake (DMI) during early lactation. If the average mature equivalent milk production for the herd falls by 220 kg (500 lb), this generates the same sense of urgency as a cow with a prolapsed uterus. A dairy veterinarian cannot truly serve a client's needs by practicing therapeutic medicine in isolation from the nutrition of the herd and thus must acquire skills to directly deal with nutrition problems.

As the average size of dairy herds increases, many dairy farmers now rely on a team of advisors rather than just one or two. Consequently, a nutritional consultant, local veterinarian, and remote specialist consultant may all be providing advice to a dairy farm, and thus awareness of and communication about the feeding program, and the indicators of performance of the farm, are critical. It imperative that, as part of the advisory team, the dairy veterinarian knows about dairy nutrition and is aware of, but preferably involved in, the ration formulation.

Levels of Nutritional Service

Having decided to be involved in a dairy's feeding program, a first step is for the client and veterinarian to discuss and agree on the level of nutritional advice that is to be provided. This varies from herd to herd, depending on the veterinarian's expertise, the client's ability and interest, and the role of other consultants. There are essentially four levels of service that might be provided, as described next.

Level 1: Problem Identification and Analysis

At level 1, the veterinarian takes on the task of monitoring the dairy herd for indicators of nutrition-related problems. Many areas need to be monitored: production, milk composition, DMI, body scores, disease rates, heifer management and growth, and feed costs. Based on these measures, the veterinarian can identify problems as they arise, form and test hypotheses about likely causes, and interact with the client and other advisors as the problems are prioritized and addressed.

Level 2: Ration Analysis

Level 2 requires assessment of the adequacy of diets that are actually being fed to the cows. Problems of balance or economics are referred to the appropriate person, for example, if reformulation of a specific diet is needed. This involvement may be difficult to sustain if the person formulating the ration resents being "second-guessed," but it can work well if a functional team approach is in place.

Level 3: Ration Formulation

If a dairy veterinarian takes responsibility for ration formulation, the veterinarian will need considerably enhanced skills in dairy nutrition, far beyond those traditionally taught at veterinary colleges. Typically, this involves using a computer program to formulate a balanced, least-cost ration for each class of animal. It requires expertise in the mechanics of how feeds are handled and fed to cows on a daily basis, and hence an intimate knowledge of the farm and its personnel and daily trends in the price and availability of feed components.

If not well managed, this level of service has several pitfalls because it lacks the on-farm follow-up, supervision of implementation, and monitoring of results that are included in level 4. There is a truism about feeding dairy cows that every cow has three rations: the one formulated, the one delivered, and the one actually eaten. The best feeding programs minimize the difference among these three rations. If the veterinary consultant's role stops at formulation, then mistakes can occur in delivery and feedbunk management that can doom the program to failure. However, if the program fails, it is the ration formulation that is most likely to be blamed.

Level 4: Total Program Consulting

Level 4 service includes the critical aspects missing from level 3 because the veterinarian plays an active role in implementing the feeding recommendations. Attention is paid to areas such as bunk management, cow comfort, feeding frequency and scheduling, quality control, and consistency of feeding management. Working closely with the producer, plans for future forage production can be generated, including attention to factors such as timing the harvest for maximum feed value. The monitoring described in level 1 is sustained, and timely adjustments and feedback are provided to ensure that the rations are accomplishing the desired ends. In the long term, this is the level of service that is most desirable for both the specialist dairy veterinarian and client. The producer benefits from the added supervision and support, and the veterinarian can assure the client that the program is implemented as it is intended. If it is not working, the total program can be modified, often with the veterinarian as a part of a team that includes a nutritionist. When multiple consultants are used in larger herds, this team approach provides the owner with the best opportunity for expert advice, and the specialist dairy veterinarian is often best suited to be the "team leader."

Nutritional Management of the Beef Breeding Herd

Good nutrition provides the essential basis for optimum productivity in cattle-breeding operations. Despite this, nutritional expertise has not been a traditional strength of many food-animal veterinarians.

Throughout the world, beef-breeding operations are generally range or pasture based. These operations are conducted in diverse environments, with great variation in nutritional management. In many countries, the area of pasture or rangeland required to maintain a cow–calf unit may vary from 0.5 to 1 ha (1 or 2 acres) in intensive high-rainfall regions to many square kilometers in remote dryland areas. However, in general, the land area or amount of pasture necessary for production is related to local economic realities. This, in turn, is related to levels of managerial and resource inputs that differ markedly between regions, markets, and enterprises. Notwithstanding this variation, there are a number of principles of good nutritional management that can be universally applied to cattle-breeding operations. Regardless of region, an important consideration is that of maintaining or improving production (increasing income) while reducing costs per unit of production. In simple terms, financial return from a beef-breeding operation is a function of number of calves, their weaning weight, and price. On the cost side is the cost of maintaining the breeding females. This varies considerably between farms, both within and between regions. Although it can be influenced, the price received is generally not significantly controlled by the farm business. However, both

the number of calves born and their weaning weights are strongly influenced by an appropriate management calendar that matches nutritional demand with the supply of pasture. For example, good nutritional management helps to ensure that as many females as possible are cycling at the start of the breeding season. This, combined with good bull management, helps to ensure that calves are born early and that they are older and heavier at weaning than later-born calves.

In general, nutrition is the most important limiting factor of beef-breeding performance, and thus an understanding of the principles underlying the nutritional management of breeding females is essential. Effective monitoring does not necessarily require a higher degree in nutrition, although it should include sufficient knowledge and wisdom to know when additional expertise is needed. A starting point is to have a working knowledge of the different energy measuring systems (total digestible nutrients [TDN], metabolizable energy [ME], and net energy, NE) that are commonly used and their applications for different classes of animals, activities, and feedstuffs, and to identify one with which the veterinarian can work best. The Nutrient Requirements of Beef Cattle from the National Research Council (NRC) in the United States is a useful document, with the 7th edition published in 2000. This is packaged with a computer program that includes ration formulators and a library of feeds and feedstuffs. A number of programs for least-cost-ration formulation in beef herds are also available from Departments of Agriculture or commercial suppliers.

Nutritional Advice for Beef Feedlots

Beef feedlots frequently consult a qualified nutritionist to assist in the formulation of cost-effective rations. In this case the veterinarian should communicate regularly with the nutritionist to be aware of the composition of the diets and any changes that are planned. Because feed is the major portion of the cost per unit of body weight gain, it is imperative that the diet be the lowest-cost diet possible while providing nutrients that allow optimum growth and finishing. Most of the emphasis in feedlot nutrition has been on the development of cost-effective diets that support a maximum growth rate without any deleterious effects. Considerable information is available on the nutrient requirements for feedlot cattle and on the feeds and feeding systems used.

The precise specifications of the diets are the responsibility of the nutritionist, but the feedlot veterinarian is often able to evaluate the quality of the feed delivery system. This includes whether cattle are fed on time, whether the feed delivered to troughs is properly mixed, and whether feed intake is intermittent as a result of insufficient trough space, poor trough and pen design, inclement weather, and muddy or slippery ground. Any deviations should be discussed with feedlot managers and the consulting nutritionist, similar to the team approach suggested for large dairy herds.

Nutritional deficiency diseases are uncommon in feedlot cattle because cattle usually receive a diet that contains the nutrients required for maintenance and promotion of rapid growth. Diets prepared according to the Nutrient Requirements of Beef Cattle should meet all the requirements under most conditions.

Specific nutrient deficiencies are extremely rare because diets are prepared every few days or daily, and it would be highly unusual for a feedlot to use a feedstuff deficient in a specific nutrient for a prolonged period. However, such a situation may occur on a small farm or opportunistic feedlot that prepares its own diet with little or no attention to the need to supplement homegrown feeds. Thus there are only a few nutrition-related diseases that may affect a well-managed feedlot, but these diseases may cause large economic losses when they occur. They include the following:

- Carbohydrate engorgement (grain overload or lactic acidosis)
- Feedlot bloat or ruminal tympany
- Feeding errors, including accidental incorporation of an excessive amount of feed additives, such as monensin or urea; sudden unintended changes in the composition of the diet; and accidental feeding of the wrong dietary mix

Nutritional Advice for Swine-Herds

Veterinarians involved in health management of swine-herds must be well informed about the nutrient requirements of the different age groups of pigs. Feed constitutes 60% to 80% of the cost of producing a market pig, so every effort is needed to increase the efficiency of feed use. Surveys of well-managed pig farms in Alberta, Canada, found a 20% difference in feed costs, and it is estimated that in the industry the range in feed costs is likely to be near 50%. Reduction of the feed cost of the highest-costing farm to that of the lowest-costing farm would save that farm more than US$23,000 annually, a reduction in the cost of production of $6.80/pig. The trend is to use complete feeds formulated by feed company nutritionists familiar with the nutrient composition of local feedstuffs. With complete diets, specific nutrient deficiencies are uncommon.

The major problem is the efficiency of utilization of the different feeds throughout the life cycle of the pig. The nutrient requirements of the pig at various phases of growth, from birth to market weight and of breeding stock, are well established. The remaining questions relate to the amount of feed provided during the different growth phases of the pig to achieve optimum production and yield the best carcass. The following are some recommended practices for increasing efficiency of feed utilization:

- Provide well-balanced diets with adequate levels of amino acids, energy, vitamins, and minerals necessary to meet the particular demands of the pig at each stage of its life cycle. The diet depends on the demands, usually characterized as the growth rate or lean deposition, with feed intake being the supply function. Feed intake is limited by appetite, and thus other nutrients are matched to expected energy intake and subsequent growth.
- Use least-cost formulation to the extent that it is feasible. The least-cost energy source in most of the pig-rearing areas is corn, and the most common protein source is soybean meal.
- Restrict the level of a properly balanced diet for sows during gestation to avoid overfeeding. Sows that have lost excessive body weight in the previous lactation need supplemental feed during the dry period to avoid thin-sow syndrome.
- Ad-lib feeding for growing pigs is usually optimal unless the genotype deposits excess fat during the latter stages of growth.
- Market pigs as close to optimum slaughter weight as possible to maximize margin over feed costs.
- Avoid feed wastage by using well-designed feeding systems and proper adjustment of feeders.
- Use pelleting of diets to increase digestibility, especially of small grains, and to decrease feed wastage. However, pelleting does predispose pigs to gastroesophageal ulcers.

The feed efficiency of the pigs from weaning to market should be monitored regularly. It is often difficult to obtain accurate data for a specific group of pigs because a common feeding system for multiple groups is often used. However, the total amount of feed used and the total weight of pigs marketed will give an estimate of feed efficiency.

Although the nutrient requirements of pigs are well known, they do continue to change because of changes in growth and production characteristics. Pigs with high lean-growth rates require higher levels of amino acids to support their increased rate of body protein deposition. Similarly, high-milk-producing sows nursing large litters have increased amino acid requirements. The NRC in the United States provides an important service in establishing the nutrient requirements of swine and other species. The 10th edition of the Nutrient Requirements of Swine was published in 1998, and it includes areas such as modeling nutrient requirements and reducing nutrient excretion, particularly nitrogen and phosphorus, which can contribute to environmental pollution.

The approach used to produce estimates of nutrient requirements account for the

pig's body weight and the accretion of lean (protein) tissue, gender, health status, and various environmental factors. To accurately estimate nutrient needs of gestating and lactating sows, there is a need to account for body weight, weight gain during gestation, weight loss during lactation, number of pigs in the litter, weight gain of the litter (a reflection of milk yield), and certain environmental factors. A series of integrated equations is used to account for the many factors known to influence nutrient requirements. These provide the framework for modeling the biological basis of predicting requirements. The NRC models predict the levels of nutrients (outputs) needed to achieve a certain level of production under a given set of environmental conditions (inputs).

Five principles were used to develop the models: (1) ease of use by people with varying levels of nutritional expertise; (2) continued relevance; (3) structural simplicity; (4) transparency, so that all equations are available to the user; and (5) empirical data at the whole-animal level was used rather than data based on theoretical values. Three independent models were developed for growth, gestation, and lactation. The growth model estimates amino acid requirements of pigs from weaning to market weight, and the gestation and lactation models estimate energy and amino acid requirements of gestating and lactating sows.

Few revisions were needed from the previously published mineral requirements; higher dietary requirements for sodium and chloride in the young pig were established, and manganese requirements were increased from 10 to 20 ppm for gestating and lactating sows.

Feed composition tables are built from multiple databases on the nutrient composition of feeds, including the feed industry and datasets outside the United States and Canada.

The information on water was expanded, with more detailed information on the factors that influence water intake. Information on nonnutritive feed additives, such as antimicrobial agents, anthelmintics, microbial supplements, oligosaccharides, enzymes, acidifiers, flavors, odor-control agents, antioxidant pellet binders, flow agents, high-mineral supplements, and carcass modifiers, is also included.

Nutritional Advice for Sheep Flocks

The influence of nutrition on the reproductive performance of ewes has been a matter of concern for many years. Clearly, the relationship between the provision of nutrients and requirements for optimum reproductive performance is seldom ideal because of the wide range of environmental conditions and the seasonal breeding patterns of most sheep breeds. Prolonged periods of undernutrition often occur during midpregnancy, partly the result of the decline in feed availability and quality over that stage of the reproductive cycle and partly from the seasonal variability in pasture growth.

Prolonged moderate to severe undernutrition of ewes bearing twins in midpregnancy reduces placental development and can cause a significant reduction in lamb birth weight and increased lamb mortalities. Considerable progress has been made in understanding the principles of nutrition of sheep and in defining their nutrient requirements for maintenance, pregnancy, and lactation. It has been established that mortality rates are high in lambs with birth weights below the breed norm, and that after birth the absolute growth rates are lower in surviving light lambs than in heavier lambs of the same breed. The plane of nutrition and the size of the placenta have been recognized as major determinants of the fetal growth rate. Fetal growth retardation in undernourished ewes has a placental component, and thus factors that affect placental growth are highly relevant.

The 21-week gestation can be divided into a number of periods to consider the effects of nutrition on reproduction within each period. In the first 4 weeks of gestation, embryonic loss is the main sequelae of inadequate nutrition. During this period, it is generally recommended that the body-condition score (BCS) of the ewe be maintained at an average of 3.0, on a scale of 1 (emaciated) to 5 (very fat), to minimize embryonic and early fetal loss. This is followed by a period of 2 months in which there is rapid growth of the placenta, but during which growth of the fetus in absolute terms is still small. Over this period, losses in body weight should not exceed 5%, and BCS should be maintained at 2.7 to 3.0. Finally, there is the phase from 90 days to parturition, in which gain in the mass of the fetus amounts to 85% of its birth weight, during which time nutrient intake must be increased if excessive weight loss in the ewe and light-birth-weight lambs are to be avoided.

Placental and Fetal Growth

Placental development in the pregnant ewe begins about 30 days after conception. The number of placentomes associated with each fetus is fixed at this time, but the total weight of the placentomes increases until about 90 days of gestation, after which there is little change. The factors that influence the ultimate size of the placenta and its weight include hormonal and nutritional factors, prolonged environmental heating of pregnant ewes, parity, and possibly genotype. However, by far the most important determinant is nutrition of the ewe. Moderately severe undernutrition during early and midpregnancy significantly reduces placental weight at term and causes chronic intrauterine growth retardation.

The size of the placenta is a major determinant of fetal growth. In well-fed ewes, the fetal growth rate until 120 days (17 weeks) of gestation is not positively correlated with placental weight, but fetal growth rate is limited by the size of the placenta during the last 3 to 4 weeks of pregnancy. However, when ewes are underfed, the influences of a lighter placenta on fetal growth rate are evident sooner, with placental weight and fetal growth positively correlated from as early as 90 days (13 weeks) of gestation. During the first 90 days of pregnancy, placental growth is reduced when ewes are moderately underfed. Light fetuses in ewes with placenta weights near the bottom of the normal range suffer chronic and progressive hypoxemia and hypoglycemia. This affects fetal metabolism, causing fetal death during late pregnancy, fetal hypoxemia during parturition, premature birth, and a high perinatal mortality rate from hypoglycemia and hypothermia, the latter being more severe in lighter lambs.

The extent to which ewes maintained on a fixed ration draw on their own body reserves in an attempt to meet the energy costs of pregnancy is determined by fetal weight. In well-fed ewes, fetal growth rate remains constant until at least 120 days of gestation and then decreases. However, the absolute growth rate increases markedly during the last 8 weeks of gestation, when fetal growth is most rapid, exceeding 100 g/day near birth. The growth rate among fetuses is highly variable, which accounts for birth weights ranging from 2 kg to over 7 kg. When ewes that have previously been well fed are severely underfed at any stage during the last 40 to 50 days of pregnancy, fetal growth rate decreases by 30% to 70% within 3 days. This demonstrates that mobilization of maternal reserves is substantially less than fetal requirements, emphasizing the importance of a continuous supply of good-quality feed during late pregnancy. The larger the fetal burden, the more susceptible an ewe is to hypoglycemia during underfeeding.

Refeeding after severe underfeeding can reverse the reduced growth rate of fetuses, but the response depends on the duration of the underfeeding. If the period of underfeeding is 16 days or less, the growth rate increases when ewes are refed, but there is no change when refeeding occurs after 21 days of severe underfeeding. Moderate underfeeding of pregnant ewes for 85 days reduces the fetal growth rate irreversibly. Refeeding them in late pregnancy does not cause fetal growth rate to increase, but it does prevent further decreases after 120 days.

Lamb Losses

The major consequences of prenatal growth retardation are on lamb survival. Neonatal mortality increases markedly in many environments when the birth weight falls below 3 to 3.5 kg. Compared with normal lambs, low-birth-weight animals have reduced insulation because of the smaller number of wool

fibers, greater relative heat loss because of their larger surface area per unit of body weight, and a reduced capability to maintain heat production because of their lower fat and energy reserves. All of these factors increase their susceptibility to environmental stress and reduce their ability to compete with normal-sized siblings.

Underfeeding during pregnancy reduces available body lipids in lambs by about 47%, and it also decreases the lactose, lipid, and protein available in colostrum during the first 18 hours after birth by about 50%. Newborn lambs have to draw on body reserves of glycogen to maintain heat production during the first 18 hours after birth. Consequently, they depend heavily on colostrum and supplements, when these are provided, to avoid hypoglycemia and hypothermia.

The effects of maternal nutrition on udder development and on the production and yield of colostrum and milk in ewes have also been examined. In the 30 days before birth, there is a marked increase in the rate of mammary tissue growth in the ewe. In well-fed ewes with one or two lambs, large volumes of colostrum accumulate in the mammary glands during the last few days of pregnancy, and copious milk secretion begins soon after birth, with averages of 1800 to 2800 mL of colostrum and milk being produced during the first 18 hours. Udder growth rates show a similar pattern to fetal growth rates, such that the greatest increase in udder weight occurs in the last 30 days of gestation, and the weight of udder tissue is 30% to 40% of the total weight of the litter. Colostrum production is proportional to udder weight, but refeeding ewes a few days before lambing fills the udder tissue present rather than increasing udder tissue weight. In underfed ewes, accumulation of colostrum before birth is reduced markedly, lactogenesis is delayed, and the total production of colostrum and milk during the first 18 h averages only 1000 mL. Subsequently, for ewes on both planes of nutrition, milk production increases, reaching a peak about 1 to 2 weeks after birth. Underfeeding ewes from 105 days (15 weeks) of gestation can reduce the total yield of colostrum during the first 18 hours after birth by decreasing mammary tissue growth. Thus the prepartum accumulation of colostrum and its subsequent rates of secretion are reduced. Improving the ewe's nutrition from 1 hour after birth can increase the secretion rates of colostrum between 10 and 18 hours.

The growth rate of lambs during the first few weeks of life is positively correlated with birth weight. Low planes of maternal nutrition during late pregnancy and early lactation are generally associated with low birth weights, milk yields, and postnatal growth rates, and high planes of nutrition are associated with the opposite effects. A marked increase in the plane of maternal nutrition at birth can overcome the inhibitory effects on lactation and lamb growth rate of underfeeding in late pregnancy.

Ewe Body-Condition Score

Target condition scores for ewes at different stages of their reproductive cycle have been developed by research groups and departments of agriculture in many countries. These vary according to the predominant breeds and production systems in each country, and they can be quite different for a Merino, Dorset, or Friesian ewe used for wool, meat, or dairy production versus a dual-purpose enterprise producing both meat and wool. Consequently, readers should directly access information appropriate to the production systems of their clients. However, in general, the aim at breeding time is to have ewes with a BCS of 3.0 to 3.5, which ensures maximum ovulation rate. Ewes with a BCS of 3.5 at breeding can be allowed to lose no more than 5% of their body weight, steadily, during the second and third months of pregnancy, equivalent to approximately 0.5 to 1 BCS units. This mild degree of undernutrition enables good placental growth, establishing the basis for maximum fetal growth in the fourth and fifth months of pregnancy, during which the fetus achieves over 80% of its growth. During these final 2 months of pregnancy, there is a limit to the extent to which body-fat reserves can be used because excessive mobilization of fat deposits as a consequence of inadequate dietary energy supply leads to pregnancy toxemia. Ewes with a BCS below 3.0 should be managed to maintain that score.

In late gestation, the optimum BCS ranges from 2.75 to 3.0. In contrast, early lactation is a period in which body fat can be safely used to meet some of the high-energy demands of lactation. During this period, a loss of BCS of from 0.5 to 1.0 (equivalent to 5 kg of fat for a 70-kg ewe at mating) may occur. However, replacement of body fat, to increase the BCS to 3.0 to 3.5 before the next mating, is important to maximize ovulation rate and achieve optimum reproductive performance.

Winter shearing of pregnant ewes during the final 10 weeks of pregnancy can cause a significant increase in lamb birth weight by stimulating ewe appetite. However, this also increases the base energy requirements of the ewe at a feed-limiting time of the year in many production systems (e.g., winter for a spring-lambing flock). Thus it is not always an optimum or profitable system, but this will vary between production systems and different countries.

The nutrient requirements for maintenance, breeding, pregnancy, and lactation of ewes have been cataloged, and optimum feeding strategies for the breeding ewe can be formulated. The evaluation of the ewes' ration during late gestation by monitoring plasma concentrations of the BHB has been described, and these evaluations have been used to provide nutritional advice in intensively managed flocks during late gestation.

In more intensively managed flocks, achieving optimum reproductive performance requires adjusting feeding strategies and the nutrient value of the diet to meet the needs of each stage of the reproductive cycle. Requirement for metabolizable energy increases above maintenance levels from 8 to 12 weeks of pregnancy, increasing further in late pregnancy and lactation. During early lactation, when the energy requirements of prolific ewes exceed the voluntary intake from all but the highest-quality diets, body-fat reserves are used and then replenished toward the end of lactation, when milk yield declines, and in the period leading up to rebreeding.

The rapid growth of the fetus after 90 days of pregnancy and increased energy demand may require the feeding of cereal or legume concentrates, rather than hay, which has far lower metabolizable energy content. This is particularly true for ewes carrying twins or triplets.

In contrast to the ability of the ewe to use body reserves when the intake of energy fails to meet her needs, particularly in early lactation, there is little scope for sustaining production by drawing on body protein. For example, lactating ewes can lose up to 7 kg of body fat during a 4-week period in early lactation, when energy intake is below requirements. For ewes on a low-protein intake, the maximum daily loss of protein is around 26 g. Therefore it is important to meet the protein needs of the ewe during pregnancy, but especially during late pregnancy, to ensure adequate fetal growth, udder development, and colostrum production.

The estimates for the minimum protein requirements of the animal are based on distinguishing between the needs of the rumen microflora for rumen-degradable protein and of the host animal for additional undegraded dietary protein when rumen-degradable protein fails to meet those requirements. In practice, the dietary allowances for late pregnancy and early lactation are higher than the sum of the rumen-degradable protein and undegradable protein.

Deficiencies of Energy and Protein

DEFICIENCY OF ENERGY

ETIOLOGY

Insufficient quantity or quality of feed is a common nutritional deficiency and practical problem of feeding livestock. The term *protein-energy malnutrition* is used to describe a form of incomplete starvation in which a suboptimal amount of energy and protein is present in the diet. Such deficiencies typically occur when livestock are underfed, and often the two scenarios cannot be separated.

EPIDEMIOLOGY

A deficiency of energy is the most common production-limiting nutrient deficiency of farm animals. There may be inadequate amounts of feed available, or the feed may be of low quality (low digestibility). The availability of pasture may be inadequate because of overgrazing, drought, or snow covering. Alternatively, it may be too expensive to provide enough supplementary feed of the required quality, or the available feed may be of such low quality and poor digestibility that animals cannot consume enough to meet energy requirements. In some cases, forage may contain a high concentration of water, which limits total energy intake.

CLINICAL FINDINGS

The clinical findings of an energy deficiency depend on the age of the animal, whether or not it is pregnant or lactating, concurrent deficiencies of other nutrients, and environmental factors. In general, an insufficient supply of energy in young livestock causes decreased growth and delayed onset of puberty. In mature animals, there is reduced milk production and a shortened lactation. A prolonged energy deficiency in pregnant beef heifers will result in a failure to produce adequate quantities of colostrum at parturition. In mature animals, there is also a marked loss of body weight, especially when demand for energy increases in late pregnancy and early lactation. There are prolonged periods of anestrus, which reduces the reproductive performance of the herd. Primigravid females are particularly susceptible to protein-energy malnutrition because of their requirements for growth and maintenance. A deficiency of energy during late gestation can produce undersized, weak neonates with a high mortality rate, whereas abomasal impaction is associated with energy deficiency during prolonged cold weather, especially in pregnant beef cattle and ewes being wintered on poor-quality roughage. Heat loss from the animal to the environment increases considerably during cold weather, and when ambient temperatures are below the critical temperatures, the animal responds by increasing metabolic rate to maintain normal body core temperature.[1] If sufficient feed is available when temperatures are below the lower critical temperature, ruminants will increase their voluntary feed intake to maintain body temperature. If sufficient feed is not available, the animal will mobilize energy stored as fat or muscle to maintain body temperature and thus lose body weight. In the case of ruminants and horses, if the feed is of poor quality, for example, poor-quality roughage, the increased feed intake may result in impaction of the abomasum and forestomaches in cattle and of the large intestine in the horse.

Cold, windy, and wet weather will increase the needs for energy, and the effects of a deficiency are exaggerated, often resulting in weakness, recumbency, and death. A sudden dietary deficiency of energy in fat, pregnant beef cattle and ewes can result in starvation ketosis and pregnancy toxemia. Hyperlipemia occurs in fat, pregnant or lactating ponies that are on a falling plane of nutrition.

Protein-energy malnutrition occurs in neonatal calves fed inferior-quality milk replacers that may contain insufficient energy or added nonmilk proteins, which may be indigestible by the newborn calf. A major portion of the body fat present at birth can be depleted in diarrheic calves deprived of milk and fed only fluids and electrolytes for 4 to 7 days. Feeding only fluids and electrolytes to normal, healthy newborn calves for 7 days can result in a significant loss of perirenal and bone-marrow fat and depletion of visible omental, mesenteric, and subcutaneous fat stores. The amount of body fat present in a calf at birth is an important determinant of the length of time an apparently healthy calf can survive in the face of malnutrition. Calves born from dams on an adequate diet usually have sufficient body fat to provide energy for at least 7 days of severe malnutrition. The absence of perirenal fat in a calf at 2 to 4 days of age suggests inadequate reserves of fat at birth and chronic fetal malnutrition.

DEFICIENCY OF PROTEIN

A deficiency of protein commonly accompanies a deficiency of energy. However, the effects of the protein deficiency, at least in the early stages, are usually not as severe as those of energy deficiency. Insufficient protein intake in young animals results in reduced appetite, lowered feed intake, inferior growth rate, lack of muscle development, and a prolonged time to reach maturity. In mature animals, there is loss of weight and decreased milk production. In both young and mature animals, there is a drop in hemoglobin concentration, packed cell volume, total serum protein, and serum albumin. In the late stages, there is edema associated with the hypoproteinemia. Ruminants do not normally need a dietary supply of essential amino acids, in contrast to pigs, which need a natural protein supplement in addition to the major portion of total protein supplied by the cereal grains. The amino acid composition of the dietary protein for ruminants is not critical because the ruminal flora synthesize the necessary amino acids from lower-quality proteins and nonprotein sources of nitrogen.

CLINICAL FINDINGS

The clinical findings of a protein deficiency are similar to those of an energy deficiency, and the clinical findings of both resemble those of many other specific nutrient deficiencies and subclinical diseases. Protein-energy malnutrition in beef cattle occurs most commonly in late gestation and is characterized clinically by weakness, clinical recumbency, marked loss of body weight, a normal mental attitude, and a desire to eat. Cows with concurrent hypocalcemia will be anorexic. If the condition occurs at the time of parturition, there will be an obvious lack of colostrum. Calves of these cows may attempt to vigorously suck their dams, attempt to eat dry feed, drink surface water or urine, and bellow continuously. Affected cows and their calves may die within 7 to 10 days.

Protein-energy malnutrition is less common in dairy cattle because they are usually fed to meet the requirements of maintenance and milk production. Dairy calves fed inferior-quality milk replacers during periods of cold weather will lose weight, become inactive and lethargic, and may die within 2 to 4 weeks. Affected calves may maintain their appetites until just before death. Diarrhea may occur concurrently and be confused with acute undifferentiated diarrhea as a result of the enteropathogenic viruses or cryptosporidiosis. Affected calves recover quickly when fed cow's whole milk.

Protein-energy malnutrition also occurs in sheep and, less commonly, in goats. Excessive dental attrition is a common cause in grazing sheep, which is exacerbated by the excessive ingestion of soil.

DIFFERENTIAL DIAGNOSIS

The diagnosis will depend on an estimation of the concentration of energy and protein in the feed, or a feed analysis, and comparing the results with the estimated nutrient requirements of the class of affected animals. In some cases, a sample of feed used several weeks earlier may no longer be available, or the daily feed intake may not be known. Marginal deficiencies of energy and protein may be detectable with the aid of a metabolic profile test. Specific treatment of livestock affected with protein-energy malnutrition is usually not undertaken because of the high cost and prolonged recovery period. Oral and parenteral fluid and electrolyte therapy can be given as indicated. The provision of high-quality feeds appropriate to the species is the most cost-effective strategy.

PREVENTION

The prevention of protein-energy malnutrition requires the provision of the nutrient requirements of the animals according to age, stage of pregnancy and production, the environmental temperature, and the cost of the feeds. Body-condition scoring of cattle and sheep can be used as a guide to monitor body condition and nutritional status. Regular analysis of feed supplies will assist in the overall nutritional management program. The published nutrient requirements of domestic animals are only guidelines to estimated requirements because they were determined in experimental animals selected for uniform size and other characteristics. Under practical conditions, all of the common factors that affect requirements must be considered.

LOW-MILK-FAT SYNDROME

In low-milk-fat syndrome, the concentration of fat in milk is reduced, often to less than 50% of normal, while milk volume is maintained. This syndrome is a significant cause of wastage in high-producing cows. Low concentration of fat in milk occurs with ruminal acidosis in cattle.[1] The cause appears to be an increase in concentrations of conjugated linoleic acid in the diet, with subsequent reduction in lipogenesis in the udder.[2] A supply of polyunsaturated fatty acids in the cows' ration and alteration in fermentation in the rumen results in biohydrogenation of linoleic acid (abundant in oils and seeds) and formation of intermediate fatty acids in the rumen. These incompletely hydrogenated fatty acids are absorbed into the blood and have an inhibitory effect on lipogenesis.[3] This syndrome occurs most commonly in cows on low-fiber diets, for example, lush, irrigated pasture or grain rations that are ground very finely or fed as pellets. Treatment is achieved by administration of sodium bicarbonate or magnesium oxide, which increase fiber digestibility and hence the propionate : acetate ratio. Magnesium oxide also increases the activity of lipoprotein lipase in the mammary gland and increases uptake of triglycerides by the mammary gland from the plasma.[4]

Diseases Associated With Deficiencies of Mineral Nutrients

There is an enormous literature about mineral nutrient deficiencies in livestock, and thus it is not possible to comprehensively review it here, but some general comments are appropriate. In developed countries, severe deficiencies of single elements affecting very large numbers of animals now seldom occur. The diagnostic research work has been done, the guidelines for preventive programs have been outlined, and these have been applied in the field. Thus the major contributions to knowledge have already been made, and what remains is essentially applying and extending that knowledge. Some loose ends remain, including preventing the overzealous or unnecessary application of minerals, which can produce toxicoses or is simply not cost-effective; sorting out the relative importance of the constituent elements in combined deficiencies, characterized by incomplete response to single elements; and devising better ways of detecting marginal deficiencies.

At least 15 mineral elements are essential nutrients for ruminants. The macrominerals, required daily in gram amounts, are calcium, phosphorous, potassium, sodium, chlorine, magnesium, and sulfur. The trace elements, or microminerals, are copper, selenium, zinc, cobalt, iron, iodine, manganese, and molybdenum. Improving trace-element nutrition of grazing livestock, in a way that is cost-effective and that meets consumer perceptions and preferences, is a continuing challenge.[1]

PREVALENCE AND ECONOMIC IMPORTANCE

Despite experimental evidence that deficiencies or excesses of trace elements can influence growth, reproductive performance, or immunocompetence of livestock, there is often a lack of information on the prevalence and economic significance of such problems. Most published reports of trace-element-related diseases are case reports and thus provide insufficient information to assess prevalence and economic impact on a regional or national scale. Many reports are also compromised by commercial bias. Despite this, Food and Agriculture Organization/World Health Organization (FAO/WHO) Animal Health Yearbooks show that of the countries providing information on animal diseases, 80% report nutritional diseases of moderate or high incidence, and trace-element deficiencies or toxicities are involved in more than half of those whose causes were identified. As a specific example, in the United Kingdom it has been estimated that despite the activities of its nutritional and veterinary advisory services, and extensive supplementation, clinical signs of copper deficiency occur annually in approximately 1% of the cattle population. Copper deficiency can also predispose to increased mortality as a result of infectious diseases in lambs, and so it is likely that the economic losses from copper deficiency may be considerably underestimated even in developed agricultural economies.

DIAGNOSTIC STRATEGIES

In developed countries with more advanced livestock industries, the emphasis is on disease prevention rather than therapy, and the cost-effective control of trace-element deficiencies is a matter of ongoing farmer education rather than research. Copper, cobalt, selenium, and iodine deficiencies can affect reproductive performance, appetite, early postnatal growth, and immunocompetence on a herd or flock basis, and thus emphasis is placed on identifying the risk of deficiency before clinical signs appear.

Monitoring the trace-element status of livestock is typically done by blood, saliva, or tissue analysis, or less commonly by measuring the concentration of the trace element in the diet. An alternative way of monitoring preclinical stages of a trace element deficiency is to identify and measure a biochemical indicator that reflects changes in the activity of an enzyme involved in a key metabolic pathway, such as vitamin B_{12} or glutathione peroxidase, which are indirect

measures of cobalt and selenium nutrition in sheep, respectively. To be useful, techniques should be able to predict the likely pathologic outcome of different suboptimal concentrations of a particular measure, and hence when it is clinically and economically justifiable to apply treatments or interventions. For example, a high proportion of grazing cattle become hypocupremic if maintained on pasture forage, but they don't develop clinical signs of deficiency, and only a small percentage exhibit any physiologic response to the administration of copper. This illustrates the variation in the development of clinical signs of copper deficiency, which can be induced by a simple dietary deficiency or by interactions between copper and other elements in the diet, such as molybdenum, sulfur, and iron. There is also evidence that genetic variation influences the utilization of trace elements by livestock. For example, there are differences in dietary requirements for copper between some breeds of sheep. Sheep can also be selected for a high or low concentration of plasma copper, which can have profound physiologic consequences in the low-copper group.

Thus although it is known from soil maps and local knowledge where trace-element deficiencies occur, their prevalence and importance may be underestimated because subclinical deficiency may go unnoticed for prolonged periods.

DEFICIENCIES IN DEVELOPING COUNTRIES

In developing countries, deficiencies of trace elements are often hidden or confounded by gross nutritional deficiencies of energy, protein, phosphorus, and water, which affect postnatal growth and reproductive performance. Undernutrition is the most important limitation to herbivore livestock production in tropical countries, but mineral deficiencies or imbalances in soils and pasture forages, particularly of phosphorus, cobalt, or copper, are also responsible for poor reproductive performance and low growth rates.

PATHOPHYSIOLOGY OF TRACE-ELEMENT DEFICIENCY

The physiologic basis of trace-element deficiency is complex.[1] Some trace elements are essential for the function of a single enzyme, whereas others are involved in multiple metabolic pathways. Consequently, a deficiency of a specific element may affect one or more metabolic processes and produce a variety of clinical signs in different classes of livestock. Furthermore, there is a wide variation in the clinical response to decreased blood or tissue concentrations of a trace element between individuals. For example, two animals in a herd or flock with the same concentration of copper in their blood may be in different body condition. Their susceptibility to clinical disease will also be influenced by their age, physiologic status (pregnant, lactating, or dry), genetic differences, and interactions with other trace elements. For example, there is good evidence that whereas dietary copper may be adequate for some breeds of sheep, such concentrations may be deficient, or even toxic, for others.

Dietary deficiency does not inevitably lead to clinical disease, but several factors interact and predispose the animal to clinical disease, including the following:

- Age—for example, late-term fetal lambs are highly susceptible to demyelination as a result of copper deficiency, which produces "swayback."
- Genetic differences and individual variation in response to deficiency.
- Fluctuating demand for trace elements because of changes in growth, physiologic status (especially lactation), and diet.
- Substitution—the use of alternative metabolic pathways in response to a deficiency, such as selenium, which may incompletely protect sheep from white-muscle disease when the diet is deficient in vitamin E.
- Size of the functional reserves.

The trace elements are component parts of many tissues and are often involved in metabolic pathways, either as a single key enzyme or in many interacting components. Consequently, their deficiency leads to a variety of pathologic consequences, metabolic defects, and clinical signs. These are summarized in Table 17-12.

The soil and its parent materials are the primary sources of trace elements from which soil–plant–animal relationships are built. Soil maps created from geochemical surveys can help identify areas in which livestock are exposed to excessive ingestion or deficiencies of trace elements. Variations in the concentration of most trace elements in soils are quite wide, ranging from soils that are grossly deficient to those that are potentially toxic. The availability of trace elements to plants is controlled by their total concentration in the soil and their chemical form. Certain species of plants take up more trace elements than others, and the ingestion of soil can also have a profound effect on the nutrition and metabolism of some trace elements.

It is often difficult to determine the role of individual trace elements in deficiency states because many trace-element

Table 17-12 Principal pathologic and metabolic defects in essential trace-element deficiencies

Deficiency	Pathologic consequence	Associated metabolic defect
Copper	Defective melanin production	Tyrosine/DOPA oxidation
	Defective keratinization; hair, wool	–SH oxidation to S–S
	Defective cross linkages in connective tissue, osteoporosis	Lysyl oxidase
	Ataxia, myelin aplasia	Cytochrome c oxidase
	Growth failure	Decreased biogenic molecules such as gastrin
	Anemia	Ceruloplasmin (ferroxidase)
	Uricemia	Urate oxidase
Cobalt	Anorexia	Methyl malonyl CoA mutase
	Impaired oxidation of propionate	Tetrahydrofolate methyl transferase
	Anemia	
Selenium	Myopathy; cardiac/skeletal	Peroxide/hydroperoxide destruction
	Liver necrosis	Decreased glutathione peroxidase
	Defective neutrophil function	OH; O_2 generation
Zinc	Anorexia, growth failure	Multifactorial; increased expression of leptin (satiety signal) and cholecystokinin (appetite regulation), reduced pyruvate kinase
	Parakeratosis	Polynucleotide synthesis, transcription, translation?
	Perinatal mortality	
	Thymic involution	
	Defective cell-mediated immunity	
Iodine	Thyroid hyperplasia	Decreased thyroid hormone synthesis
	Reproductive failure	
	Hair, wool loss	
Manganese	Skeletal/cartilage defects	Chondroitin sulfate synthesis
	Reproductive failure	

deficiencies produce nonspecific and specific clinical signs, especially when complex interactions occur. Consequently, the dose–response trial still has a significant role to investigate complex or marginal deficiencies and whether a cost-effective response will occur on a particular farm.[2] A properly conducted dose–response trial requires comparison of the response to treatment, typically a biochemical indicator and a measure of production, such as body weight, in a supplemented and control group. Ideally, animals should be randomly selected and allocated to groups, and the groups should be of sufficient size to reliably detect an economically significant difference (e.g., have a 95% chance of detecting a 1-kg difference in body weight). Where appropriate, the control (unsupplemented) group should be treated with the vehicle or inactive portion of the substance given to the supplemented group (a placebo). Additional requirements for a reliable dose–response trial include a careful appraisal of the reasons for conducting the trial, a suitable form of treatment, and a reliable biochemical method for monitoring the response to the trace element. Dose–response trials establish a link between a trace element and certain clinical signs. They can also identify factors that modify the response to a trace element and, importantly, provide some indication of the economic response to supplementation.

The ad hoc field observations made by veterinarians who make a diagnosis of a trace-element deficiency, followed by treatment or dietary changes, are subjective and usually lack controls. Nevertheless, they are useful in that they indicate the magnitude and variability of response that might be expected in future studies.

There are major challenges in predicting and diagnosing trace-element deficiencies in grazing livestock, including complex interactions between dietary constituents and the homeostatic mechanisms of the animal. Thus it is usually impossible to predict from the composition or analysis of the diet whether clinical signs of deficiency will occur. Consequently, assessment of the absorbable, rather than the total, concentration of elements in the diet is now considered to be more important in understanding the nutritional basis for the deficiencies, but tests of the livestock are a more definitive assessment of deficiency.

LABORATORY DIAGNOSIS OF MINERAL DEFICIENCIES

The diagnosis of mineral deficiencies, particularly trace-element deficiencies, relies heavily on the interpretation of the biochemical tests. This is because deficiencies of any one or more of several trace elements can result in nonspecific clinical abnormalities, such as loss of weight, growth retardation, anorexia, and inferior reproductive performance.

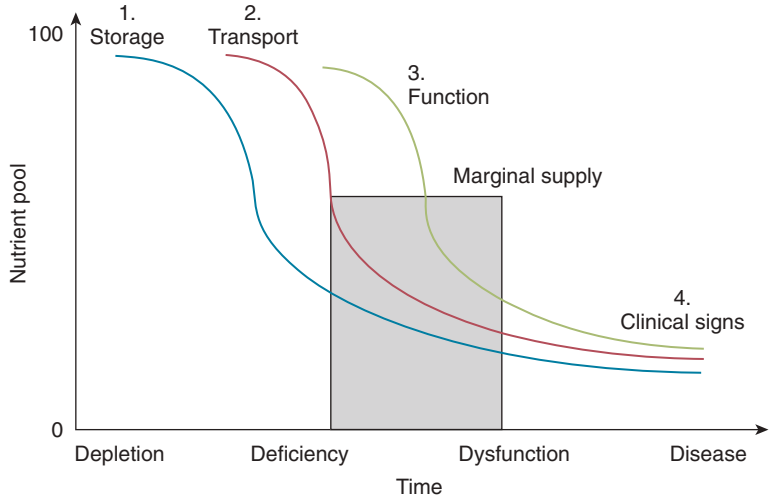

Fig. 17-11 The sequence of pathophysiological changes that can occur in mineral-deprived livestock, commencing with depletion and ending with clinical disease, and their relation to the body pools of that nutrient. (Reproduced with permission from Suttle NF. *Mineral Nutrition of Livestock*. 4th ed. Wallingford, Oxon, UK: CAB International; 2010 [Chapter 1].)

The interpretation of biochemical criteria of trace-element status is governed by three important principles: **relationship with intake, time, and function**. These are further explained as follows:

1. Relationship between the tissue concentrations of a direct marker and the dietary intake of the element will generally be sigmoid in shape (a dose–response curve). The important point on the curve is the intake at which the requirement of the animal is passed, which is the intake of the nutrient needed to maintain normal physiologic concentrations of the element and/or avoid impairment of essential functions. For several markers of trace-element status, the position on the *x*-axis at which the requirement is passed coincides with the end of the lower plateau of the response in marker concentration. Under these conditions, the marker is an excellent index of sufficiency and body reserves, but an insensitive index of a deficiency. If requirement is passed at the beginning of the upper plateau, the marker is a poor index of sufficiency, but a good index of deficiency. This principle allows direct markers to be divided into storage and nonstorage types corresponding to the former and latter positions on the *x*-axis.
2. Nonstorage criteria can be divided into indicators of acute and chronic deficiency, and two types of relationships can be distinguished: a rapid, early decline in marker concentration followed by a plateau; and a slow, linear rate of decline. Markers with a slow, linear response will be good indices of a chronic deficiency, but unreliable indices of acute deficiency, because they cannot respond quickly enough. Conversely, the marker with a rapid, early decline will be a good index of acute deficiency, but an unreliable indicator for chronic deficiency if the low plateau is reached before functions are impaired. Those biochemical criteria that are based on metalloenzyme or metalloprotein concentrations in erythrocytes are of the slow type because the marker is incorporated into the erythrocyte before its release into the bloodstream, and thereafter its half-life is determined by that of the erythrocyte, which is 150 days or more. Metalloenzymes or metalloproteins in the plasma with short half-lives provide markers of the rapid type.
3. A deficiency can be divided into four phases: depletion, deficiency (marginal), dysfunction, and clinical disease. During these phases there are progressive changes in the body pools of mineral that serve as storage (e.g., liver for copper, bone for Ca and P), transport (e.g., plasma), and function (e.g., muscle enzymes) (Fig. 17-11).[3]

Depletion is a relative term describing the failure of the diet to maintain the trace-element status of the body, and it may continue for weeks or months without observable clinical effects when substantial body reserves exist. When the net requirement for an essential element exceeds the net flow of the absorbed element across the intestine, then depletion occurs. The body processes may respond by improving intestinal absorption or decreasing endogenous losses. During the depletion phase, there is a loss of trace element from any storage sites, such as the liver, during which time the plasma concentrations of the trace element may remain constant. The liver is a common store for copper, iron, and vitamins A and B_{12}.

If the dietary deficiency persists, eventually there is a transition from a state of depletion to one of deficiency, which is marked by biochemical indications that the homeostatic mechanisms are no longer maintaining a constant level of trace elements necessary for normal physiologic function. After variable periods of time, the concentrations or activities of trace-element-containing enzymes will begin to decline, leading to the phase of dysfunction. There may be a further lag period, the subclinical phase, before the changes in cellular function are manifested as clinical disease. The biochemical criteria can be divided, according to the phase during which they change, into indicators of marginal deficiency and dysfunction. The rate of onset of clinical disease will depend on the intensity of the dietary deficiency, the duration of the deficit, and the size of the initial reserve. If reserves are nonexistent, as with zinc metabolism, the effects may be acute, and the separate phases become superimposed. The application of these principles to the interpretation of biochemical criteria of trace-element status is presented elsewhere where applicable, in the discussion of each mineral nutrient.

The definitive etiologic diagnosis of a trace-element deficiency will depend on the response in growth and health obtained following treatment or supplementation of the diet. The concurrent measurement of biochemical markers will aid in the interpretation and validation of those markers for future diagnosis. The strategies for anticipating and preventing trace-element deficiencies include regular analysis of the feed and soil, which is not highly reliable, and monitoring samples from herds and flocks to prevent animals from entering the zone of marginal trace-element deficiencies that precedes the onset of functional deficiency. The decision to intervene can be safely based on the conventional criteria of marginal trace-element status.

18 Diseases Primarily Affecting the Reproductive System

Infectious Diseases Primarily Affecting the Reproductive System

This chapter presents information related to important and selected livestock pathogens that affect not only the fertility but also the health of animals, and in some cases, such as bovine brucellosis, the health of humans. It is worth noting that national control and eradication campaigns against *Brucella abortus* infection in cattle played, and continue to play, an important global role in expanding the veterinary profession. More recently, the worldwide spread of porcine reproductive and respiratory syndrome (PRRS) virus during the last 20 years has had a marked economic impact on the swine industry. As a consequence, PRRS is currently one of the most intensively researched diseases of livestock.

Readers seeking detailed information related to reproductive performance, the estrous cycle, conception, pregnancy, and parturition are directed to the many excellent textbooks that address these subjects.

INDUCTION OF PARTURITION

CALVES

The induction of parturition in pregnant cows during the last 6 weeks of gestation by the parenteral injection of corticosteroid with or without prostaglandin F2α (PGF2α) has raised the question of animal welfare and of the possible effects of prematurity on the disease resistance of the newborn calf. The induction of premature parturition in cattle has found application in the following areas:

- With pastoral-based dairy production, synchronization of the calving period has allowed maximal utilization of seasonally available pastures by the synchronization of peak demand for dry matter intake with spring flush in pasture growth. In pastoral-based herds with breeding for seasonal calving, late-calving cows will be induced and these average approximately 8% of the herd.
- Ensuring that calving coincides with the availability of labor to facilitate observations and management of calving and to overcome the inconvenience caused by late-calving cows.
- Minimizing dystocia in small heifers and animals with exceedingly long gestation periods (past due).
- The therapeutic termination of pregnancy for various clinical reasons.
- As an aid in the control of milk fever in combination with parenteral administration of vitamin D analogs.

A variety of short-acting and long-acting corticosteroids have been used. A single injection of a short-acting formulation is used when it is desirable to induce calving within the last 2 weeks of gestation. Earlier in pregnancy short-acting corticosteroids were found to be insufficiently reliable to induce parturition, which has led to the common use of long-acting corticosteroid formulations. A variety of protocols to induce premature parturition (3–6 weeks before due date) are used in practice; the main issue is the poor predictability of the time of calving relative to treatment when using long-acting corticosteroids. Common protocols use a second treatment with short-acting corticosteroids or the administration of PGF2α 50 to 10 days after the initial treatment. The use of PGF2α at least 9 days after treatment with long-acting corticosteroids was found to reliably narrow down the calving time, with the great majority of all cows calving within 72 hours of PGF2α treatment.[1] The use of PGF2α did not improve the viability of the premature neonates or their survival rate.

For cattle near term (within 2 weeks of due date) the use of short-acting corticosteroid formulation is more appropriate with parturition generally occurring within 2 to 4 days posttreatment.[2]

The **mortality rate** of induced calves is considerable and can exceed 30%, particularly when dams are induced at or before the eighth month of gestation.[2] Mortality in calves born as a result of induced parturition is primarily a result of prematurity, and

calf mortality is generally low when calving is induced within 12 days of parturition, although there are welfare concerns. The calves born earlier in pregnancy after using long-acting corticosteroid are usually lighter in weight, lethargic, and slow to stand and to suck properly. The serum immunoglobulin concentration was found to be lower in calves born from dams induced with long-acting corticosteroids because of interference with intestinal absorption by the corticosteroid. Up to 60% of calves born following induction with long-acting corticosteroids are at risk for failure of transfer of passive immunity. The colostrum available to such calves also has a reduced immunoglobulin content, and there may also be a reduction in the total volume of colostrum available from the induced-calving cows. Immunoglobulin absorption rates were not impaired when short-acting corticosteroids are used to induce calving close to term.

Artificial induction of parturition is an important risk factor for retention of the placenta, and the incidence is reported to vary from 20% to 100%. Subsequent reproductive performance of induced cows can be impaired. A risk for acute gram-negative bacterial infections is reported in a low (0.3%) proportion of cows following induction with dexamethasone. The use of long-acting corticosteroids was also associated with a higher incidence of photosensitization in treated heifers.[2]

In a study where partus induction was systematically used in cows that exceeded a gestation length of 282 days, no detrimental effects on calf viability, cow health, and productive and reproductive performance during lactation were found compared with untreated control animals. The incidence of retained fetal membranes in untreated animals was not recorded in this study and could thus not be compared with treated animals.[2]

When parturition is induced in large herds of beef cattle, particularly with a high percentage of heifers, increased surveillance will be necessary after the calves are born to avoid mismothering. Every attempt must be made to establish the cow–calf pair (neonatal bond) and move them out of the main calving area. Heifers that disown their calves must be confined in a small pen and be encouraged to accept the calf and let it suck, which is sometimes a very unrewarding chore. Calf mortality can be very high where calving is induced earlier than 35 weeks of pregnancy.

LAMBS

The induction of parturition in sheep is not a common practice, but it can be used to synchronize lambing in flocks where there are accurate dates of mating for individual ewes. Unless accurate dates are available, there is risk of prematurity. Also, ewes that are more than 10 days from their normal parturition date are unlikely to respond.

Induction of parturition is also used as a therapeutic ploy to terminate pregnancies in sheep with pregnancy toxemia. Induction is usually performed with dexamethasone and less commonly with betamethasone or flumethasone, which is more expensive. Lambing occurs 36 to 48 hours later, and there may be breed differences in response. Variability in lambing time can be reduced by the use of clenbuterol and oxytocin.

FOALS

The induction of parturition in mares for reasons of economy, management convenience, concern for prolonged gestation, or clinical conditions such as prepubic tendon rupture or research and teaching is now being practiced.

Foaling can be induced with oxytocin, ideally administered as an intravenous (IV) drip over 15 to 30 minutes, and occurs within 15 to 90 minutes of its administration. High doses of oxytocin are potentially dangerous to the foal and low doses (10–20 IU) are preferred. Glucocorticoids, and antiprogestagens that are effective in inducing pregnancy in other species, are either ineffective in the mare or capricious in their efficacy and can also be associated with adverse effects on the foal.

Prostaglandin F2α and its analogs have been used for partus induction in the mare and low doses (5–12 mg intramuscularly [IM]) may be effective at term, but repeated treatments may be required. The time interval between treatment and delivery is difficult to predict and can range from 1 to 48 hours. The use of PGF2α for partus induction in mares has been discouraged because considerable risks such as premature placental separation and foal death that have been associated with this treatment.[3]

Induction of parturition in the mare is not without risk and has been associated with the birth of foals that are weak, injured, or susceptible to perinatal infections. The period of fetal maturation is relatively short in the horse and is considered to be the last 2 to 3 days' gestation. Because spontaneous parturition in healthy mares can occur between 320 and 360 days, there is the risk of delivering a foal that is premature and nonviable. Fetal maturity is the major prerequisite for successful induced parturition, and the three essential criteria are

- A gestational length of more than 330 days
- Substantial mammary development and the presence of colostrum in the mammary gland with a calcium concentration greater than 10 mmol/L
- Softening of the cervix

The rise in calcium concentration is the most reliable predictor of fetal maturity and milk calcium concentrations above 10 mmol/L, in combination with a concentration of potassium that is greater than sodium, are indicative of fetal maturity. Commercial milk test strips are available for estimating mammary secretion electrolyte concentrations; however, it is recommended that testing be done in an accredited laboratory.

In mature foals, head lifting, sternal recumbency, and evidence of suck reflex occurs within 5 minutes of spontaneous full-term deliveries. The foal can stand within 1 hour and suck the mare within 2 hours. The behavior and viability of the premature foal after induced parturition have been described. The overall survival rate of foals delivered from induced parturition before 320 days' gestation was 5%. Four patterns of neonatal adaptation were observed on the basis of righting, sucking, and standing ability. If the suck reflex was weak or absent and the foals were unable to establish righting reflexes, the prognosis of survival was poor. Foals born before 300 days' gestation did not survive for more than 90 minutes; foals born closer to 320 days' gestation had a better chance of survival and exhibited behavioral patterns of adaptation.

In addition to the potential delivery of a premature or weak foal, other adverse effects of induction can be dystocia, premature placental separation, and retained placenta.

PIGLETS

The induction of parturition of gilts and sows on days 112, 113, or 114 of gestation is highly reliable and can be achieved by a single IM injection of 175 μg of cloprostenol or 5 to 10 mg of PGF2α. The sows farrow approximately 20 to 36 hours later. Synchronization of farrowing can be improved by administration of oxytocin (5–30 IU) 20 to 24 hours after injection of PGF2.

Induction of parturition has been used on large-scale farms to allow a concentration of labor, to improve supervision and care at the time of farrowing, to reduce the incidence of the mastitis/metritis/agalactia syndrome, and to reduce the percentage of stillborn piglets. The end day of a batch farrowing system can be fixed and weekend farrowing avoided. The subsequent fertility of the sows is not impaired. Induction on day 110 may be associated with a slight increase in perinatal mortality.

TREATMENT

Premature partus induction cattle (>2 weeks before due date):

Dexamethasone trimethyl-acetate (or other long-acting formulation) (25–30 mg/animal IM as single dose) (R-1)

Dinoprost (or other PGF2α-analogon) (25 mg/animal IM as a single dose 5–10 days after dexamethasone treatment) (R-2)

Partus induction cattle (<2 weeks before due date):

Dexamethasone sodium-phosphate (or other short-acting formulation) (40 mg/animal IM as a single dose) (R-1)

Continued

Cloprostenol (500 µg/animal IM 36–48 h after dexamethasone treatment) (R-1)

Dinoprost (25 mg/animal IM as a single dose 36–48 h after dexamethasone treatment) (R-2)

Partus induction mare:

Oxytocin (10–20 IU/animal as IV drip over 15–30 min, several repetitions possible) (R-1)

Prostaglandin F2α (or analogon) (R-3)

Partus induction sow:

Prostaglandin F2α (or analogon) (10–25 mg/animal IM) (R-1)

Cloprostenol (175 µg/animal IM) (R-1)

Oxytocin (5–30 IU/animal IM 20–24 h after treatment with PGF2α) (R-1)

Partus induction ewe:

Dexamethasone (15–20 mg/animal IM) (R-1)

IM, *intramuscularly;* IV, *intravenously.*

FREEMARTINISM IN CALVES

A freemartin is defined as a sterile female partner of a pair of heterosexual twins. In cattle, 92% of females born cotwins to males are freemartins.

In normal calves, the chromosomal identification of females is 60,XX (60 chromosomes, both X chromosomes) and of males is 60,XY (the Y being smaller and not readily paired with its opposite X chromosome).

The freemartin is the classical example of the chimera in cytogenetics. They are the individuals that contain two or more cell types that originated in separate individuals. The only way in which a chimera can develop is via the fusion of circulations or zygotes in utero. Sex chromosome chimerism is also reported in goats, sheep, and pigs, and, although the male partners of female twins are usually anatomically normal, they often have reduced fertility. Bulls born cotwin with freemartin females may also be chimeric and have low reproductive efficiency.

The diagnosis of freemartinism has been based on physical examination, karyotyping, or blood typing, and each has its limitations. There is variation in the degree of reproductive tract abnormalities in freemartins. The external genitalia may appear normal, the vulval hair may be coarser than usual, or the clitoris may be enlarged. The vagina is generally expected to be shorter than normal. The cervix, uterus, uterine tubes, and ovaries may be absent, present in underdeveloped form, or may appear normal on rectal palpation.

Special cytogenetic techniques are also available that facilitate the diagnosis of freemartinism in a female calf of a male–female twinning. In freemartins (phenotypically female, but also carrying male cells) there is a mixture of mostly 60,XX chromosomes to a cell and a small proportion of 60,XY cells. A large number of cells need to be analyzed if only the freemartin calf is available, because the proportion of abnormal cells present may be as low as 2%. It is, however, possible to make a diagnosis on the examination of 10 to 20 cells, provided the male twin is also analyzed; the female may have very few XY chromosomes, but the male will have a very high proportion of XX chromosomes. This technique is much more accurate than blood group analysis or clinical observations of a short vagina, enlarged clitoris, and the presence of a vulval tuft of hair. Karyotyping is a definitive method of freemartin diagnosis, but it is tedious, time-consuming, and expensive. Blood typing analysis may be performed on both the male and female cotwins to demonstrate two blood group populations, but it is expensive and requires blood samples from both cotwins.

The **polymerase chain reaction** (PCR) method of freemartin diagnosis using sex-specific DNA sequences is rapid, accurate, relatively simple, and inexpensive to perform, and a blood sample is required only from the female cotwins. It allows for the accurate decision of freemartinism down to a level of 0.05% of male chimeric cells present.

BULLER STEER SYNDROME

SYNOPSIS

Etiology Unknown. Behavioral problem of steers in feedlots.

Epidemiology Prevalence varies and increases with increasing age and weight at entry.

Clinical findings and lesions Areas of denuded hair, subcutaneous hematomas, and other traumatic injuries.

Treatment Symptomatic.

Control Removal from pen.

ETIOLOGY

The buller steer syndrome is a **behavioral** problem in cattle confined in feedlots[1] of unknown etiology. Within a pen of cattle, one or more cattle persistently ride a particular individual or individuals of the group. The ridden animals are referred to as bullers. There have been several suspect etiologies. Improper placement of hormonal growth implants has been suspected as being associated with this behavioral problem.

EPIDEMIOLOGY

Occurrence

The syndrome occurs only in cattle in feedlots. A recent survey conducted among U.S. feedlots revealed a feedlot prevalence of 68.8% of all surveyed feedlots and an animal level prevalence of 2.8%.[1] The prevalence increases with increasing weight and age. The case fatality has been estimated at 1%. The incidence of occurrence is higher in the summer and the fall and during the first 30 days of the feeding period.

Epidemiologic studies indicate that bullers occur as a point source epidemic with the cause occurring soon after cattle arrive in the feedlot and mingle into pen groups. The peak incidence of bullers occurs much sooner after arrival and declines much quicker in older cattle. Bullers occur significantly sooner after mixing in older cattle than in younger cattle. The pen prevalence also increases as cattle become older on arrival at the feedlot and are more aggressive. As the prevalence of intact bulls increases in pens of cattle, so does the prevalence of bullers, presumably caused by more aggressiveness in the bulls.

Risk Factors

Postulated causative and risk factors include the incorrect timing and administration of hormonal growth implants, reimplantation and double dosing, estrogenic substances in feeds, pheromones in the urine of certain cattle, improper or late castration of young cattle, daily feedlot management, weather and seasonal factors, disease, group size, and dominance behavior. However, these factors have not been well substantiated, and controlled studies have found little influence of implant type and implant timing on buller incidence.

The mixing and confinement of **unfamiliar cattle** into pen groups, with subsequent agonistic interactions because these cattle established a social hierarchy, are considered as important risk factors. Both riding behavior and antagonistic behavior cease once cattle establish a stable social hierarchy. This suggests that riding behavior and subsequent identification of bullers is associated with this dominance behavior. It is possible that when a dominant animal becomes ill in a pen, other more subordinate animals in the pen that were previously subdued in

dominance contests may want to fight the sick animal to achieve higher social status.

Economic Importance

The syndrome has been ranked along with acute undifferentiated bovine respiratory disease and foot rot as **one of the three most important disease syndromes** in beef feedlots in North America. In addition to the economic loss from decreased weight gain, injury, treatment, death, and carcass condemnation, there are economic losses associated with extra handling necessary to accommodate affected cattle, the disruption of uniform marketing of cattle, especially in custom feedlots, and the need for extra pens in which to house the bullers. The importance of the syndrome includes animal welfare aspects.

Bullers may be at significantly greater risk of illness and mortality (from bacterial pleuropneumonia) than other steers. The association between illness, mortality, and bullers among individuals was greatest among the oldest yearling steers.

CLINICAL FINDINGS

Two types of bullers are identified. **Type 1 or true bullers** stand as if they were a heifer in estrus and do not move away or show agonistic behavior when being mounted by rider cattle. There can be several rider cattle in a pen and type 1 bullers are rapidly damaged. **Type 2 bullers** are animals that appear low in social dominance. They use aggression to discourage riders and will lie down to avoid being ridden.

Affected animals show areas of denuded hair and have extensive subcutaneous hemorrhage. The hematomas may become infected and develop to subcutaneous pockets of pus and gas. Other traumatic injuries, such as limb fractures, also occur.

CONTROL

Management of the syndrome has usually involved identification and removal from the pen to prevent injury and even death from riding-related injuries. The high rate of risk of illness and mortality in bullers relative to other feedlot steers suggests that bullers should always be checked for evidence of illness in addition to their removal from their designated pen to prevent severe riding-related injuries. Treating sick bullers may improve the chance of settling them back into their designated pen by allowing them to resume their original position in the social hierarchy.

Infectious Diseases Primarily Affecting the Reproductive System

BRUCELLOSIS ASSOCIATED WITH *BRUCELLA ABORTUS* (BANG'S DISEASE)

SYNOPSIS

Etiology *Brucella abortus*

Epidemiology Major cause of abortion in cattle in countries without a national control program. Undulant fever in humans; is an important zoonosis. Sexually mature animals susceptible; outbreaks occur in first-calf heifers, older cows are infected but do not abort. Transmitted directly from the infected animal to the susceptible animal by uterine discharges. Congenital infection occurs. Infection in wildlife species but significance to domestic animals unknown. Infection introduced into herd by unknown infected carrier animal. Natural infection and vaccination result in immunity to abortion but not infection, and infected animals remain serologically positive for a long time.

Signs Abortion epidemics in first-calf unvaccinated heifers after fifth month of pregnancy. Subsequent pregnancies carried to term. Orchitis and epididymitis in bulls. Synovitis (hygroma) occurs. Fistulous withers in horses.

Clinical pathology Serology. Serum agglutination test is standard test. Rose Bengal test (rapid screening test). Complement fixation test. ELISA test. Milk ring test. False-positive reactors are a major problem.

Lesions Necrotizing placentitis, inflammatory changes in fetus.

Diagnostic confirmation Culture organism from fetus. Positive serologic test in unvaccinated animal.

Treatment No treatment.

Control Test and reduce reservoir of infection. Quarantine. Depopulation. Vaccination to reduce incidence of abortion and percentage of infected animals. Eradication on herd and area basis by test and cull.

ELISA, *enzyme-linked immunosorbent assay.*

ETIOLOGY

Brucella abortus, a gram-negative, facultative intracellular coccobacillus of the family Brucellaceae, is the organism responsible for **bovine brucellosis**. *B. abortus* is one of 10 species with validly published names, including *B. melitensis, B. abortus, B. suis, B. ovis, B. neotomae, B. canis, B. ceti, B. pinnipedialis, B. microti,* and *B. inopinata,* each of which has specific host preferences.[1] *B. abortus* is responsible for bovine brucellosis, *B. melitensis* is the main causative agent of brucellosis in small ruminants and men, *B. suis* for brucellosis in swine, and *B. ovis* in sheep. *B. abortus* has eight recognized biovars (1–7, 9) of which the most prevalents are 1–4, and 9.[2] Approximately 5% of infections are from biovar 1. Biovar 2 was isolated in an outbreak of brucellosis in cattle in Canada in 1986. In the United States, biovars 1 to 4 are found.

EPIDEMIOLOGY

Occurrence and Prevalence of Infection

Bovine brucellosis has a worldwide occurrence and, according to the Food and Agriculture Organization (FAO), the World Health Organization (WHO), and the World Organization for Animal Health (OIE), is still one of the most important and widespread bacterial zoonoses in the world. The prevalence of infection varies considerably among herds, areas, and countries. Many countries have made considerable progress with their eradication programs, and some have eradicated the disease. However, in other countries brucellosis is still a serious disease facing the veterinary and medical professions. Currently, Australia, New Zealand, Canada, Japan, and 16 member states of the European Union (EU) have a status as officially brucellosis free.[2,3] Bovine brucellosis remains prevalent in several southern European countries and the Mediterranean basin. The seroprevalence of bovine brucellosis in the Kars district of Turkey between 2004 and 2006 was determined to be around 34%.[4] In Greece 0.97%, in Italy 0.51%, in Portugal 0.19%, in Spain 0.07%, and in the UK 0.09% of all cattle herds were positive for brucellosis in 2012.[3] Although bovine brucellosis has been reported from Egypt (biovar 1), Iran (biovar 2), and Sudan (biovar 6), little is known about the infection prevalence in the region.[5]

In the United States, the entire country is classified as class free for bovine brucellosis. Notwithstanding, infection remains highly prevalent in the wildlife population in the Greater Yellowstone area, with occasional spread to cattle. Repeated incidents of brucellosis-infected cattle in Montana, Idaho, and Wyoming have been reported in recent years.[2] Bovine brucellosis remains an important bacterial disease in Mexico, with biovars 1–6 the most prevalent. Although limited epidemiologic data are available for Central America, the disease seems to prevail widely, with an estimated animal prevalence of between 4% and 8% and a (dairy) herd prevalence between 10% and 25%.[5] In South America Chile made great progress toward eradicating the disease, but it remains prevalent in Venezuela (animal seroprevalence 3%–4%), Argentina (animal seroprevalence 2%–3%), and Brazil.[5]

The livestock prevalence was estimated at 8.2% in East Africa, 15.5% in West Africa,

14.2% in South Africa, and 13.8% in North Africa.[6]

Cattle

Infection occurs in cattle of all ages but is most common in sexually mature animals, particularly dairy cattle. **Abortions are most common during outbreaks and primarily occur in unvaccinated heifers over 5 months pregnant.** Bulls are affected with orchitis, epididymitis, and seminal vesiculitis.

Camelids

Brucellosis has been reported in the one-humped (*Camelus dromedaries*) and two-humped camel (*C. bactrianus*) and New World camelids such as llama (*Lama glama*), alpaca (*lama pacos*), guanaco (*lama guinicoe*), and vicuña (*Vicugna vicugna*) and was related to contact with small and large ruminants infected with either *B. abortus* or *B. melitensis.*[7]

Wildlife Species

The infection has been observed in American and European bison (*Bison bison, B. bonasus*); domestic buffalo (*Bubalus bubalus*); elk (*Cervus elaphus canadensis*); deer; coyotes; wild opossums; and raccoons, moose, and other wild and domesticated ruminants. Infection of moose with *B. abortus* biovar 1 is highly fatal, and it is likely that the moose is a dead-end host for brucellosis. Experimental inoculation of the organism into badgers results in the development of antibodies and elimination of the organism, which indicates that the badger is relatively resistant to infection and unlikely to be a reservoir of the organism.

Bison and elk are potential reservoirs of bovine brucellosis and have been associated with recurrence of bovine brucellosis in the Greater Yellowstone area in the United States. Brucellosis associated with *B. abortus* was first detected in bison (*B. bison*) in Yellowstone National Park in 1917 and has been present ever since. Bison can remain latently infected with virulent *B. abortus* until attainment of reproductive age despite extensive use of vaccination and serologic testing.

Cattle and bison appear to maintain *B. abortus* at higher seroprevalence than other ungulate species. The seroprevalence in the Yellowstone bison and elk population is estimated with 40% to 60% and 22%, respectively.[8,9] This has been associated with physiologic and immunologic characteristics common to bovine species but is probably also caused by typical behavioral patterns of large social groups and the periparturient behavior of bison dams that tend to calve within groups that facilitate disease transmission through direct contact around parturition.[10] In contrast elk dams segregate themselves during the periparturient period and meticulously clean the birthing site, considerably reducing the risk of disease transmission through direct contact.[11] Disease transmission may, however, be common during the abortion period in the last trimester of pregnancy from February to April, when many elk congregate in large groups on lower elevation winter habitat that overlaps with cattle-grazing areas.[11] From 2009 to 2011 eight infected cattle or captive bison herds were detected in Wyoming and Montana and all episodes were genetically or epidemiologically linked to elk, suggesting that spillover transmission from elk to cattle is epidemiologically more important than transmission from bison to cattle.[11] This has been explained with the continuously increasing elk population, which is currently above management target values in many areas of the Greater Yellowstone area and the greater mobility of free-ranging elk.[10]

Horses

In horses the organism is often found in chronic bursal enlargements as a secondary invader rather than a primary pathogen. It is commonly present with *Actinomyces bovis* in fistulous withers and poll evil. It has also been identified as a cause of abortion in mares. A serologic survey of horses over a period of 8 years revealed that 8% to 16% of serum samples were positive. However, experimentally infected horses do not excrete the organism in sufficient numbers to infect susceptible in-contact cattle.

Pigs and Sheep

The organism can be recovered from naturally infected pigs and, although not normally pathogenic in this species, may occasionally cause abortion. The disease occurs naturally in sheep exposed to infected cattle, which has significant implications for brucellosis eradication.

Dogs

Naturally acquired *B. abortus* infection can occur in dogs associated with infected cattle. Although farm dogs are not generally considered to be a major reservoir of *B. abortus,* the organism has been isolated from dogs on a farm in which several cattle were serologically positive for brucellosis, and dogs should be included in any investigation and eradication of the disease.

Methods of Transmission

Parturition/Abortion

The **risk posed to susceptible animals** following parturition or abortion of infected cattle depends on three factors:

- Number of organisms excreted
- Survival of these organisms under the existing environmental conditions
- Probability of susceptible animals being exposed to enough organisms to establish infection

The organism achieves its greatest numbers in the contents of the pregnant uterus, the fetus, and the fetal membranes, all of which must be considered as major sources of infection. The numbers of organisms in the tissues of two naturally infected cows and their fetuses were as follows: umbilicus $2.4 \times 10^8 - 4.3 \times 10^9$/g $- 1.4 \times 10^{13}$/g. This illustrates the potentially large numbers of organisms that can be shed and to which other animals and humans are potentially exposed. However, the numbers of organisms decrease when uterine discharges are cultured at sequential parturitions, and a substantial number of uterine samples from infected cows are culture negative at the second and third parturition following challenge.

Transmission

The disease is transmitted by ingestion, penetration of the intact skin and conjunctiva, and contamination of the udder during milking. The organism does not multiply in the environment but merely persists, and the viability of the organism outside the host is influenced by the existing environmental conditions. Grazing on infected pasture, or consuming feedstuffs or water supplies contaminated by discharges and fetal membranes from infected cows, and contact with aborted fetuses as well as infected newborn calves are the most common methods of spreading the disease.

Intraherd spread occurs by both vertical and horizontal transmission. **Horizontal transmission is usually by direct contamination** and, although the possibility of introduction of infection by flies, dogs, rats, ticks, infected boots, fodder, and other inanimate objects exists, it is not significant relative to control measures. The organism is ingested by the face fly but is rapidly eliminated, and there is no evidence for a role in natural transmission. Evidence exists for horizontal, dog-to-dog, cattle-to-dog, dog-to-cattle, and dog-to-human transfer of infection. The most likely and effective means of cattle-to-dog transfer is exposure to aborted fetuses or infected placental membranes, because dogs commonly ingest the products of parturition.

Spread Between Herds

Movement of an infected animal from an infected herd to a susceptible noninfected herd is a common method of transmission. The rate of spread will depend on the level of surveillance testing. In Great Britain, which is officially brucellosis free, 20% or more of both beef and dairy cattle more than 24 months old are tested routinely. A simulation model indicates that reducing the level of testing would have a major effect on the rate of spread of infection, should it be imported.

Spread Between Countries (Breach of Biosecurity)

A quantitative risk assessment model to determine the annual risk of importing brucellosis-infected breeding cattle into Great

Britain from Northern Ireland and the Republic of Ireland, which are not brucellosis free, was developed. Predictions estimated that brucellosis could be imported from Northern Ireland every 2.63 years and from the Republic of Ireland every 3.23 years. Following this assessment, the Department of Environment, Food, and Rural Affairs introduced postcalving testing for all imported breeding cattle. Under this system, all imported animals are issued a passport that records their age and pregnancy status. This information enables identification of animals that require testing and provides an additional safeguard in maintaining official brucellosis status.

Congenital Infection

Congenital infection may occur in calves born from infected dams but its frequency is low. The infection occurs in utero and may remain latent in the calf during its early life; the animal may remain serologically negative until its first parturition, when it then begins to shed the organism. Calves born from reactor dams are serologically positive for up to 4 to 6 months because of colostral antibodies and later become serologically negative even though a latent infection may exist in a small proportion of these calves. The **frequency of latent infections** is unknown, but may range from 2.5% to 9%. Latent infections in serologically negative animals are of some concern because they remain unnoticed and can potentially serve as a source of infection later. However, latent infections in calves born from infected cows are infrequent. The organism could not be isolated from any of 150 calves born to infected cows, 135 of which were experiencing their first pregnancy after infection. In one report, a heifer from a herd affected with widespread infection with *B. abortus* biotype 2 was moved to a brucellosis-free herd and remained apparently free from brucellosis until 9 years later, when the same animal produced a strongly positive serologic reaction and the same biotype was isolated from its milk. Such observations have resulted in the recommendation that calves from seropositive dams should not be used for breeding. Even vaccinated heifers from seropositive dams can harbor a latent infection. There is a risk that 2.5% of heifer calves born from serologically positive dams will react in early adulthood and constitute a threat to a reestablished herd.

Survival of Organism

The organism can survive on grass for variable periods depending on environmental conditions. In temperate climates, infectivity may persist for 100 days in winter and 30 days in summer. The organism is susceptible to heat, sunlight, and standard disinfectants, but freezing permits almost indefinite survival. The activity of several disinfectants against *B. abortus* has been examined, and representatives of the phenolic, halogen, quaternary ammonium, and aldehyde groups of disinfectants at 0.5% or 1.0% concentrations in the absence of serum generally inhibited a high concentration of the organism.

Uterine Discharges and Milk

A cow's tail heavily contaminated with infected uterine discharges may be a source of infection if it comes in contact with the conjunctiva or the intact skin of other animals. In the same way that the more common forms of mastitis can be spread during milking, *B. abortus* infection can be spread from a cow whose milk contains the organism to an uninfected cow. This may have little significance in terms of causing abortion, but it is of particular importance in its effects on agglutination tests on milk and the presence of the organism in milk used for human consumption.

Bulls and Semen

Bulls do not usually transmit infection from infected to noninfected cows mechanically. Infected bulls may discharge semen containing organisms but are unlikely to transmit the infection. The risk of spread from the bull is much higher, however, if the semen is used for artificial insemination. Some infected bulls are negative on serum agglutination tests and their carrier status can only be detected by the isolation of organisms from the semen or agglutination tests on seminal plasma.

Carrier Cows

Few infected cows ever recover from infection completely and should be considered as permanent carriers whether or not abortion occurs. Excretion of the organism in the milk is usually intermittent, is more common during late lactation, and can persist for several years. In cattle vaccinated before infection, the degree of excretion of *B. abortus* in the milk is less than in nonvaccinated animals. Embryo transfer from infected donors may be achieved without transfer of infection, and superovulation is unlikely to reactivate the release of *Brucella* into the uterus during the period when embryos are normally collected. Thus embryo transfer is a safe procedure for salvaging genetic material from infected animals.

The herd characteristics and the results of the first herd test may be used as predictors of the potential presence or absence of *B. abortus* in herds with reactors to the tube agglutination test. The presence of only single suspicious reactors on the first test is a reliable predictor of lack of infection. The presence of one or more positive reactors on the first herd test is a reliable predictor of the presence of infection.

Risk Factors

The risk factors that influence the initiation, spread, maintenance, and/or control of bovine brucellosis are related to the animal population, management, and the biology of disease. The variables that contribute significantly to seropositive animals are

- Size of farm premises
- Percentage of animals on a premises that are inseminated artificially
- Size of investment in livestock
- Number of cows that aborted in the previous year, whether or not dairying is the major agricultural activity of the premises
- Policy of the owner regarding disposal of reactor animals

The longer infected animals are in contact with the remainder of the herd, the greater will be the ultimate number of seropositive animals. In a defined geographic area in northern Mexico where a brucellosis control program did not exist, the greatest percentage of seropositive animals was related to larger farms, poor artificial insemination technique, and small financial investment in the farm.

From a practical viewpoint, the factors influencing the transmission of brucellosis in any given geographic region can be classified into two fundamental categories: those associated with the transmission of disease between herds and those influencing the maintenance and spread of infection within herds. Factors influencing interherd transmission include the purchase of infected replacement animals, which is influenced by frequency of purchase, source of purchase, and brucellosis test history of purchased animals. The proximity of infected herds to clean herds is an important risk factor. Cattle contacts at fence lines, sharing of pastures, and strays of infected animals into clean herds are common methods by which transmission occurs to adjacent herds.

The risk factors associated with spread of the disease within a herd include unvaccinated animals in infected herds, herd size, population density, method of housing, and use of maternity pens. Large herd sizes are often maintained by the purchase of replacement cattle, which may be infected. It is also more difficult to manage large herds, which may lead to managerial mistakes that allow the disease to spread. There is a positive association between population density (number of cattle to land area) and disease prevalence, which is attributed to increased contact between susceptible and infected animals. The use of maternity pens at calving is associated with a decrease in the prevalence of infection, presumably from decreasing the exposure of infected and susceptible animals.

Animal Risk Factors

Susceptibility of cattle to *B. abortus* infection is influenced by the age, sex, and reproductive status of the individual animal. **Sexually mature, pregnant cattle are more susceptible to infection with the organism than sexually immature cattle of either sex.** Natural exposure to field strains occurs

primarily at the time of parturition of infected cows. The greater the number of infected cows that abort or calve, the greater the exposure risk to the other cattle in the herd. An important application of this observation is that infected cows need to be removed from the herd before parturition. Young cattle are less susceptible to *B. abortus* than older, sexually mature cattle. Susceptibility appears to be more commonly associated with sexual maturity than age. Young, sexually immature cattle generally do not become infected following exposure, or recover quickly. Susceptibility increases with pregnancy and as the stage of gestation increases. The probability of isolation of the organism at parturition increased from 0.22 to 0.90 as fetal age at exposure of nonvaccinated heifers increased from 60 to 150 gestation days.

Management Risk Factors

The spread of the disease from one herd to another and from one area to another is almost always caused by the movement of an infected animal from an infected herd into a noninfected susceptible herd. The unregulated movement of cattle from infected herds or areas to brucellosis-free herds or areas is the major cause of breakdowns in brucellosis eradication programs. A case-control study of brucellosis in Canada indicated that herds located close to other infected herds and those herds whose owners made frequent purchases of cattle had an increased risk of acquiring brucellosis. Once infected, the time required to become free of brucellosis was increased by large herd size, by active abortion, and by loose housing.

Pathogen Risk Factors

Brucella spp., in contrast to other pathogens, do not possess typical virulence factors such as a capsule, flagella, exotoxins, or inducers or host cell apoptosis. They express a **lipopolysaccharide (LPS)** that, in contrast to LPS from other gram-negative pathogens, is nonendotoxic but is important for the protection from complement-mediated bacterial killing and the resistance against antimicrobial peptides such as defensins and lactoferrin.[12]

Brucella spp. possess a number of **outer membrane proteins (OMPs)**, some of which are required for full virulence, and that are recognized as antigen by immunity receptors such as Toll-like receptors (TLRs), triggering proinflammatory cytokine release.[13] Certain mutants of *B. abortus* lack a major 25-kDa OMP (Omp25), which renders them unable to replicate efficiently in bovine phagocytes and chorionic trophoblasts. Expression of OMPs is regulated through **the BvrR/BvrS two-component regulatory system**, which also modulates the host cell cytoskeleton on invasion, contributing to pathogen virulence.[12] The BvrR/BvrS two-component regulatory system furthermore regulates the expression of the **type IV secretion system (T4SS)**, which is crucial for intracellular survival in host cells and virulence in vivo. T4SS is required for *Brucella* spp. to reach their intracellular replication niche.[12]

Immune Mechanisms

Brucellas are able to survive within host leukocytes and may use both neutrophils and macrophages for protection from humoral and cellular bactericidal mechanisms during the periods of hematogenous spread.

Immunity against brucellosis is principally mediated by cellular immune responses because it is an intracellular pathogen. *B. abortus* is an efficient inducer of type 1 cellular immune responses, and interferon gamma (IFN-γ) is crucial for control of brucellosis. Infections are chronic and often lifelong. The bovine T lymphocyte in brucellosis is a critical component of host defense based on mononuclear phagocyte activation by IFN-γ. The killing of *Brucella*-infected mononuclear phagocytes and IFN-γ–mediated activation of mononuclear phagocytes are the major mechanisms of host defenses against brucellosis in cattle.

The antibody response to *B. abortus* in cattle consists of an early IgM isotype response, the timing of which depends on the route of exposure, the dose of the bacteria, and the health status of the animal. The IgM response is followed almost immediately by production of IgG_1 antibody and later by small amounts of IgG_2 and IgA. Most cross-reacting antibody from exposure to bacteria other than *Brucella* spp. or environmental antigens consists mainly of IgM. Serologic tests that measure IgM are therefore not desirable, because false-positive results occur. Because IgG_2 and IgA antibodies accumulate later after exposure and are usually present in small and inconsistent amounts, the main isotype for serologic testing is IgG_1.

Naturally infected animals and those vaccinated as adults with strain 19 remain positive to the serum and other agglutination tests for long periods. The serum of infected cattle contains high levels of IgM, IgG_1, IgG_2, and IgA isotypes of antibody. Most animals vaccinated between 4 and 8 months of age return to a negative status to the test within a year. All are considered to have a relative immunity to infection. Calves from cows that are positive reactors to the test are passively immunized via the colostrum. The half-life of colostral antibodies to *B. abortus* in calves that have received colostrum from either vaccinated noninfected or infected dams is about 22 days. It is possible that some calves remain immune sufficiently long to interfere with vaccination. After vaccination of cattle with strain 19 of the organism, IgM antibodies appear after about 5 days, reaching peak values after 13 days. IgG_1 antibodies appear a little later or simultaneously with IgM, and peak values are reached at 28 to 42 days, after which they decline. The same general pattern follows experimental infection with virulent strains and also in chronic field cases, except that IgM antibody declines to low levels and residual activity resides in IgG_1 and IgG_2 as well as in IgA, which remain at higher levels.

Economic Importance

Losses in animal production caused by this disease can be of major importance, primarily because of decreased milk production in aborting cows. The common sequel of infertility increases the period between lactations, and in an infected herd the average intercalving period may be prolonged by several months. In addition to the loss of milk production, there is the loss of calves and interference with the breeding program. This is of greatest importance in beef herds where the calves represent the sole source of income. A high incidence of temporary and permanent infertility results in heavy culling of valuable cows, and some deaths occur as a result of acute metritis following retention of the placenta.

Zoonotic Implications

According to the Food FAO, the WHO, and OIE, brucellosis is still one of the most important and widespread zoonoses in the world. Of the six *Brucella* spp. known to cause human disease (*B. melitensis, B. abortus, B. suis, B. canis, B. ceti,* and *B. pinnipedialis*), *B. melitensis* is the one with the largest public health impact because it is the most virulent species and has the highest prevalence in small ruminant populations in many areas of the world. *B. abortus* and *B. suis* serovars 1, 3, and 4 are also important human pathogens; *B. suis* serovar 2 and *B. canis* are uncommon human pathogens. Most cases in humans are occupational and occur in farmers, veterinarians, and slaughterhouse personnel after direct contact with infected animals or animal material contaminated with the pathogen. The organism can be isolated from many organs other than the udder and uterus, and the handling of a carcass of an infected animal may represent severe exposure. Brucellosis is also one of the most easily acquired laboratory infections.[15] Infection can also occur after ingestion of raw milk or raw milk products. Officially approved methods of commercial pasteurization render naturally *Brucella*-contaminated raw milk safe for consumption.

In endemic regions, the reported incidences of human brucellosis range from less than 0.01 per 100,000 population to more than 200 per 100,000 population.[15] In the United States, where approximately 100 cases of human brucellosis are reported annually, the incidence rate is less than 0.05 per 100,000 population.[15] In Europe the highest incidences were reported from Greece (1.09 per 100,000 population), Portugal (0.36 per 100,000 population), and Spain (0.13 per 100,000 population), which together

accounted for 67.7% of all confirmed cases of human brucellosis in member states of the EU in 2012.[14] Of the human cases reported within the EU in 2012 where species information was available 83.9% were caused by *B. melitensis,* 10.1% *B. abortus,* 3.0% *B. suis,* and 3.0% by other *Brucella* spp.[14] The importance of the disease in humans is an important justification for its eradication. The cost-effectiveness to human health and the potential net economic benefits of a nationwide mass vaccination program for livestock over a period of 10 years has been evaluated using Mongolia as the model. If the costs of vaccination of livestock against brucellosis were allocated to all sectors in proportion to the benefits, the intervention would be cost-effective and would result in net economic benefits.

PATHOGENESIS

The successful coexistence of *Brucella* spp. with its preferred host is the outcome of coevolutionary relationships and selection pressures, which result in a stalemate where the pathogen has evolved to survive within the biologic system of the host, and the host has evolved innate and acquired immune systems that allow controlled survival of infection by the pathogen, ultimately supporting the survival of the host–pathogen system.

Following ingestion most commonly through the digestive or respiratory tract *Brucella* spp. can invade epithelial cells of the host, allowing infection though intact mucosal surfaces. Once invasion successfully occurs the organism may be phagocytized by host immune cells and may also invade nonphagocytic host cells through a mechanism that is not entirely understood. Following cell invasion the organism is contained in a membrane-bound modified phagosome, the *Brucella*-containing vacuole (BCV), and interferes with intracellular trafficking, preventing fusion of the BCV with lysosome markers and directing the BCV to the rough endoplasmic reticulum, which is highly permissive for intracellular replication of *Brucella.*[12] Invaded polymorphonuclear leukocytes then transport the pathogen to regional lymph nodes, other sites such as the reticuloendothelial system, and organs such as the udder and when present the fetal placenta. In the draining lymph node, *Brucella* infection causes cell lysis and eventual lymph node hemorrhage 2 to 3 weeks following exposure. Because of vascular injury, some of the bacteria enter the bloodstream and subsequent bacteremia occurs, which disseminates the pathogen throughout the body.

B. abortus has a predilection for the placenta; udder; testicle; and accessory male sex glands, lymph nodes, joint capsules, and bursae. Erythritol, a substance produced by the fetus and capable of stimulating the growth of *B. abortus,* occurs naturally in greatest concentration in the placental and fetal fluids and is responsible for localization of the infection in these tissues. Invasion of the gravid uterus results in a severe ulcerative endometritis of the intercotyledonary spaces. The allantochorion, fetal fluids, and placental cotyledons are invaded, and the villi are destroyed. The organism has a marked predilection for the ruminant placenta. In acute infections of pregnant cows, up to 85% of the bacteria are in cotyledons, placental membranes, and allantoic fluid. The resulting tissue necrosis of the fetal membranes allows transmission of the bacteria to the fetus. The net effect of chorionic and fetal colonization is abortion during the last trimester of pregnancy. The characteristic pneumonia in aborted fetuses is caused by localization of perivascular foci in the interlobular septa of the lung, indicative of hematogenous spread in the fetus rather than aspiration of contaminated fetal fluids. Fetuses inoculated with sufficient numbers of *B. abortus* will abort 7 to 19 days postinoculation. With experimental conjunctival exposure of pregnant heifers with the organism, the numbers of infected animals and the number of tissue samples positive for the organism are increased as fetal age at exposure increases from gestation days less than 127 to more than 157. **Abortion occurs principally in the last 3 months of pregnancy**, and the incubation period is inversely proportional to the stage of development of the fetus at the time of infection.

Congenital infection can occur in newborn calves as a result of in utero infection, and the infection may persist in a small proportion of calves, which may also be serologically negative until after their first parturition or abortion.

In the adult, nonpregnant cow, localization occurs in the udder, and the uterus, if it becomes gravid, is infected from periodic bacteremic phases originating in the udder. Infected udders are clinically normal, but they are important as a source of reinfection of the uterus, as a source of infection for calves or humans drinking the milk, and because they are the basis for the agglutination tests on milk and whey. Variable disease expression may occur in the male reproductive tract and musculoskeletal system, particularly affecting large joints, of either sex.

CLINICAL FINDINGS

Abortion

The clinical findings are dependent on the immune status of the herd. In highly susceptible nonvaccinated pregnant cattle, abortion after the 5th month of pregnancy is a typical feature of the disease in cattle. In subsequent pregnancies, the fetus is usually carried to full term, although second or even third abortions may occur in the same cow. Retention of the placenta and metritis are common sequelae to abortion. Mixed infections are usually the cause of the metritis, which may be acute, with septicemia and death following, or chronic, leading to sterility.

The history of the disease in a susceptible herd can usually be traced to the introduction of an infected cow. Less common sources are infected bulls, or horses with fistulous withers. In a susceptible herd, it is common for the infection to spread rapidly and for an abortion "storm" to occur. The storm might last for a year or more, at the end of which time most of the susceptible cows are infected and have aborted and then carry their calves to full term. Retained placentae and metritis could be expected to be common at this time. As the abortion rate subsides, the abortions are largely restricted to first-calf heifers and new additions, because other animals of the herd acquire partial resistance.

In recent years, particularly in areas where vaccination is extensively practiced, an insidious form of the disease may develop, which spreads much more slowly and in which abortion is much less common.

Orchitis and Epididymitis

In the bull, orchitis and epididymitis occur occasionally. One or both scrotal sacs may be affected, with acute, painful swelling to twice normal size, although the testes may not be grossly enlarged. The swelling persists for a considerable time, and the testis undergoes liquefaction necrosis and is eventually destroyed. The seminal vesicles may be affected and their enlargement can be detected on rectal palpation. Affected bulls are usually sterile when the orchitis is acute but may regain normal fertility if one testicle is undamaged. Such bulls are potential spreaders of the disease if they are used for artificial insemination.

Synovitis

B. abortus can often be isolated from the tissues of nonsuppurative synovitis in cattle. Hygromatous swellings, especially of the knees, should be considered with suspicion. Progressive and erosive nonsuppurative arthritis of the stifle joints has occurred in young cattle from brucellosis-free herds that had been vaccinated with strain 19 vaccine. The calves may or may not be serologically positive, but synovial fluid and joint tissue samples contain immunologic evidence of strain 19 *B. abortus* antigenic material. The synovitis has been reproduced by intraarticular injection of the vaccine.

Fistulous Withers

In horses, the common association of *B. abortus* is with chronic bursal enlargements of the neck and withers, or with the navicular bursa, causing intermittent lameness, and the organism has been isolated from mares that have aborted. When horses are mixed with infected cattle, a relatively high proportion can become infected and develop a positive reaction to the serum agglutination test

without showing clinical illness. Some horses appear to suffer a generalized infection with clinical signs including general stiffness, fluctuating temperature, and lethargy.

CLINICAL PATHOLOGY

The major objective in the laboratory diagnosis of brucellosis is to identify animals that are infected and potentially shedding the organism and spreading the disease. Most infected animals are identifiable using the standard serologic tests, but latent infection occurs in some animals that are serologically negative. Furthermore, vaccinated animals may be serologically positive and uninfected, and transitory titers occur sporadically in a small percentage of animals, for which there is no clear explanation. These diagnostic problems make control and eradication programs difficult to administer and difficult to explain to animal owners.

The collection and submission of samples to the laboratory must be done with care, and careful attention must be given to recording the identity of the animal and the corresponding sample, which should be uniquely identified. For blood samples, it is recommended that silicone-coated evacuated glass tubes without additives be used to collect the blood sample, because they ensure effective clotting and clot retraction, to provide an easy source of serum without the need for centrifugation. Clotting is also aided by maintaining the sample at 25°C to 37°C for 1 to 2 hours.

Laboratory tests used in the diagnosis of brucellosis include isolation of the organism and serologic tests for the presence of antibodies in blood, milk, whey, vaginal mucus, and seminal plasma. The organism may be present in the cervical mucus, uterine flushings, and udder secretions of experimentally infected cows for up to 36 days after abortion.

Identification of *Brucella* spp.

Staining

The appearance of specifically stained smears and the colonial morphology can lead to a presumptive diagnosis of brucellosis. *Brucella* bacteria are not really acid-fast but are resistant to decolonization by weak acids, and the presence of a weakly acid-fast intracellular organism, stained with the Stamp-modified Ziehl–Neelsen method may be suggestive for the presence of *Brucella* spp. in the smear. However, staining has a very limited sensitivity because of the low number of organisms present that may be present in some tissues and body fluids of infected animals. Positive results must be interpreted carefully because of the morphologic similarities of *Brucella* organisms with other pathogens associated with abortion, such as *Coxiella burnetii* or *Chlamydia abortus*.[7] Results, positive or negative, should only be considered presumptive and always need to be confirmed ideally by culture.

Culture

The gold standard diagnostic test continues to be based on isolation and characterization of the organism from the organs and lymph nodes of the fetus, the placenta, milk, vaginal mucus, or uterine exudate. Bacteriologic methods detect the organism directly and thus limit the possibility of false-positive results. Isolation of the organism from the udder secretion of a cow is conclusive evidence of infection. Culture methods are reliable and usually definitive. A range of specific culture media are commercially available. A disadvantage is the long time required for definitive identification. Most culture results are positive between the 7th and 21st day and rarely become positive before the 4th day of culture.[16] Incubation for at least 45 days has been advised before declaring a blood sample negative for *Brucella* spp.[16] Furthermore *Brucella* organisms are among the most dangerous bacteria with which to work in terms of the risk of producing laboratory-acquired infections.[7]

Detection by Polymerase Chain Reaction (PCR)

The PCR-based assays for *Brucella* spp. have been developed and are simple. PCR has been applied to tissues such as aborted fetuses and associated maternal tissues, blood nasal secretions, semen, and food products such as milk and soft cheeses. *Brucella* spp. can be detected in the milk of naturally infected cattle, sheep, goats, and camels using a PCR assay that is more sensitive than the culture method. A further diagnostic advancement of recent years is the Bruce-ladder PCR, which is a multiplex PCR assay that helps to identify and differentiate several *Brucella* spp., including vaccine strains, in a single step.[17]

Serologic Tests

In the absence of a positive culture of *B. abortus*, a presumptive diagnosis is usually made based on the presence of antibodies in serum, milk, whey, vaginal mucus, or seminal plasma.

The antibody response following infection depends on whether or not the animal is pregnant and on the stage of gestation. On average, the agglutinins and complement fixation antibodies become positive 4 weeks following experimental infection during the fourth to sixth months of gestation and not until about 10 weeks if experimental infection occurs 2 months before or after insemination. The serologic diagnosis is considered to be unreliable when applied 2 to 3 weeks before and after abortion or calving.

Any of the currently available serologic tests or combination of tests measures the response of a single animal at one point in time and does not describe the status of the herd. When the tests are used in the recommended sequence and in combination, along with a consideration of accurate epidemiologic data, the limitations of each test can be minimized. None of the tests is absolutely accurate, and there are varying degrees of sensitivity. The result has been the development of a very extensive range of tests, each of which has its own special applicability. The salient features are as follows.

Agglutination Tests

Serum Agglutination Test

The serum (tube) agglutination test (SAT) or microtiter plate variants of it are some of the traditional standard tests, which are widely used, but are not recognized as prescribed or alternative tests. The main limitations are

- Detect nonspecific antibodies as well as specific antibodies from *B. abortus* infection and vaccination
- During the incubation stage of the disease these tests are often the last to reach diagnostically significant levels
- After abortion caused by *B. abortus* they are often the last tests to reach diagnostically significant levels
- In the chronic stage of the disease, the serum agglutinins tend to wane, often becoming negative when the results of some other tests may be positive.

Rose Bengal Test (Buffered Plate Antigen or Card Test)

The rose Bengal test (RBT) is a simple, rapid spot-agglutination test using antigen stained with rose Bengal and buffered to low pH. The test detects early infection and can be used as an initial screening test. False-positive reactions are caused by residual antibody activity from vaccination, colostral antibody in calves, cross-reaction with certain bacteria such as *Yersinia enterocolitica,* and laboratory error. False-negative reactions are observed during early incubation of disease and immediately after abortion. However, the RBT is an excellent test for the large-scale screening of sera. The application of the RBT as a screening test, followed by a confirmatory or complementary test, can markedly increase the proportion of infected cattle that test positive.

For **beef cattle**, screening of herds can be achieved by collecting blood at abattoirs and submitting it to the RBT or tube agglutination test. Reactors are traced back to the herd of origin, and the herd is tested. In heavily infected herds, it is best to remove all cows positive to the RBT even though it is highly sensitive and there will be a small percentage of false-positive cows. In herds where the prevalence of infection is low and where vaccination has been used, this procedure will eliminate too many false-positive cows. In this situation the sera positive to the RBT are submitted to a more definite confirmatory test such as the complement fixation test (CFT), and only those animals reacting to the test are discarded.

Complement Fixation Test

The CFT is one of the prescribed tests for international trade and is widely accepted as a confirmatory test. It rarely exhibits nonspecific reactions and is useful in differentiating titers of calfhood vaccination from those caused by infection. The reactions to the CFT recede sooner than those to the serum agglutination test after calfhood vaccination with the strain 19 vaccine. The CFT titers do not wane because the disease becomes chronic and often the CFT reaches diagnostic levels sooner than the serum tube agglutination test following natural infection. In addition, recent technical laboratory advances have allowed much greater speed and accuracy in doing the CFT and it is now considered to be the nearest approach to a definitive test for infection. Nonetheless, because of its complexity the CFT requires good laboratory facilities and skilled laboratory personnel.

Enzyme-Linked Immunosorbent Assays

Two main types of immunosorbent assay have been used: the indirect and competitive formats.

Indirect Enzyme-Linked Immunosorbent Assay

The indirect enzyme-linked immunosorbent assay (iELISA) has been a useful test during an eradication program, after vaccination has ceased; for screening; or as a supplementary test to the CFT. Several variations of the assay using either whole-cell, smooth lipopolysaccharide (sLPS), or O-polysaccharide (OPS) as an antigen have been validated.[7] The iELISA has gained wide acceptance for serologic diagnosis of bovine brucellosis because of its ability to detect antibody of all isotopes, unlike the conventional tests. The iELISA can be useful in conjunction with the CFT during the later stages of an eradication program, when it is important to reduce the number of false-negative serologic reactions that contribute to the persistence of problem herds. The iELISA has an excellent sensitivity and specificity but cannot distinguish between the antibody response induced by vaccination with *B. abortus* strain 19 and natural infection.

The iELISA has also been developed and validated for milk, and several different variations of this assay are currently commercially available.

Competitive Enzyme-Linked Immunosorbent Assay

The competitive ELISA (C-ELISA) uses monoclonal antibody specific for one of the epitopes of the *Brucella* spp., which makes it more specific than assays using cross-reacting antibody. The C-ELISA is thus more specific but less sensitive than the iELISA. It eliminates most but not all reactions caused by cross-reacting organisms and in most but not all cases, eliminates reactions with residual antibody in animals vaccinated with strain 19.[7] The OIE therefore recommends the further investigation of positive reactors with the C-ELISA using appropriate complementary or confirmatory diagnostic tests.[7]

Fluorescence Polarization Assay

This test can be done outside the diagnostic laboratory, allowing for rapid and accurate diagnosis. The fluorescence polarization assay (FPA) can be done almost anywhere using a portable analyzer, which receives power from a laptop computer, using serum, milk, or ethylenediaminetetraacetic acid (EDTA) anticoagulated blood. The FPA technology has been developed and validated for the serologic diagnosis of brucellosis in cattle, pigs, sheep, goats, bison, and cervids. Sufficient cross-reactivity of the common epitopes of *B. abortus, B. melitensis,* and *B. suis* OPS has allowed for the use of a single antigen for all species of smooth *Brucella* and animals. The FPA was initially developed for testing serum; however, the technology has been extended to testing whole blood and milk from individual animals or bulk tank samples pooled from 2000 or fewer animals. The accuracy results of the FPA equals or exceeds those obtained using other serologic tests such as the buffered antigen plate agglutination test, the milk ring test, the CFT, the IELISA, and the C-ELISA. Validation of studies of the FPA and the C-ELISA for the detection of antibodies to *B. abortus* in cattle sera and comparison to the standard agglutination test, the CFT, and the iELISA, found that the FPA is highly superior. It offers a clear advantage because it is easy to use. Full implementation and acceptance of FPA methods for the diagnosis of brucellosis will necessitate the use of an International Standard Serum panel containing at least a low titer-positive sample and a negative sample.

Brucellin Skin Test

The brucellin skin test presents an alternative immunologic test that can be used to test unvaccinated animals. Tested animals are injected intradermally with 0.1 mL of a standardized brucellin preparation consisting of purified, sLPS-free *Brucella* antigen. The skin thickness at the injection site is measured with Vernier calipers before and 48 to 72 hours after injection. Skin thickening of at least 1.5 to 2 mm at the injection site are considered a positive reaction. This test is among the most specific brucellosis tests available, provided it is conducted with a purified, standardized antigen preparation; serologically negative unvaccinated animals with a positive reaction to the skin test are therefore considered as infected.[7] Because not all infected animals show a positive reaction the test is not recommended as a stand-alone test for the purpose of international trade.

Sensitivity and Specificity of Serologic Tests

Serologic tests must have high sensitivity to ensure that all true serologic reactors are detected. However, with a high sensitivity, a high rate of false-positive reactions may be expected and hence the need for the use of a confirmatory test to identify false-positive reactors. Confirmatory tests must therefore demonstrate a high level of diagnostic specificity and yet maintain an effective diagnostic sensitivity.

It has been recommended to use a buffered *Brucella* antigen test, such as the buffered plate antigen test or the RBT as a screening test. Either the CFT or the indirect enzyme immunoassay is appropriate for use as a confirmatory test in situations requiring a high specificity. The relationships between the quantitative serology and infection status of brucellosis in bison in Yellowstone National Park have been evaluated and found to be similar to those in chronically infected cattle.

Antibodies in Milk

The **milk ring test** is a satisfactory inexpensive test for the surveillance of dairy herds for brucellosis. A small sample of pooled fresh milk or cream, from no more than 25 cows, is tested and the herd is classified only as suspicious or negative. Final determination of the status of a suspicious herd and each animal in it is accomplished by blood testing. The more frequently a herd is tested with the milk ring test, the more effective the test becomes as a method to detect early infections, preventing serious outbreaks in susceptible herds. At least three tests done annually are now required by some regulatory agencies. The major limitation of the test is the dilution factor, which occurs in large dairy herds where large quantities of milk are stored in bulk tanks. To adjust for this dilution effect, larger sample volumes are used with increasing herd size. Although 1 mL of bulk milk is required for herds with up to 150 head, the use of 2 mL for herds between 150 and 450 head and 3 mL for herds with 450 to 700 head has been advised.[7] False-positive reactions have been observed with cattle vaccinated less than 4 months before testing and in samples containing colostrum or mastitic milk.

The milk iELISA test is a sensitive, specific, and inexpensive method for screening large numbers of individual or bulk milk samples for the antibody to *B. abortus.* An ELISA using potassium chloride extract of the organism used on bulk tank milk samples of dairy herds was highly specific and is considered as a highly reliable test for monitoring brucellosis control programs. The combined use of an ELISA and PCR on milk samples gives a sensitivity of 100%.

False-Positive Reactors

A major problem in brucellosis eradication programs has been the false-positive animals

or singleton reactor, which may remain persistently suspicious or positive in a herd that is otherwise considered to be free of brucellosis. It is of some concern because of the unnecessary slaughter of uninfected animals.

Cross-reacting antibodies usually result from exposure to antigen(s) that share antigenic determinants with *Brucella* spp., which are found in a large number of bacteria. The most prominent cross-reaction is with *Yersinia enterocolitica* O:9, which shares the major OPS almost completely with *B. abortus*. Serologic cross-reactions have also been demonstrated between smooth *Brucella* spp. and *Escherichia coli* O116:H21 and *E. coli* O157:H7, *Francisella tularensis, Salmonella* serotypes of Kauffman–White group N, *Pseudomonas maltophilia, Vibrio cholerae,* and *Y. enterocolitica* serotype O:9. Only rarely will naturally occurring *E. coli* O157:H7 infections cause false-positive reactions with standard serologic tests for bovine brucellosis. The standard serologic tests are unreliable in differentiating between *Y. enterocolitica* and *Brucella*-infected cows, but both the lymphocyte transformation and brucellin skin tests could be used to differentiate them.

Other causes of false positives include a *B. abortus*-infected animal, strain 19 residual vaccination titer, and naturally occurring nonspecific agglutinins, which may occur in some cattle populations. These agglutinins are EDTA labile and can be differentiated from agglutinating antibodies by the addition of EDTA to the diluent used in the standard serum agglutination test. The serologic cross-reactions are of major significance when the prevalence of infection has decreased to a very low level. At this stage it becomes much more important to correctly identify the status of animals reacting to the serologic tests for brucellosis.

The incorrect attribution of such reactions to factors other than *Brucella* infection is likely to result in herd breakdowns and failure to control the disease. On the other hand, the misinterpretation of cross-reactions as evidence of brucellosis results in the imposition of unnecessary restrictions and waste of resources. The problem of serologic cross-reactions has resulted in considerable research and an investigation to find laboratory tests, which will accurately distinguish positive, infected animals from positive, noninfected animals. Differentiation of cross-reacting antibodies can be difficult to achieve, especially in the case of *Y. enterocolitica* O:9 antigen, but immunodiffusion, immunoelectrophoresis, and primary binding tests and cross-absorption procedures are useful. The DNA homology of *B. abortus* strains 19 and 2308 has been examined using restriction enzyme analysis. Strain 19 is the official U.S. Department of Agriculture (USDA)-attenuated *Brucella* vaccinal strain for cattle, and strain 2038 is a virulent laboratory-adapted strain that is pathogenic to cattle. The DNA differences between the two strains are small and will require analysis at the DNA sequence level.

The serologic assay of choice for screening samples for antibody to *B. abortus* is the FPA. It is robust, very rapid, and field-adaptable, without subjective results. The C-ELISA is a useful confirmatory assay. The sera from cattle naturally infected with *B. abortus,* vaccinated with *B. abortus* S19, or immunized with *Y. enterocolitica* O:9 or *E. coli* O157:H7, were compared for antibody content to the same bacteria by iELISA, FPA, and C-ELISA. The serologic assay of choice for screening samples for antibody to *B. abortus* is the FPA. Between the two tests, nearly all reactivity to *E. coli* O157:H7 and more than one-half of the sera with antibody to *Y. enterocolitica* O:9 could be eliminated as *Brucella* reactors. These assays, perhaps in combination with a brucellin skin test, may be capable of distinguishing virtually all reactions caused by *Y. enterocolitica* O:9.

NECROPSY FINDINGS

The host responses at the organ and tissue levels have been described and are summarized here. Lymph nodes draining the sites of the early stages of infection have marked germinal center hyperplasia and hypertrophy, accompanied by acute neutrophilic and eosinophilic lymphadenitis. In the later stages of the infection, lymph nodes draining mammary gland, head, and reproductive tract develop chronic granulomatous lymphadenitis, which is usually associated with cortical and paracortical T-cell–dependent lymphoid depletion, germinal center expansion, and deep histiocytic expansion. The spleen may develop lymphoid hyperplasia and histiocytic and plasmacytic expansion in the germinal centers, and the mammary gland usually has a pronounced interstitial lymphoplasmacytic mastitis. In the uterus, there is usually an endometritis, fibrosing mural lymphocytic metritis, and caruncular necrotizing vasculitis, whereas the placenta is colonized with *B. abortus* and has extensive desquamation of fetal chorioallantoic trophoblasts with subsequent hematogenous spread to villous trophoblastic epithelium, and **necrotizing fibrinopurulent cotyledonary placentitis of the placental arcades** accompanied by granulation and intercotyledonary inflammation exudation. The placenta is usually edematous. There may be leathery plaques on the external surface of the chorion, and there is necrosis of the cotyledons. The key microscopic feature of this inflamed chorioallantois is the presence of **intracytoplasmic coccobacilli within chorionic trophoblasts**. The use of modified Ziehl–Neelsen stains on impression smears from fresh placentas can provide a rapid presumptive diagnosis. The fetal lesions consist of marked fibrinopurulent necrotizing bronchopneumonia; monocytic and neutrophilic alveolitis; thromboembolic necrotizing arteritis and lymphangitis; fibrinopurulent pleuritis; and granulomata of the liver, spleen, kidney, and lymph nodes. In **fetuses naturally and experimentally infected** with *B. abortus*, the tissue changes include lymphoid hyperplasia in multiple lymph nodes, lymphoid depletion in the thymic cortex, adrenal cortical hyperplasia, and disseminated inflammatory foci composed mainly of large mononuclear leukocytes.

The affected joints usually develop a fibrinous and granulomatous synovitis with proliferative villous projection formation, proliferative tendovaginitis with lymphoplasmacytic nodule formation, and arthritis with articular erosions, which may be associated with suppurative, granulomatous bursitis. In the testes there are unilateral or bilateral visceral to parietal tunica adhesions, interstitial lymphocyte orchitis with seminiferous tubular degeneration, necrotizing intratubular orchitis, and acute fibrinopurulent periorchitis with infarction. The ampulla may have a unilateral or bilateral granulomatous epididymitis with focally necrotic purulent and calcified sperm granulomata, and the seminal vesicles have unilateral or bilateral necrotizing fibrinopurulent seminal vesiculitis and interstitial lymphocytic, plasmacytic seminal vesiculitis with necrosis.

The distribution of *B. abortus* in experimentally and naturally infected cattle has been examined. In experimentally infected pregnant cows, the most frequently infected specimen was the mammary lymph node; the organism could also be found in other lymph nodes, uterine caruncles, cotyledons, or fetal tissues. In naturally infected heifers, the most frequently infected specimen was the mandibular lymph node. In bulls, the most frequently infected tissues were the mandibular, caudal superficial cervical, subiliac, and scrotal lymph nodes.

The lesions in *Brucella*-positive aborted fetuses and placentas in bison are similar to those in experimental infections of *B. abortus* in bison and cattle. Both *B. abortus* biovar 1 and *B. abortus* biovar 2 were isolated from specimens collected from aborted bison fetuses or stillborn calves and their placentas. The infection can also be associated with death in calves at least 2 weeks of age.

Samples for Confirmation of Diagnosis

- Bacteriology: maternal caruncle; placenta, fetal stomach content, lung (culture, has special growth requirements; cytology, Stamp's or Koster's stain on placental smears)
- Histology: fixed placenta, lung, spleen, brain, liver, kidney; maternal caruncle (light microscopy, immunohistochemistry)

Note the zoonotic potential of this organism when handling carcasses and submitting specimens.

DIFFERENTIAL DIAGNOSIS

The diagnosis of the cause of abortion in a single animal or in a group of cattle is difficult because of the multiplicity of causes that may be involved. When an abortion problem is under investigation, a systematic approach should be used. This includes a complete laboratory evaluation and follow-up inquiries into each herd.

The following procedure is recommended:

- Ascertain the age of the fetus by inspection and from the breeding records.
- Take blood samples for serologic tests for brucellosis and leptospirosis.
- Examine uterine fluids and the contents of the fetal abomasum at the earliest opportunity for trichomonads, and subsequently by cultural methods for *B. abortus, Campylobacter fetus,* trichomonads, *Listeria* spp., and fungi.
- Supplement these tests by examination of urine for leptospires, and of the placenta or uterine fluid for bacteria and fungi, especially if the fetus is not available.
- Examine placenta fixed in formalin for evidence of placentitis.

It is most important that all examinations are done in all cases because coincident infections with more than one agent are not uncommon.

In the early stages of the investigation, the herd history may be of value in suggesting the possible etiologic agent. For example, in brucellosis, abortion at 6 months or later is the major complaint, whereas in trichomoniasis and vibriosis, failure to conceive and prolongation of the diestrual period is the usual history.

Of special interest is epizootic bovine abortion, which is a major disease of rangeland cattle in the western United States. A spirochete has been isolated from the soft tick *Ornithodoros coriaceus* and from the blood of fetuses with lesions of epizootic bovine abortion. The disease occurs at a very high level of incidence but only in cattle introduced to a certain area; resident cattle are usually unaffected. Cattle returned to the area each winter are unaffected after the first abortion. The cows are unaffected systemically. Aborted fetuses show characteristic multiple petechiae in the skin, conjunctiva, and mucosae; enlargement of lymph nodes; anasarca; and nodular involvement of the liver.

In most countries where brucellosis is well under control and artificial insemination limits the spread of vibriosis and trichomoniasis, leptospirosis may be the most common cause of abortion in cattle.

However, surveys in such countries reveal that in about two-thirds of the abortions that occur no causative agent is detectable with routine laboratory techniques. In only 35% of cases was the cause determined, and brucellosis accounted for less than 1% of the total. In an Australian experience, the cause of abortion was determined in only 37% of cases in spite of the submission of the fetus, placenta, and maternal serum. The general procedures for submission of specimens to the laboratory and laboratory methods are available.

Bulls

Infected bulls may be serologically positive or negative, and their semen may be culturally positive or negative, but the organism may be isolated at slaughter. Clinical examination may reveal the presence of epididymitis, orchitis, seminal vesiculitis, and ampullitis. All bulls from known infected herds should therefore be considered as suspicious, regardless of their serologic status, and not be used for artificial insemination.

TREATMENT

Treatment is unsuccessful because of the intracellular sequestration of the organisms in lymph nodes, the mammary gland, and reproductive organs. *Brucella* spp. are facultative intracellular bacteria that can survive and multiply within the cells of the macrophage system. Treatment failures are considered to be caused by the inability of the drug to penetrate the cell membrane barrier instead of the development of antimicrobial resistance.

CONTROL AND ERADICATION

Most countries with brucellosis have programs designed to control and ultimately eradicate the infection in cattle to reduce economic losses and protect the public from the disease. These programs usually have several components, and to ensure effectiveness each component needs to be scientifically sound and accepted by all concerned. The major components of a control and eradication program are as follows.

Test and Reduction of Reservoir of Infection

All breeding cattle in the herd are tested, and those that are positive are culled and sent for slaughter. This removes infected cows from the herd and reduces exposure and transmission within the herd. Of particular importance is the detection and removal of infected cows before parturition.

Quarantine

This is a period of time during which cattle movement is restricted and the cattle are tested. This will prevent interherd transmission by infected cattle, especially those that are test negative and incubating the disease. The quarantine period should be sufficiently long that all cattle have had sufficient time to develop brucellosis and ensure that the remaining cattle will not be a source for interherd transmission. The time will usually range from 120 days to 1 year, or until all breeding animals have completed a gestation without test evidence of infection.

Depopulation

Depopulation is slaughter of all cattle in a herd when all animals have been exposed and are capable of becoming infected and acting as a source of new infection.

Vaccination

Properly vaccinated cattle are less likely to be infected and, therefore, are less likely to shed field strains of the organism. Vaccination strategies will be discussed in more detail below.

Education

All participants in a program must understand and adopt the scientific basis for the program. This includes livestock producers, veterinarians, and regulatory officials.

Guidelines

To be successful, any program needs guidelines and policies, which must be followed and modified to meet the needs of certain areas or herds.

Apart from the question of human exposure to infection, the cost and economic benefits of an eradication program must be assessed against the costs and benefits from a vaccination control program. Certain basic considerations apply to all programs aimed at the eradication of brucellosis.

- The control programs indigenous to any given area must receive primary recognition, and any plan or plans must be adapted to that area
- Cooperation at all levels of government from local to the national is essential for the success of a program. This is attained only after an intensive program of education has been performed. The individual owner of an infected herd must recognize the problem of brucellosis and express a willingness to cooperate. Experience has shown that the owner must be impressed with the hazards of the disease for human health and with the economic losses in the herd
- A reliable and uniform diagnostic procedure must be generally available.
- If disease is detected in a herd, established procedures should be available for handling the disease. If immunization is to be used, a standardized and effective vaccine must be readily available. The disposal of infected animals may create a serious economic threat for the owner and the possibilities of financial compensation must be explored
- Finally, and of major importance, the movement of animals from one area to another must be controlled at a high level, because a rigid eradication program in one area may be nullified by neglect in a neighboring area.

Sufficient information exists about bovine brucellosis that it can be eradicated. The

disease was considered to have been eradicated from Great Britain in 1981; in 1985, having met certain European Community criteria for national surveillance and with over 99.8% of the cattle herds free from brucellosis, all herds within the country not under restrictions were designated as being officially brucellosis free for trade purposes. However, small foci of infection persisted, and following the prohibition of the use of *Brucella* vaccines the national herd was becoming fully susceptible to brucellosis. This was followed by outbreaks of brucellosis in southwest England from 1984 to 1986. The movement of cattle through premises owned by dealers who specialized in the purchase and sale of newly calved cattle was a significant epidemiologic feature of these herd breakdowns.

Control by Vaccination

Because of the serious economic and medical consequences of brucellosis, efforts have been made to prevent the infection through the use of vaccines. Historically brucellosis vaccines were composed of attenuated strains of *B. abortus* and *B. melitensis*. These vaccines were shown to be effective in reducing pathogen transmission and production loss, but were less effective in preventing infection. Another inconvenience of these whole-cell vaccines was that they interfere with diagnostic assays detecting antibody against the O-side chain of the *Brucella* LPS.[18] Currently vaccines used to protect livestock against infection with *B. abortus* contain one of three attenuated live strains of *B. abortus:* strain 19, RB51, and strain 82.

Brucella abortus Strain 19 Vaccine

Vaccines containing the live *B. abortus* strain 19 are the most widely used vaccines to prevent bovine brucellosis and are considered the reference vaccines to which any other vaccine is compared.[7] The vaccine protects uninfected animals living in a contaminated environment, enabling infected animals to be disposed of gradually. This overcomes the main disadvantage of the test and disposal method of eradication, in which infected animals must be discarded immediately to avoid spread of infection. *B. abortus* strain 19 has a low virulence and is incapable of causing abortion except in a proportion of cows vaccinated in late pregnancy. Strain 19 is a smooth *B. abortus* strain expressing the O-antigen on its LPS. Antibody produced in response to vaccination will interfere with diagnostic assays identifying this antigen, which is a major problem with the use of these vaccines. Another weakness of the vaccines is that it cannot completely prevent infection.[18]

Strain 19 vaccines are normally administered to female calves between 3 and 8 months old as a single subcutaneous dose of 5 to 8 $\times$ 10^{10} organisms (**calfhood vaccination**). There is no significant difference between the immunity conferred at 4 and at 8 months of age. Calves vaccinated with strain 19 at 2 months of age have resistance comparable to those vaccinated at 4 to 8 months of age. However, generally, calves under 75 days of age are immunologically immature in response to strain 19 vaccine. Vaccination of calves with a single dose at 3 to 5 weeks of age does not provide protection compared with vaccination at 5 months of age.

In calves vaccinated between the recommended ages, the serum agglutination test returns to negative by the time the animals are of breeding age, except in a small percentage (6%) of cases. The LPS with an O-chain on *B. abortus* strain 19 explains the appearance and persistence of antibodies in serum following vaccination. These antibodies are detectable in the serologic assays used for the diagnosis of brucellosis and are the major problem with strain 19 vaccination, because they prevent easy differentiation of vaccinated from infected cattle. The appearance and persistence of these antibodies depends on age, dose, and route of vaccination. This situation makes the continued use of the vaccine incompatible with simultaneous application of test and slaughter procedures for the control of brucellosis.

In brucellosis-free herds where heifers are vaccinated between 4 and 9.5 months of age, positive titers may persist for up to 18 months if they are tested with screening tests such as the RBT. This supports the official policy in some countries not to test vaccinated heifers before 18 months of age and to retest positive cases with the CFT.

In most control programs, vaccination is usually permitted up to 12 months of age, but the proportion of persistent postvaccinal serum and whey reactions increases with increasing age of the vaccinates. Such persistent reactors may have to be culled in an eradication program unless the reaction can be proved to be the result of vaccination and not due to virulent infection.

Vaccination of adult cattle is usually not permitted if an eradication program is contemplated, but it may be of value in reducing the effects of an abortion storm. Under specific circumstances vaccination of adult cattle with a reduced single subcutaneous dose of 3 $\times$ 10^8 to 3 $\times$ 10^9 viable organisms can be used but will result in persistent antibody titers in some animals. Furthermore, the risk of abortion when vaccinating pregnant animals and the risk of excretion of the vaccine strain in milk has been reported.[7] An alternative vaccination protocol for adult cattle consists in the single or repeated subconjunctival administration of a dose of 5 $\times$ 10^9 living organisms. This latter protocol was reported to reduce the risk of abortion and shedding in milk while providing similar protection.[7]

Vaccination of bulls is of no value in protecting them against infection and has resulted in the development of orchitis and the presence of *B. abortus* strain 19 in the semen. For these reasons the vaccination of bulls is discouraged.

Efficiency of Brucella abortus Strain 19 Vaccine

Calfhood Vaccination. This can be assessed by its effect on both the incidence of abortion and the prevalence of infection as determined by testing. Field tests show a marked reduction in the number of abortions that occur, although the increased resistance to infection, as indicated by the presence of *B. abortus* in milk, may be less marked. Vaccinated animals have a high degree of protection against abortion and 65% to 75% are resistant to most kinds of exposure. The remaining 25% to 35% of vaccinated animals may become infected but usually do not abort. Experimentally, 25% of cattle vaccinated with strain 19 will become infected following challenge. Vaccinated animals continually exposed to virulent infection may eventually become infected and act as carriers without showing clinical evidence of the disease.

In summary, vaccination with a single dose of *B. abortus* strain 19 vaccine given subcutaneously at 3 to 8 months of age confers adequate immunity against abortion for five or more subsequent lactations under conditions of field exposure. Multiple or late vaccinations have no appreciable advantage and increase the incidence of postvaccinal positive agglutination reactions. When breakdowns occur, they are caused by excessive exposure to infection and not by enhanced virulence of the organism. In herds quarantined for brucellosis, calfhood vaccination reduces reactor rates, duration of quarantine, and the number of herd tests.

Adult Vaccination. Vaccination of adult cows with strain 19 vaccine is highly successful in reducing the number of infected cows in large dairy herds in which it is impossible to institute management procedures for the ideal control of brucellosis.

The vaccination of adult cattle with a reduced dose of vaccine is efficacious and results in an agglutinin response that declines more rapidly after vaccination than when the full dose is used. The reduced dose also provides protection comparable to the standard dose. Vaccination eliminates clinical disease and reduces exposure of infection to susceptible cattle. The reduction of infected adult cattle may vary from 60% to 80% in 6 to 9 months following vaccination. The CFT becomes negative sooner than the standard tube agglutination test following vaccination and can be used to distinguish postvaccine titers from culture-positive cows. The use of reduced doses of strain 19 vaccine in adult cows will also help to eliminate the problem of postvaccine titers.

The protection provided by **subcutaneous and conjunctival routes of vaccination** is the same but the subcutaneous route may result in a persistent serologic response, which requires complement fixation testing and milk culture to identify infected animals.

The principal advantages of adult vaccination include the following:

- An effective method of control of abortion
- Reduction in the reactor losses in herds
- Reduction of the number of tests required to eliminate brucellosis from infected herds

The major disadvantages of adult vaccination are

- Residual vaccine titers
- Persistent positive milk ring test
- Persistent strain 19 infection in a small percentage of adult vaccinates
- The stigma attached to adult vaccinates, which identifies them with infected herds, even though brucellosis has been eliminated and the herd released from quarantine

B. abortus strain 19 has been recovered from the supramammary lymph nodes of cattle at slaughter that were vaccinated with a low dose of the vaccine 9 to 12 months previously and had persistent titers to the CFT. The stage of gestation affects the immune responses of cattle to strain 19 vaccination. Cattle that are late in the first or early in the second trimester of gestation (84 to 135 days) at the time of administration of a low dose of strain 19 are at greater risk of being positive by official tests for brucellosis. Vaccination of cattle during the third trimester with a low dose of the vaccine is not as efficacious as when performed earlier. Although reduced-dose strain 19 vaccination is a possible alternative to the total depopulation of problem herds, its use during pregnancy should be avoided because of the risk of abortion and positive serologic titers and positive bulk milk ring tests.

The results expected following adult vaccination depend on the disease situation. In herds vaccinated in the acute phase of the disease, abortion may continue for 60 to 90 days but the incidence begins to decline by 45 to 60 days. A large number of serologic reactors will be present for the first 120 days following vaccination, and testing is usually not done for the first 60 days. The rate of reactors declines rapidly after 120 days and with good infected herd management most adult vaccinated herds can be free of brucellosis 18 to 24 months following vaccination.

The prevalence of *B. abortus* strain 19 infection in adult vaccinated cattle is low and is often not permanent. The prevalence is lower among cattle given the reduced dose of the vaccine subcutaneously. Bacteriologic examination of the milk and serologic examination of the infected cattle are necessary to identify strain 19 infected cattle, which can be retained for milk production because the infections are temporary.

Adult vaccination, even with a low dose, should **not be used in uninfected herds** because of persistent titers, which may last for more than 12 months in up to 15% of vaccinated animals, and because of the potential for abortion. The illegal or unintentional use of the standard dose of strain 19 vaccine in adult cattle will result in a sudden steep antibody titer response in the CFT, which declines in 6 to 11 months. In herds where adult vaccination with a reduced dose of vaccine is used, blood samples should be collected about 4 months after vaccination and subsequently at intervals of 2 months. Those positive to the CFT should be culled. In one study of three large dairy herds in California, the CFT at 2 and 4 months after vaccination was used to identify and cull pregnant reactor cows that were at risk of aborting or calving. The prevention of parturition of infected cows is an effective management technique.

Systemic Reactions to Vaccination With Strain 19

These occur rarely in both calves and adults, and may be more severe in Jersey calves than in other breeds. A local swelling occurs, particularly in adult cattle, and there may be a severe systemic reaction manifested by high fever (40.5–42° C; 105–108° F) lasting for 2 to 3 days, anorexia, listlessness, and a temporary drop in milk production. An occasional animal goes completely dry. The swellings are sterile and do not rupture, but a solid, fibrous mass may persist for many months.

Deaths within 48 hours of vaccination have been recorded in calves after the use of lyophilized vaccine.

B. abortus strain 19 vaccine has been associated with lameness in young cattle with synovitis following vaccination. Experimentally, the intraarticular injection of the vaccine strain can produce synovitis similar to that which occurs following vaccination.

Septicemia due to *B. abortus* may cause some deaths but in most cases the reaction is anaphylactic, and vaccinated calves should be kept under close observation. Immediate treatment with epinephrine hydrochloride (1 mL of 1:1000 solution subcutaneously) or antihistamine drugs is recommended and is effective provided it can be administered in time.

Cows in advanced pregnancy may abort if vaccinated, but the abortion rate is only about 1%; although *B. abortus* strain 19 organisms can be recovered from the fetus and placenta, their virulence is unchanged and they do not cause further spread of infection. Vaccination with strain 19 does not have a deleterious effect on the subsequent conception rate.

Brucella abortus Strain RB51 Vaccine

Brucella abortus strain RB51 (SRB51) is a live, stable, rough mutant of *B. abortus* strain 2308 that lacks much of the LPS O-side chain, therefore, it does not interfere with serologic surveillance tests. Since 1996 vaccines containing SRB51 have become the official vaccines for prevention of brucellosis in several countries.[7] The results of studies comparing the efficacy of SRB51 and strain 19 vaccines in the literature are inconsistent. Generally, SRB51 vaccines are administered subcutaneously to female calves between 4 and 12 months old with a dose of 1 to 3.4×10^{10} living organisms.[7] Heifer calves vaccinated at 3 months, 5 months, or 7 months of age with the SRB51 vaccine were protected when challenged against infection and abortion during their first pregnancy. None of the heifers developed antibodies that reacted in the standard agglutination test. A reduced dose of 1×10^9 viable organisms administered as calfhood vaccine does not protect against *B. abortus* infection.

Vaccination of cattle over 12 months of age may be permitted under some circumstances and is performed by subcutaneous administration of a single dose of 1 to 3×10^9 viable organisms. The use of SRB51 vaccines in pregnant cows is discouraged. The strain RB51 has a tropism for the bovine placental trophoblast and has been associated with placentitis and abortion under field conditions.[7] A reduced dose of an SRB51 vaccine containing 1×10^9 viable organisms given to pregnant cattle was protective against infection with *Brucella abortus* without causing placentitis or abortion but resulted in shedding of the vaccine strain in a significant proportion of vaccinated animals.[7] Vaccination of mature sexually intact bulls and heifers with a standard calfhood dose of SRB51 is not associated with shedding or colonization in tissues, and does not appear to cause any reproductive problems when administered to sexually mature cattle. Use of the vaccine in cattle already vaccinated with strain 19 vaccine will not cause positive responses on confirmation tests and does not interfere with brucellosis surveillance.

Studies with strain RB51 vaccine indicate that it is as efficacious as *B. abortus* strain 19 vaccine but is much less abortigenic in cattle. It does not produce any clinical signs of disease after vaccination and does not produce a local vaccination reaction at the injection site. The organism is cleared from the bloodstream within 3 days and is not present in nasal secretions, saliva, or urine. Immunosuppression does not cause recrudescence, and the organism is not spread from vaccinated to nonvaccinated cattle. The vaccine is safe in all cattle over 3 months of age.

In the United States, strain RB51 vaccine was licensed by the USDA's Animal and Plant Health Inspection Service (APHIS) in 1996 for use in cattle and was approved for use in

the Cooperative State–Federal Brucellosis Eradication Program. Strain RB51 vaccine must be administered by an accredited veterinarian or by a state or federal animal health official. Calves must be vaccinated with the calf dose ($1–3.4 \times 10^{10}$ organisms) between 4 and 12 months of age. Only animals in high-risk areas should be vaccinated over 12 months of age.

Vaccinates must be identified with the standard metal vaccination eartag and a vaccination tattoo. The tattoo will be the same as the tattoo for *B. abortus* strain 19 vaccination except the first digit for the quarter of the year will be replaced with an R to distinguish animals vaccinated with RB51 from those vaccinated with strain 19. Recording and reporting are the same as with strain 19 vaccine. The diagnosis requires special diagnostic tests that are not routinely available in most hospitals. Both strains are sensitive to a range of antimicrobials. Physicians deciding to initiate a metaphylactic treatment in a human patient exposed to the RB51 vaccine strain must be advised that this strain is resistant to rifampin, one of the antimicrobials of choice for the treatment of human brucellosis.

Brucella Vaccines in Wildlife

A reservoir of *B. abortus*-infected bison in the Greater Yellowstone area in the United States is an obstacle in the effort to eradicate brucellosis from the United States and a source of potential reinfection for livestock in the states of Wyoming, Idaho, and Montana. The free-ranging and infected bison in the area migrate from public land on to private lands and may come into contact with cattle. *Brucella*-induced abortions in bison have occurred under experimental and field conditions, and infected bison can transmit brucellosis under range conditions. Wild and free-ranging bison in parts of western Canada have also been shown to be infected with bovine brucellosis. Therefore a safe and effective vaccine suitable for delivery to free-ranging bison in the Greater Yellowstone area and in Canada is considered useful in reducing the risk of transmission and an aid in the prevention and control of the disease.

Brucella abortus Strain 19 in Bison

The use of strain 19 vaccine has been evaluated in pregnant bison and 10-month-old calves, and the results have been unsatisfactory. In adult bison, strain 19 was found to be highly abortigenic, and animals vaccinated as calves were not protected from infection after experimental inoculation in later life.[18]

Brucella abortus Strain RB51 in Bison

The vaccine is safe for vaccination in herds of naive and previously exposed bison calves, young growing bison, adult males, and adult pregnant and nonpregnant females. Fetal lesions do not appear to be significant with bison cows vaccinated with RB51 in early gestation, but placentitis and abortion have occurred incidentally in advanced stages of pregnancy. Limited data from efficacy studies indicate that booster vaccination with strain RB51 vaccines may increase the protection after experimental challenge.[18]

Calfhood vaccination of bison with SRB51 vaccines is efficacious in protecting against intramammary, intrauterine, and fetal infection following exposure to a virulent strain of *B. abortus* during pregnancy. However, these vaccines appear to be less effective in bison than in cattle in protecting from experimental infection. Limited data from efficacy studies indicate that booster vaccination with strain RB51 vaccines may increase the protection after experimental challenge.[18] Calfhood vaccination with SRB51 would be beneficial in a program to reduce the prevalence of *B. abortus* field stains in American bison. As with cattle, SRB51 calfhood vaccination provides a method to prevent transmission and reduce the numbers of susceptible individuals in a bison herd without interfering with serologic identification of *Brucella*-infected animals. Brucellosis management programs in bison and elk are unlikely to be successful if capture and hand vaccination is necessary. The effect of hand vaccination versus ballistic vaccination for vaccination of bison and elk on the immunologic responses to SRB51 has been evaluated. Ballistic delivery may require a greater dose of SRB51 to induce cell-mediated immune responses in bison that are comparable to those induced by hand injection.

Brucella abortus Strain RB51 in Elk (*Cervus elaphus canadensis*)

Several studies conducted in elk using strain 19 and SRB51 vaccines have yielded disappointing results with poor or no protection against experimental infection. Neither single nor repeated doses provided significant protection against *B. abortus*–induced abortion. Following vaccination, elk remain bacteremic for a prolonged period of time, rapidly develop high antibody titers while the cellular immune response is poor or lacking.[18]

Control Programs on a Herd Basis

The following recommendations are based on the need for flexibility depending on the level of infection that exists and the susceptibility of the herd and the disease regulations in effect at the time.

During an Abortion Storm

Test and disposal of reactors may be unsatisfactory during an outbreak because spread occurs faster than eradication is possible. Vaccination of all nonreactors is recommended in some countries or, if testing is impracticable, vaccination of all cattle. It is preferable to retest the herd before the second vaccination and to cull cows with a threefold rise in agglutination titer.

Heavily Infected Herds in Which Few Abortions Are Occurring

These do not present an urgent problem because a degree of herd resistance has been reached. All calves should be vaccinated immediately, and positive reactors among the remainder should be culled as soon as possible. Periodic milk ring tests (preferably at 2-month, and no more than 3-month, intervals) on individual cows are supplemented by complement fixation and culture tests.

Lightly Infected Herds

These present a special problem. If they are situated in an area where infection is likely to be introduced, calfhood vaccination should be implemented and positive reactors immediately culled. If eradication is the goal in the area, culling of reactors will suffice, but special market demands for vaccinated cattle may require a calfhood vaccination policy. When a herd is declared free of brucellosis on the basis of serum agglutination tests, its status can be maintained by introducing only negative-reacting animals from brucellosis-free herds and annual blood testing. In areas where dairying predominates, semiannual testing of milk may be substituted for blood testing.

In all of the previously mentioned programs, the careful laboratory examination of all aborted fetuses is an important and necessary corollary to routine testing. There are many difficulties achieving control and eventual eradication on a herd basis. These relate mainly to the failure of owners to realize the highly infectious nature of the disease and to cooperate fully in the details of the program. Particularly, they may fail to recognize the recently calved cow as the principal source of infection. In a herd control program, such cows should be isolated at calving and blood tested at 14 days, because false-negative reactions are not uncommon before that time.

Hygienic Measures

These include the isolation or disposal of infected animals; disposal of aborted fetuses, placentas, and uterine discharges; and disinfection of contaminated areas. It is particularly important that infected cows be isolated at parturition. All cattle, horses, and pigs brought on to the farm should be tested, isolated for 30 days, and retested. Introduced cows that are in advanced pregnancy should be kept in isolation until after parturition, because occasional infected cows may not show a positive serum reaction until after calving or abortion. Chlorhexidine gluconate is an effective antiseptic against *B. abortus* and is recommended for washing the arms and hands of animal attendants and veterinarians who come into contact with contaminated tissues and materials.

Eradication on an Area Basis by Test and Slaughter and Cessation of Calfhood Vaccination

Following a successful calfhood vaccination program, eradication on an area basis can be considered when the level of infection is below about 4% of the cattle population. Brucellosis control areas must be established and testing and disposal of reactors and their calves at foot is performed. Financial compensation is paid for disposal of reactors. Infected herds are quarantined and retested at intervals until negative; in heavily infected herds complete depopulation is often necessary. Brucellosis-free areas are established when the level of infection is sufficiently low, and the movement of cattle between areas is controlled to avoid the spread of infection.

Farms with a low incidence may find it possible to engage in an eradication program immediately provided the incidence on surrounding farms is low. Breakdowns may occur if there are accidental introductions from nearby farms, and in these circumstances it is hazardous to have a herd that is not completely vaccinated. When the area incidence is low enough (about 5%) that replacements can be found within the area or adjoining free areas, and immediate culling of reactors can be performed without crippling financial loss, compulsory eradication by testing and disposal of reactors for meat purposes can be instituted. Compensation for culled animals should be provided to encourage full participation in the program.

The work of testing can be reduced by using screening tests to select herds for more intensive epidemiologic and laboratory investigation. In dairy herds, the milk ring test conducted on bulk milk samples is useful. In beef herds, the favored procedure is the collection of blood from drafts of cattle at the abattoir and use of the RBT. The same technique has also been used to screen shipments of beef destined for countries with an aversion to meat infected with *B. abortus*. An additional means of reducing labor costs in an eradication program is the use of automated laboratory systems such as the one available for the RBT and the one based on agglutination and CFT. An educational program to promote herd owners to voluntarily submit all aborted fetuses to a laboratory for bacteriologic examination is also deemed necessary in any eradication scheme. When an area or country is declared free, testing of all or part of the population needs to be performed only at intervals of 2 to 3 years, although regular testing of bulk milk samples (milk ring test) and of culled beef cows in abattoirs and examination of fetuses should be maintained as checks on the eradication status. In all eradication programs, some problem herds will be encountered in which testing and disposal do not eliminate the infection. Usually about 5% of such herds are encountered and are best handled by a "problem herd" program. Fifty percent of these herds have difficulty because of failure to follow directions. The other half usually contain infected animals that do not respond to standard tests. Supplementary bacteriologic and serologic tests as set out previously may occasionally help these spreader animals to be identified and the disease to be eradicated.

United States

Efforts to eradicate brucellosis associated with *B. abortus* in the United States began in 1934 as an economic recovery program to reduce the cattle population because of the Great Depression. Brucellosis was considered the most significant livestock disease at that time, with a reactor rate of 11.5%. In 1954, a cooperative federal and state program was launched based on calfhood vaccination and test and slaughter with compensation. Two very effective surveillance programs for detecting brucellosis were the market cattle testing and milk ring testing of dairy herds. On July 10, 2009, all 50 states, Puerto Rico, and the U.S. Virgin Islands were officially classified as class free for bovine brucellosis.[19] The number of human cases of brucellosis declined with the decline in number of cases in animals. As of 2013, about 100 human cases per year are reported of which most cases are associated with consumption of unpasteurized milk and milk products of goat origin infected with *B. melitensis*.

Bison and elk in the Greater Yellowstone area are the last known remaining reservoir of *B. abortus* in the United States. Control of brucellosis in these species on public lands requires special consideration to preserve the largest wild, free-ranging population of bison in the United States. Vaccination trials are under way.

The primary surveillance methods for testing eligible cattle in the United States have been the **market cattle testing** program in the beef industry and the **milk ring testing** in the dairy industry. In 2009, the National Surveillance Unit USDA-APHIS identified considerable redundancies in bovine brucellosis surveillance in regions classified as class free for bovine brucellosis for at least 5 years.[19] Consequently, slaughter surveillance was reduced, and brucellosis milk surveillance was eliminated in 2011.

Market Cattle Testing

Surveillance by this method is part of the marketing process. Testing is done at livestock markets, slaughterhouses, livestock buying stations, or dealer premises. This type of testing is very effective, especially if required at the first point of assembly of cattle after leaving the farm of origin. Until 2011 95% or more of cows and bulls 2 years of age or older were required to be tested for brucellosis at slaughter in the United States. As of 2011 the number of slaughter plants participating in slaughter surveillance testing was reduced to 13 of the 40 top establishments and two bison slaughter plants. These slaughter plants are located in 13 states, representing all regions of the country.

Milk Ring Testing

Surveillance by this method involves the regular, periodic testing of milk or cream from commercial dairy herds. Milk ring testing is required twice annually in commercial dairy herds in states officially declared free of brucellosis, and four times annually in states not officially free of brucellosis. This test is very sensitive and is done on a small sample of milk from the entire herd. The milk ring test itself is simple and inexpensive. A well-managed testing program is important to public health and can reduce the exposure potential of contaminated dairy products to humans by quickly identifying affected herds. Routine brucellosis ring testing was discontinued in the United States in 2011, following the recommendation of the National Surveillance Unit of the USDA-APHIS that had identified redundancies in the diagnostic surveillance of bovine brucellosis in regions free of brucellosis for over 5 years.[19]

Australia

In Australia, under range conditions, considerable progress toward eradication of brucellosis in large beef herds has been possible. Management must be motivated and confident that the disease can be permanently eradicated. All cattle should be permanently identified, security between subherds must be good, vaccination histories must be accurate, and accurate round-up (mustering) of cattle must be possible. Quarantine facilities for infected subherds must be strict and absolutely reliable, and fence lines must be impenetrable. The development of a two-herd system, based on segregation of weaned heifer calves from adult cows and maintenance of testing pressure on the adults, will reduce the chance of infection of heifers. All calves from reactor dams are discarded, which necessitates positive identification. Only bulls or semen from brucellosis-free herds should be used in clean herds. In some situations, a laboratory is established on the ranch and equipped to do RBT and CFT. This increases the efficiency of the testing program and creates an excellent team effort between management, laboratory personnel, and the field veterinarian.

New Zealand

In New Zealand, the brucellosis status of accredited herds is monitored by a triennial CFT with a sensitivity of greater than 95%. Slaughterhouse surveillance, as performed in Australia, has a low probability of identifying infected herds. A skin test for brucellosis is attractive because it could be used at the same time as routine tuberculin testing.

Canada

In Canada, the bovine brucellosis eradication program is a success story that began in 1950 when the national prevalence of infection was about 9%. With the cooperative Federal–Provincial Calfhood Vaccination Program, the prevalence of infection was reduced to 4.5% by 1956. In 1957, a test and slaughter program was begun in which brucellosis control areas were established and mandatory testing of all cattle was done using the tube agglutination test. Reactors were identified and ordered to be slaughtered, and compensation was paid. Infected herds were quarantined and retested until negative or in some cases completely depopulated. When the infection rate was reduced to below 1% of the cattle population and 5% of the herds, the area was certified for a period of 3 years. When the infection rate was reduced to below 0.2% of the cattle in the area and 1% of the herds, the area was designated brucellosis free and certified for a period of 5 years. In the 1960s, the milk ring test and the market cattle testing programs were introduced as surveillance procedures. These are done on a continuing basis, are effective in locating infected herds, and have reduced the volume of on-farm testing required to recertify areas.

When the national level of infection was reduced to below 0.2%, calfhood vaccination was deemphasized to overcome the problem of distinguishing between persistent vaccination titers and titers caused by natural infection. Thus all seropositive animals could be disposed of and no vaccination privileges allowed. In 1973, an increase in the incidence of brucellosis occurred, which necessitated some modifications in the eradication program. The intensity of milk ring testing was increased, herds adjacent to infected herds were tested, the length of quarantine of infected herds was increased, and calves from reactor dams were ordered to be slaughtered. In heavily infected herds and in those in which it is not possible to maintain effective quarantine, it was preferable to completely depopulate a herd rather than conduct tests and successive retests. In the Canadian experience, brucellosis-free herds usually became infected when the owner unknowingly purchased an infected animal. The uncontrolled movement of infected animals from infected herds to brucellosis-free herds was a major obstacle in the final stages of the eradication.

The rate of progress in an eradication program is determined mainly by the rate at which herds that are accredited free of the infection become reinfected. The severity of reinfection (or **breakdown**) is dependent on the proportion of the herd that has been vaccinated as calves. The cessation of compulsory calfhood vaccination results in a large proportion of cattle that are fully susceptible to *B. abortus* infection. The prevention of reinfection requires a constant surveillance system.

Canada was declared free of bovine brucellosis in 1985. In 1997, a comprehensive review of Canada's bovine brucellosis surveillance program was undertaken. As a result of the findings of this review, a number of modifications to the surveillance program were introduced in 1999. The routine serologic testing of market and slaughter cattle and the routine milk ring testing of all dairy cattle were discontinued in 1999. However, auction market testing of cattle 24 months and older continues in the five markets in northern Alberta and British Columbia in response to the disease risk associated with the infected free-roaming bison herds in and around Wood Buffalo National Park.

In April 2000, the vaccination of calves with reduced dosage strain 19 *B. abortus* vaccine was discontinued. Strain RB51 *B. abortus* vaccine is not licensed for use in Canada.

Bovine brucellosis in wildlife is restricted to free-roaming bison in and around Wood Buffalo National Park in northern Canada. Information on this occurrence is found in Canada's report to the OIE Wildlife Diseases Working Group.

BRUCELLOSIS ASSOCIATED WITH *BRUCELLA OVIS*

SYNOPSIS

Etiology *Brucella ovis.*

Epidemiology Organism carried by sexually mature rams with spread by direct contact or passive venereal infection. Predominantly a disease of sheep, but red deer stags can be naturally infected.

Clinical findings Complete or partial infertility in rams caused by epididymitis. Epididymal abnormality can be detected by palpation in some affected rams. Occasionally abortion in ewes and neonatal mortality in lambs.

Clinical pathology Serology of most value including complement fixation, gel diffusion, and ELISA; semen examination.

Diagnostic confirmation Physical palpation of scrotal contents; serology; culture or PCR of semen, testes, and seminal vesicles, aborted material.

Treatment Oxytetracycline in valuable rams.

Control Total segregation of normal and young rams. Initial culling of rams with palpable scrotal abnormality and subsequent repeated serologic testing and culling of seropositive rams. Where permitted, vaccination with live *B. melitensis* strain Rev. 1 is an alternative.

ETIOLOGY

Brucella ovis has significant DNA homology with other members of the *Brucella* genus and shares antigenic and other characteristics. However, it has a permanently rough phenotype, whereas *B. melitensis* and *B. abortus* colonies are smooth.[1]

EPIDEMIOLOGY

Geographic Occurrence

Brucellosis of sheep associated with *B. ovis* has been reported in most of the major sheep-producing regions of the world, including Australia, New Zealand, North and South America, Central Asia, Russia, South Africa, and Europe, but is not a major cause of ram wastage in Great Britain. When the disease is first diagnosed in a country, and before control procedures are established, the flock prevalence of infection can be as high as 75% and as many as 60% of rams may be infected. The prevalence of infection is generally much lower in

countries and in flocks that have established control programs.

Host Occurrence

In nature mainly sheep are affected, with the ram more susceptible than the ewe. A small number of natural cases occur in farmed red deer (*Cervus elaphus*) in New Zealand, but most infections resolve after 340 days and it is regarded as a self-limiting disease.[2] It is difficult to establish infection in laboratory animals. However, white-tailed deer and goats can be infected experimentally and develop epididymitis. There is no evidence of natural infection in goats, even in those that graze with infected sheep.

The Merino breed and Merino-derived crossbreeds show a much lower incidence of the disease than do British breeds. The disease is most important in large flocks where there is multisire breeding.

Source of Infection

The infected ram is the source of infection and perpetuates the disease in a flock. The majority of infected rams excrete the organism in semen, and in most rams the active excretion in semen probably persists indefinitely. Ewes are more resistant to infection, but the organism can be isolated from them in infected flocks. After being bred by an infected ram, the majority will not carry infection for more than one or two heat cycles. Infection may result in early embryonic death and occasionally abortion or the birth of weak and poorly viable lambs. In ewes where the infection does persist to produce abortion, the organism is present in the placenta, vaginal discharges, and milk.

Transmission

Transmission between rams occurs via passive venereal infection and by direct ram-to-ram transfer. Passive venereal infection occurs from ewes that have been bred by an infected ram in the same heat cycle. Under natural conditions, this may be the major form of transmission from ram to ram during the breeding season. Infection can also be transmitted between rams in the nonbreeding season when housed or grouped together on pasture. This occurs as they sniff and lick each other's prepuce and by homosexual activity. Submissive rams may lick the prepuce of dominant rams as a trait in the dominance hierarchy. Spread of infection in a group of virgin rams is recorded. Lambs born from infected ewes and drinking infected milk do not become persistently infected.

The organism can survive on pasture for several months, but transmission by fomites appears to have no practical significance. However, transmission from infected rams to infection-free red deer stags grazed on the same pasture can occur, and it is not known if this results from direct contact between the animals or indirectly via environmental and pasture contamination.

Host Risk Factors

All postpubertal rams are susceptible to infection, but disease is more common in adult rams and disease prevalence increases with age, probably because of greater exposure to infection. Differences between flocks in the prevalence of disease suggest that environmental factors and stress may modulate susceptibility, but the risk factors are poorly defined. When the number of affected rams in a flock is greater than about 10%, the fertility of the flock is appreciably decreased.

Experimental Reproduction

Experimentally, rams can be infected by the IV, subcutaneous, intratesticular, oral, conjunctival, and preputial routes, but the latter two are the most effective. The first observable abnormality is the presence of inflammatory cells in the semen, which appear at 2 to 8 weeks. *B. ovis* appears in the ejaculate at approximately 3 weeks, but it is not always present in an infected ram after that.[3] Testicular and epididymal lesions can be palpated at about 9 weeks after infection but may occur earlier in some rams. A significant proportion of infected rams have no palpable lesions but still excrete the organism.

Ewes in early pregnancy can also be infected by the oral and IV routes, but many of these infections are transient and do not result in abortion. Abortion caused by placentitis has been produced experimentally. Intrauterine infection produced experimentally also causes lesions in and death of the fetus, but the significance of this to natural cases is undetermined.

Economic Importance

The economic effects of the disease are subtle but significant. The effect of the disease on ram fertility can influence the number of rams that are required in a flock, with the required ram to ewe ratio significantly reduced in *B. ovis*–free flocks. The percentage of lambs born early and within the first 3 weeks of the lambing period is also markedly increased. Lambing percentage may be reduced by 30% in recently infected flocks and by 15% to 20% in those where the infection is endemic. The loss of rams of high genetic potential and the need for repeat serologic testing are additional costs. In the United States, the advantage in a control program has been calculated as an additional return of $12 per ewe mated.

Zoonotic Implications

B. ovis is not a zoonosis, but live *Brucella* vaccines used for prevention of this infection in some countries, such as Rev. 1 *B. melitensis* vaccine, are pathogenic to humans and should be handled and used with care.

PATHOGENESIS

There is an initial bacteremia, often with a mild systemic reaction, and the organism can be isolated from the internal organs of animals slaughtered after experimental infection. However, systemic disease is not a feature of the natural disease, and clinical disease results from localization and inflammation in the epididymides, typically in the tail. Inflammation in this area results in sperm stasis and extravasation with a subsequent immunologic reaction that is often unilateral, causing a spermatocele and reduced fertility. Not all infected rams have palpable lesions in the epididymis, and infection can also establish in the seminal vesicles and ampullae. In either case the organism is shed in the ejaculate.

Generally, *B. ovis* has low pathogenicity for ewes. The primary effect is a placentitis, which interferes with fetal nutrition, sometimes to the point of causing fetal death, but more commonly producing lambs of low birth weight and poor viability.

Analysis of the immune response by microarray hybridization and reverse transcription (RT)-PCR found that infection with *B. ovis* causes upregulation of genes involved in phagocytosis and downregulation of host defense mechanisms, both of which probably contribute to the chronic nature of the infection.[4]

CLINICAL FINDINGS

The first reaction in rams is a marked deterioration in the quality of the semen together with the presence of leukocytes and *Brucella*. Acute edema and inflammation of the scrotum may follow. A systemic reaction, including fever, depression, and increased respiratory rate, accompanies the local reaction.

Regression of the acute syndrome is followed, after a long latent period, by the development of palpable lesions in the epididymis and tunicae of one or both testicles.

The palpation of both testicles simultaneously is the best method of examination. The epididymis is enlarged and hard, more commonly at the tail; the scrotal tunics are thickened and hardened; and the testicles are usually atrophic. The groove between the testis and epididymis may be obliterated.

The abnormalities are often detectable by palpation, but many affected rams show no acute inflammatory stage and others may be actively secreting *Brucella* and poor-quality semen in the chronic stage in the absence of palpable abnormalities. Palpable abnormality of the scrotal contents may be present in less than 50% of serologically positive rams. Affected rams have normal libido.

There are usually no clinical signs in the ewe but in some flocks infection causes abortion or the birth of weak or stillborn lambs, associated with a macroscopic placentitis.

In red deer, only a small proportion of stags infected with *B. ovis* develop epididymitis detectable by scrotal palpation.[5] In contrast to rams, in most stags the infection resolves within 12 months following infection.[2]

CLINICAL PATHOLOGY

Semen examination, including culture of the ejaculate, and serologic tests are used in suspect individuals and in groups of rams. The complement fixation and ELISA tests are by far the most useful; many infected rams have palpably normal scrotal contents and microbiologically negative semen. Ultrasound examination of the scrotal contents can reveal anechoic areas that correspond to foci of fibrosis, but these appear no earlier and are nonspecific, offering no real advantage over scrotal palpation.

Multiplex PCRs to differentiate *B. ovis* from *Actinobacillus seminis* and *Histophilus ovis* have been described for use on semen or urine.[6,7] Real-time PCR has also been used to type *Brucella* from field material, such as ovine placenta, without the need for culture.[8]

Semen Examination

A combination of semen examination and palpation of the testicles for abnormalities will identify approximately 80% of infected rams. In affected animals the findings are a general reduction in semen quality, a reduced total sperm output, poor motility, and a high proportion of spermatozoa with secondary morphologic abnormalities.

Culture

B. ovis is fastidious in its growth and requires special cultural techniques. The examination of the semen for the presence of leukocytes has been used to determine those sheep that should be cultured for *B. ovis,* but it is not a highly sensitive screening test. PCR for detection of *B. ovis* in semen has an equivalent sensitivity to culture.

Serology

The CFT, the standard test in many countries, is the prescribed test for international trade, and when used in conjunction with genital palpation has allowed the eradication of *B. ovis* from flocks. However, a small proportion of infected rams are negative to CFT, which can compromise or delay eradication programs. The sensitivity and specificity of the various serologic tests depend mainly on the antigens used and the serologic cut points, which may vary between countries and laboratories. A UK study reported the sensitivity of an ELISA, gel diffusion, and CFT as 97.6, 96.4, and 92.7%, respectively, with all tests 100% specific. Studies in other countries support this ranking, but others suggest that the ELISA has no advantage over the classic complement and gel diffusion tests. A combination of serologic tests may increase the sensitivity closer to 100%, but will obviously increase testing costs. Seroconversion occurs slightly earlier with the ELISA, compared with the complement fixation and gel diffusion tests, so it may be useful in situations where infection is rapidly spreading within a group of rams.[9]

Serologic tests will not differentiate vaccinated from infected sheep or sheep infected with *B. melitensis.*

NECROPSY FINDINGS

In the acute stage, there is inflammatory edema in the loose scrotal fascia, exudate in the tunica vaginalis, and formation of granulation tissue. In the chronic stage, the tunics of the testes become thickened and fibrous and develop adhesions. There are circumscribed indurations in the epididymis and these granulomata may also be present in the testicle. In advanced stages, they undergo caseation necrosis. As the epididymis enlarges the testicle becomes atrophied. *B. ovis* can usually be isolated from the genital organs, especially the tail of the epididymis, and rarely from internal organs and lymph nodes. Similar lesions are described in red deer stags.[5]

The abortus is characterized by thickening and edema, sometimes restricted to only a part of the placenta, with firm, elevated yellow-white plaques in the intercotyledonary areas and varying degrees of cotyledonary necrosis. Microscopically, organisms are visible within the cytoplasm of trophoblasts of the inflamed placenta. A vasculitis is often present. The organism can be isolated from the placenta and the stomach and lungs of the lamb.

Samples for Confirmation of Diagnosis

- Bacteriology and PCR: epididymal granuloma, seminal vesicle, inguinal lymph node/fetal lung, stomach content, placenta (culture, has special growth requirements; cytology, Stamp's or Koster's stain on placental smear; PCR)
- Histology: formalin-fixed epididymis, testicle, seminal vesicle, inguinal lymph node from rams; in abortions placenta, fetal lung, liver, spleen, kidney, heart, brain

DIFFERENTIAL DIAGNOSIS

Infection with *Actinobacillus seminis* and *Histophilus ovis* can cause similar scrotal lesions, although many rams with abnormalities of intrascrotal tissues do not have brucellosis or infectious epididymitis.

Abortion in ewes may be associated with a number of infectious diseases, which are summarized in Table 18-1.

TREATMENT

Treatment of naturally occurring cases is rarely undertaken. IM administration of long-acting oxytetracycline at 20 mg/kg body weight (BW), given every 3 days for 24 days, along with the daily IM administration of 20 mg/kg of dihydrostreptomycin sulfate, resulted in bacteriologic cure of 90% of experimentally infected rams. Oxytetracycline alone is less effective, but the use of dihydrostreptomycin is prohibited in food-producing animals in many countries. Treatment is economically feasible only in valuable rams and must be instituted before irreparable damage to the epididymis has occurred. The treatment of rams that are infected but without palpable lesions results in a significant improvement in breeding soundness classification on examinations subsequent to treatment.

CONTROL

Control is by preventing the spread of infection between rams and detecting and culling infected rams. In small flocks, culling of all rams and replacement with *B. ovis*–free rams may be the most cost-effective approach. Some control can be achieved using scrotal palpation to detect infected rams, but this must be combined with repeated serologic testing if eradication is the goal. Vaccination may be the most economical and practical means of controlling the disease in areas with a high incidence of infection and in regions of the world where eradication by test and slaughter is impractical.

Eradication

In a flock where the diagnosis has been confirmed all rams are palpated and those with scrotal abnormalities are culled. The remaining rams are tested serologically and reactors culled. Serologic tests are repeated at monthly intervals, with culling of reactors, until all rams are serologically negative. Further tests, 6 and 18 months later, are used to confirm eradication.

Infection spreads rapidly during the mating season, so eradication should be delayed until after the breeding season. During breeding it may be wise to run two breeding flocks, with virgin rams and rams known to be free of infection separated from older or suspicious rams (seropositive and/or those with scrotal lesions). Strict separation of the two ram flocks must be maintained at all times, and the clean group must not mate ewe flocks that have been mated to the suspect rams.

Several countries have voluntary accreditation schemes based on inspection of boundary fencing, restricting the introduction of new rams to those from accredited flocks and serologic testing.

Vaccination

A number of vaccines have been used, but none is fully effective. In some countries, vaccination is not permitted and eradication by test and slaughter is the only method of control.

Table 18-1 Diagnostic summary of infectious abortion in ewes

		Epidemiology and diagnosis			Laboratory findings	
Disease	*Transmission*	*Time of abortion*	*Clinical data*	*Fetus*	*Serology*	*Vaccination*
Brucellosis (*Brucella ovis*)	Passive venereal, ram to ram	Late or stillbirth, weak lambs	Abortion in ewes, epididymitis in rams	Organisms in fetal stomach and placenta	CFT or ELISA	In some countries simultaneous *B. abortus* strain 19 and killed *B. ovis* vaccine, or *B. melitensis* Rev. 1 vaccine
Campylobacter fetus or *C. jejuni*	Ingestion High stocking rate, intensive grazing, and supplementary feeding on the ground increases risk	Mainly young ewes; last 6 weeks of pregnancy, stillbirths, weak lambs	Metritis in ewes after abortion	*Campylobacter* in stomach, large necrotic foci in liver	Agglutination test, flock only	Formalin-inactivated bivalent vaccine can increase live lambs by around 10%; variable efficacy depending on which strains are present
Enzootic abortion of ewes (*Chlamydophila abortus*)	Ingestion	Last 2–3 weeks. Stillbirths, weak lambs	No sickness in ewes, neonatal mortality	*Chlamydophila* in fetal cotyledons Degenerative changes in placenta	ELISA, CFT, PCR	Killed vaccine gives moderate immunity. Live attenuated vaccine
Listeriosis (*Listeria monocytogenes*)	Probably ingestion	After 3 months	Retained placenta and metritis Septicemia in some ewes	Organisms in fetal stomach Autolysis, necrotic foci in liver	Agglutination and complement fixation of doubtful value	In some countries killed or live attenuated vaccines
Salmonellosis (*Salmonella abortusovis*)	Probably ingestion Carrier sheep	Last 6 weeks	Metritis after abortion	Organisms in fetal stomach Not in the United States	Agglutination test	Doubtful efficacy
Salmonellosis (*S. dublin, S. montevideo, S. typhimurium*)	Ingestion	Last month	Abortion: fetal metritis, neonatal mortality	Organisms in stomach	Agglutination test	—
Toxoplasmosis	Ingestion	Late or stillbirths Live-born weak lambs	Abortion, stillbirths, and neonatal mortality; no illness in ewe	Multiple small necrotic foci in fetal cotyledons Toxoplasma in cells of trophoblast epithelium	Modified agglutination test, ELISA of limited value in adult; test pleural fluid of fetus PCR	Live S48 tachyzoite in some countries (e.g., UK, New Zealand); single dose 3 weeks before mating
Rift Valley fever	Insects	—	Important cause of abortion in all species in Central Africa Heavy mortality in young animals	Acidophilic inclusions hepatic cells	Hemagglutination inhibition and ELISA Fluorescent antibody for tissues	Available in endemic countries
Coxiellosis (Q-Fever)	Inhalation, ingestion	Later term and weak lambs	No illness in ewe, neonatal mortality	Fetus fresh, Intercotyledonary necrotizing placentitis	Fluorescent and PCR; serology of limited value	Vaccine available in Europe but not in most other countries
Tick-borne fever	Ticks	Late, following systemic disease	Fever and abortion	None specific	Giemsa smear of blood, PCR Counterimmunoelectrophoresis	None
Border disease	Ingestion	All stages, stillbirth	Infertility in ewes, hairy shaker lambs	Virus isolation	See text description	None that are specific for sheep strains

CFT, *complement fixation test;* ELISA, *enzyme-linked immunosorbent assay;* PCR, *polymerase chain reaction.*

Killed *B. ovis* vaccines, even with adjuvants, have poor efficacy. The use of a killed vaccine may be inadvisable in flocks where eradication is being attempted, because it may protect against clinical disease but allow a carrier state in some rams in which there is excretion of the organism in animals that become seronegative. An experimental vaccine prepared from enriched OMPs and rough LPS of *B. ovis* gave equivalent protection in challenge studies to that given by *B. melitensis* Rev. 1 vaccine.

A combined vaccine containing killed *B. ovis* in an adjuvant and *B. abortus* strain 19 also provided durable immunity but had several disadvantages. Vaccinated animals become seropositive, which compromises the subsequent use of serologic tests for eradication. Strain 19 also can cause epididymitis, and vaccinated rams may excrete strain 19 in their semen.

Live *B. melitensis* strain Rev. 1 has been found to be most effective and is the most widely used vaccine, where permitted. This strain was developed in the 1950s from a virulent isolate that had become streptomycin dependent. It is avirulent for rams, and subcutaneous or conjunctival vaccination provides protection against experimental and field challenge. Vaccinated animals become positive to the complement fixation and ELISA tests, but titers are low and can be minimized by using the conjunctival route for vaccination. However, vaccinated animals can excrete *B. melitensis* strain Rev. 1, and it can cause abortions, so alternative vaccine candidates are being evaluated. These include an OMP extracted from *B. melitensis* (Omp31) and an attenuated strain of *B. ovis* (Delta abcBA). The latter protects against experimental challenge with virulent *B. ovis* and is considered a potential vaccine strain for rams.[10]

If vaccination is used there should also be a program of culling clinically abnormal rams, and ram replacements should be yearlings vaccinated at 4 to 5 months.

BRUCELLOSIS ASSOCIATED WITH *BRUCELLA SUIS* IN PIGS

Brucella suis infection may be inapparent or may result in stillbirths, abortion, and infertility in both sexes. In boars it causes infection of the testicles and accessory sex glands. It will cause disease in man[1].

SYNOPSIS

Etiology Disease in pigs is caused by *Brucella suis* biovars 1–3. Biovars 1–4 cause rare disease in cattle.

Epidemiology Disease in pigs is transmitted by contact, ingestion, and venereally.

Clinical findings
Sows: Infertility, irregular estrus, small litters, and abortion.
Boars: Orchitis, lameness, incoordination, and posterior paralysis.
Piglets: Mortality.

Clinical pathology Isolation of organism. Several serologic tests available but none with good sensitivity.

Necropsy Metritis, orchitis, osteomyelitis. Granulomatous inflammation and foci of caseous necrosis.

Diagnostic confirmation Isolation of *B. suis* and herd serology tests.

Treatment None satisfactory.

Control Serologic testing and disposal of reactors. No effective vaccine. Humans, and occasionally cattle. Transmission congenital or by ingestion or contact with infected placenta, vaginal discharge, or milk.

Clinical findings Abortion storms, abortions often in last 2 months of pregnancy. Weak-born lambs.

Clinical pathology Culture of organism. Serologic tests and skin hypersensitivity testing for herd diagnosis.

Necropsy findings Placentitis.

Diagnostic confirmation Only by isolation of the organism.

Control Slaughter eradication. Vaccination with Rev. 1 vaccine, which will produce abortion in pregnant animals.

ETIOLOGY

It is a small, aerobic, gram-negative *Bacillus*. Remember that *B abortus* and *B. melitensis* will also occasionally infect the pig, however, only *B. suis* will cause systemic and generalized infections in pigs. The other species will infect pigs, but the infection is self-limiting and the infection is usually restricted to the local lymph nodes. There are five biovars.

EPIDEMIOLOGY

Geographic Occurrence

Biovar 1

Biovar 1 is important in pigs and occurs worldwide, but the disease has not been recorded in the UK, Canada is disease free, and the prevalence is very low in the United States. It is particularly important in the Philippines and the Pacific islands and Africa.

Biovar 2

Biovar 2 occurs in pigs in west central Europe, particularly Croatia and Czechoslovakia, and also in hares. There appears to be a close relationship between pigs and wildlife in this strain and wild boar in particular.[2] Occasionally it appears in cattle, dogs, and horses.

Biovar 3

Biovar 3 has a close similarity to *B. melitensis* biovar 2 and requires phage typing, oxidative metabolic testing, or PCR for differentiation. It also occurs in pigs in the United States, South America, and southeast Asia. It is a problem in wild boar where it may reach 8% to 32% prevalence,[3,4] and particularly in Italy[5] and Spain[6] the spill over from wild boar to domestic pigs is a particular problem.[7]

Biovar 4

Biovar 4 is a cause of rangiferine brucellosis (reindeers, caribou, bison, moose, etc.) and can transmit to cattle but does not appear to be a disease of pigs. It will transmit to humans.

Biovar 5

Biovar 5 is murine brucellosis. It may also include *B. microti,* which has been isolated from voles and wild rodents in Russia.[8]

Host Occurrence

Domestic, wild, or feral pigs are the host for biotypes 1 and 3, and widespread infection in feral pigs is recorded in Queensland, Australia, and the southern states of the United States. Bison may remain reservoirs. Incursion to domestic pigs from wild boar is an increasing problem.

Cattle and horses may be infected, especially if they share a range with feral pigs, and this association adversely affects the status of cattle herds undergoing brucellosis eradication programs. Cattle are noncontagious hosts, but an outbreak in Switzerland where the disease had not appeared since 1946 has been attributed to a spread of infection from horses.

Biovar 1

Biovar 1 has been isolated from the semen of a ram. Infection in dogs, usually symptomless but occasionally producing orchitis or epididymitis, or granulomas can result from eating raw pig meat.

Biovar 2

In addition to the pig, the European hare (*Lepus capensis*) is also a major host for biovar 2, and this biovar is common in central Europe. Some studies have suggested that the type found in hares in Europe is a different strain from the wild boar.[9]

Biovar 4

Biovar 4 can transmit to cattle in contact with infected reindeer. Wild canids can also be naturally infected with biovar 4, presumably by ingestion.

Source of Infection

Infected boars can shed 10^4 to 10^7 colony-forming units (CFU) of *B. suis* per milliliter of semen. The bacterium is also shed in the milk.

The introduction of infected pigs, usually a boar or the communal use of an infected boar, is the common means of introduction of the bacterium into a pig unit. Artificial insemination using noncertified or untreated semen can also spread the disease as can ova. Transmission usually requires direct or close contact and is usually oral. Discharges in milk and uterine secretions are infectious. Sows may be carriers and piglets can spread the disease horizontally. It is thought that infection through the conjunctiva is also a possibility. It probably does not survive in the environment unless contained in organic matter under cold conditions. Within a piggery the disease is spread by ingestion and by coitus. The ingestion of food contaminated by infected semen and urine and discharges from infected sows are also important methods of spread. Dried secretions, if frozen, may remain infective. Most disinfectants and sunshine kill the virus.

The feeding of kitchen waste containing raw pig meat also presents a risk. Domestic herds are also at risk when they are kept under extensive husbandry methods in areas where there is a high prevalence of infection in feral pigs. Cattle infected with biovar 1 are noncontagious to other livestock and can have normal pregnancies and give birth to uninfected calves.

Wild animals, including hares and rats, may provide a source of infection with biovar 2, and ticks are also suspected of transmitting the disease.

Host and Pathogen Risk Factors

The fact that *B. suis* survives so well in raw meat, e.g., 128 days in sausage meat, means that prepared pork products are always a source of infection. They can survive freezing for over 2 years. Environments and pastures can be infected for a long period of time.

B. suis is more resistant to adverse environmental conditions than *B. abortus,* although its longevity outside the body has not been fully examined. It is known to survive in feces, urine, and water for 4 to 6 weeks. As the environmental temperature rises, the survival in the environment decreases. It is also deactivated by bright sunlight. It has also been known to survive desiccation.

Among pigs, susceptibility may vary with age. The prevalence of infection is much higher in adults than in young pigs, although this may represent an exposure risk rather than an age-related risk. Susceptibility is much greater in the postweaning periods and is the same for both sexes, but there may also be genetically determined differences in susceptibility. Some piglets acquire infection from the sow, either from the ingestion of infected milk or by congenital infection.

Lateral spread through a herd is rapid because of the conditions under which pigs are kept. No durable herd immunity develops and, although a stage of herd resistance is apparent after an acute outbreak, the herd is again susceptible within a short time and the bacteria can spread rapidly on entry to a herd. Within a few months 50% may be infected and 70% to 80% may be involved at the start of the outbreak. Further outbreaks may occur if infection is reintroduced.

In an enzootic area, the proportion of herds infected is usually high (30%–60%). The prevalence of seropositivity in an infected herd varies but can be as high as 66%. Seroprevalence in feral pigs is also high, is higher in adult pigs than pigs under 6 months of age, and varies between populations of feral pigs.

Economic Importance

The disease is economically important because of infertility and reduction in numbers of pigs weaned per litter. Mortality in live-born piglets, which occurs during the first month of life, may be as high as 80%. The mortality rate is negligible in mature animals, but sows and boars may have to be culled because of sterility, and occasionally pigs are culled because of posterior paralysis. In addition, eradication involves a great deal of financial loss if complete disposal of a registered herd is undertaken.

Zoonotic Implications

Biovar 2 is not a zoonosis, but biovars 1, 3 (as pathogenic as *B. melitensis*), and 4 have considerable significance for public health and are very pathogenic to humans. In countries where pigs are a significant part of animal farming and the human diet, *B. suis* is the major cause of human brucellosis (e.g., South America).[10,11]

B. suis presents an occupational hazard, particularly to abattoir workers, and to a lesser extent to farmers and veterinarians and hunters.[12] *B. abortus* and *B. melitensis* may also be found in pig carcasses and present similar hazards. *B. suis* can be widespread in the carcass of infected pigs, and undercooked meat can be a source of human infection. This is particularly true for wild boar and feral pig meat. A recent experiment described infection with biovar type 1 and its transmission to negative pigs after 4 to 6 weeks. Antibody was detected in blood samples from farmers and abattoir workers.

In infected cattle, *B. suis* localizes in the mammary gland without causing clinical abnormality and, where cattle and pigs are run together, the hazard to humans drinking unpasteurized milk may be significant. Biovar 4 causes human disease associated with consumption of caribou.

Human brucellosis at a pig slaughterhouse in Argentina has been described.[13] The median age of the slaughterhouse workers was 40 (23–65) and they had worked for 1 to 9 years in the slaughtering or butchery part of the plant. A systemic or localized disease with recurrent episodes was described. The chronic disease may be progressive. The patients' serum antibody titers (SAT) titers ranged from 1:25 to 1:12.800 and CFT from 1:10 to 1:1280. Of the pigs tested, 11% of the males (7/62) and 18% of the females (25/138) were positive. It is suggested that the swine keepers did not send infected animals for incineration but sent them to slaughter. Diagnoses are rarely made on farms that breed pigs. Such pigs arriving at packing plants have high levels of organisms but rarely have lesions and genital infections that may be a major source of infection. Protective clothing, such as gloves, protective clothing, eye protection, and protection of any bare skin, is essential.

PATHOGENESIS

Infection is followed by multiplication in the local lymph nodes. Only $10^{4\text{-}7}$ organisms will produce an experimental infection, but the severity of the infection is not correlated with either the dose or the route of infection. As for the other species, *B. suis* requires the *vir*B operon-encoded T455 for intracellular invasion and multiplication within host cells. The T455 mutants are not able to survive and multiply in macrophages or epithelial cells.

As in brucellosis associated with *B. abortus,* there is initial systemic invasion possibly through the M cells of the lymphoid tissue in the gut, but also possibly the oral, nasopharyngeal, conjunctival, or vaginal mucosa. There is generally a long period of incubation before clinical signs appear. In young animals these are not necessarily visible and will depend mainly on the age, sex, and physiologic state of the animals at the time they are infected. The organism then appears in the bloodstream, usually within 1 to 7 weeks, and often lasts for 5 weeks but can persist for up to 34 weeks. However, infection with *B. suis* differs from that associated with *B. abortus* in that localization occurs in several organs in addition to the uterus and udder, and the organism is found in all body tissues and produces a disease similar to undulant fever in humans. The organisms persist in lymph nodes, joints, bone marrow, and the genital tract. The more common manifestations of localization are abortion and infertility caused by localization in the uterus; lymphadenitis, especially of the cervical lymph nodes; arthritis and lameness caused by bone and joint localization; and posterior paralysis caused by osteomyelitis. In boars, involvement of the testicles

often leads to clinical orchitis, and the boars are probably infected for life. Widespread infection makes handling of the freshly killed carcass hazardous and creates a risk for brucellosis in humans eating improperly cooked pork.

CLINICAL FINDINGS

Do not forget that clinical signs in pigs may also be produced by *B. abortus* and *B. melitensis*. Porcine brucellosis is usually a more generalized and chronic disease than bovine brucellosis.[14]

The clinical findings in swine brucellosis vary widely, depending on the site of localization. The signs are not diagnostic, and in many herds a high incidence of reactors is observed with little clinical evidence of disease. Reproductive inefficiency is the common manifestation.

Sows

Infection at service usually results in early abortion, sometimes as early as 17 days after natural service with infected boars, with return to estrus at 5 to 8 weeks after service, which may be the only sign that infection has taken place.

Infertility, irregular estrus, small litters, and abortion occur. Later infection will give rise to mummification and stillbirths. The incidence of abortion varies widely between herds but is usually low and is usually early. Infection of the fetus may lead to abortion. As a rule, sows abort only once in a lifetime, and this is most common during the third month of pregnancy. Affected sows usually breed normally thereafter. Sows may remain carriers and may shed organisms in milk and uterine discharges, which may be extremely bloody and may be accompanied by endometritis and retained fetal membranes.

Boars

Orchitis with testicular swelling, epididymitis, and necrosis of one or both testicles is followed by sterility usually within 7 weeks of infection. Lameness, incoordination, and posterior paralysis are fairly common. The onset is gradual, and signs may be caused by arthritis or, more commonly, osteomyelitis of lumbar and sacral vertebral bodies. Testicular atrophy may result at around 19 weeks. Boars have a low rate of recovery (less than 50%). After infection, enough animals remain infected to perpetuate the disease.

In both sows and boars, the bones and joints may be involved, and in these cases there may be posterior paralysis and lameness. Nodules may be seen in the spleen and liver and abscesses may be seen in boars.

Piglets

A heavy mortality in piglets during the first month of life is sometimes encountered, but most piglet loss results from stillbirths and the death of weak piglets within a few hours of birth. Up to 10% may contract infection when they are young and retain the infection until adulthood.

CLINICAL PATHOLOGY

Culture

Laboratory identification of the disease is difficult. It should be routine to use more than one culture method.[15] Isolation of the organism should be attempted if suitable material is available. Such material for culture includes aborted fetuses, testicular lesions, abscesses, blood and lymph nodes (particularly the submandibular, gastrohepatic, and external iliac nodes).[16] The organism is a small, slender, aerobic gram-negative organism that produces 1- to 2-mm colonies on blood agar after 2 to 4 days. A new method of culture has been described for *B. suis* called LNIV-M.[17] Interestingly, in a study of wild boar the organism was isolated from 93% of males but only 61% of females.[18]

PCRs using the *omp* 2b gene or RT-PCR may be more reliable.[19] *B. suis* can be differentiated from the other species by PCR,[20-22] although it may be less successful than culture.[23]

A fingerprinting technique based on a PCR method for multilocus variable number tandem repeat analysis (MLVA) has been developed.[24]

There is no PCR test for differentiating the five biovars from each other.[25]

Serology

Antibodies are usually developed 6 to 8 weeks after infection. These tests are only useful on a herd basis. There is no satisfactory serologic test. Some animals remain seronegative to all tests. Recently indirect or competitive ELISAs have been developed and may be 98% and 100% specific.[26]

An ELISA compared with complement fixation was found to be just as sensitive and as specific a test for both pigs and hares for *B. suis* infections. A meat juice ELISA has also been shown to be a valuable method for testing both hares and wild boars. There is considerable individual variation in the antibody response of pigs following infection, and some may be culture positive but have negative or indefinite titers to the common tests. Pigs under 3 months of age have a poor antibody response to infection.

Serologic tests in common use include the rose Bengal plate agglutination test, Rivanol test, rose Bengal card test, complement fixation, agar gel immunodiffusion, and tube agglutination. The preferred test varies between countries but most use the rose Bengal plate or card test. *B. abortus* antigens are used for diagnosis because *B. suis* has the same surface LPS antigens. Estimates of the sensitivities of the complement fixation and tube agglutination tests range from 40% to 51%, and they range from 62% to 79% for the rose Bengal plate test. The immunodiffusion test has poorer sensitivity than the standard serologic tests. The sensitivity and specificity of all the tests have been shown to vary with the stage of infection in the experimental disease, and it has been recommended that more than one test should be used for diagnosis. A recent study showed a range of sensitivity from 84% to 100% with the CFT low at 84% and the serum agglutination test high at 100%. The sensitivities ranged from 79.7% to 100%, with the serum agglutination test low at 79.7% and iELISA and C-ELISA high at 100%. A recent validation of the polarization assay as a serologic test for the presumptive diagnosis of porcine brucellosis has shown promise. Tests have been reviewed,[26,27] and both authors say that the problem is cross-reaction with *Yersinia* O9.

NECROPSY FINDINGS

On necropsy, there may be arthritis, posterior paralysis, spondylitis, and abscess formation in both sexes. The lesions are usually granulomatous as a result of persistent cytokine release, and these may be in the liver, kidney, spleen, and reproductive tracts.

Many organs may be involved in chronic cases. Chronic metritis manifested by nodular, white, inflammatory thickening, 2 to 5 mm in diameter, and abscessation of the uterine wall is characteristic with or without hemorrhage and necrosis. Arthritis may be purulent, and necrosis of vertebral bodies in the lumbar region may be found in lame and paralyzed pigs. The clinical orchitis of boars is revealed as testicular enlargement or atrophy and testicular necrosis, often accompanied by lesions in the epididymis and seminal vesicles. Splenic enlargement and pronounced lymphadenopathy, caused by hyperplasia of mononuclear phagocytes, occur in some cases. Typical histologic changes consist of granulomatous inflammation with neutrophils, macrophages, and giant cells and hyperplasia of reticular tissues and foci of caseous necrosis in the liver, kidney, spleen, and reproductive tract.

DIAGNOSIS

Diagnosis is suggested by the clinical signs, the necropsy findings, clinical pathology, and epidemiologically by the presence of wild boar locally. None of the tests is capable of diagnosing disease in the individual animal. The real problem of diagnosis is the cross-reactions with *Y. enterocolitica* O:9 infection.[28] In a survey of slaughter pigs in the UK 10% were found to have *Y. enterocolitica* in their gut.[29] There are false positives caused by this organism in initial screenings as the antibody lasts 2 to 9 weeks following *Y. enterocolitica* infection. They can be eliminated by testing for cellular immunity by measuring the IFN-γ generation by leukocytes.

Internationally accepted tests for swine brucellosis include ELISAs, FPA, RBT, buffered plate agglutination test, and the CFT.

Samples for Confirmation of Diagnosis

- Bacteriology: *adults,* culture swab from joint, lymph nodes, spleen, uterus, epididymis, or other site of localization; *fetus,* lung, stomach content, placenta (has special growth requirements)
- Histology: formalin-fixed samples of above tissues (light microscopy)

Note the zoonotic potential of this organism when handling carcasses or submitting specimens.

DIFFERENTIAL DIAGNOSIS

The protean character of this disease makes it difficult to differentiate. Syndromes that need differentiation include:

- Abortion and infertility in sows
- Posterior paresis diseases of spinal cord
- Mortality in young pigs is also caused by many agents, and the important entities are listed in Chapter 19 in the section on Perinatal Disease—General Epidemiology.

TREATMENT

Treatment with a combination of streptomycin parenterally and sulfadiazine orally, or with tetracycline, is ineffective, although combinations of oxytetracycline, streptomycin, and possibly gentamicin have been used.[30] It is unlikely that treatment will ever be attempted on a commercial scale.

CONTROL

Vaccination

No suitable vaccine is available.[31] Strain 19 *B. abortus, B. abortus* "M" vaccine, living attenuated *B. suis* vaccines, and phenol and other extracts of *B. suis* are all ineffective. In a recent study, a natural rough mutant of *B. suis* that does not induce adverse clinical effects or tissue localization but does induce significant humoral and cellular immune responses after vaccination in swine has been observed.[32] The antibody responses to infection in any case are often not powerful enough to eliminate infection.

Test and Disposal

In herds where the incidence of reactors is high, complete disposal of all stock as they reach marketing age is by far the best procedure because of the difficulty in detecting individual infected animals. This is most practicable in commercial pork-producing herds. Restocking the farm should be delayed for 6 months after thorough disinfection is complete. The existing serologic tests can be used for certifying herds free of infection that can then provide replacement stock. Repopulation programs can also use specific pathogen-free pigs.

The alternative is to commence a two-herd segregation program, and this is recommended for purebred herds that supply pigs for breeding purposes. Total disposal is not usually economical in these herds. Once a herd diagnosis has been established, all the breeding animals must be considered to be infected; all piglets at weaning are submitted to the serum agglutination, Rivanol, or other test and, if negative, go into new quarters to start the nucleus of a free herd. It is probably safer to wean the pigs as young as possible and test again before mating. If complete protection is desired, these gilts should be allowed to farrow only in isolation, should then be retested, and their piglets used to start the clean herd. A modified scheme based on the previously mentioned method of weaning and isolating the young pigs as soon as possible but without submitting them to the serum agglutination test has been proposed, but its weakness is that infections may occur and persist in young pigs.

After eradication is completed, breakdowns are most likely to occur when infected animals are introduced. All introductions should be from accredited free herds, should be clinically healthy, and be negative to the serum agglutination test twice at intervals of 3 weeks before introduction.

Eradication of swine brucellosis from an area can only be achieved by developing a nucleus of accredited free herds and using these as a source of replacements for herds that eradicate by total disposal. Sale of pigs for breeding purposes from infected herds must be prevented.

With the advent of infection in wild boar and feral pigs, it is essential to maintain an effective separation from them when there are domestic pigs, and this is especially true where there are outdoor pig units. Recently contaminated wood has been shown to be a problem.[33]

BRUCELLOSIS ASSOCIATED WITH *BRUCELLA MELITENSIS*

SYNOPSIS

Etiology *Brucella melitensis.*

Epidemiology Disease of goats, sheep, humans, and occasionally cattle. Transmission congenital or by ingestion or contact with infected placenta, vaginal discharge, or milk.

Clinical findings Abortion storms, abortions often in last 2 months of pregnancy. Weak-born lambs. Important zoonotic disease in humans.

Clinical pathology Polymerase chain reaction (PCR) and culture of organism. Serologic tests and skin hypersensitivity testing for herd diagnosis.

Necropsy findings Placentitis.

Diagnostic confirmation Isolation of the organism, PCR.

Control Slaughter eradication. Vaccination with *B. melitensis* Rev. 1 vaccine, but this can cause abortion in pregnant animals.

ETIOLOGY

B. melitensis causes brucellosis in goats and sheep, is capable of infecting most domestic animal species, and is the primary cause of brucellosis of humans (Malta fever) in many countries. There are three biovars of the organism that have differing geographic distribution, but no difference in pathogenicity or animal species affected. There is a close relationship to other members of the genus, which currently has 10 species but is expanding with the advent of molecular typing.[1]

EPIDEMIOLOGY

Geographic Occurrence

The distribution of *B. melitensis* is more restricted than that of *B. abortus* and its primary area of occurrence is in the Mediterranean region, including southern Europe. Infection is also present in west and central Asia, Mexico, countries in Central and South America, and in Africa. Northern Europe is free of infection, except for periodic incursions from the south, as are Canada, the United States, southeast Asia, Australia, and New Zealand.

The prevalence of infection varies between countries and regions, but in many

countries the prevalence has declined in the past 20 years in association with mandatory vaccination policies. However, in many others it is not effectively controlled because of the low incomes or nomadic nature of those who farm small ruminants. Hence it is regarded as a neglected but very important disease of livestock and humans in developing countries.[2,3]

Host Occurrence

Goats and sheep are highly susceptible. Susceptibility in sheep varies with the breed, with Maltese sheep showing considerable resistance. The organism is capable of causing disease in cattle and has been isolated from buffalo, yaks, camels, and pigs.

Source of Infection

The source of infection is the infected carrier animal. Introduction to a naive herd or flock occurs with the introduction of an infected animal, and persistence results from sheep or goats that are prolonged excreters. Excretion is from the reproductive tract and in milk.

Reproductive Tract

Infected does and ewes, whether they abort or give birth normally, discharge many brucellas in their uterine exudates and placenta. The organism can be present in uterine discharge for at least 2 months following parturition in infected goats. The vaginal exudate of infected virgin or open animals may also contain the bacteria, but transmission between animals is most likely from the massive exposure provided by an infected placenta.

Milk

The majority of goats infected during pregnancy will excrete the organism in milk in the subsequent lactation and many will excrete it in all future lactations. In sheep, the period of excretion of the organism from the uterus and in milk is usually less than in goats, but the organism can be present in milk throughout lactation. The duration of excretion in cattle is not known.

Transmission

Routes of infection for both adults and young are via ingestion, by nasal or conjunctival infection, and through skin abrasions, with infected placenta and uterine discharge as a major source.

In Utero Infection

Infection of the fetus during pregnancy does not necessarily result in abortion: infected kids and lambs may be born alive but weak, or they may be quite viable. In some cases the infection persists in a latent form until sexual maturity, when pregnant animals may abort the first pregnancy. However, others, if weaned early from their dams and from the infected environment, become free from the infection as adults.

Colostrum and Milk

Latent infection can also be acquired from the ingestion of infected colostrum and milk. This is a major route of transmission and perpetuation of infection in a herd or flock.

Host and Pathogen Risk Factors

The organism is reasonably resistant to environmental influences and under suitable conditions can survive for over 1 year in the environment. *B. melitensis* is susceptible to disinfectants in common use at recommended concentrations.

In goats and sheep, the infection of a naive herd or flock will produce an abortion storm, following which most animals are infected but immune, and further abortions are usually limited to young or introduced animals. Because of the limited periods of excretion in sheep the disease tends to be self-limiting in small flocks that have few new introductions. It can be a continuing problem in large flocks because of massive environmental contamination of areas used for pregnant and lambing ewes. In some areas the prevalence of brucellosis associated with *B. melitensis* is linked to the practice of animal movement to summer and mountain pastures in which there is commingling of sheep and goats from a variety of sources on the same pasture.[3]

Spread in beef cattle is slow, presumably because they are usually farmed at lower stocking rates, whereas spread in dairy herds can be more rapid and extensive.

Economic Importance

Brucellosis has major veterinary and human importance in affected countries. Costs include production loss associated with infection in animals, the considerable cost of preventive programs, and human disease. There is further loss from restriction in international trade in animals and their products.

The occurrence of *B. melitensis* in the sheep and goat population of countries that have eradicated *B. abortus* poses a threat for the continuing occurrence of brucellosis in cattle herds.

Zoonotic Implications

B. melitensis is the most invasive and pathogenic for humans of the three classical species of the genus, and is the cause of Malta or Mediterranean fever in humans, which is an extremely debilitating disease. It is an important zoonosis in areas of the world in which *B. melitensis* is enzootic in goats and sheep. The disease in humans is severe and long-lasting and often occurs in communities with limited access to antimicrobial therapy. Control and eradication of the infection in animal populations has high priority in all countries.

Large numbers of organisms are excreted at and following parturition, providing a source of infection for humans managing the herd or flock and also for people in the immediate vicinity from aerosol infection with contaminated dust. The risk of infection is high in cultures that cohabit with their animals or when weak, infected newborn animals are brought into the house for warmth and intensive care. Milking of sheep and goats is usually manual, often with poor sanitation and milking-time hygiene. Raw milk and cheese products from infected goats, sheep, or cattle also provide a risk and were the mechanism for the occurrence of Malta fever that initiated the definition of the disease.

Abattoir workers, shearers, and people preparing goat and sheep skins are also at risk. The risk for veterinarians is primarily from assisting birthing in infected animals and herds, but is also the examination of any animal that is subclinically infected. There is also the risk of accidental self-inoculation with live vaccine.

Vaccination of small ruminants with *B. melitensis* Rev. 1 vaccine is a primary method in controlling the human disease. In Greece, a 15-year period of vaccination was associated with a drop in the incidence of human brucellosis, but when this program was stopped the prevalence of abortions in animals and the incidence if brucellosis in humans increased dramatically, only to be controlled by the reinstitution of vaccination of animals as an emergency mass vaccination program. However, although the Rev. 1 vaccine is attenuated compared with field strains, it retains some virulence and incorrect selection from the seed stock can result in vaccines with considerable virulence for both vaccinated animals and in-contact humans.

Because of its pathogenicity to humans and animals, *B. melitensis* is listed as an agent of bioterrorism and agroterrorism. It is thought that fewer than 10 CFU are capable of infecting humans via aerosols. This would require mass therapy of human populations and destruction of animal populations.

PATHOGENESIS

The organism is a facultative intracellular parasite. As in other forms of brucellosis, the pathogenesis depends on localization in lymph nodes, udder, and uterus after an initial bacteremia. In goats, this bacteremia may be sufficiently severe to produce a systemic reaction, and blood culture may remain positive for a month. Localization in the placenta leads to the development of placentitis, with subsequent abortion. After abortion, uterine infection persists for up to 5 months, and the mammary gland and associated lymph nodes may remain infected for years. Spontaneous recovery may occur, particularly in goats that become infected when they are not pregnant. In sheep, the development of the disease is very similar to that in goats. In cattle, *B. melitensis* has a similar pathogenesis and produces a persistent

infection in the mammary gland and the supramammary lymph node, with obvious significance for public health.

CLINICAL FINDINGS

Abortion during late pregnancy is the most obvious sign in goats and sheep, but as in other species there may be a storm of abortions when the disease is introduced, followed by a period of flock resistance during which abortions do not occur. Abortion is most common in the last 2 months of pregnancy. The excretion of the organism in milk is not accompanied by obvious signs of mastitis. Infection in males may be followed by orchitis, which is frequently unilateral.

In experimental infections, a systemic reaction occurs with fever, depression, loss of weight, and sometimes diarrhea. These signs may also occur in acute, natural outbreaks in goats and may be accompanied by mastitis, lameness, and hygroma; however, they are uncommon in the natural disease and their occurrence in the experimental disease reflects a massive challenge dose. Osteoarthritis, synovitis, and nervous signs may occur in sheep.

In pigs, the disease is indistinguishable clinically from brucellosis associated with *B. suis.*

In many instances, *B. melitensis* infection reaches a high incidence in a group of animals without signs of obvious illness, and its presence may be first indicated by the occurrence of disease in humans infected from the herd or flock. This is so in cattle where the infection is subclinical and does not produce abortion, but the organism is shed in milk.

CLINICAL PATHOLOGY

Culture and Molecular Tests

Positive blood culture soon after the infection occurs and isolation of the organism from the aborted fetus, vaginal mucus, or milk are the common laboratory procedures used in diagnosis. The organism is moderately acid fast, and staining smears from the placenta and fetus with a modified Ziehl–Neelsen method may give a tentative diagnosis; however, this does not distinguish this infection from *B. ovis* or the agent of enzootic abortion (*Chlamydia abortus*), and culture is required.

The organism can be detected by PCR in the abomasal fluid of aborted fetuses and, compared with culture, PCR has a sensitivity and specificity of 97.4% and 100%, respectively. PCR can also be used to detect the organism in tissues, semen, and milk. A real time RT-PCR has been used to type Brucella from field samples, such as ovine placenta, without the need for culture.[4]

Multilocus variable-number tandem repeats analysis (MVLA) is an alternative to classical biotyping and may be useful in analyzing the epidemiology and source of outbreaks. For example, in 2011 a strain of *B. melitensis* in a single infected flock in Sardinia, a region of Italy free from this disease since 1998, was confirmed as being a rare America lineage and probably originating from Spain.[5] Multiplex PCR and high-resolution melt point analysis has also been used to differentiate *Brucella* spp.

Serology

The conventional serologic tests for the diagnosis of *B. melitensis*—agglutination, CFT, and the rose Bengal or card test—use the same antigens that are used for the diagnosis of *B. abortus* infections (either whole cells or sLPS).

The RBT and CFT are the most widely used. These, plus iELISA and FPA are prescribed tests for international trade.[6] The RBT is not 100% specific, but is typically used as a screening test with the CFT applied in series or parallel. RBT or CFT is not sufficiently sensitive to accurately detect infection in an individual animal. Nevertheless, they can be used to detect infected herds for slaughter eradication of the disease. They can be used for test and slaughter programs within an infected herd, but their reduced sensitivity makes this strategy less effective in sheep and goats compared with cattle. A combination of these tests and tests performed on several occasions may increase the accuracy of detection of infected animals. If only one test is possible, the CFT is recommended, but it suffers from the requirement for a sophisticated laboratory, which is not always available in affected areas.

Conventional serologic tests will not differentiate infection with different species of *Brucella* and will not differentiate infection associated with *Y. enterocolitica* type O:9.

Several ELISA tests have been evaluated for use in small ruminants, some using recombinant antigens such as Omp31 and others using whole-cell antigens. These include indirect, competitive, and blocking ELISAs. A C-ELISA had a diagnostic sensitivity ranging from 74% to 89%, depending on cutoff values, and a specificity from 93% to 97%.[7] Comparisons of the FPA and commercial ELISA tests with the RBT and CFT have shown no great advantages over the older tests, with the iELISA often having a slightly greater sensitivity. Overall testing sensitivity may be improved if these tests are used in parallel.[7,8]

Brucella-free animals are serologically positive for long periods following vaccination with *B. melitensis* Rev. 1, with varying persistence in different serologic tests. The period of seropositivity is shorter in animals vaccinated conjunctivally.

Milk Tests

The milk ring test used for testing pooled (bulk) milk in cattle is not useful in small ruminants. Other tests include whey CFTs, whey Coombs or antiglobulin test, whey agglutination tests, and a milk ELISA. They have no apparent advantage over serologic tests, and in many cases they are less sensitive, hence, they are not suitable as screening tests using pooled milk samples.

Allergic Tests

An intradermal allergic test using 50 mg of brucellin INRA (purified and free from LPS) can be used for diagnosis. The injection sites in goats are the neck or caudal fold and in sheep the lower eyelid, with reactions read in 48 hours. The test has high specificity in flocks that are free of infection and not vaccinated. However, it has little advantage over conventional serologic tests in infected herds, and Rev.-1–vaccinated animals can react for at least 2 years. It has particular value in identifying some animals that are false-positive reactors, differentiating infections with *Y. enterocolitica* but not *B. ovis.* Anergy occurs between 6 and 24 days after injection.

NECROPSY FINDINGS

There are no lesions that are characteristic of this form of brucellosis. The causative organism can often be isolated from all tissues but the spleen, lymph nodes, and udder are the most common sites for attempted isolation in chronic infection.

Samples for Confirmation of Diagnosis

- Bacteriology: *adults,* spleen, lymph node, udder, testicle, epididymis; *fetus,* lung, spleen, placenta (culture: has special growth requirements; cytology: Stamp's or Koster's stain on placental smear; PCR); *fetus,* PCR of fetal abomasal fluid
- Histology: formalin-fixed samples of the previously listed tissues

The zoonotic potential of this organism means care needs to be taken when handling potentially infected material, and specimens should be properly packaged when submitted to a laboratory.

DIFFERENTIAL DIAGNOSIS

The primary differential is from other forms of brucellosis (seen in this chapter) and other causes of abortion in small ruminants.

TREATMENT

Treatment is unlikely to be undertaken in most animals because it is unlikely to be economically feasible or therapeutically effective. For example, a dose of 1000 mg per animal of long-acting tetracycline given every 3 days for 6 weeks achieved a cure rate of 75%.

CONTROL

Hygiene

Control measures must include hygiene at kidding or lambing and the disposal of infected or reactor animals. Separate pens for kidding does that can be cleaned and

disinfected, early weaning of kids from their does and their environment, and vaccination are recommended. In endemic areas, all placentas and dead fetuses should be routinely buried.

Eradication

Where a group is infected for the first time it may be most economical to dispose of the entire herd or flock, because eradication by test and slaughter is prolonged by the lack of sensitivity of the serologic tests.

Many countries that have this disease have statutory control measures and the disease can be eradicated, such as from Cyprus. *B. melitensis* also can be eradicated, with difficulty, from dairy cattle. However, vaccination may be the only practical method of control in areas in which there is a high prevalence of the disease, extensive management systems, communal and nomadic grazing, and a low socioeconomic level.

Rev. 1 Vaccination

Rev. 1 vaccine is a live, attenuated *B. melitensis* strain derived from a virulent *B. melitensis* isolate that is resistant to dihydrostreptomycin. It is the reference vaccine strain that provides protection against infection with *B. melitensis* in sheep and goats and against infection with *B. ovis* in rams. However, this vaccine has significant disadvantages, including persistent serologic response and, although attenuated compared with field strains, it retains some virulence. Incorrect selection from the seed stock can result in vaccines with considerable virulence for both vaccinated animals and in-contact humans.

Vaccination with Rev. 1 produces a bacteremia that is cleared by 14 weeks in goats and a shorter time in sheep. Vaccination at 3 to 8 months of age confers a high degree of immunity that lasts for more than 4 years in goats and 2½ years in sheep. The initial recommendations were to vaccinate replacement animals with the expectation that herd/flock immunity would develop over time. However, this has proved ineffective in some regions, and whole-flock/herd vaccination is now recommended in certain countries.

Vaccination of pregnant goats and sheep, especially in the second and third month of pregnancy, will result in abortion and the excretion of the living *B. melitensis* vaccine organism in the vaginal discharge and the milk. Consequently, the vaccine should not be used in pregnant animals or for 1 month before breeding. Vaccination of lactating animals may be followed by excretion of the organism in the milk for a short time. Reduced dose vaccination or conjunctival vaccination does not significantly reduce the risk of vaccine-induced abortions in pregnant animals, although reduced-dose Rev. 1 vaccination has been shown to provide protection for at least 5 years in endemically infected areas.

Conjunctival vaccination does decrease the period of seropositivity following vaccination. Vaccine efficacy and safety can vary with the manufacturer. National policies promoting widespread vaccination of sheep and goats with Rev. 1 vaccine have resulted in a significant reduction in the prevalence of small ruminant brucellosis and in the incidence rates of human brucellosis. However, Rev. 1 vaccine is also pathogenic to humans and its excretion, and persistence in milk following vaccination can result in human infection.

The general approach in endemically infected countries is to institute a whole-flock vaccination scheme followed by a young-stock vaccination until the prevalence of the disease is reduced, at which time test and slaughter can be implemented to eradicate the disease. This ignores the risk of adverse disease in the vaccinated animals and the risk for human infection from the vaccine strain. There is an urgent need for a nonvirulent vaccine that induces seropositivity that can be differentiated from the seropositivity resulting from natural infection.

Other Vaccines

To circumvent the problem of persistent serologic response, ongoing efforts have been made to develop defined rough mutant vaccine strains that would be more effective against *B. melitensis*. Various studies have examined cell-free native and recombinant proteins as candidate protective antigens, with or without adjuvants. However, limited success has been obtained in experimental models with these, or with DNA vaccines encoding known protective antigens.[9]

B. abortus strain 19 has been used for vaccination and appears to give protection that is as good as that achieved with the attenuated *B. melitensis* vaccine.

ABORTION IN EWES ASSOCIATED WITH *SALMONELLA ABORTUSOVIS*

Salmonella abortusovis (*S. enterica* serovar Abortusovis) is a gram-negative rod-shaped aerobic bacterium of the family Enterobacteriaceae. The pathogen is highly adapted to sheep and is considered to be host specific for this species in which it can cause abortion. *S.* Abortusovis infection has a worldwide occurrence with a generally low prevalence. The infection appears to be more common in some European and Western Asian countries.

Transmission and spread of the infection occurs through infected animals that are introduced to flocks naive to the pathogen. The reservoir of infection is infected animals that do not abort. The organisms persist in internal organs of the **asymptomatic carriers** for up to 6 months and are excreted in the feces and vaginal mucus for periods up to 4 months. Infection can occur through the oral, conjunctival, or respiratory route, but oral ingestion is thought to be the main mode of infection. Venereal spread has been postulated, and rams certainly become infected, but all the evidence is against spread at coitus. Intrapreputial inoculation results in infection of rams and the passage of infected semen for up to 15 days.

The only significant clinical sign of *S.* Abortusovis infection is abortion, which is common during the second half to last third of gestation. Lambs may also be stillborn or die within the first day of life. Mortality in lambs is common from either weakness and ensuing hypothermia and hypoglycemia or to the development of acute pneumonia in previously healthy lambs up to 2 weeks old.

In flocks naive to the infection, introduction of the pathogen can cause abortion storms, with up to 60% of ewes aborting generally in the last trimester of gestation. Ewes rarely develop clinical signs, although some may transiently have a fever or develop postabortive endometritis with vaginal discharge. Septic metritis and peritonitis in dams has been associated with deaths among ewes. Spread of the disease is strongly associated with the presence of aborting ewes and subsequent heavy environmental contamination. In flocks where the pathogen is endemic, abortion occurs sporadically, mainly affecting primiparous and newly introduced ewes. The infection appears to induce a strong immune response preventing abortion during the following pregnancies.[1]

Identification of the disease depends on isolation of the organism, which is present in large numbers in the fetus, placenta, and uterine discharges. Use of PCR to identify *S.* Abortusovis is feasible because the organism has an IS200 element in a distinct chromosomal location. The resulting PCR assay has high specificity for *S.* Abortusovis, effectively

discriminating it from other *S. enterica* serovars. The disease can be diagnosed in fetuses by using a coagulation test on fetal stomach contents. The test had a sensitivity and specificity of 100% and 90% in a small number of samples.

Serologic tests to detect antibody to *S. abortusovis* include the SAT, hemagglutination inhibition, complement fixation, indirect immunofluorescence, gel immunodiffusion, and ELISA.

A strong immunity develops after an attack, and an autogenous vaccine has shown good results in the control of the disease.[1] The results of vaccination need to be very carefully appraised because flock immunity develops readily and the disease tends to subside naturally in the second year.

The clinical findings in *S.* Dublin infections in ewes are very similar, and infection has become more important as a cause of abortion in ewes in the UK than *S.* Abortusovis. *S.* Ruiru has also been recorded as a cause of abortion in ewes, and ewes with salmonellosis associated with *S. typhimurium* may also lose their lambs. *S.* Brandenburg is a cause of illness and abortion in sheep, horses, calves, goats, and humans in New Zealand. Other **differential diagnoses** for abortion in ewes include chlamydiosis, brucellosis, campylobacteriosis, listeriosis, coxiellosis (Q-fever), and toxoplasmosis.

The administration of broad-spectrum antibiotics might aid in controlling an outbreak, but available reports are not generally encouraging. Chloramphenicol and the trimethoprim and sulfadiazine combination are considered effective for treatment, but use of chloramphenicol in animals intended for human food production is not permitted in many countries. A live *S. typhimurium* vaccine with optimal level of attenuation for sheep constructed by means of "metabolic drift" mutations was highly effective in preventing *S.* Abortusovis–induced abortions under field trial conditions. Subcutaneous and conjunctival vaccination with a live attenuated strain of *S.* Abortusovis confers immunity for at least three lambing periods. More recent vaccines, including those containing plasmid-cured strains of *S.* Abortusovis, are effective in preventing pregnancy loss in response to experimental challenge with wild-type *S.* Abortusovis.

To contain the spread of the infection during an outbreak aborted ewes should be isolated and abortion products that contain large amounts of bacteria must be destroyed. Disinfection of stalls and fomites with an agent with proven efficacy against *Salmonella* spp. is important.

ABORTION IN MARES AND SEPTICEMIA IN FOALS ASSOCIATED WITH *SALMONELLA ABORTUSEQUI* (*ABORTIVOEQUINA*) (EQUINE PARATYPHOID)

This is a specific disease of Equidae characterized by abortion in females, testicular lesions in males, and septicemia in the newborn.

ETIOLOGY

Salmonella abortusequi (*abortivoequina*) (also known as *Salmonella enterica* serovar Abortusequi) is a host-adapted serovar causing abortion in mares and donkeys. *S.* Abortusequi strains vary in virulence, with more virulent strains having greater in vitro cytotoxigenicity. It is possible to determine the origin and progression of outbreaks of the disease by determining pulsed-field gel electrophoretic patterns of *S.* Abortusequi.

EPIDEMIOLOGY

The infection appears to be limited to horses and donkeys. Although widely reported in the early 1900s, this disease is rarely encountered and is one of the less common causes of either abortion or septicemia in horses. Recent reports of the disease are from Austria, Brazil, Croatia, Japan, and India, although the disease occurs in other countries. However, in the early 1990s, an outbreak of abortion occurred in a herd of 38 horses, in which 21 mares aborted between 5 and 10 months of gestation.

Natural infection may be caused by the ingestion of foodstuffs contaminated by uterine discharges from carriers or mares that have recently aborted. Transmission from the stallion at the time of service is also thought to occur. The infection may persist in the uterus and cause repeated abortion or infection of subsequent foals. Transmission from a female donkey to mares is reported with abortion a result in both species.

PATHOGENESIS

When infection occurs by ingestion, a transient bacteremia without marked systemic signs is followed by localization in the placenta, resulting in placentitis and abortion. Foals that are carried to term probably become infected in utero or soon after birth by ingestion from the contaminated teat surface or through the umbilicus.

CLINICAL FINDINGS

Abortion usually occurs at about the seventh or eighth month of pregnancy. The mare can show signs of impending abortion followed by difficult parturition, but other evidence of illness is usually lacking. Retention of the placenta and metritis are common sequels and may cause serious illness, but subsequent sterility is unusual. A foal that is carried to term by an infected mare may develop an acute septicemia during the first few days of life or survive to develop polyarthritis 7 to 14 days later. Polyarthritis has also been observed in foals from vaccinated mares that showed no signs of the disease.

Infection in the stallion has also been reported with clinical signs including fever, edematous swelling of the prepuce and scrotum, and arthritis. Hydrocele, epididymitis, and inflammation of the tunica vaginalis are followed by orchitis and testicular atrophy.

CLINICAL PATHOLOGY

The organism can be isolated from the placenta, the uterine discharge, the aborted foal, and the joints of foals with polyarthritis. A high titer of *Salmonella* agglutinins in the mare develops about 2 weeks after abortion. Vaccinated mares will give a positive reaction for up to a year.

NECROPSY FINDINGS

The placenta of the aborted foal is edematous and hemorrhagic and may have areas of necrosis. The nonspecific changes of acute septicemia will be manifested in foals dying soon after birth; polyarthritis is found in those dying at a later stage.

Samples for Confirmation of Diagnosis

- Bacteriology: placenta, fetal stomach content, lung, culture swabs of joints (culture)
- Histology: formalin-fixed placenta, various fetal tissues including lung, liver (light microscopy)

TREATMENT

The antimicrobials recommended in the treatment of salmonellosis should also be effective in this disease.

CONTROL

Careful hygiene, including isolation of infected mares and disposal of aborted material, should be practiced to avoid spread of the infection. Infected stallions should not be used for breeding. In the past, when this disease was much more common than it is now, great reliance was placed on vaccination as a control measure. An autogenous or commercial bacterin, composed of killed *S.* Abortusequi organisms, was injected on three occasions at weekly intervals into all mares on farms in which the disease was enzootic, commencing 2 to 3 months after the close of the breeding season. A smaller dose (5 mL) of vaccine of higher concentration is as effective as a larger dose (20 mL) of vaccine of lower concentration. A formol-killed, alum-precipitated vaccine is considered to be superior to a heat-killed, phenolized vaccine. In China, a virulent strain vaccine is credited with effective protection after two injections 6 months apart.

The widespread use of vaccines and hyperimmune sera is credited with the almost complete eradication of the disease in developed countries.

CHLAMYDIAL ABORTION (ENZOOTIC ABORTION OF EWES, OVINE ENZOOTIC ABORTION)

SYNOPSIS

Etiology *Chlamydia abortus.*

Epidemiology Prevalence varies within regions and between countries. Oral route of infection, with the placenta and uterine discharge of aborting ewes the major source of infection. Pregnant sheep infected by contact with aborting ewes usually do not abort until the next lambing season. Zoonotic.

Clinical findings Abortion, stillborn and weak-born lambs.

Necropsy findings Necrotic and hemorrhagic placental cotyledons, intercotyledonary areas thickened, edematous, and leathery.

Diagnostic confirmation Demonstration of the organism in the placenta by polymerase chain reaction, rising titer in paired serum samples.

Control Isolation of aborting ewes. Killed vaccine with adjuvant gives short-term protection and can be used in pregnant ewes during an outbreak in an attempt to reduce the number of abortions. Live attenuated vaccines may be more effective but cannot be used during pregnancy.

ETIOLOGY

Chlamydia abortus (previously known as *Chlamydophila abortus* and *Chlamydia psittaci* biotype 1/serotype 1) has a tropism for ruminant placenta and causes the disease commonly referred to as ovine enzootic abortion (OEA). The organism causes a similar disease in goats, and although this organism also can produce abortion in cattle, pigs, and horses, abortion associated with this organism is not common in these species. There is considerable genetic diversity among strains that cause abortion.

EPIDEMIOLOGY

Occurrence

The disease is one of the most common causes of diagnosed abortion in sheep and goats in the UK, Europe, Asia, the United States, and other countries. In the UK, it accounts for approximately 45% of abortions, and it is particularly common in lowland flocks that are intensively managed at lambing. However, its importance varies from country to country. It is an uncommon cause of abortion in Northern Ireland, and the disease does not occur in Norway, Australia, or New Zealand.

There have been several studies of seroprevalence in Europe that show a high seroprevalence in both domestic and wild ruminants but, until recently, most surveys have used the complement fixation test (CFT), which is not specific for *C. abortus;* therefore, the true seroprevalence of *C. abortus* in many countries is not well established.

Source of Infection and Transmission

Infection is introduced into a flock by the purchase of latently infected replacements that usually abort at the end of their first pregnancy. Within a flock, the major source of infection is the placenta and the uterine discharge of aborting ewes. The main routes of transmission of *C. abortus* are oral or nasal: either ingestion of organisms shed in vaginal fluids and placental membranes at the time of abortion or lambing, or the inhalation of aerosols from contaminated areas. Pasture and the environment are contaminated by vaginal discharges, placenta, and aborted fetuses, and infected ewes shed the organism for a week before aborting and 2 weeks afterward. The elementary body of *C. abortus* is resistant to both physical and chemical influences, because it is metabolically inactive and the rigid cell envelope is osmotically stable and poorly permeable. Consequently, the organism is thought to survive for several days on pasture and longer in cold weather.

Infection of the ewe lamb may occur at birth, shortly following, or at subsequent lambing periods. Infection of pregnant ewes in early or midgestation results in either abortion in the final 2 to 3 weeks of gestation or the birth of stillborn or weak lambs that frequently die in the first few days of their life. Abortion always appears in the last weeks of gestation regardless of the time of infection. Infection of ewes in the last 5 to 6 weeks of pregnancy usually leads to the development of a latent infection, in which ewes appear to be uninfected until the next lambing season, when they abort. Thus late pregnant sheep may be infected by contact with aborting ewes, but usually do not abort until the next lambing season.

The common pattern of infection and disease is the small number of abortions in year 1 following the introduction of infected replacement ewes and then an epidemic abortion storm, in which up to 35% of ewes abort in the last 3 weeks of gestation or give premature birth to weak or dead lambs. After aborting, ewes develop a protective immunity and, in endemically infected flocks, 5% to 10% of the ewes abort annually. Surviving lambs born to infected mothers may be affected by enzootic abortion in ewes (EAE) in their first pregnancy.

Sheep that have aborted, subsequently rebreed successfully, do not have further abortions, and the organism is not present in the placenta or vaginal discharge of subsequent pregnancies. However, levels of immunity vary and some may excrete organisms at estrus or seasonally for up to 3 years.

In chronically infected sheep, persistent infection can be demonstrated in the endometrial cells of the reproductive tract, and the organism is excreted in vaginal fluids during estrus.

Vaginal challenge of ewes at breeding time will result in infection and subsequent abortion. Thus venereal or passive venereal transmission is a possible route of infection but is not common. Chronic infection of the male genital tissues has been recorded, and infection may impair fertility in both rams and bulls.

The epidemiology of abortion with this agent in cattle is unknown, but it may transmit to cattle from infected sheep on the same farm.

Experimental Reproduction

The disease is readily reproduced experimentally. Following subcutaneous injection there are no signs of clinical disease other than a modest increase in rectal temperature for 2 days after infection. There is a systemic antibody response that peaks 2 weeks after infection and then decreases until just before abortion or parturition, during which there is a second increase in antibodies to *C. abortus.* Experimental infection at 70 to 75 days pregnancy can cause abortion in the last 2 to 3 weeks of pregnancy or the birth of stillborn or live lambs. There is variation in the severity of the placental lesions in experimental infections. Abortion is associated with severe placental lesions, but the reason for the variation in severity and fetal manifestations is not known.

Economic Importance

In the UK, enzootic abortion is the most common infectious cause of abortion in lowland flocks that are intensively managed at lambing time and has a major economic impact on agricultural industries worldwide. There are no recent estimates, but losses in the UK were estimated in the early 1990s at £15 to £20 million per annum.

Zoonotic Implications

There is some risk for people working with livestock, such as shepherds and abattoir workers, for respiratory infection with this organism. However, the major zoonotic risk is to pregnant women because of the ability of *C. abortus* to colonize the human placenta. Human infection in early pregnancy results in abortion, whereas later infection can result in stillbirth or preterm labor. Infection is probably oral, from infected hands or food following handling of infected sheep or goats, or contaminated fomites such as clothing. Practices at lambing, such as mouth to mouth resuscitation of weak lambs or bringing weak lambs into the house to be warmed, promote zoonotic spread. Consequently,

infected placentas and dead lambs should be handled using gloved hands and disposed of by burning or burial. The organism can be detected in the milk of both sheep and cattle, so consuming raw milk also poses a risk for zoonotic infection.

PATHOGENESIS

Following infection, it is thought that the organism resides first in the tonsil and is then disseminated by blood and lymph to other organs, although the site of latent infection is not definitely known. Release from the latent state during pregnancy is thought to be caused by immune modulation and leads to bacteremia and infection of the placenta. Despite being a key feature of infection with *C. abortus,* little is understood about the underlying mechanisms that result in latent infections. However, experimental intranasal infection of nonpregnant ewes with a low or moderate dose of organisms induced latent infection and subsequent abortion, whereas a higher dose stimulated protective immunity.[1]

The organisms invade the trophoblast cells of the fetal cotyledon then spread to the intercotyledonary regions of the chorion, producing a necrotic suppurative placentitis and impairment of the maternal–fetal exchange of nutrients and oxygen, hence, fetal death and abortion. An inflammatory response in the fetus may also contribute to fetal death.

It is not known why, regardless of the time of infection, pathologic changes in the placenta do not commence before 90 days' gestation, or even as late as 120 days, although this coincides with the commencement of rapid fetal growth.

CLINICAL FINDINGS

There are generally no premonitory indications of the impending abortions, which occur in late pregnancy. Ewes suffer no obvious systemic effects, but retained placenta and metritis can occur in goats. A vaginal discharge, lasting up to 3 weeks following the abortion, is common. Additional losses are caused by stillbirths and weak-born lambs and kids that die soon after birth.

In cattle, the infection causes abortion in the last third of pregnancy. Infected calves born alive may show lethargy, depression, and may be stunted. Mixed infections with *C. abortus, C. suis* and Chlamydia-like organisms (*Parachlamydia* and *Waddlia* spp.) are recorded in cattle and associated with abortions featuring necrotic placentitis, but the true prevalence and significance of these infections is not clear.[2,3]

CLINICAL PATHOLOGY

If the flock history and placental lesions suggest OEA, smears from affected and adjacent chorionic villi of the placenta can be appropriately stained (e.g., Giemsa or modified Ziehl–Neelsen) and examined under high magnification. Single or clumps of small, coccoid elementary bodies (300 nm) will stain red compared with blue cellular debris. Vaginal swabs from recently aborted ewes and smears of the fleece of uncleaned lambs or fetal abomasal contents can also be examined but contain fewer organisms. The organisms appear similar to *Coxiella burnetii,* the agent of coxiellosis (Q fever), so this is not a definitive test.

Commercial antigen detection kits (fluorescent antibody test [FAT] and ELISA) are available but do not discriminate between Chlamydial species.

Chlamydial DNA can be amplified by conventional or real time RT-PCR. These are highly sensitive, but can result in false positives if samples are cross-contaminated or false negatives if samples contain PCR-inhibitory substances. RT-PCR is rapid and relatively easily standardized and can demonstrate the DNA of *C. abortus* in tissues and swabs, such as of vaginal fluid, conjunctivae, and fetal membranes.[4,5] A number of multiplex PCR tests are described and can differentiate between Chlamydial species and other agents of infectious abortion, such as *Toxoplasma gondii* and *C. burnetii.*[6]

C. abortus can be isolated in embryonated chicken eggs or cell culture, but most diagnostic laboratories do not do this because of the zoonotic risk and requirement for level 2 biocontainment.

Infection in aborting animals can be demonstrated by rising serologic titers in paired serum samples collected 3 weeks apart. The CFT is commonly used but has only moderate sensitivity and is not specific because of common antigens shared with other Chlamydiae and some gram-negative bacteria. It will also be positive in vaccinated animals. Ambiguous results, such as suspected false-positive tests in flock accreditation programs or export testing, can be analyzed further by a Western blot using specific antigens.

A number of research and commercial ELISA tests have been developed. Those based on whole-cell or extracts of chlamydial elementary bodies have better specificity than the CFT but are less sensitive. Those based on segments of the outer membrane protein (OMP) or synthetic peptide antigens have greater sensitivity and specificity and are now more frequently used in diagnostic, epidemiologic, and seroprevalence studies.[7]

Vaccinated animals will react to the currently used serologic tests, but wild-type and vaccine strains of *C. abortus* can be differentiated by PCR-restriction fragment length polymorphism (RFLP).[8] This has provided evidence that the temperature sensitive mutant strain 1B used in vaccines is associated with ovine abortions in Scotland.[9,10]

NECROPSY FINDINGS

Aborted fetuses typically have no gross abnormalities. Fetal fluid may contain chlamydial antibody and, although less sensitive than either isolation in McCoy cells or detection of chlamydial LPS antigen, can be useful when placenta is not available**.** Histologically, there may be mononuclear cell infiltration of hepatic portal areas and multifocal areas of hepatitis. The placenta is critical for diagnosis of chlamydial abortion in both cattle and sheep.

Placental cotyledons are necrotic and hemorrhagic, and the intercotyledonary areas are thickened, edematous, and leathery. This is in direct contrast to the targeting of cotyledons seen with toxoplasmosis. Chlamydial organisms can be seen in tightly packed sheets within the cytoplasm of swollen trophoblasts in formalin-fixed tissues or in direct placental smears using modified Gimenez, Koster's, or other appropriate stains. Well-preserved, fresh placenta should be examined because the organisms are difficult to demonstrate in the fetus. Immunohistochemical stains perform well on formalin-fixed specimens. Most laboratories are reluctant to culture *Chlamydia* spp. because of their zoonotic potential.

Samples for Confirmation of Diagnosis

- **Bacteriology:** chilled liver, lung, placenta (cytology, PCR, ELISA)
- **Histology:** fixed placenta, liver (light microscopy, IHC)

The zoonotic potential of this organism means care needs to be taken when handling potentially infected material, and specimens should be properly packaged when submitted to a laboratory.

DIFFERENTIAL DIAGNOSIS

Other causes of abortion in cattle and ewes are given in Tables 18-1 and 18-2.

CONTROL

Ewes that have aborted should be isolated from the rest of the flock. There should be proper hygiene of the lambing areas, including disposal of bedding and aborted materials, and disinfection of pens with intensive lambing systems. Long-acting oxy tetracycline has been used at 20 mg/kg IM in early pregnant sheep within an aborting flock to reduce subsequent abortions. However, treated ewes still shed the organism in vaginal discharges, and treatment at 10-day intervals may be needed.

Vaccines

Killed and live attenuated vaccines are available, but none are fully protective. **Killed vaccines**, composed of egg-derived or tissue culture organisms of one or two strains have been used for several decades. They are variably effective, but can reduce the frequency of abortion and shedding of the organism. However, outbreaks have occurred in vaccinated sheep, with strain variation a possible

Table 18-2 Diagnostic summary of causes of abortion in cattle

				Field examination		Laboratory diagnosis	
Epidemiology disease	*Clinical features*	*Abortion rate*	*Time of abortion*	*Placenta*	*Fetus*	*Isolation of agent*	*Serology*
Brucellosis (*Brucella abortus*)	Zoonotic disease, chronic infection, abortion, retained placenta, and metritis	High, up to 90% in susceptible herds	5 months +	Severe placentitis, thickened placenta with surface exudate	Possibly pneumonia	Culture of fetal stomach, placenta, uterine fluid, milk, and semen	Serum and blood agglutination test, milk ring test, whole milk plate agglutination test; whey plate agglutination, semen plasma, and vaginal mucous agglutination test
Trichomoniasis (Trichomonas *foetus*)	Venereally transmitted disease resulting in early embryonic loss with occasional abortion and pyometra	Moderate, 5%–30%	Primarily first 5 months	Flocculent material and clear, serous fluid in uterine exudate	Usually no gross lesions, histologically fetal giant cell pneumonia may occur	Hanging drop or culture examination of fetal stomach and uterine exudate within 24 hours of abortion; isolation, best source in female pyometra fluid if pyometra exists; best method is InPouch; in male bull's preputial smegma with InPouch	Cervical mucous agglutination test; serology rarely performed, mucus agglutination or complement fixation hemolytic assay
Neosporosis (*Neospora caninum*)	Worldwide distribution of infection in both dairy and beef cattle, most abortions reported in dairy cattle In addition to abortion, mummification and birth of full-term infected calves can occur with or without clinical signs Chronic infection in which congenital transmission commonly occurs during pregnancy, acquired postnatal infection may also occur	Sporadic or outbreaks common (20%–40%) Repeat abortions from same cows can occur	3–8 months of gestation (mean 5.5 months)	No characteristic gross lesions in placenta Parasite may be present	Autolyzed midgestation fetus, widespread histologic inflammatory lesions in fetus including nonsuppurative necrotizing encephalitis and myocarditis	Identify parasite in fetal tissues by immunohistochemistry stain or PCR	Antibodies in fetus and cow IFAT and ELISA antibodies used for serologic detection Positive result supports infection in cow and/or fetus but is not causal proof; negative result in dam strong evidence that neosporosis not involved in abortion; serologic comparison of groups of aborting and nonaborting herdmates useful in establishing the role in herd outbreaks of abortion
Vibriosis (*Campylobacter fetus* subsp. *venerealis*)	Venereally transmitted, resulting in infertility, irregular, moderately prolonged diestrus with occasional abortion Epidemiology similar to trichomonosis except for a longer vaginal carrier state (up to 4 months after uterus has cleared organism) Significance: fertility returns but is still a threat to any uninfected bull	Low, up to 5%, may be up to 20%	46 months	Semiopaque, little thickening Petechiae, localized avascularity and edema	Flakes of pus on visceral peritoneum Fibrin may be present in serosal cavities Usually associated with suppurative pneumonia in fetus	Culture of fetal stomach, placenta, and uterine exudate Sporadic abortion, not venereally transmitted, can be associated with *C. fetus* subsp. *fetus* and *C. jejuni,* which need to be differentiated from *C. fetus* subsp. *venerealis*	Blood agglutination after abortion (at 3 weeks) Cervical mucous agglutination test at 40 days after infected service

Table 18-2 Diagnostic summary of causes of abortion in cattle—cont'd

				Field examination		Laboratory diagnosis	
Epidemiology disease	*Clinical features*	*Abortion rate*	*Time of abortion*	*Placenta*	*Fetus*	*Isolation of agent*	*Serology*
Leptospirosis (*Leptospira interrogans* serovar pomona and *Leptospira hardjo*) *L. borgpetersenii* serovar hardjo (formerly serovar hardjo-*bovis*) occurs worldwide; *L. interrogans* serovar hardjo (formerly hardjo-prajitno) primarily in the UK	Abortion may occur at acute febrile stage, later, or unassociated with illness	25%–30%	Abortions may occur throughout gestation; Late, 6 months +	Avascular placenta, atonic yellow-brown cotyledons, brown gelatinous edema between allantois and amnion	Fetus usually autolyzed, occasional icterus Fetal death common	Fluorescent antibody stain of smears of fetal kidney or PCR Direct examination of urine of cow by dark-field or fluorescent antibody stain	Positive serum agglutination test 14–21 days after febrile illness Titers usually at or near maximum at time of abortion Chronically infected *L. hardjo* dams may have low or negative titers
Infectious bovine rhinotracheitis (IBR)	Abortion storms in inadequately vaccinated animals. May be associated with upper airway disease in one or several animals	Variable	Most in second half of gestation	No significant gross lesions	Autolyzed fetus, rarely may have pale foci of hepatic necrosis Histopathology characteristic with multifocal necrosis	Virus isolation or PCR on placenta or fetal tissues Immunohistochemistry or fluorescent antibody stain on fetal tissues	Acute and convalescent sera
Mycoses (*Aspergillus, Absidia*)	Variable incidence, more common in cooler moist climates, retained placenta may occur	Unknown. 6%–7% of all abortions encountered	3–7 months	Necrosis of maternal cotyledon, adherence of necrotic material to chorionic cotyledon causes soft, yellow, cushion-like structure Small yellow, raised, leathery lesions on intercotyledonary areas	Minority of fetuses have skin lesions May be small raised, gray-buff, soft lesions, or diffuse white areas on skin Resemble ringworm	Direct examination of cotyledon and fetal stomach for hyphae, suitable cultural examination Histopathology on placenta	

Continued

Table 18-2 Diagnostic summary of causes of abortion in cattle—cont'd

				Field examination		Laboratory diagnosis	
Epidemiology disease	*Clinical features*	*Abortion rate*	*Time of abortion*	*Placenta*	*Fetus*	*Isolation of agent*	*Serology*
Listeriosis (*Listeria monocytogenes*)	May be an associated septicemia (Cows that abort may die of septicemia near term.) Retained placentas and metritis may also occur	Low, rare abortion storms related with poorly fermented silage	About 7 months	—	Autolysis Foci of necrosis in liver and other organs	Organisms in fetal stomach, liver, and throughout fetus placenta and uterine fluid	Agglutination titers higher than 1:400 in contact animals classed as positive
Epizootic bovine abortion	Tick-transmitted bacterial infection, occurs in dry foothill pastures in the western United States in which tick vector resides No clinical signs in aborting cattle Herd immunity develops Incubation period ≈3 months after exposure to agent	Abortion storms may occur, usually in heifers and newly introduced cattle High, 30%–40%	Third trimester abortion or birth of premature weak calves	Negative	Fresh fetus with petechiae in mucosa, enlarged lymph nodes and spleen, subcutis edema, ascites, nodular swollen liver	Diagnosis based on typical histologic lesions, etiologic bacterial agent has been identified by DNA analysis but is not culturable on artificial media Bacterial rod can be detected with special stains (Steiner silver stain and immunohistochemistry)	No serology test, elevated fetal IgG levels
Bovine viral diarrhea (BVD)	Variable outcome of fetal infection depending on timing of infection and other factors. Persistent bovine viral diarrhea virus infection in full-term live calves a significant problem for exposure of other animals	Less than 10%	Any time during gestation Most common in first trimester	No obvious gross lesions	Mummification, variable fetal lesions possible including deformities (cerebellar, pulmonary, or renal hypoplasia), myocardial lesions with congestive heart failure, thymic depletion or no lesions	Immunohistochemical or fluorescent antibody examination of tissues to detect virus Virus isolation or PCR also available Animals affected early with congenital lesions may no longer be positive for virus at time of abortion	Fetal antibody, evidence of seroconversion in dam and/or herd

Nutritional: *Ingestion of excessive amounts of performed estrogens in the diet may cause abortion. There are usually accompanying signs due to increased vascularity of the udder and vulva. Possible dietary factor in so-called lowlands abortion.*
Isoimmunization: *Has not been observed to occur naturally in cattle. It has been produced experimentally by repeated IV injections of blood from the one bull of pregnancy. Intravascular hemolysis occurs in the calves.*
Unknown: *30%–75% of most abortions examined are undiagnosed. The ingestion of large quantities of pine needles is suspected as a cause of abortion in range cattle in the United States. Infection with* Ureaplasma *and* Mycoplasma *spp. are other causes of undetermined relative importance.*
ELISA, *enzyme-linked immunosorbent assay;* IFAT, *indirect fluorescent antibody test;* PCR, *polymerase chain reaction.*

explanation when using monovalent vaccines. The addition of Freund's incomplete adjuvant provides better protection, and some other adjuvants may improve the efficiency of killed vaccines against naturally occurring enzootic abortion. Killed vaccines can be used in pregnant ewes and have been used in the face of an outbreak in an attempt to reduce the prevalence of abortion.

A live vaccine containing a temperature-sensitive attenuated strain of *C. abortus* (strain 1B) provides reasonable, but not complete, protection against *C. abortus*. It is registered for use in sheep (not goats). Live attenuated vaccines should not be used in pregnant ewes because they may pose a risk of zoonotic infection and have been associated with abortions.[8-10]

Recombinant and DNA vaccines have shown little protection against experimental challenge with *C. abortus*.

COXIELLOSIS (Q-FEVER)

SYNOPSIS

Etiology *Coxiella burnetii.*

Epidemiology High seroprevalence in ruminants. Latent infection with recrudescence and excretion at parturition. Infection by direct contact and inhalation. Persists in the environment. Important zoonotic disease.

Clinical findings Infection in ruminants is common. Clinical disease is less common and presents mainly as abortion in sheep and goats.

Necropsy findings Placentitis. Organisms demonstrable in placental trophoblast cells by fluorescent antibody.

Diagnostic confirmation Fluorescent antibody staining and PCR of aborted material and vaginal discharge. Acid-fast rodlike organisms in stained impression smear of placenta. Serology (ELISA, CFT, immunofluorescent antibody) or bulk tank milk test to establish herd infection status.

Control Vaccination possible in many countries. Isolation of aborting ruminants. Destruction of bedding and straw contaminated with birth fluids.

Zoonotic aspects Infection of humans can vary from asymptomatic to severe and even fatal. Presents mainly as a mild influenza-like illness with pneumonia, but chronic infections can have serious outcomes, including endocarditis and osteoarticular disease. Mainly follows contact with sheep and goats around parturition rather than cattle.

CFT, *complement fixation test;* ELISA, *enzyme-linked immunosorbent assay;* PCR, *polymerase chain reaction.*

ETIOLOGY

Coxiellosis (Q) fever is a zoonosis associated with *C. burnetii,* which is an obligate intracellular parasite classified within the family Coxiellaceae (formerly Rickettsiaceae). It can be divided into six genotype clusters on the basis of RFLP, although different methods can be used such as multispacer sequence typing (MST) or MLVA, which can identify up to 17 different microsatellite markers.[1] The presence or absence of specific genotypes could explain inconsistencies in reports on the effects of coxiellosis, particularly on reproduction in cattle. Coinfection with multiple genotypes can occur, although a large study of milk samples in the United States identified predominantly genotype ST20 in bovine milk and mainly ST8 in caprine milk,[2] whereas ST20 was associated with an abortion storm in a goat dairy in the UK[3] and ST33 with the large outbreak in the Netherlands.[4] Unlike other rickettsiae, *C. burnetii* it is quite resistant to environmental influences and is not dependent on arthropod vectors for transmission. It displays two antigenic phases or phenotypes: Phase 1 is more infectious and able to replicate in the host, and Phase 2, which is unable to replicate (these phases correspond to the smooth and rough phases of other gram-negative bacteria, respectively).

EPIDEMIOLOGY

Occurrence

The organism has worldwide distribution, although serologic surveys have found no evidence of infection in New Zealand.

C. burnetii cycles in a wide variety of wildlife species and their ectoparasites. The infection also cycles in domestic animals; cattle, sheep, and goats are the main livestock reservoirs of infection for humans. Rates of infection in farm animals vary considerably between locations, between countries, and with time, because there appears to be cycles of infection within regions.[5]

There can be a wide range in the seroprevalence of Q fever within regions and within individual herds or flocks. In cattle, from 4% to 100% of herds have been reported as positive (either seropositive or bulk milk test), and the within-herd prevalence varies from 0% to 49%.[6] The flock and within-flock prevalence in sheep and goats shows similar ranges and, as for cattle, varies according to year and region.[5,6] There is little information on management or other factors that might influence this variation in prevalence, but one study found a significantly higher prevalence in housed cattle compared with cattle kept on pasture. Analysis of data from 69 publications found the overall mean prevalence to be slightly higher in cattle (estimate of 20% and 38% for herd and within-herd prevalence, respectively) than for small ruminants (sheep and goat; 15% and 25% for flock and within-flock prevalence, respectively).[6] The prevalence in flocks of dairy goats and dairy sheep is much higher than in nondairy flocks.

Source of Infection and Transmission

Infection and transmission is by direct contact and by inhalation. Infection of nonpregnant animals is clinically silent and is followed by latent infection until pregnancy, at which time there is recrudescence with infection in the intestine, uterus, placenta, and udder and excretion from these sites at parturition. The organism is present in high concentration in the placenta and fetal fluids and subsequent vaginal fluids, is also excreted in urine, and is present in the feces of sheep from 11 to 18 days postpartum. In a longitudinal study in a naturally infected sheep flock in France, the number of *C. burnetii* was higher in vaginal mucus and feces compared with milk, peaked 3 weeks after abortion or birth, and was highest in primiparous and aborting ewes.[7] Shedding of *C. burnetii* in the feces can be persistent, so this can contribute significantly to environmental contamination with the organism. Infection can result in abortion, stillbirths, or poorly viable lambs, but the neonates of infected, excreting ewes are often born clinically normal.

Abortion usually does not occur at successive pregnancies. However, there can be recrudescence of infection and excretion at these pregnancies, especially the one immediately following, and reproductive failure at a second consecutive pregnancy is recorded in goats.[8] Goats excrete the organism in vaginal discharges for up to 2 weeks, it is present in milk for up to 52 days after kidding, and is also found in the feces. It also strongly adheres to the zona pellucida not removed by standard washing procedures. Thus the possibility of transfer of *C. burnetii* by embryo transfer cannot be ruled out.[9]

In cattle, maximum shedding also occurs at and 2 weeks following parturition, the organism is excreted in milk for at least

several months and can be detected for up to 2 years in bulk tank milk. Abortion in cattle is less common than in goats and sheep and is sporadic rather than occurring as abortion storms like occur with sheep and goats. The organism is present in the semen of seropositive bulls, and venereal transmission is suspected.

There is a significant contamination of the environment of infected animals at the time of parturition and abortion. This is a major risk period for transmission of the disease within herds and flocks and presents a significant zoonotic risk. The organism is still present in large concentrations in soil 12 months after outbreaks of coxiellosis on goat farms.[10]

Pathogen Risk Factors

C. burnetii is very resistant to physical and chemical influences and can survive in the environment, manure, and soil for several months. It can resist common chemical disinfectants but is susceptible to sodium hypochlorite, 1:100 Lysol solution, and formalin fumigation provided a high humidity is maintained.

There is strain variation in the organism, and differences in genotypes and DNA sequences have been correlated with differences in the type of disease occurring in humans and domestic ruminants. The organism is highly infectious, with the infective dose for humans estimated to be one organism.

Zoonotic Implications

In humans infection is primarily by inhalation. Sources of infection include such diverse materials as soil; airborne dust; wool, bedding; and other materials contaminated by urine, feces, or birth products of animals. The potential for human infection from these sources is substantial (e.g., ovine manure used as a garden fertilizer has been incriminated).

Sheep and goats have traditionally been identified as the major reservoir of infection for humans, and the location of urban populations in proximity to large dairy goat herds was a significant reservoir in the Dutch outbreak from 2007 to 2010.[1]

The organism is present in the milk of infected cattle, sheep, and goats. A significant proportion of seropositive cattle excrete the organism in milk, and periods and duration of excretion are variable but may persist at least 2 years. *C. burnetii* is destroyed by pasteurization but there is a risk for people who consume raw milk, particularly unpasteurized milk from sheep and goat.

Rates of seropositivity in humans vary markedly between surveys, but there is a higher rate of seropositivity in people that are associated with domestic animals and their products and with farm environments (such as farm workers, veterinarians, livestock dealers, dairy plant and slaughterhouse workers, and shearers).[5]

Many instances of infection in humans have been linked to exposure to parturient sheep and goats. A spectacular example is the 2007 to 2010 epidemic in the Netherlands, in which over 3000 notifications of human disease were analyzed and only 3.7% of people had worked in agriculture or slaughterhouses.[11] This outbreak was attributed to airborne transmission of contaminated dust originating from dairy goat farms located in densely populated areas. The number of human cases abruptly declined after control measures were implemented on the goat and sheep farms, including vaccination, the mass culling of more than 50,000 pregnant does and ewes on infected farms to reduce shedding of the organism, and mandatory PCR testing of bulk tank milk for *C. burnetii*.[11] Living close (<2 km) to a large dairy goat farm that had an abortion storm caused by *Coxiella burnetii* was identified as the major risk factor for human cases during the Netherlands epidemic.[12]

Coxiellosis in humans is referred to as Q-fever and is often asymptomatic, but can result in acute disease characterized by fever, general malaise, headache, and less commonly, pneumonitis, hepatitis, and meningoencephalitis. Endocarditis, hepatitis, and osteoarticular diseases are manifestations of chronic disease in around 2% of human infections.[11] Those at most risk of chronic disease are immunocompromised individuals and pregnant women. There is a concern that the prevalence of infection in farm animals is increasing and spreading geographically, so that there is a greater risk for human infection, particularly when dairy farms are located near urban populations. Epidemics of human infection have been documented in several countries including Australia, France, Germany, the United States, Bulgaria, the UK, and the Netherlands.[11]

C. burnetii is considered a potential agent for bioterrorism because of its survival in the environment, the ease with which it can be transmitted by aerosol and wind, and the very low infectious dose.

CLINICAL FINDINGS

Infection of ruminants can occur at any age and is usually clinically inapparent. In the experimental disease in cattle, anorexia is the only consistent clinical finding. *C. burnetii* is a cause of abortion storms and sporadic abortion in sheep and goats but only rarely associated with sporadic abortion in cattle.[13] Abortion occurs during the latter part of pregnancy in individual does or ewes, usually with no sign of impending abortion.

In the 2007 to 2010 epidemic in the Netherlands, abortion storms were reported on 28 dairy goat and 2 sheep dairy farms, with up to 60% of goats aborting compared with an average of 5% abortions on the sheep farms.[11]

CLINICAL PATHOLOGY

There are a number of serologic tests, including complement fixation, microagglutination, ELISA and indirect immunofluorescence, and PCR (both conventional and quantitative real-time PCR). A comparison of these tests concluded a combination tests was preferable, such as ELISA for serology and PCR for detection of DNA of the organism.[14]

The immunofluorescence assay is used as the seroreference test for the serodiagnosis of coxiellosis. It can detect antibody to phase variants and can provide epidemiologic information because Phase 1 antibody is associated with recent and acute infections and Phase 2 antibody with chronic infections.

Conventional and quantitative real-time PCR tests can be conducted on bulk tank milk and are a useful means of monitoring herd or flock prevalence within regions and outbreaks within herds or flocks.[15,16]

NECROPSY FINDINGS

There are seldom gross lesions in aborted fetuses, but foci of necrosis and inflammation are occasionally seen in the liver, lung, and kidney microscopically.[13] The placenta from aborting animals is usually thickened and a purulent exudate or large, red-brown foci of necrosis is typically seen in the thickened intercotyledonary areas. Microscopically, large numbers of necrotic neutrophils are usually visible on the chorionic surface, and swollen trophoblasts filled with the organisms can also be found in well-preserved specimens. This is consistent with bacterial replication occurring only in the trophoblasts of placenta, and not in other organs, of experimentally infected pregnant does and their kids.[17] Examination of placental impression smears stained with Gimenez, Koster's, or other appropriate techniques provides a means of rapid diagnosis. However, care must be taken to avoid confusing *Coxiella*-infected trophoblasts with cells containing *Chlamydophila* organisms. Coxiellosis can be confirmed by PCR, fluorescent antibody staining of fresh tissue, or immunohistochemical staining of formalin-fixed samples. In most laboratories, culture is not attempted because of the zoonotic potential of this agent.

Samples for Confirmation of Diagnosis

- **Bacteriology and detect DNA:** chilled placenta (fetal liver and spleen) (cytology, FAT, PCR)
- **Histology:** fixed placenta and fetal lung, liver, kidney (light microscopy, immunohistochemistry)

Note the zoonotic potential of this agent when handling aborted material and packaging and submitting specimens.

DIFFERENTIAL DIAGNOSIS

- Other causes of abortion in sheep and goats (*Campylobacter, Chlamydophila,* and *Toxoplasma*, Table 18-1).
- The diagnosis of the disease in farm animals, other than abortion, suspected as associated with this agent is difficult and relies on the detection of the organism.
- A positive serologic test in an animal or herd is indicative of infection at some time but does not indicate an association with the problem at hand.
- PCR or PCR-ELISA has been used for detection of the organism in milk.

ELISA, *enzyme-linked immunosorbent assay;* PCR, *polymerase chain reaction.*

CONTROL

Aborting animals should be isolated for 3 weeks and aborted and placenta-contaminated material burnt. Ideally, manure should be composted for 6 months before application to fields to inactivate the organism, and closed composting with CaO or $CaCN_2$ has been practiced following outbreaks in the Netherlands, France, and Germany.[5] Feed areas should be raised to keep them free from contamination with feces and urine.

Although Q fever has significant implications for human health, until recently it has not been regarded as important enough to justify national or regional control strategies based on control in the animal population. In the Netherlands, a seasonal epidemic of animal and human *C. burnetii* infections occurred in 2007, but was no different from several previous isolated outbreaks in Europe. Subsequently, the unexpected scale of the outbreak in 2008 meant that national and regional public health authorities were largely unprepared for the expanding epidemic.[5,18]

The response in the Netherlands was to cull all pregnant dairy goats on affected farms before the 2010 kidding season, without reference to individual testing, and to vaccinate dairy goats and dairy sheep.[18,19] A retrospective analysis identified that testing pregnant goats by PCR or ELISA, followed by culling only the positive goats, would not have effectively reduced the massive bacterial shedding on these farms because many infected goats would not have been detected.[20]

Inactivated Phase 1 vaccines show a good and persistent antibody response, suggesting that vaccination should limit the excretion of the organism. However, there is little economic incentive for vaccination of livestock when an outbreak of coxiellosis is not occurring, and a vaccine for livestock is not available in many countries. A systematic review and meta-analysis of investigations into the use of inactivated Phase 1 vaccines, such as used in the Dutch outbreak, found a significantly reduced risk of shedding in vaginal mucus, uterine fluids, milk, and feces of vaccinated goats exposed to infection compared with controls. However, it was concluded that there was no reduction in the risk or amount of shedding in vaccinated ewes compared with unvaccinated ones.[21]

Vaccination of humans has reduced infection rates in high-risk groups and is used in the appropriate circumstances in Australia, such as workers on goat and sheep dairy farms, abattoir workers, veterinarians, and veterinary students.

During a natural outbreak of coxiellosis in a dairy flock, two treatments with oxytetracycline at days 100 and 120 of pregnancy failed to reduce shedding of the organism in vaginal fluids, milk, or feces compared with untreated ewes.[22] In this flock, vaccination for three consecutive seasons reduced the proportion of ewes shedding the organism to around 4%.

Pasteurization of milk that is consumed fresh is preferable, but veterinarians dealing with herds that provide raw milk should ensure that these herds are seronegative or bulk tank milk is PCR negative for *C. burnetii.* In a study of manufactured dairy products in France (mainly cheese, but also yogurt, cream, and butter), the DNA of *C. burnetii* was detected in 64%, but no viable organisms were recovered. A greater proportion of food products from large-scale manufacturers were positive compared with artisan food.[23]

DISEASES OF THE GENITAL TRACT ASSOCIATED WITH *MYCOPLASMA* SPP.

Vulvovaginitis in cattle, sheep, and goats may be associated with ***Mycoplasma agalactiae* var. *bovis.*** The same infection, when introduced with semen into the uterus, can cause endometritis and salpingitis, resulting in temporary infertility and failure to conceive. Persistent infection of the genital tract of bulls has also been produced experimentally.

Although **ureaplasmas** and ***M. bovigenitalium*** are considered to pertain to the normal flora of the lower urogenital tract of ruminants, these organisms have also been associated with reproductive disease.[1] In healthy individuals *Ureaplasma diversum* is usually limited in its distribution to the vestibule and vulva. Both microorganisms have been isolated from the vulva of animals with granular vulvovaginitis, and the disease could be transmitted experimentally. *M. bovigenitalium* infection has further been associated with infertility, abortion, and birth of weak calves.[1] These infections adversely affect reproduction when they are either acute or chronic; along with producing granular vulvovaginitis, some strains can, if introduced to the upper reproductive tract, cause transitory endometritis and salpingitis. Because *U. diversum* is a normal inhabitant of the upper respiratory tract and the lower urogenital tract of ruminants, contamination of fetal membranes or fetal tissue submitted to the diagnostic laboratory should be considered.[2] The diagnosis of *U. diversum* as a causative agent for abortion should therefore ideally be based on isolation of the pathogen from fetal lung tissue, stomach content, or placenta, coupled with the presence of compatible lesions in the lung and placenta.[2]

Ureaplasmas, *M. bovis,* and *M. bovigenitalium* have been found in the reproductive tract of bulls and their semen. Using PCR for the detection of mycoplasma in semen, *M. mycoides* subsp. *mycoides* SC (the causative agent of the contagious bovine pleuropneumonia) has been found in semen of yearling bulls with seminal vesiculitis. Mycoplasmas in semen can be transmitted through in vitro fertilization (IVF) and infect embryos, and

supplementation of culture media with standard antibiotics and washing embryos as recommended by the International Embryo Transfer Society are not effective in making IVF embryos free from *M. bovis* and *M. bovigenitalium*. *M. bovis* in frozen semen can survive the antibiotic combination of gentamicin, tylosin, and lincomycin and spectinomycin.

In horses, ***M. equigenitalium, M. subdolum***, and ***Acholeplasma* spp**. have been associated with infertility, endometritis, vulvitis, and abortion as well as with reduced fertility and balanophostitis in stallions.[3] Notwithstanding, these microorganisms are also commonly isolated from clinically healthy horses, which has raised questions about their direct association with genital disease. Two microorganisms frequently isolated from the upper respiratory tract of horses, ***M. equirhinis*** and ***M. felis***, have also been isolated from the genital tract of stallions but have not been associated with any clinical disease.[3]

In pigs infection with ***M. suis,*** the causative agent of eperythrozoonosis, has also been associated with infertility, abortion, stillbirth, and birth of weak piglets.[1]

EQUINE COITAL EXANTHEMA

Equine coital exanthema is a **venereal disease** associated with infection of equids by equine herpesvirus-3 (EHV-3). The genome of EHV-3 has been sequenced.[1] The disease is highly contagious and has economic importance because of disruptions to breeding programs on stud farms when stallions have clinical signs or there is an outbreak of disease among mares. The economic impact is greatest in those breeds or studbooks, such as Thoroughbreds, that do not permit artificial insemination of mares.[2]

Transmission is usually venereal from affected or clinically normal carrier animals in which the infection is thought to be latent in sciatic ganglion.[3] The virus is highly contagious, and outbreaks among mares in an embryo transfer facility in which both donor and recipient mares were affected is strongly suggestive of iatrogenic spread by personnel or on equipment such as ultrasound probes.[2] Inapparent or latent infection is apparently common, with 14% of 220 Thoroughbred mares on a stud farm having EHV-3 genome detectable by PCR in swabs of the perineum and vagina and 48% having serum antibodies to the virus.[3] The virus can be excreted intermittently by infected mares, although the factors determining reactivation have not been determined.[3] Efforts to demonstrate that administration of corticosteroids induces reactivation of EHV-3 shedding are inconclusive.[4]

The disease can be reproduced experimentally with more severe disease and longer shedding of the virus in mares that are seronegative at the time of infection than in seropositive mares.[5]

The disease is relatively mild and causes only local signs manifested by papular, then pustular, and finally **ulcerative lesions** of the vaginal mucosa, which is generally reddened. The ulcers can be as large as 2 cm in diameter and 0.5 cm deep and are surrounded by a zone of hyperemia. In severe cases the lesions extend onto the vulva and the perineal skin to surround the anus. There can be pain on passage of feces, and the anorectal lymph nodes are enlarged.[2] In the male, similar lesions to those on the perineum of the mare are found on the penis and prepuce. Many mild cases are unobserved because there is no systemic disease and affected horses eat well and behave normally. The effect on fertility is equivocal although there might be a loss of libido during the active stage of the disease in stallions. The **incubation period** is 2 to 10 days and the course up to complete healing of ulcers is about 14 days, although depigmented lesions on the perineum can persist for months.[3]

EHV-3 has been associated with **unilateral rhinitis** in adult horses examined with the same endoscope. All horses were affected unilaterally and in the nostril through which the endoscope was passed.[6]

Diagnosis can be achieved by use of virus isolation or demonstration of viral DNA in skin lesions or swabs of the vaginal or perineal regions.[3] Secondary bacterial infection can lead to suppurative discharge and a longer course. In some outbreaks lesions occur on the skin of the lips, around the nostrils, and on the conjunctiva and can also be present on the muzzle of the foal. Ulcerative lesions of the pharyngeal mucosa also occur in infections with EHV-2 and with equine adenovirus. Ulcerative lesions of the oral mucosa are of great importance because of the necessity to diagnose vesicular stomatitis early.

Treatment is symptomatic and can include cleaning of lesions, although this might not be necessary in uncomplicated disease. Mares with severe inflammation of the perianal tissues with or without enlargement of the anorectal lymph nodes and signs of pain on defecation might benefit from administration of fecal softening agents (mineral oil) or diets.

Control can be achieved by use of artificial insemination, but careful attention must be paid to biosecurity measures that minimize the opportunity for iatrogenic spread on stud farms or embryo transfer facilities. Recommendations for control in embryo transfer facilities and stud farms include the following[2,7]:

- Strict adherence to hygiene procedures designed to prevent both the direct and indirect transmission of the virus.
- Personnel with direct contact with mares should wear long, disposable examination sleeves and short latex gloves, which should be changed between subsequent inspections.
- Ultrasonography probe should be covered with a disposable glove or be carefully disinfected before the inspection of each mare.
- All instruments and other devices used during the inspection procedure, artificial insemination, and embryo collection must be either disposable or washed and sterilized between uses.

PORCINE REPRODUCTIVE AND RESPIRATORY SYNDROME (PRRS)

SYNOPSIS

Etiology Porcine reproductive and respiratory syndrome virus belonging to the Arteriviridae family.

Epidemiology Highly contagious disease of swine manifested by reproductive failure, and respiratory disease in young pigs. Worldwide occurrence; spreads rapidly in swine-raising areas during the last 20 years. Subclinical infection endemic in most swine herds; incidence of clinical disease lower but causes severe economic losses. Pigs become infected in nursery from older infected pigs; persistent infection for several months is common. Different antigenic strains with variable virulence. Natural infection or vaccination results in immunity, but viremia still common. Infection with virus may predispose to secondary infections of respiratory tract. Transmitted by direct contact, feces and discharges, importation of infected pigs into herds, aerosol infection, and semen.

Signs Highly variable clinical syndrome.

Reproductive failure Outbreaks of late gestation abortions, stillbirths, mummified fetuses, weak neonates, and high rate of return to estrus. Problem may persist and recur for many months.

Respiratory form Anorexia, fever, dyspnea, polypnea, coughing, unthriftiness, high mortality in young pigs and low in older pigs and breeding stock. Deaths occur in acute phase.

Lesions Interstitial pneumonia with reduction in alveolar macrophages. Aborted and mummified fetuses, stillbirths, and weak neonates with pulmonary lesions.

Diagnostic confirmation Serologic testing for viral antibody titers. Detection of virus in tissues and alveolar macrophages using immunofluorescent microscopy and other techniques.

Differential diagnosis list Major differential is porcine circovirus infections

Respiratory disease:

Pneumonia caused by
- *Mycoplasma hyopneumoniae*
- *Actinobacillus pleuropneumoniae*
- *Pasteurella multocida*
- Glasser's disease (*Haemophilus parasuis*)
- *Streptococcus suis*

Reproductive failure
- Leptospirosis
- Parvovirus
- Brucellosis
- Aujeszky's disease
- Hog cholera virus

Treatment Must clinically manage outbreak to minimize mortality in young pigs.

Control Segregation and off-site rearing of recently weaned pigs. Nursery depopulation and clean up protocol. Import only virus-free breeding stock into breeding herds. Both live attenuated and dead vaccines available for sows and piglets.

INTRODUCTION

PRRS is a significant cause of respiratory disease in its own right but is also a significant contributor to the porcine respiratory disease complex (PRDC).[1] The ever-expanding diversity of porcine reproductive and respiratory syndrome virus (PRRSV) infections has been emphasized.[2] This agent is one of the three major contributors to the continuing evolution of respiratory disease in pigs (swine influenza virus [SIV], PRRS, and porcine circovirus type 2 [PCV2]).

ETIOLOGY

PRRS is caused by an RNA virus morphologically, structurally, and genomically similar to members of the genus *Arterivirus* of the family **Arteriviridae** belonging to the Order Nidovirales[3] including equine arteritis virus. The virus was first isolated in Lelystad in the Netherlands in 1991 (it was initially called the "Lelystad virus"). The mystery swine disease in North America was then shown to be a similar virus. These two strains are considered to be one virus but differ genetically and antigenically. The North American and European strains are only 60% identical at the nucleotide level.[4]

In terms of evolution, it is possible that lactic dehydrogenase virus of mice infected wild boar in Central Europe and became adapted. It then went to North Carolina in the United States possibly in wild boar. It is thought that the most likely date for a common isolate of the European strains is before 1981. The two species of PRRSV then developed separately on the two continents. Some evidence of this comes from a study of the number of nucleotides in open reading frame 7 (ORF7) of the virus from the United States (372 nucleotides), and the European virus (Lelystad types) had 387 nucleotides, but the Lithuanian strains that were collected had 378 nucleotides.

The European viruses (Lelystad type) have become known as type 1, and the North American viruses as type 2 viruses (ATC-2332 was the first).

There is the implied existence of two distinct genotypes derived from a common ancestor.[5] New clinical cases may occur because of other microbes interacting with the virus but also because new viral variants escape the neutralizing responses of pigs to the previous pig strains of PRRSV.[6]

Genome

The virus has a genome of approximately 15.4 kb consisting of 10 ORFs. ORF1a and ORF1b comprise 80% of the genome and encode polyproteins that are processed to 14 nonstructural proteins (nsps)[7] by viral proteases. ORF 2a, ORF2b, ORF3, ORF4, ORF5a, and ORF5-7 encode eight structural proteins: GP2a, GP2b, GP3, GP4, ORF5a, GP5, matrix protein (M), and nucleocapsid (N).[8,9]

All of these structural proteins have been shown to be important for virus infectivity because of their critical roles in virion assembly and/or interaction with cell-surface receptors.[8] N-linked glycosylation of GP5 is critically important for virus replication.[10] The heterodimer consisting of the GP5 and M proteins is required for infectivity of arteriviruses. GP5 plays a key role in viral entry by interacting with the host cell receptor.[11] ORF2b is also essential for virus infectivity and is likely to function as an ion channel to facilitate uncoating of the virus.[12,13] GP3 is found in type 1 and 2 viruses.[14]

One other protein, (N) or nucleocapsid, synthesized by ORF7 is highly immunogenic and has been used for most antibody studies. It is found in the cytoplasm and the nucleus in which it has an important role in antagonizing cellular gene function. The more recent type 2 strains still exhibit variability in sequence and pathogenicity.[15]

A novel structural protein in PRRSV has been discovered to be encoded by an alternative ORF5, and this protein is referred to as ORF5a and is expressed in infected cells. Pigs infected also express ORF5a antibodies. It is found in all PRRSV subgenomic RNA5 genes as an alternative reading frame and in all other arteriviruses, which suggests that it may play an important role.[16]

There is evidence of recombination between vaccine and wild-type PRRSV strains.[17] There is an exceptional diversity in PRRSV strains in Eastern Europe,[18] which is developed from European viruses and the use of attenuated virus vaccines (containing North American viruses) and these are associated with new genetic subtypes.

GP4-specific neutralizing antibodies might be a driving force in PRRSV evolution.[19] Amino acid substitutions in the GP4 neutralizing epitope may abrogate antibody recognition and favor the development of neutralizing antibody-resistant variants.

The genetic and antigenic characterization of the complete genomes of type 1 PRRSV isolated in Denmark over a period of 10 years have been described. In Denmark, more than 50% of the herds are affected[20] by type 1 and/or type 2.[20] The study showed that there were two major clusters within the type 1 genotype. The differences from the original Lelystad virus varied from 84.9% to 98.8% for ORF5 and 90.7% to 100% for ORF7 for the nucleotide identities. The results strongly suggest that there have been at least two independent introductions of type 1 PRRSV into Denmark with significant drift in several regions of the virus. The genetic dissection of complete genomes of type 2 PRRS viruses isolated in Denmark over 15 years has been described.[21] The virus arrived at the same time as Ingelvac PRRS-MLV, and since then the viruses were found to be 94.0% to 99.8% identical to the vaccine strain. The nucleotide identity was 90.9% to 100% for ORF5 and 93.0% to 100% for ORF7. There was wide diversity in the nsp2 with some deletions in the NSP2 region. The analysis showed that all Danish isolates belonged to a single cluster (sublineage 5.1) resembling the type 2 prototype isolate VR-2332.

North American Viruses (Type 2 Porcine Reproductive and Respiratory Syndrome Virus)

The North American genotype PRRSVs in China have evolved independently from those in other countries, suggesting that geographic separation might be one factor influencing the molecular evolution of PRRSV.[22]

There is an exceptional diversity of North American type 1 PRRSV[4,5] in China.[23]

Korean strains have evolved from North American strains imported some years earlier and have evolved separately from other Asian countries, suggesting that geographic separation may influence the molecular evolution.[24]

European Viruses (Type 1 Porcine Reproductive and Respiratory Syndrome Virus)

In a study of over 100 new PRRSV UK isolates, all type 1, in the period from 2003 to 2007, it was found that some strains were

similar to those found in the early 1990s.[25] It was also found that the diversity is greater now than it was then.[26]

The evolution of Spanish strains of PRRSV from 1991 to 2005 has been studied from 1991 to 2005 using the ORF5 of the virus.[27,28]

The emergence of PRRSV in Sweden was described in 2007 when it was detected through a national surveillance program.[29]

In a study in Thailand, European isolates seem to have evolved from the Lelystad virus, whereas the Thai U.S. isolate may have come from vaccine strains that were not available in Thailand so they may have been imported in pigs or semen and later spread.[30]

High Pathogenicity Viruses

In June 2006, an unknown disease characterized by high fever, high morbidity, and high mortality was seen in many areas of China. It was highly pathogenic and characterized by a unique discontinuous deletion of 30 amino acids in the nsp2 protein with extensive substitutions in the GP5 sequence from the ORF5 gene. This epidemic has affected over 2 million pigs in China, with over 400,000 deaths.[31] A further 140,000+ pigs with 40,000 deaths occurred between January and July 2007.[32] A similar outbreak in Vietnam caused huge losses in 2007.[33,34] The genetic variation and pathogenicity of a highly virulent PRRSV has been described.[35] The genomic diversity of Chinese PRRSV isolates from 1996 to 2009 has been described.[36] They are divided into four highly diverse groups, and it is suggested that they developed from the domestic Chinese viruses by gradual variation and evolution. A new variant has since been described.[37] The complete genome sequences of two other variant PRRSVs isolated from vaccinated pigs have been described.[38] The high pathogenicity (HP)-PRRSV strain has become the predominant strain in China.[39] This virus has undergone rapid evolution and can circumvent immune responses induced by currently used vaccines.

A 1-year study of dynamics and evolution of type 1 and 2 PRRSV in a swine farm in Korea[40] showed the farm was first infected with a type 2 virus and then with a type 1 virus of unknown etiology. The type 1 virus has undergone further change.[41]

The magnitude of differentially expressed gene profiles in HP-PRRSV–infected pigs compared with the original VR-2332–infected pigs is consistent with the increased pathogenicity of HP-PRRSV in vivo.[42]

Spread of High Pathogenicity Porcine Reproductive and Respiratory Syndrome

Highly pathogenic strains of PRRSV have been identified within both genotypes[43-45] and have been isolated in China and Southeast Asia.[31,34,45] A 59 amino acid discontinuous deletion has been found in an HP-PRRSV Chinese virus,[46] whereas most of the previous HP-PRRSVs have had a 30 amino acid deletion.[47] Six different subgenotypic isolates have been found in pigs in China from 2006 to 2008.[48] New genomic characteristics of HP-PRRSV do not lead to significant changes in pathogenicity.[49] High pathogenicity strains have been described in Vietnam.[50] These have been found to be different from the Chinese strains and cause different pathogenic outcomes in American high-health swine.[51]

A highly pathogenic PRRSV virus isolated from a piglet stool in North America was sequenced.[52]

Experimental Infections With High Pathogenicity Porcine Reproductive and Respiratory Syndrome

Experimental infection with a Chinese HP-PRRSV in American swine showed that it replicated in swine with at least a 100-fold increased kinetic activity over VR-2332, which is the American reference strain. It caused significant weight loss, exacerbated disease because of bacterial sepsis, and had more severe histologic lesions. It rapidly transmitted between animals. It also greatly increased serum cytokine levels associated with innate (IFN-α and IFN-β; TNF-α;, and IL-1β, IL-6, and IL-8) and adaptive immunity (IL-2, IL-4, IL-10, IL-12, and IFN-γ) in bronchoalveolar lavage fluid and most of them in serum and tracheobronchial lymph node homogenates.[53] These included IFN-α, IL-1β, IL-2, IL-10, and IFN-γ. In addition, IL-12 was also elevated 11 days postexposure. None of the pigs inoculated with VR-2332 had significant elevations in the serum levels of the 10 cytokines. It may be that this represents a severe cytokine release syndrome or cytokine storm, as has been suggested for humans.[54-56] These conditions share many features including massive inflammatory responses, elevated serum cytokine levels, and multiorgan disease often with death.[57]

ECONOMIC LOSS

A recent study of economic loss caused by PRRSV was made in the Netherlands, and it was found that the loss varied between €59 and €379 per sow per 18-week period of the outbreak. The mean loss was €126. The costs after the outbreak varied from €3 to €160 per sow.[58]

EPIDEMIOLOGY

Occurrence

PRRSV was first reported as a new disease in swine-raising areas in North America in 1986 to 1987, and in 1991 it was recognized in, and spread rapidly across, Western Europe. The disease was first recognized in Germany in 1990 and in the Netherlands in 1991 and then spread rapidly. Based on serologic surveys, there is no evidence of infection in swine herds in Switzerland[59] and Australia.

The introduction of legislation in some countries to restrict the movement of pigs from affected farms slowed the spread of the disease, but the rapid spread of the disease initially to the southwest of Europe and then to the north, paralleled the direction of the wind. Airborne spread was also suspected because even well-managed and isolated herds became infected, but airborne spread over distances of a few kilometers continued to occur, particularly in areas with high pig population density.

The terms ***mystery pig disease*** and ***blue-eared pig disease*** were used because the etiology was unknown and the skin of the ears of affected pigs commonly appeared blue. The disease affects pregnant gilts and sows, unweaned and recently weaned pigs, and growing–finishing pigs. Outbreaks of late-term abortions, high numbers of stillbirths and mummified or weak newborn piglets, and respiratory disease in young unweaned and weaned pigs are common. After 10 or more years of acceptance and relief that the European virus was not as pathogenic as the North American virus, it is now accepted in Europe that the recent evolution of the virus may now be causing as many problems as the North American virus always has done.

A high seroprevalence of PRRSV and SIV on Spanish farms was found to be over 85% for sows, around 80% for finishers, and around 50% for boar studs.[60]

It has also been studied in wild boars in Germany and 15.9% of 531 examined were found to be positive.[61] The genetic diversity of PRRSV in selected herds in the pig-dense region of northwestern Germany showed that of 65 samples tested 5 were the North American type and 60 were the European type 1.[62] Of the original 18 herds visited only 2 reported clinical signs 2 years later.

Both the European genotype (type 1) and the North American (type 2) genotype now circulate globally.[63]

Strains within the genotype may differ by as much as 20% with the GP5 protein showing the widest heterogeneity with 50% to 55% difference between types 1 and 2.[5]

The distribution of genotypes of PRRSV in Ontario from 2004 to 2007 and the association between genotype and clinical signs of disease have been described,[64] and four RFLP types were recognized. In a further study, it was suggested that the diversity in Canada is not described adequately by RFLP typing.[65]

Prevalence of Infection

In endemic herds 30% to 70% of pigs may be seropositive to the virus and about 60% of herds have some seropositive pigs. Although the seroprevalence may be high in herds in some regions, the incidence of clinical disease is lower and variable. Although the number of herds with the acute form of the disease has been decreasing, the infection is now **endemic** in many herds, characterized

by increased mortality and suboptimal performance in nursery pigs, with active spreading of the virus mainly in nurseries. In endemically infected herds, **subpopulations of infected animals** may exist consisting of a low prevalence (<10%) of seropositive animals in the breeding animals and a high prevalence (>50%) of seropositive nursery piglets. The elimination of these susceptible subpopulations, by exposing all members of a population to the virus, is used as a control strategy in large herds in which there may be subpopulations of highly susceptible breeding females. The virus can persist in nonpregnant sows and be transmitted to naive in-contact sows. A PRRSV strain may persist in a herd for up to 3.5 years displaying as little as 2% variation in ORF5 during this period. In 78% of herds with multiple submissions, genetically different strains were identified within 1 year of the original identification. Virulent PRRSV isolates exhibit longer viremias but not more elevated levels; they induce higher death rates and cause more severe clinical signs in a respiratory disease model. More virulent strains grew to significantly higher levels in pigs than did cell culture–adapted isolates. Pathogenic consequences and immunologic responses of pigs to PRRSV are closely related to viral load in acute infections as reflected in viral titers in blood.

On some farms in Great Britain, PRRSV fails to persist indefinitely on some infected farms, with fade-out more likely in smaller herds with little or no reintroduction of infectious stock. Persistence of infection may be associated with large herds in pig-dense regions with repeated introductions.[66]

In a study of 33 sites established as PRRSV free, it was found that 40% became positive within 1 year of establishment.[67]

Morbidity and Mortality

The morbidity rate in young pigs may be up to 50%, and mortality in nursery piglets can reach 25%. Death is usually associated with secondary bacterial infections such as *Salmonella* Choleraesuis, *Streptococcus suis, Actinobacillus pleuropneumoniae,* and *Haemophilus parasuis.* Major losses occur in reproductive failure, but figures for the magnitude of reproductive losses during an outbreak are not readily available. Generally, the reproductive performance of positive herds is significantly lower than negative herds.

Risk Factors

The severity and duration of outbreaks following infection are variable. Some herds may be devastated by high production losses, whereas other herds may have almost no losses. Differences in morbidity and mortality may be caused by dose of virus at exposure, differences in host susceptibility, differences in strain virulence, environmental or housing differences, or the production practices in the herd.

A study of risk factors in Quebec[68] suggested that the transmission of PRRSV is likely to occur through the sites belonging to the same owner or through a 5-km area.

In a study of risk factors for PRRSV infection, it was found that there was a higher proportion of infected farms in areas of high pig density (more than 15,000 pigs within a 10-km radius from the farm), if they used live virus vaccines, if they were located in a high-density pig area, or if dead pigs had been collected. Farms weaning at 28 days or more had lower odds of being PRRSV positive compared with those weaning at 21 to 27 days.[69]

Animal Risk Factors

Nursing piglets lacking maternal immunity, young growing and finishing pigs, and sows lacking acquired immunity from natural infection or vaccination are highly susceptible to infection and clinical disease. Severe disease appears to be more likely in large herds that have a large turnover of pigs, purchase replacements from other herds, and do not use a quarantine system. Introduction of the virus to previously virus-naive herds may cause severe economic losses. In the recent outbreaks in Denmark, the study of 107 herds showed that a variety of hazards were identified including close neighboring herds, increasing herd size, and purchase of semen from infected studs used for artificial insemination.

There is a within-breed genetic variation for commercially relevant traits that could be exploited in future breeding programs.[70] A significant line difference in growth in two genetically diverse commercial pig lines was seen during infection with PRRSV.[71]

One study has shown that the number of piglets per litter infected by PRRSV was lower for the Landrace breed than for Large White, Duroc, and Pietrain breeds.[72]

In a study of 316 herds in Canada, it was found that the three most important factors for the spread of PRRSV RFLP 1-18-4 were sharing the same herd ownership, gilt source, and market trucks.[73] Spatial proximity could not be identified as a contributor to the spread.

Environmental and Management Risk Factors

Housing of all age groups in one building, introduction of new animals, housing on slatted floors, storage of slurry under floors, exposure to transport vehicles, and lack of disinfection procedures have been suggested as factors that increase the probability of herd infection. Lack of quarantine facilities for recently imported pigs is a major risk factor. There appears to be infrequent spread during warm weather compared with cold weather.

Pathogen Risk Factors

PPRS virus strains have many identical properties with some antigenic differences. Strains of the virus from the United States and Canada are antigenically similar but different from the European Lelystad virus isolate. All the strains appear to be highly infectious. There are serologic differences between the European and American strains, and the antigenic and genomic differences between the North American and European isolates suggest the existence of two genotypes. There are different genotypes and at least three minor genotypes within the major U.S. genotype. The simultaneous coexistence of the strains has been shown, but the significance of the observation is not understood. Genetic variations exist not only between European and U.S. strains but also among the U.S. isolates, indicating the heterogeneous nature of the virus. Antigenic variation may affect the accuracy of diagnostic tests and the efficacy of vaccines. The North American strains have been called type 2 virus, and they are continually varying. The European type 1 virus was thought to be less virulent and less likely to change, but this may not be so because recent isolations show that it is also continuing to change.

Infection with the virus does not always result in clinical disease, and the detection of high levels of serum antibody in many herds without history of clinical disease suggests that the consequences of natural and experimental infection depend on a complex of factors associated with host susceptibility and virus virulence. From 2000 to 2001, there were severe outbreaks in the United States associated with new isolates. There are now both European and U.S. strains originating from viral vaccines in Poland. The effects of the virus on reproductive performance are strain dependent. Strains of the virus cross the placenta when given to pregnant sows, and most sows will remain clinically normal and farrow normally. However, depending on the strain used, the number of late-term dead fetuses from gilts infected experimentally at 90 days' gestation may vary widely, and all gilts become viremic and develop antibodies. There are also marked differences in pathogenicity for the respiratory tract between U.S. strains of the virus compared with the Lelystad virus when inoculated experimentally into 4-week-old cesarean-derived colostrum-deprived pigs. Some strains cause severe lesions of the lymphoid and respiratory systems, which appear to be the major sites of viral replication. The difference in pathogenicity may explain the variation in severity of clinical disease observed in field outbreaks.

Field observations have suggested that the presence of the virus in a herd may increase the susceptibility of animals to other infections. However, studies with sequential infection of the virus followed by experimental inoculation with *H. parasuis, Pasteurella multocida,* or *A. pleuropneumoniae* have failed to demonstrate increased severity of disease. There is, however, strong evidence to

say that PRRSV predisposes to *S. suis.* It may also predispose to *Salmonella* Choleraesuis, *Bordetella bronchiseptica,* or *M. hyopneumoniae.* This view is not universal in that infection with the virus did not increase the severity of experimental *M. hyopneumoniae* (MH) infection in young piglets. However, in the laboratory investigation of PRDC the most potent combination of agents is PRRSV and MH. A model of the dual infection has recently been described in which MH was shown to predispose to PRRSV infection. Based on diagnostic submissions, however, concurrent pulmonary bacterial infections may occur in up to 58% of cases in which the virus was also isolated.

There is also the possibility that many strains may be found in the same herd, e.g., three strains were found in one herd. Several viruses have been found in the same pig, and one great authority has expressed the view that each virus in each pig may be different from every other virus.

A syndrome was described in neonatal pigs marked by neurovirulence. Replication in the brain was verified by IHC in brain sections. Meningoencephalitis induced by the virus was unusually severe.

Methods of Transmission

Virus is produced rapidly after infection, probably within 12 hours. The virus was shown to evolve continuously in infected pigs with different genes of the viral genome undergoing various degrees of change.

There are unlikely to be any wildlife reservoirs (except for feral and wild pigs), although infected mallard can still excrete the virus 39 days later. Most pigs clear PRRSV within 3 to 4 months but some may remain persistently infected for several months. The antibody response does not reflect the carrier status. It is possible that cytokines can switch the balance from a subclinical infection to disease manifestation. There is no evidence that PRRSV is found in the tonsils as a representative tissue.

The virus spreads rapidly within herds when infected pigs are housed in confinement. Up to 90% of sows may seroconvert within 3 months of the virus being introduced into a closed breeding herd. The mode of spread is presumed to be by direct contact, probably nose to nose. The virus generally requires close pig-to-pig contact to achieve an exposure dose.

Presence Within the Herd

The virus is present in a variety of biologic fluids; nasal discharge (positive 21 days later); oropharyngeal scrapings (158 days later); possibly mammary secretions, although this is probably uncommon as previous vaccination does appear to prevent shedding; urine (28 days) and feces (28 days); and intranasal inoculation has been used to reproduce the disease experimentally. The feces may be an intermittent source, a usual source, or not a source. The virus is present in saliva and, considered in the context of the **social behavior** of pigs, may play an important role in transmission.

The virus may persist in, and circulate between, different age groups and locations in a herd for several months despite the absence of clinical disease and may be transmitted by contact to replacement animals or to uninfected farms. Infected pigs may remain carriers of the virus for up to 15 weeks. Persistent and contact infection can be maintained in a nursery if uninfected pigs are continuously exposed to infected pigs. Pigs in the nursery become infected through contact with older infected pigs and not by in utero or postpartum exposure to infected sows. Long-term surveys of farrow-finish herds reveal that isolation rates of the virus reach highest level of 70% to 100% of pigs, 6 to 8 weeks of age, which coincided with the lowest level of maternal immunity. If you rely on infected nursery pigs to transmit infection to incoming gilts in acclimatization studies, then nursery pigs may only be viremic for a maximum of 60 days. There is no association between lymphadenopathy and PRRSV viremia in nursery pigs 4 and 6 weeks postweaning. Viremia cannot be predicted solely on the basis of clinical signs. Large finishing enterprises purchasing pigs of variable infection and immune status provide ideal conditions for persistent virus circulation. Breeding herd subpopulations of infected pigs may exist and perpetuate and enhance the infection in a herd. The inability to control such subpopulations may reduce opportunities for successfully controlling the disease.

Infection may **persist** for an extended period of time because of the following:

- Incomplete infection of the susceptible population during the acute phase
- Introduction of susceptible breeding stock
- A persistent viral infection in individual pigs with the potential of shedding virus under certain conditions, such as grouping for weaning or farrowing
- A rapid decline in passive immunity in young pigs and variable periods of active immunity

Genetic randomness of isolates does not correlate with geographic distance. Movement on to the farm of PRRSV does not generally occur by distance-limited processes, such as the usual wildlife vectors, but more typically occurs because of long-distance transport of animals or semen.

It is likely that piglets born with infection from in utero exposure probably may remain viremic for life, even in the face of antibody formation. Neonatal infection is probably cleared slowly, but infection in the older animal may be cleared much more quickly.

Experimental infection suggests that PRRSV infection is eventually cleared from the host and persistent infection rarely lasts more than 200 days.

In a study in France, a semiquantitative real time RT-PCR was developed to assess the evolution of the viral genome in blood and nasal swabs from inoculated and contact pigs with time. Viral genome was detected from 7 to 77 days postinfection (DPI), whereas viral genome shedding was detectable from nasal swabs from 2 to 48 DPI. The infections increased from 7 to 14 days and then decreased slowly to 42 DPI. The evolution of infectiousness was mainly correlated with the time course of viral genome in the blood, whereas the decrease of infectiousness was strongly related to the increase in total antibodies.[74]

A mathematical model of within-herd transmission dynamics of PRRSV, fade-out and persistence, has been described.[75] It was found that fade-out was likely to occur when breeding females failed to pass the virus on to the piglets. Persistence was more likely to occur once infection was present in piglets, which in turn infected rearing pigs. The probability of persistence was higher in large herds, increased contact between different age groups, and increased reintroduction of infectious gilts.

Possible routes of transmission include introduction of vaccinated animals, use of semen from vaccinated artificial insemination boars, and aerosol spread.

Introduction of Vaccinated Animals

The disease has occurred in PRRSV-seropositive herds in Denmark with no previous clinical evidence of PRRSV. These herds were then vaccinated with a modified live virus vaccine licensed for use in pigs 3 to 18 weeks of age. Boars entering artificial insemination units were also vaccinated. Following vaccination, a large number of herds experienced an increased number of abortions and stillborn piglets and an increasing mortality in the nursing period. The problems occurred mainly in herds without clinical signs among sows and with sows with low antibody titers in the period immediately before vaccination. The PRRSV was isolated from fetuses and identified as the vaccine virus. The evidence suggested that the vaccine virus had spread to nonvaccinated sows followed by transplacental infection of the fetuses. Spread of the vaccine virus was also demonstrated in a nonvaccinated and previously virus-free breeding herd. There are three main methods of spread:

1. Introduction of infected animals: Spread between herds is associated with the introduction of infected carrier pigs.
2. Use of semen from vaccinated or infected boars: Infected boars may shed the virus in their semen for up to 40 days after experimental infection. In boars, the virus can be found in semen by PCR for much longer periods than

can be found in the blood by virus isolation or antigen detection, and the likelihood is that monocytes enter the bulbourethral glands, which then contaminate the semen. Following experimental infection of sexually mature boars the virus was present in the semen 3 to 5 days after infection and on days 13, 25, 27, and 43. Using a PCR assay the virus can be detected in semen for up to 92 days after experimental infection. The insemination of gilts with semen from experimentally infected boars resulted in clinical signs of disease and failure to conceive. Following artificial insemination of gilts with semen from experimentally infected boars, the gilts will seroconvert. The use of the modified-live PRRS virus vaccine in boars is controversial because some boars may still shed wild-type virus in semen after challenge exposure 50 days after vaccination. The inoculation of PRRSV-negative replacement gilts with serum from nursery pigs presumed to be viremic resulted in seroconversion of all 50 gilts tested.

Exposure of pregnant gilts to either attenuated (vaccine) or virulent (field) strains of the virus can result in congenital infection. Congenitally infected pigs can support virus replication for a long period of time during which the viral replication is confined to the tonsils and lymph nodes. After 260 days there were no serum antibodies, and between 63 and 132 days there was no evidence of virus in the lung. Vaccine and field strains can be transmitted postnatally from infected to noninfected littermates. Pigs infected with field strains have an inferior rate of survival and growth than do noninfected pigs. This suggests that use of attenuated virus vaccine during gestation is questionable.

3. Aerosol spread: Airborne spread across regions and between countries was suspected in Europe during the winter of 1990 to 1991. The infection appeared to spread by the airborne route from Germany, across the Netherlands, and into Belgium. Low temperatures, low sunlight, and high humidity may have facilitated airborne spread. Airborne spread up to 20 km has been suggested, but most airborne spread is probably limited to less than 2 km. Usually it is difficult to transmit the agent 1 m. Although an experiment failed to transmit infection from pig to pig in a trailer parked 30 m away, there is a suggestion that it is transmitted for a short distance, but this possibly only occurs intermittently. Aerosol infection might be responsible in the absence of any other means of spread.[76, 77] The effect of temperature and relative humidity on an aerosol of PRRSV has been calculated, and it is more stable at lower temperature and/or lower humidity.[78]

In a study of aerial transmission,[79] it was found that 21/21 aerial samples were positive from exhaust gases from an experimentally infected pig group. Five of 114 long-distance samples were positive and were collected 2.3, 4.6, 6.6, and 9.1 km from the experimentally infected herd. Interestingly, only PRRSV variant 1-8-4 was detected, whereas 1-18-2 and 1-26-4, the other two strains given to the source pigs, were not detected. A production region model to assess the airborne spread of PRRSV has been produced by the same team.[80] Animal age, MH coinfection, and PRRSV isolate pathogenicity did not significantly influence the concentration of aerosol shedding. The shedding of PRRSV in aerosols may be isolate dependent.[81]

A production region model has been used to assess the airborne spread of PRRSV.[82]

The median infectious dose of PRRSV via aerosol exposure has been described.[83] The MN-184 isolate was far more infectious than the VR-2332 isolate.

Long-distance transmission of PRRSV was confirmed in a study where 1.3% of 306 samples were positive. These samples were positive 4.7 km away from the source population.[84]

Other Sources

Fomites

Fomites and infected personnel were shown to be capable of transmitting the virus following contact with infected material. Infected hands, boots, and protective clothing can transmit it.[85] Needles will transmit the virus. People do not usually act as vectors.

Meat

Pig meat does not retain detectable amounts of the virus, and it is unlikely that the transmission through meat occurs. PRRSV can survive in fresh pork at refrigerator temperatures, and the moving of meat juice may increase the risk of viral spread from personnel to pigs.[86] In a study of PRRSV in muscle it was found that 13/89 samples between 28 and 202 days after inoculation were found to be positive by quantitative RT-PCR, but if fed to pigs there was no evidence of infection, suggesting that the test detected noninfectious PRRSV in pig meat.[87]

Insects

Mosquitoes were not seen in one study to be a likely vector for PRRSV. Houseflies may pose some level of risk for the transport and transmission of PRRSV between pig populations under field conditions.[88] The intestinal tract of houseflies will support infectious PRRSV for up to 12 hours following feeding on an infected pig but only for a short period of time on the surface of the fly.

Virus Survival

The PRRS virus is fairly labile and does not survive for more than 1 day on solid fomites, but does survive for several days in well and city water. It may survive for several years in deep frozen tissues, but only 1 month at 4° C (39° F), 48 hours at 37° C (99° F), and less than 45 minutes at 56° C (133° F). There appears to be a low risk from contaminated lagoon water, and the viability of PRRSV in swine effluent is relatively short (18 days), although this is very temperature dependent.

Economic Importance

The export market for pork from a country can be seriously affected when a disease such as PRRSV occurs. When the disease was recognized in the United States, countries such as Mexico, Japan, Canada, and South Korea banned the importation of pork from the United States or required certification that the swine originated from premises where, within the 30 days before the issuance of the health certificate, no swine were introduced from a municipality in which a premises infected with the virus is located.

The economic losses may be very high because of stillbirths, abortions, small litter sizes, and birth of weak pigs, which increases preweaning mortality and increased nonproductive days. In weaned pigs, losses are associated with respiratory disease. In addition, there are the costs of control, which may be high, dependent on the control strategies undertaken. Typically, about 20% loss in annual production can be expected from a severe outbreak.

Negative weaned pigs had an increased margin per pig of $2.12 over the pigs minimally affected by PRRSV in the nursery but which seroconverted in the finishing herd and $7.07 over the pigs with persistently circulating PRRSV in the nursery.

PATHOGENESIS

Effects on Macrophages and Dendritic Cells

PRRSV has a very restricted tropism for porcine alveolar macrophages (PAMs) and some peripheral blood monocytes.[63]

Replication of PRRS in the PAMs directly impairs their basic functions including phagocytosis, antigen presentation, and production of cytokines.[89,90] The virus undergoes a productive replication in these cells leading to cell death via both apoptosis and necrosis mechanisms. In addition, there is also a reduced expression of major histocompatibility complex (MHC) class I and MHC class II, CD14, and CD11 cells.

PRRSV also induces necrosis or apoptosis of macrophages and lymphocytes in the lung and lymphoid organs, impairing the host response.[91]

In eukaryocytes, autophagy is a widely found mechanism that transports damaged cell organelles and long-lived proteins to lysosomes for degradation.[92] The autophagy induced by PRRSV infection plays a part in sustaining replication in host cells.[93]

PRRSV causes a massive increase in the number of B cells, resulting in lymphoid hyperplasia, hypergammaglobulinemia, and autoimmunity in neonatal piglets. There is a preferential expansion of certain clones bearing certain H chain third complementary lengths. The same dominant B-cell type clones occur throughout the body. The authors believed that hypergammaglobulinemia results from the products of these cells.[94]

Many piglets are probably infected in utero. PRRSV infection modulates the leukocyte subpopulations in peripheral blood and bronchoalveolar fluids. Following infection the number of CD8+ cells increased in systemic lymphoid tissue, whereas numbers of B cells increased in mucosal associated lymphoid tissue. Virus infection induces a simultaneous polyclonal activation of B cells mainly in the tonsils and an exaggerated and prolonged specific humoral immune response caused by persistent viral infection in lymphoid organs. Piglets surviving in utero infections have a high count of CD8+, CD2 +, CD4+, and SLA-class II cells in the peripheral blood.

Persistent infection occurs in these pigs. Virus appears to persist in the lymphatic organs and particularly the tonsils and the lungs. Lymphoid tissue tropism occurs during persistent infection when the piglets have been exposed in utero.

Neonatal or nursery infection is probably through the virus reaching the nasopharyngeal epithelium following inhalation from the nose-to-nose contact with other pigs. It is then probably removed to the tonsils in which they are internalized into cells of the macrophage/monocyte series.

Initially, a viremia occurs, with subsequent distribution and multiplication of the virus in multiple body systems and organs causing interstitial pneumonia, vasculitis, lymphadenopathy, myocarditis, and encephalitis. Alveolar macrophages are primary targets for virus multiplication, but this does not fully explain the pathogenesis. Multiple glycoproteins appear to be involved in infection of pulmonary alveolar macrophages. Possibly up to 40% of alveolar macrophages are destroyed. Whether it is a particular group that is damaged or all the alveolar macrophages are damaged is not known, but after about 28 days there is a resumption of normal alveolar macrophage function. PRRSV causes the apoptosis of alveolar macrophages and pulmonary intravascular macrophages. The increase in IFN-γ–positive cells correlated well with the severity of the lung lesions, which may be because of the presence of PRRSV in the lung. IFN-γ markedly inhibits the replication of PRRSV in macrophages.

RECEPTORS

As few as 10 or even fewer virus particles inoculated into the nose or given IM will infect a pig. The virus may enter the cell through an endocytic pathway or through a virus receptor. A third possibility is that the virus may enter the cell through an antibody-dependent enhancement with virus–antibody complexes entering the cell through Fc receptors on the cell surface.

There may be a PRRSV ligand for a cell-surface heparin-like receptor on pulmonary alveolar macrophages.

Several receptors have been described including heparin sulfate, sialoadhesin,[95] and vimentin.[96] The interaction of PRRSV with sialoadhesin inhibits alveolar macrophage phagocytosis.[97] Recently, CD163, a molecule that is expressed solely on the monocytic lineage,[98] has been identified as a possible cellular receptor for PRRSV.[99] This is a receptor that allows previously nonpermissible cells to become susceptible to PRRSV. It is a hapten/hemoglobin scavenger in the scavenger receptor cysteine-rich superfamily. Other factors also appear to be necessary for PRRSV permissiveness.[100] The initial step in infection involves heparin sulfate glycosaminoglycans as an initial attachment receptor and subsequent engagement of the Siglec sialoadhesin resulting in a virus internalization via clathrin-mediated endocytosis. The viral membrane M and the M/GP5 complex were identified as ligands for the initial attachment receptor. Sialic acids present on the surface of the PRRS virions have been shown to play an essential role in PRRSV infection. Recently CD163 was identified as a key receptor and involved in the entry into macrophages.[101] In a recent study,[102] it was suggested that expression of CD163 on macrophages in different microenvironments in vivo possibly may determine the replication levels of PRRSV and the virus pathogenicity.

VIRUS ENTRY

For productive infection, viruses need to enter the target cell and release their genome.[103,104] It has been shown that PRRSV entry into the alveolar macrophage involves attachment to a specific virus receptor followed by a process of endocytosis by which virions are taken into the cell within vesicles by a clathrin-dependent pathway.

It has recently been shown that PRRSV enters early endosomes after internalization but does not continue through the endocytic pathway to late endosomes. It colocalizes with its internalization receptor sialoadhesin on the cell surface and beneath the plasma membrane.[105] Sialoadhesin downregulates phagocytosis in PAMs (not CD163).[97]

There is a significant role for IL-10 in the CD163 and PRRSV susceptibility during the differentiation of macrophages. Possibly the internalization of PRRSV via CD163 in the target cells may induce the expression of IL-10, which in turn induces the expression of CD163 on neighboring cells.

Virus entry into the porcine macrophage has been reviewed[106] as has the virus structural and nonstructural proteins in viral pathogenesis.[107]

REPLICATION

The primary targets for replication are alveolar macrophages of the lung and other cells of the monocyte/macrophage lineage including pulmonary intravascular macrophages, subsets of macrophages in lymph nodes, and spleen and intravascular macrophages of the placenta and umbilical cord. A highly pathogenic strain may possess an expanded tropism to include epithelial cells.

The virus can persist in the pig for up to 132 days after birth in tonsil and lymph nodes infected in utero and from 105 to 157 days from pigs infected in postnatal infection. Over time the initial levels of viral load may decrease 10,000-fold in the tonsil or lymph nodes. The wild-type virus is capable of inducing a higher level of viral load than the mutations.[108-111]

The high pathogenicity strains from China in 2006 contain a unique 30 amino acid deletion in the nsp2 coding region, but this is not associated with virulence of these strains but nsp2 can attenuate replication and virulence.[112] The virus can cross the placenta at about 90 days' gestation and infect the fetus and can use the thymus as the principal site of replication and induce antiviral cytokines.[113]

Macrophages are activated by endogenous danger signals.[114]

There are mitogen-activated protein kinase cascade pathways, which are essential building blocks in the intracellular signaling systems. There are four of these pathways that have been identified, and one of these is the extracellular signal-regulated kinase (ERK) signaling pathway. This has been shown to play an important role in the postentry steps of PRRSV replication cycle and contributes to viral infection.[115]

PRRSV E protein is likely to be an ion-channel protein embedded in the viral envelope and facilitates uncoating of the virus and release of the genome in the cytoplasm.[116] This E protein is probably nonessential for virus infectivity but promotes growth of the virus.[117]

PRRSV can infect and replicate in monocyte and bone marrow–derived dendritic cells.[90,118,119] The exposure of bone marrow–derived immature dendritic cells to PRRSV produced a downregulated expression of MHC class I.

The monocytes and macrophages are the main cellular target for PRRSV replication, particularly the alveolar macrophages. It also replicates in vitro in dendritic cells and bone

marrow–derived monocytes.[118-121] It has a higher predilection for PAMs than septal macrophages.[122] PAMs phagocytose whereas septal cells may modulate immune responses. There is a complex viral replication mechanism in immune cells such as alveolar macrophages for PRRSV.[123]

General Effects of Porcine Reproductive and Respiratory Syndrome Virus on the Immune System

Generally, both innate and adaptive immune responses to PRRSV are suppressed. It produces modest levels of IFN-α and proinflammatory cytokines.[120] In addition, the response is weak and slow. Neutralizing antibodies are slow to be produced. Cell-mediated responses in the form of IFN-γ producing cells can take 4 to 8 weeks to develop. The virus produces an increase in IL-10, which is possibly immunosuppressive because it suppresses antigen-presenting cell activities such as processing and presenting antigen and expression of IL-1, IL-12, IL-18, TNF-α, and type I IFN expression.[119]

Macrophage Damage

The PRRSV nucleocapsid protein regulates alveolar macrophages and, in a study of infected macrophages, 23 protein spots were found that were differentially expressed. Of these, 15 had a statistically significant alteration including 4 upregulated and 11 downregulated[124] spots. Individual mature nsps are found in virus-infected cells.[125]

The alveolar macrophages when infected round up, show bleb formation, and eventually rupture. TNF-α released from damaged macrophages after PRRSV infection may induce apoptosis in uninfected lymphoid cells. In a study of cells in the lungs, it was found in both noninfected and infected cells. The majority of the apoptotic cells were noninfected. The peak of apoptosis was at 14 days and was preceded by a peak of IL-1 and IL-10 production at 9 DPI. The PRRSV infection directly interferes with type I IFN transcriptional activation.

Toll-Like Receptors

PRRSV inhibits TLR expressions in PAMs at 6 hours postinfection and it is then restored at 24 DPI when the cells showed upregulated IL-12.[126]

The possibility of increased expression of TLR mRNA and cytokines in pigs with PRRSV has been shown.[127] In these experiments there was an upregulation of TLR 2, 3, 4, 7, and 8 in at least one of the lymphoid tissues and cells.

Modulation of Immune Responses

Cellular Changes (Natural Killer, T-Regulatory, etc.)

The original VR-2332 prototype North American strain of the virus induces immune modulatory changes at mucosal tissues. Peak antibody response and cytokine IFN-γ were detected at PID30 with increased TGF-β until PID60. Populations of CD4+, CD8+, CD4+ CD8+ T cells, natural killer (NK) cells, and γδ T cells in the lungs and lymphoid tissues were significantly modulated favoring PRRSV persistence. The NK-cell–mediated cytotoxicity was significantly reduced in infected pigs. In addition, increased populations of immunosuppressive T-regulatory cells (T-regs) and associated cytokines were also observed in infected pigs.[128] These results suggest that both innate (γδ T cells and NK cells) and adaptive immune cell subsets were modulated in mucosal tissues in which the virus persists for a long time. IL-10 and TGF-β are immunosuppressive in nature produced by T-regs and are upregulated in PRRSV-infected pigs.[129] Although wild-type parenteral strain VR-2332 is avirulent it dampens the most essential immune components at the site of replication, which are the lung parenchyma and lymphoid tissue, resulting in weak and delayed anti-PRRSV immunity.

NK cells are only a small fraction of circulating lymphocytes that are not B or T cells. Cytokines IL-2 and IFN-α are activators of T cells.[130] PRRSV is a poor inducer of IFN-α. These cells early in infections kill infected cells and produce cytokines.[131] PRRSV-infected macrophages are less susceptible to NK cells. This reduced activity begins at 6 hours postinfection and coincides with the detection of observable PRRSV structural proteins.[132] It is likely that the transcription of viral genes and proteins also contributes to the resistance of PRRSV-infected macrophages toward NK cells. PRRSV infection inhibits both NK and cytotoxic T-cell activity via a common mechanism.[133] It might be that during PRRSV infection the virus may modulate the ligands for the NK receptors on the surface of pulmonary alveolar macrophages, leading to insufficient NK cytotoxicity.

The PRRSV has a suppressive effect on the NK cells, which are part of the innate immune response. They are usually activated by IL-2, IL-12, IL-15, IL-18, and IFN-α and by the interaction between NK activating receptors and their ligands on target cells.[134] One of the components of reduced NK cell activity is the possibility that there is incomplete activation of NK cells by a lower level of activating cytokines.[135] PRRSV-infected pulmonary alveolar macrophages showed a reduced susceptibility toward NK cytotoxicity, and this may represent one of the multiple evasion strategies of PRRSV.[133]

Replicating PRRSV in both infected and contact pigs was responsible for rapid modulation in NK cell–mediated cytotoxicity and alteration in the production of important immune cytokines. These changes produce a delay in adaptive immunity. At 2 DPI 50% of viremic pigs had a greater than 50% reduction in NK cell–mediated cytotoxicity, and nearly a onefold increase in IFN-α was found in the blood of some pigs. Enhanced secretion of IL-4 was found in 90% of pigs and IL-10 and IL-12 in a few pigs. IFN-γ was not enhanced. There was a reduced frequency of myeloid cells, CD4+ CD8+ T cells, and CD4– CD8+ T cells, and upregulated frequency of lymphocytes bearing natural T-reg cell phenotype were detected in viremic pigs.[136]

This is associated with a decrease in cytotoxicity but not the number of NK cells (increased IL-4, IL-10, and IL-12).[136] Regulatory T cells (induced by type 2 but not type 1 PRRS) also impair the host.[137-140]

There is a decrease in the number of antigen-presenting cells and T cells in the tonsil and lymph nodes of PRRSV-infected pigs, suggesting a modulation of the host immune response.[141]

CD14 + monocytes may also infiltrate the interstitial tissue in the lung and develop into interstitial macrophages. The early development of subneutralizing or nonneutralizing antibody may have a significant effect on the development of PRRS by antibody-dependent enhancement, which can facilitate the attachment and internalization of the virus onto host cells through Fc receptor-mediated endocytosis.[142]

A higher expression of proinflammatory cytokines is also expressed in septal macrophages in pigs.[122,143] T-regs[143] control the immune response and maintain homeostasis and are natural or induced. Induction of T-regs during the early stage of PRRSV infection is one of the ways pathogens escape the immune response.[138,139,144-147]

Cytokines

Many cytokines influence the immune response to PRRSV infection (Table 18-3). TNF-α may act as an antiviral cytokine protecting cells from infection by an IFN-independent mechanism, and several strains of PRRSV have a low ability to induce the expression.

The cytokines IL-10 and IL-12 are expressed in inflammatory lesions in the lung and play an important role in the defense against PRRSV. In some PRRSV infections, there was no change in the levels of IL-10, IL-12, and IFN-γ in PRRSV infections. It also induces minimal levels of T-helper-1 (Th1) cytokines (IL-12 and IFN-γ).[90]

In utero–infected pigs showed significantly increased IL-6, IL-10, and IFN-γ mRNA expression (IL-2, IL-4, and IL-12 remained the same) and this was concurrent with a significant decrease in the number of CD4+ CD8+ T cells. The cell-mediated and cytokine message profiles returned to normal.

The increased expression of IL-1α, IL-6, and TNF-α in the lungs of pigs with PRRSV is correlated with the development of interstitial pneumonia.[122] Different isolates induce

Table 18-3 Cytokines and porcine reproductive and respiratory syndrome[139]

Cytokine	Function
IL-1	Attracts macrophages, monocytes, polymorphs
IL-6	Induces acute phase proteins Upregulates CD163 receptor
IL-10	Upregulates CD163 receptor Upregulates in the lung
TNF-α	Inhibits replication of PRRSV Induces acute phase proteins Downregulated in PRRSV-infected macrophages Downregulates CD163 receptor
IFN-α	Interferes with replication of PRRSV Downregulated in PRRSV-infected macrophages
IFN-γ	Inhibits replication of PRRSV Enhanced by vaccination with IL-12/IFN-α Downregulates CD163 receptor
IL-10	Correlates with expression in the lung Inhibits IFN-γ in the lung
TGF-β	Induces T-regs after PRRSV infection Correlates with expression in the lung Downregulates CD163 receptor

IFN, *interferon;* PRSSV, *porcine reproductive and respiratory syndrome virus.*

different patterns of IL-10 and TNF-α. Four possible phenotypes were identified, but different cells had different capabilities. In addition, cytokine-release profiles on antigen-presenting cells could induce different expressions of cell markers.[121]

Certain regions of nsp2 also downregulate IL-1β and TNF-α.[148] The inhibition of early cytokine production contributes to the weak innate immune response, delayed neutralizing antibody, slow IFN-γ response, and a depressed cytotoxic T-cell response.[149]

In PRRSV infections, the production of proinflammatory cytokines is limited.[150] The nsps may downregulate TNF-α.[151,152]

IL-10 inhibits the synthesis of proinflammatory cytokines as well as inhibiting the production of IFN-α, and may also suppress the proinflammatory response to PRRSV-infected pigs. There is a significant correlation between the response to PRRSV antigen expression and the expression of regulatory cytokines, such as IL-10 and TGF-β in the lungs but not in the lymph nodes.[153,154]

There may be, as a result of the cytokine expression, a reduction of the infiltration and proliferation of inflammatory cells.[155] IL-10 is expressed mainly by septal macrophages and TGF-β mainly by PAMs. There may be different expressions of different cytokines by different subsets of the lung cells. TGF-β production may be dependent on the PRRSV strain.[156] CD163 is one component of a complex of receptors required for entry of PRRSV entry into the cell including heparin sulfate and sialoadhesin. It is upregulated by IL-10 and IL-6 promoting PRRSV entry into the cell and replication but downregulated by TNF-α, TGF-β, and IFN-γ.[102,157]

The induction of the IL-10 response may be one of the strategies used by PRRSV to modulate the host immune responses.[158] Increases in IL-4, IFN-γ, and TNF-α were found in the lymphocytes of infected piglets, but IL-8 showed a decrease. Other authors have the opposite view, which suggests that T cells showed an increase in CD8+ CD4+ and CD4– CD8+ subsets within activated cells, whereas CD4+ CD8– cells decreased with time. T cells responding to the virus showed a Th1 type cytokine production pattern. These authors[158] also reported a decrease in TNF-α and a decrease of IL-1α and macrophage inflammatory protein.

Perhaps this is the key to PRRSV infections in that all pigs may respond differently. There may be either depressive or stimulatory effects. The imbalance of IL-12 and IL-10 produced in PRRSV-infected pigs may favor the humoral responses and suppress cell-mediated immune responses for the first 2 weeks of life.

PRRSV was detected in the cytoplasm of macrophages at two peaks, 3 to 7 DPI and second at 14 DPI. IFN-α increased at 3 DPI, and IFN-γ and IL-12 were increased at 3 to 7 DPI and 14 to 17 DPI, but IL-10 was lower than the others suggesting that other factors also play a part.[153]

Interferons

PRRSV is able to downregulate the production of inflammatory cytokines such as type I interferons (IFN-α, IFN-β, TNF-α, and IL-1). Pigs that can clear PRRSV early have early expression of these cytokines.[160] Five of the 13 nsps were found to inhibit IFN-β promoter activation, particularly nsp1β[161] as well as TNF-α promoter activity.[162] One of the mechanisms to suppress the immune response would be to suppress several key immune regulatory cytokines, such as type IFN, IL-1, TNF-α, IL-12, and IL-6, and upregulate to aberrant levels the antiinflammatory cytokines IL-10.[162]

IFN-α is an early response to PRRSV, but the virus circumvents the host innate response with an inadequate production of type I IFNs, resulting in a delayed IFN-γ production, cellular immunity, and neutralizing antibodies and a delayed viral clearance.[163]

PRRSV is able to suppress the transcription of key antiviral genes, TNF-α and IFN-β, when infection was antibody-dependent enhanced. This pathway of infection allows PRRSV to specifically target antiviral genes and alters the innate intracellular immune responses in macrophages.[164]

The proposed model of how PRRSV nsp1 negatively regulates IFN-β has been shown.[165] Plasmacytoid dendritic cells are not present in large numbers in blood but, when exposed to viruses, usually morph into dendritic cells but not when exposed to PRRSV and may help in the persistence of the virus.[166]

In the bone marrow–derived monocyte cells, there was also a significantly increased secretion of IL-1, IL-6, IL-8, IL-10, and IFN-γ but not IL-12 or TNF-α.[167]

Infection with PRRSV increased serum levels of IL-1β, IL-6, TNF-α and IFN-γ. It also increased mRNA for the proinflammatory cytokines as well as the mRNA for TLR3, LR4, and TLR7 in the tracheobronchial tree. Most of the proinflammatory genes were also upregulated in the discrete brain areas.[168]

PRRSV does not elicit a specific IFN-γ response in nonadult animals, and IFN-γ cells may be present in similar numbers in both infected and control animals.[169] PRRSV suppresses T-cell recognition of infected macrophages.[170]

The ORF1a and ORF1b are translated to generate polyproteins, which are processed by viral proteases to form 14 different nsps.[7] Several of the nsps have been identified as integral members of viral replication and transcription machinery, whereas others might be involved in these processes through their interaction with host cell factors.[7,171] The nsps are also likely to regulate viral pathogenesis through their involvement in modulation of host innate immune responses. The nsp1β–mediated subversion of the host innate response plays an important role in PRRSV pathogenesis.[172]

The type I IFNs constitute a major player of the host innate immune system Viral replication intermediates like double-stranded RNA (dsRNA) are sensed by cytoplasmic (RIG-1–like helicases) as well as endosomal (TLR3) sensors, which trigger a complex signaling cascade.[173,174] These signaling events result in an activation of several transcription factors including interferon regulatory factor 3 (IRF3), nuclear factor kappa B ($NF\text{-}_{\kappa\beta}$) and activating transcription factor-2. These factors drive expression of type I IFN genes. Once secreted, they bind to receptors on the cell surface, which ultimately leads to the synthesis of IFN-stimulated genes.[175] Viruses have produced several measures to counteract the IFN production,[176] and PRRSV infection results in poor type I IFN production. The nsps of PRRSV inhibit IFN-dependent transcription. The nsp1α and nsp1β proteins suppress both IRF3 and $NF\text{-}_{\kappa\beta}$–mediated IFN gene induction.[148,177,178] The nsp1β also interferes with IFN signaling.[148,179] The nsp2 is likely to play an important role in the subversion of innate antiviral defenses and provides a basis for elucidating the mechanisms underlying

PRRSV pathogenesis.[180] The PRRSV nsp2 has a cysteine protease domain at its N terminal, which belongs to the ovarian tumor protease family and which appears to antagonize the type I IFN induction.[181]

It also interferes with the activation and signaling pathway of type I IFNs by blocking nuclear translocation.[179] Certain regions of nsp2 are nonessential for PRRSV replication but may play an important part in modulation of the host immunity.[148] PRRSV nsp2 interferes with NF-κβ signaling, which is important for its activation.[181] The virus lasts up to 5 months after infection in some lymphoid tissues. The levels of proinflammatory cytokines are also low, and the development of other effector components is slow (neutralizing antibodies and antigen-specific T cells). Therefore there is an inappropriate suboptimal initial innate response to PRRSV.[182] A nonsuppressive PRRSV virus could therefore be expected to stimulate a strong adaptive immune response.[183] The IFN inhibitory nature of PRRSV nsp1 in the context of virus infection was confirmed.[175,184,185] The nsp1 is cleaved into nsp1α and nsp1β, and the nsp1β has the ability to inhibit IFN synthesis and signaling.[186]

Type I IFNs (IFN-α and IFN-β) promote production of antiviral mediators and elicit NK-cell activity for killing viral-infected cells. They also induce the maturation of dendritic cells into antigen presenting cells, macrophage development, and maturation and together with IL-6 convert B cells into plasma cells.[187] How this might be achieved by the PRRSV has been suggested.[178,181,188] Increased levels of IFN-α at the time of challenge delays PRRSV viremia[189] and lessens the severity of the disease. That the presence of IFN-α at the time of infection can alter the innate and adaptive immune responses was confirmed.[190]

PRRSV encodes viral products that are able to suppress type I IFN production in different ways by interfering with the various transcription factors in the regulation of IFN expression.[172,180,181,190-192] The impairment of type I IFN induction seems to be linked to a weak adaptive immunity, which includes a delayed or slow development of humoral and cellular immunity responses leading to viral persistence in infected pigs.[193,194] Pigs infected with PRRSV had moderate interstitial pneumonia, and the virus was found in all tested tissues. Peak antibody response and IFN-γ occurred at 30 DPI with increased TGF-β until 60 DPI.[128]

The nsp2 inhibits the antiviral function of IFN-stimulated gene (ISG) 15.[195] IFN-stimulated genes are the ISGs of which ISG15 is one of the most highly expressed proteins that functions as an effector molecule in the host cell response to viral infection.

The induction of the IL-10 response may be one of the strategies used by PRRSV to modulate the host immune responses.[158] Increases in IL-4, IFN-γ, and TNF-α were found in the lymphocytes of infected piglets, but IL-8 showed a decrease. It has been shown that T cells show an increase in CD8+ CD4+ and CD4– CD8+ subsets within activated cells, whereas CD4+ CD8– cells decreased with time. T cells responding to the virus showed a Th1-type cytokine production pattern. There is also a reported decrease in TNF-α and a decrease of IL-1α and macrophage inflammatory protein. Perhaps this is the key to PRRSV infections in that all pigs may respond differently. There may be either depressive or stimulatory effects. The imbalance of IL-12 and IL-10 produced in PRRSV-infected pigs may favor the humoral responses and suppress cell-mediated immune responses for the first 2 weeks of life.

DIFFERENTIAL EFFECTS IN DIFFERENT PARTS OF THE BODY

The differential expression of proinflammatory cytokines in the lymphoid organs of PRRSV-infected pigs has been described.[196] The expression was different in the different body compartments. IL-1α and TNF-α were the most highly expressed in the mediastinal lymph nodes. IL-6 was most expressed in the retropharyngeal lymph nodes, but none was expressed in the tonsil. Proinflammatory cytokines are able to modulate the expression of CD163, a hemoglobin scavenger receptor that also acts as a PRRSV receptor and is involved in viral uncoating.[197] Whereas IL-6 can upregulate this receptor expression, TNF-α can downregulate it, inhibiting PRRSV replication. The imbalance in cytokines may play a role in the susceptibility to PRRSV replication.

Recombinant porcine IFN-α given to cells before infection reduced the cytopathogenicity of PRRSV, and viral propagation and antibody responses were delayed. It might be that the IFN alleviated damage to the immune system or enhanced the propagation of host cytotoxic T lymphocytes.[198]

Cytokine expression by macrophages in the lungs of pigs infected with PRRSV has been described.[122] Expression of IL-1α, IL6, and TNF-α correlated with the severity of pulmonary pathology and the numbers of pulmonary macrophages. Significant correlations were found between PRRSV infection and the expression of IL-12p40 and IFN-γ and between the expression of TNF-α and IFN-γ. These findings suggest that PRRSV modulates the immune response by the upregulation of IL-10, which may in turn reduce the expression of cytokines involved in viral clearance (IFN-α, IFN-γ, IL-12p40, and TNF-α). The results also suggest that expression of IFN-γ is stimulated by IL-12p40 and TNF-α but not IFN-α. All of these cytokines were expressed mainly by septal macrophages with weaker expression by alveolar macrophages, lymphocytes, and neutrophils. There appears to be a differential activation of septal and alveolar macrophages in PRRSV infection, with septal macrophages as the major source of cytokines.

There is probably a regulatory role of PRSSV ORF1A on porcine alveolar gene expression.[199]

The expression of PRRSV antigens is correlated with the expression of regulatory cytokines such as IL-10 and TGF-β in the lungs of pigs.[122,154] There are no substantial changes in the level of serum proinflammatory cytokines. Expression of proinflammatory cytokines were increased in mediastinal lymph nodes, but there was little increase in the tonsils and retroperitoneal lymph node.[196]

DIFFERENTIAL EFFECTS OF DIFFERENT STRAINS

There is a differential expression of cytokines by different PRRSV isolates[121] and within different lymphoid organs.[196]

The virulence of these strains may be caused by the impairment of TNF-α by inhibiting the ERK signaling pathway.[200] The limited expression of TNF-α with some strains of PRRSV may be a mechanism in which some are able to impair the host immune response and prevent viral clearance. These downregulations have been associated with nsps1α and 1β and 2.[148]

TGF-β and IL-10 are immunomodulatory cytokines that are able to downregulate the host response. An increased mRNA and protein expression of TGF-β has been observed in PRRSV infection with the North American type II PRRSV.[122,138,201] There is an enhanced expression of TGF-β protein in lymphoid organs and the lung following PRRSV, and this may be important because it is an immunomodulatory cytokine.[202]

In some cases new strains can induce a preferential cytokine profile,[203] and the experimental results show a defective pattern of both innate and adaptive immunity that underlies the long-term persistence of PRRS-infected pigs. Both serum-neutralizing antibody and IFN-γ secreting cells were defective in experimental infections.[204]

On the other hand, in the field, there are complex interactions of virus/host further complicated by interactions with bacterial agonists such as LPS. Under field conditions there was poor or no development of a specific IFN-γ response rather than a delayed one.[170,205] Type 2 isolates are more pneumovirulent than type 1 isolates as seen by clinical signs and macroscopic and microscopic lesions.[206]

Genotype 2 strains of PRRS are more efficient at escaping the intrinsic antiviral activity induced by type I and type II IFNs. Monocyte-derived macrophages can be used by the virus instead of alveolar macrophages.[207]

In a study comparing 39 isolates, there were different effects depending on the strain and the host cell infected.[121] All strains produced high levels of IL-1 and IL-8 in

macrophage cultures but could be differentiated in their responses with IL-10 and TNF-α.

STRAIN VARIATIONS

A comparative analysis of the immune response in experimental infections with three strains of PRRSV showed that although the outcome of infection was similar with clearance at 33 DPI, there were differences in the immune response to the viruses. The "Lena" strain produced fever and clinical signs, whereas the Lelystad virus and Belgium strain A did not. It also resulted in high virus titers in serum, low numbers of IFN-γ secreting cells, a change in leukocyte populations, and a delayed antibody response to immunization with Aujeszky's disease virus. Levels of IL-1β, IFN-α, IL-10, IL-12, TNF-α, and IFN-γ mRNA of the Lena-infected pigs were also increased but not in the other two infections.[208]

The phenotypic modulation and cytokine profiles of antigen presenting cells infected with European type subtype 1 and 3 PRRSV strains in vitro and in vivo was described.[209] The subtype 3 strains (largely Eastern European, e.g., the Lena strain) are more virulent than the type 1 strains. Bone marrow–derived dendritic cells and alveolar macrophages were infected. The Lena strain caused more apoptosis and a higher level of infectivity and some downregulation of the cell-surface molecules. These facts may have explained the increased pathogenicity of the Lena strain and have dampened the specific immune responses. This could explain the delayed and decreased adaptive immune responses observed after infections with this strain.

The effect of genotypic and biotypic differences among PRRS viruses on the serologic assessment of pigs for virus infection has shown that[210] all of the pigs inoculated with field virus became seropositive (indirect fluorescent antibody [IFA] and ELISA). There was a great deal of variation in the onset and level of serum virus neutralization antibody in individual pigs and with each virus. The authors concluded that biotype differences may affect the kinetics of humoral immune response.

Recent studies have suggested that the new strain (Lena) replicates more efficiently than the old Lelystad virus in nasal mucosal explants. This is probably caused by the use of a broader population of entry receptor cells.[211]

HIGH PATHOGENICITY PORCINE REPRODUCTIVE AND RESPIRATORY SYNDROME PATHOGENESIS

Classical PRRS produces apoptosis in a variety of organs including lungs, testes, lymph nodes, and thymus. Apoptotic changes in peripheral immune organs and lungs, following experimental infection of piglets with highly pathogenic and classical PRRS, have been described.[212] Previous reports have suggested that HP-PRRS induces thymic atrophy with related thymocyte apoptosis, but there have been no reports in other tissues. The HP-PRRS exhibited much greater cell tropism than the usual PRRS and led to serious injury in tonsil, spleen, and lymph nodes. There were large numbers of apoptotic cells in the organs examined. In HP-PRRS alone, in comparison with vaccinated pigs receiving HP-PRRS, piglets showed thymus atrophy, decreased serum levels of IL-4, and increased serum levels of IL-10 and IFN-γ. The results suggested that elevated IL-10 levels at the early stage of infection may enhance viral survival and delay the onset of protective immunity.[213] The HP-PRRSV affects all stages of production. Pregnant sows manifest abortion and give birth to weak and stillborn piglets, and there are morbidity and mortality rates of 50% to 100%.

DEVELOPMENT OF LESIONS

There was also a temporary immunosuppression in piglets at about 4 weeks postinfection. Vascular lesions associated with PRRSV infection are analogous to those observed in horses with equine arteritis virus, which is also a member of the Arteriviridae family, and the renal lesions of equine viral arteritis infection correspond to those of PRRSV. Inflammatory infiltrates are seen at the junction of the renal cortex and medulla, with vascular changes associated with the muscular tunics of small arterioles.

The characteristic lesions can be reproduced in conventional pigs at 1 week, 4 weeks, or 10 weeks of age, and the variation in severity of clinical disease can be attributed to differences in strain virulence. The effects of the virus on reproductive performance are also strain dependent. There is no evidence that virus will grow in the ovarian tissues but may be taken into them by circulating macrophages. PRRSV can replicate in the testicular germ cells, but there is no evidence that there is any PRRSV in ova, indicating that the female gonad is resistant to persistent infection. Some strains are of low pathogenicity, whereas others are highly pathogenic. The reproductive disease has been reproduced experimentally, and the effects on the fetus are dependent on the stage of gestation. Aerosol exposure of nonimmune pregnant gilts to the Lelystad virus in late gestations (84 days) results in clinical disease. After an incubation period of 4 to 7 days, all sows are inappetent and listless for 6 to 9 days. Some sows develop blue-colored ears accompanied by abdominal respirations. Sows may farrow at days 116 and 117 of gestation, giving birth to dead, mummified, and live piglets. Many of the live-born piglets are pale, listless, and weak, and some are in respiratory distress and exhibit varying degrees of splayleg or muscular tremors. The virus may be isolated from stillborn piglets or those born alive. Antibody is present in precolostral serum samples or ascitic fluids of piglets, which demonstrates transplacental passage of the virus.

The gross and microscopic lesions in the fetuses from sows experimentally infected oronasally with the virus at 90 days' gestation consist of hemorrhage of the umbilicus and necrotizing umbilical arteritis with periarterial hemorrhage. Severe pulmonary lesions are present in fetuses inoculated in utero with the virus between 45 and 49 days' gestation. Even the lowest PRRSV exposure dose caused reproductive failure in naive, unvaccinated animals. When sows are inoculated oronasally with the virus in midgestation, the virus does not readily cross the placenta but replicates in fetuses that are inoculated directly in midgestation. It is suggested in prenatal piglets that PRRS replicates primarily in lymphoid tissues, having gained access to them from the placenta via the bloodstream. Thus the fetuses are more susceptible in late gestation than earlier in midgestation, or there is greater likelihood of transplacental infection during late gestation. Experimentally, the intrauterine inoculation of the virus into gilts on the day after natural breeding may have little or no effect on their reproductive performance. There appears to be no direct or indirect effect on luteal function contributing to PRRSV-induced abortion. The virus may cause cell death directly, such as the alveolar macrophages, or in lymphoid tissues. PRRSV affects Marc 145 cells, which undergo necrosis at a much higher rate than apoptosis, and increases with virus levels used to infect the cells. Apoptosis does occur in PRRSV-infected cells, but it is a late event during PRRSV replication and rapidly results in a necrotic-like death. Lesions have been seen in the placenta and in the vessels of the umbilical cord, but these are rarely reported with European strains, although they may be more common with the North American strains.

The original descriptions of porcine necrotizing pneumonia (PNP) were associated with swine influenza, but more recent research has shown that PRRSV is consistently and predominantly associated with PNP and should be considered the key etiologic agent for PNP together with PCV2.

The pathogenesis of a Korean type 1 PRRSV in experimentally infected pigs has been described.[214] Infected pigs developed multifocal, tan-mottled areas of lung. Microscopic lesions were multifocal, mild to moderate, and generally most extensive at 5 to 7 DPI and were nearly resolved by 28 DPI. PRRSV nucleic acid was detected in cytoplasm of macrophages and type 1 and II pneumonocytes.

HIGH PATHOGENECITY PROCINE REPRODUCTIVE AND RESPIRATORY SYNDROME RESPONSES

HP-PRRSV infection could impair TNF-α production by inhibiting the ERK signaling pathway.[215]

In HP-PRRS the marked inappetence and severe respiratory signs are related to the severe interstitial pneumonia and high levels of expression of IL-1α in the lungs compared with other PRRSV strains.[215]

High pathogenicity PRRSV displays an expanded tissue tropism in vivo suggesting that this may contribute to its high pathogenicity. Positivity was recorded in macrophages in lymphoid organs but also in the epithelium including gastric mucous membrane and mucous glands.[216]

The HP-PRRS epidemic in China, the so-called high fever disease with nervous signs, has been on the increase in China since 2009. There was a nonsuppurative encephalitis with lymphohistiocytic perivascular cuffing and infiltration of leukocytes into the neuropil. The electron microscope showed that the virus that infected the endothelial cells crossed the blood-brain barrier into the central nervous system (CNS) and then induced cellular damage to the neurons and neuroglial cells.[217]

An HP-PRRSV strain (HuN4) was shown to produce a loss of appetite, decrease in BW, raised body temperature, and respiratory signs. Lesions were of multifocal interstitial pneumonia with macrophage infiltration. The lesions in the lymph nodes were characterized by collapsed follicles, depletion of germinal centers, and reduction in lymphocytes. Perivascular cuffing and glial nodules were observed in some brains. PRRSV was detected in macrophages, alveolar epithelial cells, and vascular endothelial cells in the tonsil and lymph nodes. It is more pathogenic than some strains because of its higher replication rate.[218]

Chinese and Vietnamese strains of HP-PRRSV cause different outcomes in U.S. swine.[53,218] The Vietnamese virus replicated in an approximately 10-fold lower level in serum than did the Chinese virus. It also produced a lower temperature response and resulted in a lower mortality. The cytokine responses in a 9-plex panel varied between the strains, between the tissues examined, and by the inoculum dose. In this study, also using the U.S. prototype strain VR-2332, all three produced detectable levels of TNF-α, IL-1β, IFN-γ, IL-10, and IL-12p70, but the levels and the kinetics also differed. There was also a high sustained level of IL-10 and IFN-γ, and these might impair effective immune clearance.[53,219,220] Polyclonal B-cell activation can result in IL-10 producing B cells.[221] PRRSV produces a polyclonal activation of B cells accompanied by a hypergammaglobulinemia.[222-224] This leads to deregulated cytokine production.

IMMUNOLOGY

The immune responses generated by PRRSV and control of the disease by immune mechanisms are not yet completely understood.

There are highly conserved T-cell epitopes on nsps9 and 10 of type 2 PRRSV,[225] and these may be important in the formulation of immunogens to provide broad cross-protection against diverse strains of PRRSV.

Inoculation with different PRRSV strains results in different virologic and immunologic outcomes and in different degrees of homologous and heterologous protection.[156] The core effect of the virus is to infect and cause abnormalities in the macrophages. Disturbed macrophages may fail to present antigen successfully. More important, whatever cytokines are present in the pig or are induced by the PRRSV in that particular host may determine the outcome. It was shown that PRRSV is slow to produce both neutralizing antibodies and cell-mediated immunity, but it does produce an IFN response in PRRSV-infected lymphoid tissue.

Following natural infection, most pigs are resistant to subsequent infection, but the mechanisms of protective immunity are not understood. It has been suggested that the immune response to PRRSV has some degree of strain specificity. Indeed, it has also been suggested that the ability to cross the placenta is also strain specific and that although maternal immunity may not prevent transplacental infection, it may exert additional selection pressure. Circulating antibodies to the virus are detectable within 14 and 21 DPI based on indirect immunofluorescence test or ELISA, and 15-kDa protein is the most immunogenic of the viral proteins and may provide the antigenic basis for the development of improved diagnostic tests. However, this response is not of neutralizing antibodies. These may take a long time to develop. At the same time the occurrence of IFN-γ–producing cells is initially weak, but this becomes much stronger from 3 to 6 months after infection. This response may be enhanced by the use of IL-12. Several structural, functionally distinct, and specific antibodies to the virus are generated following infection or vaccination. Cell-mediated immune responses specific to the virus also occur. The relative role of humoral and cell-mediated immunity in providing protection against disease is unknown.

A unique feature of infection is that viremia and circulating antibodies may exist together; the antibodies protect pigs from reinfection and reduce or eliminate shedding of the virus in the semen of boars. Sows are immune to further disease associated with the virus following recovery from acute infection. Following an outbreak of reproductive disease the level of performance will return to normal, suggesting that immunity develops following natural exposure. Protection against subsequent reproductive losses is of long duration in individual animals. However, cross-protection to different strains may not occur. Experimentally infected sows are protected against reproductive losses when challenged with homologous virus over 300 days after initial exposure. Extended studies against homologous infection found that the duration of protection was at least 604 days, which is essentially lifelong protection. Protective immunity was based on two criteria: the absence of transplacental transfer of challenge virus and the apparent lack of virus replication in the dam 21 days following inoculation.

Piglets born from seropositive sows acquire **colostral antibodies** that decline at highly variable rates from 3 to 8 weeks after birth. Passive immunity provides effective immunity for the piglets, but loss of passive immunity at various ages results in susceptible pigs and infection that results in persistence of the virus in pigs 6 to 9 weeks of age, which are considered as the major reservoir of the virus in farrow-finish herds. In the absence of natural infection, maternal antibodies become undetectable between 6 and 10 weeks of age. Some litters do not have maternal antibodies and may not have detectable antibodies until 4 weeks of age, and clinical disease may occur at 2 weeks of age. By 8 weeks of age, antibodies are usually detectable in all pigs and they persist for several months. However, there may be a large variation in the levels of antibodies in piglets at 10 to 12 weeks of age when they are moved to the finishing units. In longitudinal surveys, the seroprevalence of the virus in the 4- to 5-week-old pigs was higher than in the 8- to 9-week-old pigs, and most pigs were negative when they entered the finishing units. In herds where the virus persists, sows did not suffer repeated reproductive losses, indicating that some form of protective immunity develops.

The virus has a predilection for immune cells, and disease manifestations can be linked directly to changes in the immune system. The replication of the virus in the cells of the immune lineage, especially macrophages, may lead to immunosuppression and predispose to secondary infections. Thus immunity to the virus may be a double-edged sword; the virus attacks the immune system, which may cause immunosuppression, while inducing protective antibodies.

Antibody-dependent enhancement of infection may also occur, because low levels of antibody enhance the ability of the virus to enter the pulmonary alveolar macrophage cells and replicate and destroy the cells. This may be important in sucking and nursery pigs exposed to the virus during a period of declining maternal antibody.

PRRSV complicates the ability of the host to respond to infection through several immune evasion mechanisms.[63,226] PRRSV infection is characterized by a delayed appearance of neutralizing antibodies (3–4 months) and a slow development of virus-specific IFN responses. PRRSV nsp2 is increasingly emerging as a multifunctional protein possibly with a profound impact on PRRSV replication and viral pathogenesis.[227] Acquired immunity has been reviewed.[63,184,204,226] After

infection, most antibodies are nonneutralizing and are principally targeted to N and nsp2 proteins. Neutralizing antibodies appear from 2 to 4 weeks but do not peak until several weeks to months later. Virus persists in the presence of neutralizing antibody. It is possible that PRRSV produces "decoy" epitopes that produce nonneutralizing antibodies.[228]

The T-cell responses to PRRSV are induced 2 to 8 weeks postinfection and are detected against all structural proteins encoded by ORFs 2 to 7 but are considered to be weak, transient, and highly variable.

GP5 and M are the major proteins of the envelope of PRRSV, and the GP5/M ectodomain peptide epitopes are available for host antibody recognition but are not associated with antibody-mediated virus neutralization.[229]

CLINICAL FINDINGS

The main feature of clinical disease associated with this virus was the extreme variability of the clinical signs. Generally, signs associated with PRRSV appear to result from a combination of genetic factors and herd management characteristics. The relative influences of these two factors differ depending on the specific clinical signs in question. These may vary from inapparent infection to sudden death and abortion storms (the sow abortion and mortality syndrome).

The condition continues to evolve from the first descriptions of mystery swine disease in the United States and Canada and blue-eared pig disease in Europe. The swine mortality and abortion syndrome was then described in the United States. Then, there have been the high pathogenicity cases in China ("high fever disease") characterized with greater than 20% mortality[230-232] and the highly virulent 1-18-2 strain that occurred in the north central United States in 2007.[233]

Concurrent Infections

The increased secondary bacterial infection has been linked to an upregulation of CD14 and LPS-binding protein in PAMs.[234] The effects of the virus on the immune system may explain the suspected immunosuppression and secondary infections, which are recognized clinically but have not been reproduced experimentally.

Its synergism with PCV2 is in doubt. It does not seem to be potentiated by the other great pig pathogen PCV2 virus, but it has been proposed that it may increase the severity of PRRSV-induced interstitial pneumonia. PRRSV infection may enhance PCV2 replication. It is predisposed by MH, and this can be reduced by vaccination for MH. In turn, PRRSV predisposes to *B. bronchiseptica*. Both may interact to reduce the efficiency of lung defense mechanisms and facilitate infection with *P. multocida*. There is little effect on *H. parasuis* secondary infection with a slight increase in macrophage uptake of *H. parasuis* during the early infection, which is reduced after 7 days. There is evidence that concurrent infection with transmissible gastroenteritis virus and PRRSV is likely to have little or no effect on subsequent shedding or persistence of infection. Infection with PRRSV is common in pigs with postweaning multisystemic wasting syndrome (PMWS), but there is no evidence that PRRS is necessary for the development of it. PRRSV has been seen in a swine herd with porcine cytomegalovirus. Synergism between PRRSV and *S.* Choleraesuis has been described with unthriftiness, rough hair coats, dyspnea, and diarrhea. Pigs that received dexamethasone were the most severely affected and half died, but they also shed significantly more organisms in feces and also had significantly higher PRRSV titers. Simultaneous infection between PRRSV and *S. suis* is much more severe than with either agent on its own. PRRSV-induced suppression of pulmonary intravascular macrophage function may in part explain PRRSV associated susceptibility to *S. suis* infection.

There is also a clear synergism between PRRSV and LPS in the exhibition of respiratory signs in conventional pigs. In these infections with the virus and bacteria, the rise in TNF-α, IL-1, and IL-6 was 10 to 100 times higher than in the single infections. Reproductive failure and respiratory disease are the major clinical findings that are also highly variable between herds. All age groups in a herd may be affected within a short period of time.

Pigs infected with both PRRSV and MH had a greater percentage of pneumonic lung, increased clinical disease, and lower viral clearance than pigs with single infections. There were also increased levels of IL-β, IL-8, IL-10, and TNF-α in lung lavage fluid, and this may be the way that the combined infection increases the pulmonary response.

Clinical disease is often more severe when accompanied by infection with PCV2[1] and is associated with other conditions in the field that often appear as indicators of the underlying PRRSV infection.[135,235] These are mainly caused by the pneumovirulence of the virus and its persistence in lymphoid organs. There is a decrease in NK cell cell–mediated activity caused by a decreased expression of IFN. The adaptive immune response is also impaired, leading to an increased apoptosis of PAMs caused by increased IL-6 and IL-10.[135,236]

Pigs with PRRSV and subsequently exposed to porcine respiratory coronavirus (PRCV) had reduced weight gains, higher incidence of fever, and more severe pneumonia compared with either single infection.[236] This was caused by reduced IFN-α in the lungs and reduced NK cells, and it coincided with the pneumonia. The subsequent PRCV enhanced the level of PRRSV replication in the lung and a tendency to increased serum Th1 activity (IFN-γ) but decreased type II activity (IL-4) responses, further exacerbating the PRRSV pneumonia. More severe alveolar macrophage apoptosis then occurred.

Pulmonary function has been studied in PPRRS-affected pigs.[237] Infected pigs developed fever, reduced appetite, respiratory distress, and dullness within 9 DPI. The noninvasive pulmonary tests revealed airway obstruction, reduced lung compliance, and reduced lung gas transfer. The effects were worst at 9 to 18 DPI in which they were accompanied by an increased respiratory rate and decreased tidal volume. Expiration was affected more than inspiration, and this is caused by airflow limitation predominantly in the peripheral airways. Pigs have both obstructive and restrictive disorders and have shorter breathing cycles and shallower respiration. The energy requirement for breathing increases because of the increased effort.

Infection with the European PRRSV causes CNS disorders in the suckling pig.[238] PRRSV was detected in the macrophages in the cerebrum by IHC.

Reproductive Failure

If 90-day gestational gilts are given vaccine or field strains of PRRSV then some pigs are born dead, most pigs survive, and some pigs are infected in utero. Vaccine strains did not affect postnatal growth, but field strains reduced growth. It may be that the virus entered the reproductive tract through the viremia and then the seeded tissues may release the virus back into the serum at low levels.

The infection of fetuses with an attenuated virus shows the same immune dysfunction as in wild-type infections in piglets kept in isolators.[224]

All sows given IM injections of a mild strain of PRRSV at 90 days' gestation showed transmission of the virus in utero. The proportion of virus-positive pigs and their level of viremia were higher at 4 days of age than at birth or weaning. The findings suggest that monitoring piglets in late lactation will enable assessment of the shedding of the virus from sows.[239]

Landrace gilts when given PRRSV had a significantly reduced number of fetuses but a similar effect in crossbred pigs was not found. The Landrace had less weight loss during pregnancy, suggesting greater tolerance of PRRSV infection. Breeds do differ in phenotypic impacts of PRRSV.[240]

Anorexia, lethargy, depression, and mild fever in pregnant gilts and sows are common initial clinical findings affecting 5% to 50% of animals. This is commonly followed by a sudden increase in early farrowings at 108 to 112 days' gestation, late-term abortions, stillborn and mummified fetuses, partially autolyzed fetuses, weak neonates with high mortality within a few hours or days after

birth, late returns to estrus, and repeat breeders. This is generally followed by midgestation abortions and marked increases in the percentage of mummified fetuses, early embryonic death, and infertility. In large herds, successive groups of 10% to 20% of gilts and sows may become anorexic over a period of 2 to 3 weeks. Cyanosis of ears, tails, vulvas, abdomens, and snouts may occur in a small number of sows, which is more common in European outbreaks and uncommon in North America. Following the initial outbreak, a storm of reproductive failure may occur consisting of premature farrowings, late-term abortions, an increase in stillbirths, mummified fetuses, and weak neonates. This second phase of reproductive failure may last 8 to 12 weeks. Stillbirths may reach 35% to 40%. Weak-born piglets die within 1 week and contribute to a high preweaning mortality.

The interaction between PRRSV and the late gestation pig fetus has been described.[113] The major site of replication was the thymus. There were elevated IFN-γ and TNF-α in tissues from infected piglets. The hyperplastic fetal lymph nodes had large numbers of B cells. Fetal infection can alter the selection of PRRSV variants and may represent a source of PRRSV genetic diversity.

The pathogenesis of PRRSV in experimentally infected pregnant gilts has been described.[241] There was a significant increase in apoptotic cells in lung, heart, thymus, liver, adrenal gland, and spleen of stillborn fetuses compared with live-born piglets. The majority of cells were either full of PRRSV or apoptotic but not both. Apoptotic cells outnumbered PRRSV cells. PRRSV may replicate in the fetal implantation sites and cause apoptosis of infected macrophages and the surrounding cells.[242] In a review of the pathogenesis and prevention of placental and transplacental PRRSV infection, it was found that the virus replicates in the endometrium and placenta in late gestation, and this is responsible for the range of PRRSV-related reproductive problems.[243]

PRRSV is shed in the milk of infected sows, and the antigen is present in the in the mammary glands of experimentally infected sows.[244]

Today with the original European strains there may be just outbreaks of rolling inappetence or occasional early farrowings. However, there are serious clinical outbreaks in Italy, Poland, and the UK associated with new variants.

Reproductive disease may be preceded by, or follow, respiratory disease in the breeding herd, finishing pigs, or younger pigs. The reproductive aspect of the disease typically lasts from 4 to 5 months, occupying an entire reproductive cycle within a herd. This is followed by a return to normal performance. Repeated incidents of reproductive failure in individual gilts and sows are unusual, but recurrent episodes may occur in herds purchasing replacement gilts that do not have sufficient immunity.

Vaccinating sows with the North American PRRSV-based modified live vaccine does not prevent reproductive failure after insemination with European PRRSV-spiked semen.[245]

Outbreaks of the disease are characterized by a period of severe reproductive problems in the breeding herd, followed by a return to near normal reproductive performance, punctuated by recurrent episodes of reproductive failure. Most herds eventually return to preoutbreak levels of reproductive performance, but some herds never achieve preoutbreak performance levels.

Boars may also be affected with anorexia, fever, coughing, lack of libido, and temporary reduction in semen quality. PRRSV infection affects seminal quality for a limited period only. The virus can be transmitted to sows through insemination.[238]

Boars naturally coinfected with PRRSV and PCV2 can be found, and at least two different strains of virus from serum and semen can be detected.[246] A group of spontaneously infected boars seroconverted 4 weeks postinfection. There was an increase in the acrosome-defective spermatozoa and sperm motion patterns.[247]

Respiratory Disease

The most important problem facing many of the larger pig industries in the world is PRDC. The most important contributor to this syndrome is PRRSV. The generation of immunity capable of protecting pigs by mediating virus inhibition through virus-neutralizing antibodies or IFN takes time.

Disease occurs in pigs of any age, but especially in nursing and weaned pigs, and is characterized by anorexia, fever, dyspnea, polypnea, coughing, and subnormal growth rates. A bluish discoloration of the ears, abdomen, or vulva may also occur (blue-eared disease). Death may occur in the acute phase. In some herds, up to 50% of pigs are anorexic, up to 10% may have a fever, up to 5% are cyanotic, and up to 30% have respiratory distress. In weanling pigs, the morbidity may be as high as 30%, with a mortality of 5% to 10%. Nursery pigs exhibit respiratory distress and growth retardation. Conjunctivitis, sneezing, and diarrhea are common. All of these signs may appear to move through the various age groups in the herd over several days and a few weeks. The course of the disease in a herd may last 6 to 12 weeks. In gilts and sows of any parity, anorexia and fever, lasting for several days, are noted initially. The acute-phase respiratory disease may last several months but is often followed by a long period of postweaning respiratory disease, which may last up to 2 years. This long course is often accompanied by secondary infections in successive batches of weaned pigs. Unthriftiness may persist throughout the finishing period with an ineffective response to antibiotics and vaccines.

Preweaning morbidity and mortality is a major feature of the disease. Litters are often unthrifty, and many deaths occur within the first week of age.

In a study of a newly established farrow-to-finish farm in Poland that was negative for PRRS on establishment but positive for PCV2, it was found that the conception rate dropped from 89% to 51% and the abortion rate increased from 0.5% to 11.0% with the onset of PRRS infection. Then the mortality was elevated, and clinical disease typical of PMWS occurred. The abortion level returned to normal 4 months later, and the conception rate returned to normal 4 months after that.[248]

CLINICAL SIGNS IN HIGH PATHOGENICITY PORCINE REPRODUCTIVE AND RESPIRATORY SYNDROME VIRUS

Infection with these signs is associated with severe clinical signs, pulmonary lesions, and aberrant host responses.[249,250]

CLINICAL PATHOLOGY

Acute Phase Proteins

Acute phase proteins (APPs) are synthesized by the liver hepatocytes in response to proinflammatory cytokines. They induce inflammatory reactions and fever, but overproduction may produce an antiinflammatory state. PRRSV may not produce an APP response caused by a poor preinflammatory cytokine response. There is an early expression of haptoglobin (modulates immune response and interacts with CD163), which is the receptor for PRRSV, increasing expression of IL-10 (antiinflammatory), and pig major acute protein, but the response of C-reactive protein (CRP; activates complement and opsonization) and serum amyloid A (chemoattractant for monocytes, T cells, and polymorphs) is delayed and variable.[201] The haptoglobin may modulate the immune response and induce the antiinflammatory IL-10.

The CD163 removes the hemoglobin–haptoglobin complexes circulating in the blood and decreases the amount of iron available for bacteria and reduces oxidative stress.

Haptoglobin levels and pig major acute proteins were increased at 10 DPI, but CRP and serum amyloid showed a delayed and highly variable increase. All three proinflammatory cytokines (IL-1β, IL-6, and TNF-α) were poorly expressed, and only a mild increase in IL-1β was observed at 7 DPI. The increased expression of haptoglobin coincided with the light enhancement observed in both IL-6 and TNF-α and might be related with an increased expression of IL-10. The low expression of TNF-α may point to a possible mechanism of viral evasion of the host immune response.[201]

An 8-plex Luminex assay has been developed to detect swine cytokines after vaccination. It will detect innate (IL-1β, IL-8, IFN-α, TNF-α, and IL-12), regulatory (IL-10), Th1 (IL-4), and Th2 (IL-4) cytokines.[251]

PRRSV infection significantly increases the number of alveolar macrophages in bronchoalveolar lavage fluid approximately 10-fold between day 10 and day 21 of infection. Approximately 63% of the cells were cytotoxic T cells (CTLs) and NK cells. Serum haptoglobin levels were increased from 7 to 21 DPI.

Piglets also become anemic in PRRSV infections, and the most highly pneumovirulent strains induced the most severe anemia. This is probably caused by a direct or indirect effect on the erythroid precursor cells of the bone marrow.

A definitive diagnosis requires detection of virus in infected animals and detection of antibodies in fetal fluid or in precolostral blood of stillborn and weak-born piglets. Detection of antibodies in sera of groups of pigs of different ages is also necessary. The most suitable body fluid and tissue samples and diagnostic tests for the etiologic diagnosis of PRRS are dependent on several variables including:

- Age of pigs from which samples are collected
- Stage of infection (acute or persistent)
- Available complement of diagnostic reagents
- Urgency of obtaining results

When congenitally or neonatal pigs are affected, both serum and alveolar macrophages are reliable samples. For older pigs, alveolar macrophages are more reliable than serum.

Detection or Isolation of Virus

The gold standard is the isolation of the virus. A PAM cell line has been developed for the growth of PRRSV.[252]

In an interlaboratory ring trial in Europe to test the real-time RT-PCR tests it was found that there were great differences in the qualitative diagnostics as well as analytical sensitivity. False negatives were a problem, and to achieve maximum safety in the results it was suggested that different assays or kits should be used.[253]

Boars

Serum is the best method to detect PRRSV during an acute infection in boars.[254] Semen samples failed to detect the virus in most cases. Pooling of samples resulted in a decline of sensitivity.

In a study of commercial tests (RT-PCRs) for diverse strains of PRRSV in boars, in serum, semen blood swabs, and oral fluids[255] from experimentally infected animals, it was found that serum and blood swabs had the best performance and highest detection rates. These were at their highest between 3 and 5 DPI. Oral fluids had the lowest detection rates. The virus can be demonstrated by isolation using cell cultures, by direct detection of viral antigen in tissue sections, or by the detection of virus-specific RNA. Two commercial ELISAs and an in-house florescent microbead immunoassay were tested to detect IgG antibodies in serum and oral fluids for both type 1 and type 2 virus. The tests were similar in sensitivity and specificity but the commercial test kit IDEXX Se detected positive animals earlier than the test kit HIPRA Se. The oral fluid and serum had similar detection rates.[256]

Samples used for virus isolation include serum, thoracic fluid, spleen, and lung. Porcine pulmonary alveolar macrophages are used for isolation of virus. Alveolar macrophages using immunofluorescence microscopy can be used for detection of virus during acute infections. The PCR assay is a reliable, sensitive, and rapid test for the detection of virus in boar semen. It can also be used to determine whether suckling piglets are infected with PRRSV before vaccination and for determining the relationship between parity and shedding of virus. It can also be used to obtain PRRSV piglets. PCR followed by RFLP analysis using several restriction enzymes provides a good genetic estimate for isolate differentiation. A reverse transcription and PCR, coupled with a microplate colormetric assay, is an automated system that is a reliable and easy test for the routine detection of the virus in semen samples from seropositive boars. Multiplex RT-nested PCR can be applied to formalin-fixed tissues.

A nested PCR has been described that is 100 to 1000 times more sensitive than the usual PCR. An assessment of the viral load can possibly be made by using the quantitative competitive RT-PCR. A quantitative TaqMan RT-PCR is time-saving, easy to handle, less likely to be cross-contaminated, and highly sensitive and specific. Immunohistochemical techniques are available for the detection of virus in formalin-fixed tissues. The virus was detected in 11% to 23% of animals with interstitial pneumonia. It was found in 21% to 31% of animals less than 3 months of age but in only 6% to 17% of those more than 4 months of age. The immunogold silver staining i s superior to the immunoperoxidase staining systems for detection of virus in formalin-fixed tissues. RT-PCR is also available and can distinguish between North American and European strains.

A double in situ hybridization (ISH) technique has been developed that can show both PRRSV and PCV2 and a small number of alveolar macrophages stain for both antigens.

A rapid detection method using RT-loop mediated isothermal amplification assay has been described.[257,258]

RT-PCRs have been developed for the detection and differentiation of European and U.S. PRRSV.[259,260] These cannot differentiate U.S. and HP-PRRS, but the duplex real-time RT-PCR test developed[261] will do this. The test was also compared with standard single PCRs, and the results were found to be in 98.7% agreement.

A method using phages harboring specific peptides that recognize the N protein of PRRSV has been used to distinguish it from other viruses.[262]

Serology

A recent study has described the production of GP3, GP5, and N-specific hybridomas and an extensive collection of monoclonal antibodies that may help in diagnosis because they reacted with a range of genetically different PRRS viruses.[263] ELISAs differ in their sensitivity, and those that showed higher sensitivity could be used for early detection in individual pigs, especially in PRRSV-free herds.[264]

In a study of the humoral responses in boars measured in serum samples and oral fluid specimens, it was found that IgM, IgA, and IgG were first detected in serum samples collected on DPI 1, 7, and 10, respectively, and in oral fluids from 3 to 7 DPI for IgM, 7 to 10 DPI for IgA, and 8 to 14 DPI for IgG, respectively.[265]

Serologic tests have good sensitivity and specificity for diagnosis on a herd level but less so on the individual animal. The tests in common usage are described below. One of the problems is that the serologic response to a nonvirulent strain is the same as it is to a virulent strain. It is also important to realize that although a positive result for antibody indicates exposure to virus, a negative test does not necessarily mean that the pig is free from PRRSV or has not been in contact with the virus.

Immunoperoxidase Monolayer Assay Test

The immunoperoxidase monolayer assay (IPMA) is often the first test used. Approximately 75% of sows infected with the virus seroconvert to the Lelystad virus. However, the IPMA does not allow for large-scale surveys.

Indirect Enzyme-Linked Immunosorbent Assay (iELISA)

The iELISA is used for the routine serodiagnosis; it is simple, inexpensive, effective, and a better alternative to the indirect immunofluorescent assay or the immunoperoxidase assay. It is suitable for the screening of large numbers of samples and is best used as a herd test. Because of marked differences between and within North American and European virus isolates, serologic tests using only one antigenic type of the virus may potentially yield false-negative results with antisera against diverse antigenic types of the virus. A mixture of ELISA antigens from North American and European strains gives

superior results when both types of viruses are known to exist.

A meat juice ELISA has been developed that gives complete agreement with the serum ELISAs.

Unexpected positives have been shown following the use of commercial ELISA testing kits, and these results can be improved by using competitive and blocking ELISA.[266]

A multiplex method for simultaneous serologic detection of PRRS and PCV2 has been described.[267]

Indirect Florescent Antibody Assay (IFAT)

The IFAT is a highly sensitive test. Antibody titers are detectable in infected pigs 8 days after inoculation. The IgM IFAT is also a rapid and simple test for diagnosing recent infection as early as 5 to 28 DPI in 3-week-old piglets, and 7 to 21 DPI in sows.

Modified Serum Neutralization Test

This test is useful for the detection of later and higher levels of antibody when the conventional methods cannot detect antibody. The test can differentiate between strains. The serum neutralization test is not used for routine diagnosis because neutralizing antibodies do not appear early in the infection.

Herd Diagnosis

The serologic diagnosis must be used and applied on a herd basis and acute and convalescent sera submitted for optimal results. A baseline herd sampling is necessary to evaluate the status of a herd and to determine whether and in which groups the virus is circulating. In large herds of over 500 sows, samples are taken from 30 animals in each breeding, gestation, and farrowing group, with representation from all parties. In addition, 10 nursery pigs (5 weeks old), 10 pigs at the end of the nursery period, and 10 pigs in the late finishing stage constitute a **herd profile**. Thus serologic monitoring can be used to monitor the circulation of virus within a closed herd and to determine infection status of breeding animals that are to be introduced into seronegative herds. Results from the sow sera indicate whether the sow herd is virus negative, stable, or has an active virus circulation. Comparison of the early and late nursery pigs indicates if the virus is circulating in the nursery. Comparing the nursery results with the end of the finishing period indicates if the virus is circulating in the finishing groups of pigs. IFAT titers in pigs range from 1:256 to 1:1024 by 2 to 3 weeks after infection. Titers decline over 3 to 4 months unless reintroduced by exposure to circulating virus. Uninfected nursing pigs are negative or have maternal antibody. Seropositive 9- to 10-week-old pigs leaving the nursery indicate virus circulation in the nursery. If pigs leaving the nursery are negative and positive later in the finishing unit, virus circulation is occurring in the finishing unit.

Sera from outbreaks of the disease in the United States, Canada, and Europe have been compared, and although the isolates from both continents are closely related, the strains isolated in the United States and Canada are more closely related serologically than they are to the European strains.

Oral Fluids

Saliva has also been used for haptoglobin and CRP estimations in PRRS-affected pigs under field conditions.[268,269] The values were higher in a conventional herd with chronic PRRS than a specific pathogen-free herd. Increases were also found independently with age. The use of preweaning oral fluid samples detects the circulation of wild-type PRRSV.[270] Overall, preweaning litter oral fluid samples could provide a sensitive approach to surveillance for PRRSV in infected, vaccinated, or presumed negative pig breeding herds.

Antigen Detection

PCR reactions were partially inhibited in the oral fluid matrix compared with RNA extraction, and it should not be assumed that methods designed for use in serum would perform as well in oral fluid.[271-275] Oral fluid testing was found to be useful for virus detection[276] and superior to serum for the detection of PRRSV using PCR over the 21-day observation period of their study. Individually penned oral-fluid sampling could be an efficient, cost-effective way to maintain surveillance in a boar stud.

Serology

An assay was developed and validated for use in oral fluids.[277] A titer of 1:8 in oral-fluid samples was considered to be virus specific and could be detected 28 days after vaccination or infection. It had 94.3% specificity and 90.5% repeatability. The levels were correlated with serum levels.

The IgG oral fluid ELISA can provide efficient, cost-effective PRRSV monitoring in commercial herds and be used in elimination programs.[278] In a study of 100 oral-fluid samples from pens containing positive pig at five levels of PRRSV prevalence tested at six laboratories, it was found that the mean positivity for PRRSV RNA was 62% and for antibodies it was 61%. The study supported the use of pen-based oral-fluid sampling for PRRSV surveillance.[279] An oral fluid assay was ring tested in the United States [280] in 12 laboratories and was found to be highly repeatable and reproducible.

NECROPSY FINDINGS

There is a high level of viremia for 102 weeks, then a lower level for another 2 to 3 weeks, and subsequently low levels of virus may persist for several months, but finally PRRSV is eliminated after 2 to 4 months. PRRSV-specific nonneutralizing antibodies arise quickly from 7 DPI, but low titers of neutralizing antibody are only detected from 25 to 35 DPI. In some pigs, both low levels of replicating virus are found in the presence of neutralizing antibodies. The adaptive cell-mediated immune response is exerted by CTLs and Th cell lymphocytes in cooperation with Th1-activated NK and macrophages. The CTLs may reduce viral replication in the lungs and lymphoid tissue after 2 weeks DPI and in the complete clearance of virus in 2 to 4 months. It was shown that peripheral blood monocytes fail to exert CTL activity toward PRRSV-infected macrophages.[281]

Type 2 PRRSV is more virulent than type 1in the experimental setup with higher mean viral titers and greater macroscopic and microscopic lesions at the same points on a timescale similar to a type 1 virus. Mean numbers of PRRSV-positive cells in lungs and lymph nodes were also higher for the type 2 virus.[282]

Type 2 PRRSV infection mediates apoptosis in B- and T-cell areas in lymphoid organs of experimentally infected pigs, and the increased apoptosis may play a part in the impairment of the host immune response during PRRSV infection.[283]

In a study of three European viruses it was shown that a Belgian strain was more highly pathogenic than the Lelystad virus and a British field strain, not because of increased viral load and better replication but because of an enhanced inflammatory immune response.[284]

A series of postmortem examinations of different aged pigs from different stages of production will reveal what is going on over time. A series of such examinations will probably show more than any other investigations.

No characteristic gross lesions are present in sows, aborted fetuses, or stillborn piglets. Microscopic lesions that may be present in aborted fetuses include vasculitis of the umbilical cord (not recorded in European strain infections) and other large arteries, myocarditis, and encephalitis. Unfortunately, none of these changes is present consistently, and the majority of fetuses and placentas are histologically normal. These lesions are all more common in the North American virus infections.

In suckling and grower pigs, infection with the PRRSV is usually characterized by an interstitial pneumonia. The PRRSV affects both pulmonary intravascular macrophages, which may be important as a replication site, and alveolar macrophages. Loss of bactericidal function in pulmonary intravascular macrophages may facilitate hematogenous bacterial infections. When Danish isolates were injected into piglets, PRRSV was isolated from the lungs and/or tonsillar tissues from both dead and culled piglets under 14 days of age. Tracheobronchial and

mediastinal lymph nodes are usually enlarged and firm. The gross pulmonary changes vary from lungs that appear normal but fail to collapse, to lungs that are diffusely red, meaty, and edematous. Porcine proliferative and necrotizing pneumonia has been linked to infection with PRRSV, although the involvement of an unidentified copathogen cannot yet be discounted. Grossly, this form of pneumonia appears as confluent consolidation of the cranial, middle, and accessory lobes, together with the lower half of the caudal lobe. Affected lobes are red-gray, moist, and firm (meaty) in consistency. On cross-section, the affected lobes are bulging and dry, and the pulmonary parenchyma appears similar to thymic tissue.

Generally, histologic lesions in piglets are focal nonsuppurative inflammatory conditions particularly in the lung and heart. Most of the cells undergoing apoptosis do not have markers for PRRSV, which suggests that there is an indirect mechanism for the induction of apoptosis.

Multifocal areas of interstitial pneumonia (more extensive at 10 DPI rather than 21 DPI) were regarded as the structural basis for reduced lung compliance and gas exchange disturbances.[237] There was a cough that the authors interpreted as caused by bronchospasm because there was no evidence of tracheitis, bronchiolitis, or airway mucus, and this was supported by the presence of peripheral airway obstruction. Cell death occurs through both apoptosis and necrosis.[285]

Histologically, in addition to marked proliferation of type II pneumocytes in alveoli, there is severe necrosis of bronchiolar epithelium, with necrotic cellular debris plugging the airway lumina.

In pigs infected with HP-PRRSV, there was a distinct thymus atrophy. The lesions in the thymus were found to have severe cortical depletion of thymocytes. There was a 40-fold increase in apoptosis of thymocytes compared with piglets infected with non–HP-PRRSV at 7 DPI.[286]

In the less severe and more common forms of PRRSV pneumonia, the alveoli contain protein-rich fluid and large macrophages, some of which may appear degenerate. There is patchy thickening of the alveolar septa caused by infiltrating mononuclear leukocytes and mild, type II pneumocyte hyperplasia. Lymphoplasmacytic cuffing of arterioles is common, and syncytial cells are occasionally seen. In field outbreaks, it is usual for the lung pathology to be complicated by concurrent respiratory pathogens.

Microscopic lesions may be found in many other tissues and include multinucleate cell formation within lymph nodes; infiltrates of lymphocytes and plasma cells in the heart, the brain, and the turbinates; and a lymphocytic perivasculitis in various sites. Thymic lesions include severe cortical depletion of thymocytes. An ISH technique is a rapid, highly specific, and sensitive detection method for the diagnosis of PRRS virus in routinely fixed and processed tissues. Immunohistochemical techniques can also be used to detect the virus in neurovascular lesions. PRRSV and reovirus 2 have been found in brain, lung, and tonsil by inoculation into Marc 145 and CPK cells. IHC on one section would give a positive in 48% of cases, but if five sections were studied then there are positives in >90% of PRRSV-infected pigs. If the animals are vaccinated then the positives fall to 14%.

PNP is a common finding in Spain and is characterized by hypertrophy and proliferation of type 2 pneumonocytes and the presence of necrotic cells in the alveolar lumina. PCV2 was found in 85.1% of the cases by ISH and IHC and PRRSV was found in 44.6% of the cases; 39.1% had PCV2 as the sole agent and only 4.1% had PRRSV as the sole agent.[287]

Samples for Confirmation of Diagnosis

Lung appears to be the best tissue for identification of the virus in various ages of the pig and at various times following infection. Thymus is probably the best choice for aborted fetuses.

- **Histology:** lung, tonsil thymus, thoracic lymph node, brain, kidney, heart, (umbilicus from fetus) (light microscopy, immunohistochemistry (IHC)); a monoclonal antibody-based IHC method for the detection of European and U.S. PRRSV was shown to be useful in detecting both types.[288]
- **Virology:** lung, thoracic lymph node, tonsil (virus isolation, fluorescent antibody test (FAT), PCR).

DIFFERENTIAL DIAGNOSIS

Respiratory disease must be differentiated from the following:

- Swine influenza
- Porcine respiratory coronavirus
- Enzootic pneumonia (*Mycoplasma hyopneumoniae*)
- *Actinobacillus pleuropneumoniae*
- *Pasteurella multocida*
- Glasser's disease (*Haemophilus parasuis*)
- *Streptococcus suis.*

Reproductive disease must be differentiated from other causes of abortion, stillbirths, and weak neonates in pigs:

- Leptospirosis
- Encephalomyocarditis virus
- Hog cholera virus
- Pseudorabies virus
- Parvovirus
- Fumonisin, which is a recently identified mycotoxin produced by *Fusarium moniliforme,* has been associated with the appearance of PRRS in swine herds in the United States

A definitive diagnosis requires a detailed epidemiologic investigation of the epidemic including a detailed analysis of the breeding and production records for the previous several months, and the submission of tissue and serum samples for laboratory investigation.

TREATMENT

There is no specific treatment against the virus. In outbreaks of respiratory disease, mortality can be reduced by ensuring that the environmental conditions in the barns and pens are adequate, the stocking density is kept low, and the feeds and feeding programs are monitored. Routine procedures such as tail docking, iron injections, castrations, teeth clipping, and cross-fostering should be delayed or not done during the acute phase of the disease. Supplemental heat for neonatal pigs should be provided if necessary. Sows that have aborted their litters should not be bred until the normal time of weaning. This will reduce the incidence of infertility common at the first estrus after the abortion or premature farrowing. Culling of sows should be minimized and weekly breedings increased by 10% to 15%. Replacement gilts may be introduced into the premises for exposure to infection before breeding. The consequences of boar infertility and low libido may be minimized by use of artificial insemination or by using multiple sires on each sow. Recurrent illness and secondary infections in weaner and growing pigs can be continuing problems for a few months after an acute outbreak. Reducing the stocking density and an all-in/all-out strategy have been successful in reducing the chronic problem. If there is the possibility of treating secondary infections, then this should be undertaken. Serum inoculation of naive gilts has been described, and this was shown to be capable of stabilizing sow herds, as shown by the production of negative weaned pigs.

Tylvalosin, a macrolide antibiotic, and to some extent tilmicosin inhibit the in vitro replication of European and American PRRSV possibly by raising the endosomal pH (PRRSV requires a low endosomal pH).[289]

A report has suggested that *N*-acetylpenicillamine will inhibit PRRSV replication.[290]

CONTROL

It is the stealthy nature of PRRSV infection and its efficient transmission that has prevented elimination.[291] The challenges of control have resulted in the development of regional control systems.[292,293] These involve cooperation in a region, new technologies, and the demonstration that PRRSV has been eliminated.

The potential role of noncommercial swine populations in the United States in the spread of PRRSV have been highlighted.[294] They comment on the lack of knowledge of biosecurity in this group of swine herders,

the practice of showing pigs at many events, evidence that exposure to PRRS is very frequent, and close interactions with commercial herds and that these facts make it necessary to involve these groups in regional control.

Control of PRRSV is difficult, unreliable, and frustrating because of the complexity of the disease; the uncertainty of some aspects such as immunity, persistence, diagnosis, and the lack of published information based on control programs have been evaluated under naturally occurring field conditions. Much of the information available on control is anecdotal and not based on well-designed control programs that can be compared and evaluated. A major problem is the difficulty of obtaining a definitive etiologic diagnosis when presented with young growing pigs with respiratory disease and the possibility that other pathogens could be involved. The diagnosis of reproductive failure in gilts and sows is also commonly uncertain.

Some characteristics of the disease are important in planning control programs for individual herds:

- Infection is highly contagious and is transmitted by direct contact. Nonimmune pregnant gilts and sows and young pigs are highly susceptible to infection, resulting in large economic losses.
- Infection of breeding stock results in immunity. The efficacy of vaccination is not well established.
- Maternal immunity is present in piglets born from seropositive sows.
- Infection can persist for many weeks and months in individuals and in subpopulations of animals.
- Infections are usually introduced into a herd by the introduction of infected pigs.

There are two main options for control: eradication of the virus from individual swine herds and controlling the disease in individual herds to create a stable positive system that allows to live with the disease. Controlling the disease requires developing strategies to make pigs immune to the infection by controlling infection pressure in the herd and inducing naturally acquired immunity in the herd or inducing acquired immunity through vaccination. The recommendations for control set out here are guidelines that can be applied and modified to meet different circumstances.

Dietary plant extracts (capsicum, garlic, and turmeric) improve immune responses and growth efficiency of pigs experimentally infected with PRRSV.[295]

FILTRATION SYSTEMS

A production region model was used to assess the spread of PRRSV[296] and showed the importance of aerosol spread. More than 30 swine systems in the Midwest have remained free from PRRSV for 2 to 3 years following implementation of an air-filtration system using MERV 16 filters, and this system should be regarded as the gold standard.[297-299]

Retrograde air movement is a real risk for PRRSV introduction into filtered airspaces in animal houses, and different treatments have been investigated.[300]

In a study of before and after filtration it was found that outbreaks occurred at a rate of 0.5 outbreaks a year before filtration, but after the risk was reduced by introducing air filtration the outbreaks were reduced to 0.06 to 0.22 outbreaks a year.[301]

The financial implications of air-filtration systems have been studied.[302] Model outputs suggested that the filtered farm produced 5927 more pigs on a 3000-sow farm and paid for the installations within 5.35 to 7.13 years, depending on the sow herd productivity. If there was a premium of $5 per PRRS-negative piglet, then the payback period was reduced to 2.1 to 2.8 years.

Eradication of the Virus From the Herd

Depopulation and Repopulation

Eradication of the virus from the herd by depopulation of the entire herd followed by repopulation with virus-free breeding stock is biologically possible, but in most cases it is impractical and too expensive. Obtaining virus-free breeding stock is usually not possible and, if possible, the herd is highly susceptible to accidental reinfection.

Control in Infected Herds

Nursery Depopulation

Control within a breeding herd is based on the observation that pigs commonly seroconvert to the virus during the nursery period. Pigs are seronegative shortly after weaning, but 80% to 100% are seropositive at 8 to 10 weeks of age. A control program based on **nursery depopulation** consists of emptying the nurseries and moving **all of the pigs** to off-site finishing facilities or selling them as feeder pigs. Test and removal has been described. This is combined with batch farrowing and weaning at intervals of at least 3 weeks. The nurseries are completely emptied, cleaned three times with hot water and disinfectant, the slurry pits are pumped out after each cleaning, and the facilities are kept empty for 14 days, during which time all pigs weaned are moved to off-site nurseries and after which the conventional flow of pigs into the cleaned facilities is resumed. The control program can result in significant improvements in both average daily gain and percentage mortality, but it will not eliminate the virus from the herd. Using a partial budget model to measure the profitability of nursery depopulation, the financial consequences indicate that it is a profitable strategy to improve pig performance in herds affected with the virus. Additional income is generated by the increased number and weight of marketable pigs, as a result of their increased growth rate and decreased mortality. Lower treatment costs reduce overall expenses, but there are additional costs because of the extra feed necessary to raise the additional pigs and the costs required to house the depopulated pigs. However, it is possible that the economic benefits are from the control of other pathogens and not merely the PRRS virus.

Table 18-4 Nursey depopulation and cleanup protocol for elimination of PRRS

Day	Procedure
1	Empty all nurseries, off-site wearing, pump out slurry pits, clean and wash rooms with hot water (>95°C, 203°F), and disinfect with formaldehyde-based product; allow disinfectant water to remain in pits overnight
2	Pump out pits, repeat washing procedure, and disinfect in phenol-based product; allow disinfectant to remain in pits
311	Allow facility to remain vacant
12	Pump out slurry pits, repeat washing procedure, and disinfect with formaldehyde-based product
13	Allow facility to remain vacant
14	Resume conventional flow of pigs into clean nurseries

The details for nursery depopulation and cleanup protocol for the elimination of the virus are shown in Table 18-4.

In an experimental infection with PRRSV, it was found that the infected pigs had greater serum concentrations of IL-1β, TNF-α, IL-12, IFN-γ, IL-10, and haptoglobin than sham controls. The results indicated that PRRSV-stimulated secretion of cytokines involved in innate, Th1, and T-reg immune responses. Mannan oligosaccharides regulated the expression of nonimmune and immune genes in pig leukocytes[303] and were able to enhance the immune response without overstimulation. Mannan oligosaccharide-containing compounds were found to decrease the levels of the serum TNF-α. The levels of IL-1β and IL-12 may help to promote innate and T-cell immune functions.[304]

Management of the Gilt Pool

Management of the gilt pool is the single most important strategy for long-term effective control. Controlling the infection in the breeding herd is a prerequisite to controlling infection in the nursery and finishing pig groups. Strategies like partial depopulation and piglet vaccination are ineffective unless the breeding herd is first stabilized, preventing piglets from becoming infected

before weaning. Replacements are a major source of introduction of the virus and activating existing virus in the breeding herd. They also initiate the formation and maintenance of breeding herd replacements.

Subpopulations are subsets of naive or recently infected gilts or sows that coexist within chronically infected herds. These subpopulations perpetuate viral transmission in the breeding herd and farrowing units, which ultimately produces successions of infected piglets before weaning. Modifications in gilt management that may minimize subpopulations include ceasing introduction of replacement animals for a 4-month period, beginning to select replacements from the finishing unit, or introducing a 4-month allotment of gilts at one time.

Exposure to the virus in the breeding herd can be controlled by managing the gilt pool using two strategies. In one strategy, herds may be closed to outside replacements, and replacement males and females are raised on the farm. In the other strategy, replacement gilts are held in an off-site holding facility from 9 to 12 weeks of age until breeding age at 7 to 7.5 months, or even much earlier. This is combined with nursery depopulation as described earlier. Before entry of the gilts into the herd, they are serologically tested for evidence of seronegativity or a declining titer, which is required for entry into the herd. The gilts are isolated and quarantined for acclimatization for 45 to 60 days. This may be combined with two vaccinations, 30 days apart, after entering quarantine. This method reduces the risk of introducing potentially viremic animals into the existing population. The method selected will depend on the production system, management capabilities, and facilities available on each farm. The introduction of younger gilts, in larger groups, less frequently throughout the year, is being recognized as the most effective method for introducing replacement stock to virus-infected herds and long-term control of the disease.

Controlled Infection of Breeding Herd

The presence of subpopulations of highly susceptible breeding animals in the herd can be a major risk factor for maintaining viral transmission within problem herds and may explain recurrent outbreaks of reproductive failure. By intentionally exposing all members of a population to the virus, it may be possible to eliminate subpopulations and produce consistent herd immunity. In endemic herds, exposure of gilts to the virus before breeding is critical for prevention of reproductive failure. Seronegative replacement gilts can be introduced into seropositive herds at 3 to 4 months of age to allow for viral exposure before breeding. If the status is uncertain, quarantine and exposure to nursery pigs of the importing unit is a suitable policy if replacement gilts are bought in before they are bred. It is possible to convert a PRRS-positive unit to a negative herd by managing the gilt pool and regulating the pig flow. It appears that PRRSV infection eventually either disappears or becomes inactive in the donor gilt population. Similarly, serum from nursery pigs (thought to be PRRSV viremic) given to negative replacement gilts resulted in seroconversion of all 50 gilts receiving the serum.

Control of Secondary Infections

When outbreaks of the disease occur in nursing piglets, and virus circulation is occurring continuously in the farrowing facility, the following are recommended:

- Cross-foster piglets only during the first 24 hours of life
- Prevent movement of pigs and sows between rooms
- Eliminate the use of nurse sows
- Euthanize piglets with low viability
- Minimize injections of suckling pigs
- Stop all feedback of pig and placental tissues
- Follow strict all-in/all-out pig flow in the farrowing and nursery rooms.

These are similar to the system developed in the United States called the McRebel system. This was a method of control showing that cross-fostering of piglets should be minimal within the first 24 hours and banned after this time.

Feedback has been tried, although there are a lot of reasons not to do so. Minced whole piglets were fed to sows and the herd then closed for 23 weeks. No clinical signs were observed. One-third of the sows present at the time of the outbreak were still seropositive 20 months after the deliberate infection. Disinfection at cold temperatures was described.

Biosecurity

Standard methods, such as quarantining and serologic screening of imported breeding stock and restrictions on visitors, are recommended to keep units free of infection. Control of infection between herds depends on restricting the movement of pigs from infected herds to uninfected herds. If pigs have to be bought in, then seropositive animals should be imported into seropositive herds. Only seronegative boars should be allowed entry into artificial insemination units.

Biosecurity practices regarding PRRSV have been investigated in Quebec in two areas of different swine density. A questionnaire was sent to 125 breeding sites and 120 growing sites. The frequency of biosecurity practices ranged from 0% to 2% for a barrier at the site entrance, 0% to 19% for showering, 20% to 25% for truck washing between loads, 51% to 57% for absence of rendering or rendering without access to the site, and 26% to 51% for absence of gilt purchase or purchase with quarantine. Better practices were found in the breeding herds. In the high-density area, there was a lower level of biosecurity on the growing sites. There were two patterns of biosecurity, a low one and a high one. For the breeding sites the higher pattern was observed when the site was away from other pig sites, more than 300 m from a public road, with a higher number of sows or being part of integrated production.[305] In a second part of the study, on prevalence and risk factors, it was found that the overall prevalence of PRRS was 74.0%. Four main factors were associated with PRRS positivity, and these were large pig inventory, proximity to closest site (16%), absence of shower (27%), and free access to the site by the rendering truck (10%).[305] Boar studs that are free should only import boars that are certified free from tested herds. The status of the boar stud should be tested every 2 weeks with a combination of ELISA and PCR.

Testing protocols that used PCR on serum detected the PRRSV introduction earlier than the protocols that used PCR on semen, and these were earlier than those that used ELISA on serum. The most intensive protocol (testing 60 boars three times a week by PCR on serum) would need 13 days to detect 95% of the PRRSV introductions.[306]

A vaccination study using a modified live PRRSV vaccine on European and North American PRRSV shedding from boars showed that boar vaccination decreased the shedding of U.S. PRRSV but not the European strain.[307]

Vaccine and Vaccination

The inefficiency of current vaccines to cross-protect against all strains of PRRSV may be caused by variability within GP5.[2]

Adjuvants for use in PRRSV vaccines have been reviewed.[308] Of 11 adjuvants tested 5 enhanced cell-mediated immunity to PRRSV. In particular, IL-12 and CpG ODN significantly enhanced the protective efficacy of PRRSV vaccines in challenge models. The immunostimulatory oligodeoxynucleotides have been used previously.[309]

TLR ligands enhance the protective effects of vaccination against PRRS syndrome in swine using killed vaccines.[310]

Vaccination with a combined PRRSV/MH vaccine did not differ in protective efficacy compared with the protective efficacy of the two single vaccines. This indicates that neither vaccine interfered with each other.[311]

Vaccine efficacy of PRRSV chimeras has been described,[312] and the study suggested that only specific chimeras can attenuate clinical signs in swine and that attenuation cannot be directly linked to primary virus replication.

Pigs infected with PRRSV at the time of vaccination for swine influenza had an increased level of macroscopic and microscopic pneumonia, suggesting that there was

a reduced SIV vaccine efficiency.[313] In addition, there was also increased clinical disease and shedding of SIV during the acute phase of SIV infection.

Immunologic solutions for the treatment and prevention of PRRSV have been reviewed.[314] No differences were found between intradermal and IM vaccinated pigs and those subsequently exposed to a heterologous Italian strain.[315]

The antibody response and the maternal immunity when PRRSV-immune sows were boosted with experimental farm-specific and commercial PRRSV vaccines has been described.[316] The study was designed to boost PRRS-immune sows against circulating viruses. Three PRRSV isolates were taken. Booster vaccinations used either commercial vaccines or inactivated farm-specific isolate vaccines. A boost was found in all three farm-specific vaccinations. The commercial attenuated vaccine boostered immunity in 2/3 herds but the commercial nonattenuated dead vaccine did not affect the immunity on any of the three farms. In a second part of the study, similar vaccines were given at 60 days' gestation. The farm-specific vaccines produced a significant increase in farm-specific neutralizing antibodies in all sows. Virus-neutralizing antibodies were also transferred to the piglets via colostrum and were detectable in the serum of these animals until 5 weeks after parturition. Not all sows vaccinated with the commercial attenuated vaccine showed an increase in the farm-specific virus-neutralizing antibodies, and the piglets in this group received a lower level of colostral antibodies. The number of viremic animals was significantly lower in the piglets of both groups of vaccinated animals than among mock vaccinated animals until at least 9 weeks of age.

Vaccination of Gilts

The two commercial modified live virus vaccines against PRRSV in pregnant gilts were shown to replicate in pregnant gilts and to cross the placenta.[317] It was concluded that the vaccines had no marked detrimental effects in pregnant gilts but that they could cross the placenta and lead to the birth of congenitally affected piglets.

Intranasal delivery of PRRS-MLV with a potent adjuvant (from *M. tuberculosis* whole-cell lysate) to elicit cross-protective immunity to a heterologous strain of PRRSV generated effective cross-immunity. There was reduced lung pathology, enhanced neutralizing antibodies, and reduced viremia. There was a reduced secretion of immunosuppressive cytokines (IL-10 and TGF-β) and an upregulation of the Th-1 cytokine IFN-γ in blood and lungs.[318]

The ORF5a antibody response is neither neutralizing nor protective.[319]

Vaccination is an aid to management in developing effective immunity. The goal is to produce a constant level of immunity across a defined population. This effectively immunizes the entire population and eliminates the nonimmune, susceptible subpopulations. Vaccination is most effective when used in replacement gilts combined with adequate isolation and acclimatization and in sows after farrowing and prebreeding. The routine vaccination of sows is not economically viable in herds affected with PRRSV. The vaccine is best suited for stabilizing the herd and is a necessity before nursery depopulation or commingling segregated early weaning piglets from virus-positive herds. Vaccination is also intended to produce protective immunity in weaned and growing pigs. The PRRS virus exists in many forms and therefore the closer the genetic makeup between the immunizing virus and the challenge virus the better.

Both inactivated and modified live virus vaccines are available.

Previous vaccination with a live attenuated strain produced an increase in proinflammatory cytokines and proimmune cytokine gene expression. In addition, a higher level of cortisol production suggested that there was an activation of the hypothalamus-pituitary-adrenal axis response. Vaccination produces an early immune response in pigs and a more efficient control of inflammation.[320]

Inactivated Vaccines

Immunization of pigs with a genotype I attenuated vaccine provided partial protection against challenge with a highly virulent genotype II strain. There was a lower mortality, fewer days of fever, lower frequency of catarrhal bronchopneumonia, higher weight gains and lower viremia compared with unvaccinated control pigs.[321]

Killed vaccines that are inactivated using methods that preserve the PRRSV entry-associated domains are most useful for the development of effective inactivated vaccines because they facilitate internalization into macrophages.[322] An experimental inactivated PRRSV vaccine that induces virus-neutralizing antibodies has been described.[323] The vaccine uses an optimized inactivation procedure and a suitable adjuvant, and by using these methods it was shown that inactivated PRRS vaccines can be developed that induce virus-neutralizing antibodies and offer partial protection on challenge.

Killed vaccines may not produce a measurable antibody response stimulation, but activation of lymphocytes does occur and any subsequent exposure with vaccine or field virus increases that response. There is no possibility of producing a viremia and no chance of producing shedding, and there are no detrimental effects on the host. However, there is no evidence that killed vaccines protect against heterologous challenge.

A killed, oil-adjuvanted vaccine based on a Spanish isolate of the virus is intended for protection against reproductive disease in gilts and sows. Initial vaccination involves 2 vaccinations, 21 days apart, with the second vaccination at least 3 weeks before breeding and with booster vaccinations recommended during subsequent lactations. Experimental challenge provides 70% protection based on pigs born alive and surviving to 7 days.

An autogenous inactivated vaccine was compared with commercial vaccines against homologous and heterologous challenge.[324] In this study the experimental inactivated homologous vaccines shortened the viremia on challenge, but the experimental heterologous and commercial inactivated vaccine had no or only a limited effect on the viremia.

Live Vaccines

A study in China[325] on farms with a complex microbial ecology showed that mass vaccination with an attenuated virus vaccine can improve health status and production performance of sows and their offspring.

Modified live vaccines do give a safe and efficacious protection against a wide variety of heterologous challenge strains. The vaccine virus can be transmitted from vaccinated to naive pigs and to naive herds. Vaccination of boars causes the virus to be shed, but if they have been previously exposed and then are vaccinated then there is no release of virus.

The live vaccine given to finishing pigs will protect against respiratory infections. A modified live virus vaccine given once is safe for use in pregnant sows, and vaccine virus is not transmitted to susceptible contact pigs. In growing pigs vaccinated at 3 to 18 weeks of age, the vaccine elicits protective immunity within 7 days and lasts 16 weeks. Compared with controls, vaccinated animals have a reduced level of viremia, their growth rates are superior, and they have a reduced number of lung lesions. Field trials suggest that the vaccine provides protection to nursery pigs in units with endemic infection. Live viral vaccines in sows may or may not be a good idea because they demonstrated that reduced numbers of pigs were born alive and there were increased numbers of stillborn piglets to vaccinated sows irrespective of the stage of vaccination. Both single-strain and multi-strain vaccines can be attenuated and be useful immunogens, but additional studies are needed to make sure that the multistrain vaccines can be recommended for routine field use.

In Denmark in 1996, the use of a modified live virus vaccine licensed for use in pigs 3 to 18 weeks of age was used in a large number of PRRSV seropositive herds. Following vaccination, a large number of herds experienced an increased incidence of abortions, stillbirths, and poor performance during the nursery period. The vaccine virus was isolated from fetuses, and it was concluded that the virus was transmitted to seronegative nonvaccinated pregnant gilts and sows (see the section Methods of

Transmission). The viruses were collected and sequenced and shown to have only a 60% homology to Lelystad virus, the European type strain, but a 98.5% homology to strain ATC-2332, which is the North American reference strain. It was therefore thought that the vaccine viruses were reverting to their natural antecedents and their virulence. Describing the vaccine virus it was shown that given to piglets it could infect nonvaccinated sows. Given to sows it can produce congenital infection, fetal death, and an increased preweaning mortality.

The vaccine virus can be maintained in the population where it may undergo considerable genetic change and then lead to the establishment of new variants. Vaccination with the U.S. type vaccine produces little effect on viremia with EU PRRSV. Vaccination with EU type vaccines produced complete suppression of EU PRRSV isolates.

A modified live virus vaccine has been evaluated in pigs vaccinated at 3 weeks of age and challenged at 7 weeks of age. Efficacy was evaluated using homologous and heterologous strains of virus known to cause respiratory and reproductive disease. The vaccine controlled respiratory disease but did not prevent infection and viremia. There are no published reports of randomized clinical trials evaluating the vaccines under naturally occurring conditions. In many cases of PRDC, vaccination fails simply because it was given too late or because there was no cross-protection to heterologous strains.

DNA vaccination is said to produce both humoral and cellular responses and neutralization epitopes on the viral envelope glycoproteins encoded by ORF4. Possibly recombinants can be used as vaccines.

In a survey in Germany, 18.5% of the samples were positive for the EU wild-type virus, EU genotype vaccine virus was detected in 1.3%, and the North American genotype vaccine virus was found in 8.9% of all samples. North American vaccine virus was frequently detected in nonvaccinated animals.[326]

The first modified-live vaccine was first released in 1994 and since then a number of other modified live and killed-virus vaccines have been developed. Vaccines should induce rapid immunity, have no adverse reactions, and be able to differentiate vaccinated from naturally infected animals (DIVA vaccine).[308,327,328]

Mass vaccination using modified live virus against homologous infection was shown to be effective in reducing economic losses from PRRSV. It did not eliminate the virus but it did reduce viral shedding 97 DPI.[329] Two vaccines were compared (one inactivated and one modified live), and the modified live virus was the only type of vaccine capable of establishing protective immunity as measured by viral load in blood and tissues. The inactivated vaccine evoked no measurable protective immunity. The modified live vaccine seemed to be based on cell-mediated immunity.[330]

A modified live vaccine partially protected a group of pigs given a heterologous virus vaccine; intervention reduced the duration of shedding but did not reduce the viral load in tissues or the proportion of persistently infected pigs. When the pigs were subsequently given the highly virulent virus, infection and shedding were not prevented.[331]

The modified live vaccines for PRRSV have been reviewed.[332] None of the vaccines studied (Ingelvac PRRS MLV, Amervac PRRS, Pyrsvac-183, and Porcilis PRRS by the IM route) caused detectable clinical signs in vaccinated pigs, although lung lesions were found. Neither Pyrsivac-183 nor Porcilis PRRS could be detected in the pulmonary alveolar macrophages or in lung sections by IHC, suggesting that these viruses may have lost their ability to replicate in PAM. In these pigs, there was also a lower transmission rate and a delay in the onset of viremia, which may be explained by the lack of infection and therefore replication in the alveolar macrophage.

Novel strategies for the next generation of vaccines have been described[333] and stress the future importance of reverse genetics system-based vaccine development. Serologic marker candidates have been identified.[334,335] Vectored vaccines may have a place in the future.[336-338]

Recombinant fowlpox virus-based virus with coexpression of GP5/GP3 proteins of PRRSV and swine IL-18 has been described[339] as potential vaccines.

The fusion of the heat shock protein (HSP70) of *H. parasuis* with GP3 and GP5 of PRRSV enhanced the immune responses and protective efficacy of a vaccine.[340] The strategy of coexpressing GPGP-linked GP5 and M fusion protein may be a promising approach for future PRRSV vaccine development.[341] A canine adenovirus has also been used as a vehicle.[342]

Overattenuation of an HP-PRRSV (over 100 passages) was used to produce a possible vaccine[343] suggesting that loss of pathogenicity has to be balanced with loss of antigenicity.

Vaccination against PRRSV resulted in significantly lower viral loads of PCV2 in animals over 13 weeks compared with nonvaccinated animals but it had no effect on quantitative PCR results for PRRSV in 4- to 12-week-old pigs. PRRS vaccinates had significantly lower levels of PCV2 viral loads when peak wasting disease was seen.[344]

Concurrent PRRSV and PCV2 vaccination produced no interference with the development of the specific humoral and cell-mediated immunity and is associated with clinical protection on natural challenge.[345] PRRSV vaccine induced a low but significant virus-specific response IFN-γ secreting cell response on stimulation with both the vaccine strain and two heterologous PRRSV isolates.[346]

An isolate of PRRSV has been shown to produce IFNs and may be useful for the development of vaccines.[347]

Vaccination Against High Pathogenicity Porcine Reproductive and Respiratory Syndrome

A live attenuated vaccine was successfully produced from an HP-PRRSV strain TJ and the attenuation produced a further 120 amino acid deletion as well as the 30 amino acid deletion found in these HP-PRRSV strains.[348] The pigs were protected from the lethal challenge and did not develop fever and clinical disease. The vaccinated pigs also gained more weight and had milder pathologic lesions. The effective protection lasted at least 4 months.

A live attenuated vaccine has been used against HP-PRRSV.[349]

Vaccination of Boars

The use of an attenuated virus vaccine in boars resulted in a marked reduction in viremia and shedding of the virus in semen compared with nonvaccinated control animals. Introducing a vaccination program using the live virus vaccine may be considered as a potential method to reduce the risk of transmission of virus by artificial insemination. In contrast, no changes in onset, level, and duration of viremia, or shedding of virus in semen, were observed using the inactivated virus vaccine.

MENANGLE

This causative virus was first identified in a three-farm disease outbreak in New South Wales in 1997. It causes reproductive problems in pigs and congenital defects and has the fruit bat as an asymptomatic reservoir. It can cause a flu-like disease in man. Only one outbreak has been described. It normally lives asymptomatically in fruit bats.

ETIOLOGY

The causative agent is an RNA virus in the family Paramyxoviridae in the genus *Rubulavirus*. It is closely related to Tioman virus found in fruit bats on Tioman Island, Malaysia.

EPIDEMIOLOGY

A variety of fruit bats are seropositive, including the gray-headed flying fox, black fruit bat, and spectacled fruit bat, but the virus has not been isolated from them. These fruit bats have been found in other areas of Australia as well as the original area around Menangle, New South Wales.

Bat feces and urine are probably the source of infection. Transmission from pig to pig is slow and probably requires close contact. In one building, it took a long time for the sows to become affected. It probably spreads from farm to farm via infected animals. There is no sign of persistent infection and no evidence of long-term virus shedding. Present evidence suggests that

virus survival in the environment is short because sentinel pigs placed in an uncleaned area did not seroconvert.

CLINICAL SIGNS

There is no knowledge of the incubation period as yet. In the initial outbreak, clinical signs were seen only on the farrow-to-finish farm but infected pigs were found in all three farms.

The disease was an outbreak of reproductive disease with fetal death; fetal abnormalities including congenital defects, such as skeletal and neurologic defects[1]; mummified fetuses; stillborn fetuses; smaller litters with fewer live piglets; and a reduced farrowing rate. The farrowing rate fell from over 80% to around a low of 38% reaching an average of 60%. Many sows returned to estrus 28 days after mating, which suggests that there has been an early death of the litter. Some sows remain in pseudopregnancy for more than 60 days. It probably crosses the placenta and spreads fetus to fetus. Once the infection became endemic in the farrow-to-finish herd the reproductive failures ceased.

PATHOLOGY

The mummified fetuses vary in size and are 30 days or older. The virus causes the degeneration of brain and spinal cord. In particular, the cerebral hemispheres and cerebellum are smaller. Occasionally there may be effusions and pulmonary hypoplasia. Eosinophilic inclusions are found in the neurons of the cerebrum and spinal cord. Sometimes there is a nonsuppurative meningitis, myocarditis, and hepatitis. Experimental infections show shedding 2 to 3 days after infection in nasal and oral secretions. A tropism for secondary lymphoid tissues and intestinal epithelium has been demonstrated.[2] No lesions have been seen in piglets born alive or other postnatal pigs.

DIAGNOSIS

The diagnosis is suspected when the reproductive parameters change very suddenly, as shown earlier.

Diagnosis is confirmed by virus culture, and electron microscopy and virus neutralisation tests confirm the identity of the virus. Serologic tests include ELISAs, and the best way to test the herd is to use this for the sows for antibody.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis includes porcine parvo virus (PPV), classical swine fever (CSF), porcine reproductive and respiratory syndrome (PRRS), encephalomyocarditis virus (EMCV), pseudorabies virus (PRV), Japanese encephalitis, swine influenza virus (SIV), and blue eye. Noninfectious causes such as toxins or nutritional deficiencies should also be considered.

TREATMENT

It seems likely that young pigs are infected by the virus when the maternal antibody concentration declines at 14 to 16 weeks of age. By the time they enter the breeding herd their immunity is quite strong.

CONTROL

The best advice is to avoid contact with all fruit bats.

JAPANESE ENCEPHALITIS (JE; JAPANESE B ENCEPHALITIS)

Japanese encephalitis is an infectious disease primarily affecting horses and to a lesser extent pigs, with important zoonotic potential. It causes in excess of 50,000 human cases a year, with a case mortality rate of 25%. The condition in equides is associated with encephalitis and is covered in detail in Chapter 14 under Japanese encephalitis. In pigs the condition is associated with reproductive failure, whch is covered hereunder.

ETIOLOGY

The causative agent is the Japanese encephalitis virus of the family Flavivirdae, genus *flavivirus*. Based on the phylogenetic analysis of the viral envelope "E" gene, 5 different genotypes have been identified.

EPIDEMIOLOGY

The natural distribution range of the virus is southeast Asia and Australasia. The vectors are *Culex* spp and in particular *C. tritaeniorhynchus*. The virus activity is naturally maintained through bird–mosquito cycles with the heron family in particular. The night herons, little egrets and plumed egrets are particularly active as a reservoir. Pigs are important "amplifying hosts." Pigs and these birds may allow the overwintering of the virus when mosquitoes are absent.

PATHOGENESIS

Viremia results from the mosquito bite and usually nothing is seen. Occasionally there may be a mild fever. but quite often the virus goes straight to the testicles and causes an orchitis.

CLINICIAL SIGNS

Fetal death is common with mummified fetuses as well as stillborn and weak pigs. Boars undergo reproductive failure.

PATHOLOGY

Largely related to the abnormal fetuses.

DIAGNOSIS

RT-PCR and nested RT-PCR can be used to detect the virus when virus isolation is negative. Antibody can be detected by haemagglutination inhibiton, ELISAs (IgM capture ELISA), and latex agglutination tests.

CONTROL

Live attenuated vaccines should be given to breeding stock 2 to 3 weeks before the start of the mosquito season. Attenuated and adjuvanted vaccines are also available.

NEOSPOROSIS

SYNOPSIS

Etiology The protozoan parasite *Neospora caninum;* the dog is identified as the definitive host of *N. caninum,* but the main route of infection in cattle appears to be by vertical transmission.

Epidemiology An infection of cattle worldwide and associated with epidemic and endemic abortion. Point source and congenital infections occur.

Clinical findings Abortion in cows and perinatal mortality and encephalomyelitis in congenitally infected calves.

Clinical pathology Serologic testing of maternal serum and fetal fluids.

Necropsy findings Fetal lesions of multifocal nonsuppurative encephalitis, myocarditis, and/or periportal hepatitis. Infection confirmed by immunohistochemistry or polymerase chain reaction-based tools.

Diagnostic confirmation A presumptive diagnosis can be based on the fetal histologic lesions and seropositivity of the dam, but the definitive diagnosis requires the demonstration of the parasite in fetal tissues by immunohistochemical labeling, coupled with serologic examinations.

Control Feed hygiene and calving hygiene. Cull congenitally infected cattle.

ETIOLOGY

Neospora caninum is a cyst-forming coccidial (apicomplexan) parasite with an indirect life cycle.[1-9] *N. caninum* primarily infects dogs and cattle; however, it has a **wide host range** and infects all major domestic livestock species as well as companion animals and some wildlife animals. Dogs are the definitive host and cattle the major intermediate host. Natural infection is infrequently reported in sheep, goats, and deer.[1-3] *N. caninum* is a sporadic cause of

encephalomyelitis and myocarditis in several species, but its principal importance is its association with **endemic and epidemic abortion in cattle.** It is now the most common diagnosis for abortion in cattle in most countries.

EPIDEMIOLOGY

Occurrence

N. caninum was initially associated with abortion in the early 1990s in pastured cattle in Australia and New Zealand and as a major cause of abortion in dairies in the United States. Since then, abortion associated with *N. caninum* has been reported in many countries in cattle under varying management conditions and has a **worldwide occurrence.**[2,3]

Abortion may be **epizootic or sporadic**. In epizootic abortion, the number of cows aborting varies. It is usually between 5% and 10%, but up to 45% of cows may abort within a short period. The period of abortion may be a few weeks to a few months. There is no major seasonal occurrence, and abortion occurs in both beef and dairy cows. Sporadic abortions occur mainly in cows that have been infected congenitally, and seropositive cows have greater risk for repeat abortions. Seropositivity in herds can be high but varies considerably. Seropositive dams have a 3- to 7-fold greater risk of abortion than seronegative dams.

Methods of Transmission

There are two routes of infection of cattle. The dog is the definitive host of *N. caninum*. Infection of cattle can occur via the ingestion of oocytes from dog feces contaminating feed or water. However, vertical (i.e., congenital) transmission occurs in both cattle and dogs, and vertical transmission appears the major route for infection in most cattle.[1-3] Live-born calves from congenitally infected cows are themselves congenitally infected; the infection is thought to be **persistent and lifelong**. A study conducted on two dairies found 81% of seropositive cows gave birth to congenitally infected calves.[1] Seroprevalence did not increase with cow age and was stable through the study period. The probability of a calf being congenitally infected was not associated with dam age, dam lactation number, dam history of abortion, calf gender, or length of gestation. Other studies have shown that this route of transmission is highly efficient, resulting in infection of 50% to 95% of the progeny of seropositive dams.

Congenital infection can result in abortion or the birth of a "normal," infected calf, and an infected cow can give birth to a clinically normal, infected calf at one pregnancy and abort in the subsequent pregnancy.[2,3] The occurrence of infection in some herds can be associated with specific family lines.

Although vertical transmission is the major route of infection that leads to sporadic abortions in cattle associated with *N. caninum,* epidemiologic evidence suggests that postnatal (point) infection is often the cause of outbreaks of abortion. Where dog feces are the source of infection, many cattle are often exposed, and this point source of infection commonly results in outbreaks of abortion. Farm dogs have been shown to have a higher seroprevalence to *N. caninum* than urban dogs, suggesting that neosporosis cycles between cattle and dogs in rural environments.[4]

The importance of postnatal infection versus vertical infection in the genesis of abortion may vary among countries, and be associated with differences in farm management systems.[4]

Experimental Studies

Abortion has been produced by experimental challenge of fetuses and pregnant cattle with culture-derived tachyzoites of *N. caninum.*[1] Fetal death and resorption or abortion has been reproduced in ewes challenged at 45, 65, and 90 days' gestation, but not 120 days, and lesions resemble those of ovine toxoplasmosis.[2] The disease has also been reproduced experimentally in goats,[1] but the importance and prevalence of this infection in naturally occurring abortions in small ruminants remains to be determined. Contaminated placenta, milk, and colostrum can result in infection of calves less than 1 week of age.

Risk Factors

Outbreaks of abortion often appear to be point source infections, but the risk factors, other than probable mass exposure to dog feces containing sporulated *N. caninum* oocysts, are not known. Neosporosis in dairy herds often occurs as an epizootic, with multiple abortions occurring in a 1- to 2-month period. Severely autolytic fetuses are aborted between 5 and 7 months of pregnancy in most reports, but earlier or later abortions can occur (range is between 3 and 8.5 months of pregnancy).

Endemic abortion is more likely associated with the presence of **congenitally infected** cattle in the herd, which are at **high risk of aborting**, particularly in the initial pregnancy and in the pregnancy during the first lactation.[2,3] Cows that have aborted have a higher risk for abortion in subsequent pregnancies, but this risk decreases with each subsequent pregnancy. It has been postulated that immunosuppression resulting from concurrent infection with other agents, such as bovine viral diarrhea virus (BVD) , may increase the risk for infection with *N. caninum* and precipitate abortion outbreaks.

Economic Importance

Economic losses relate to abortion and costs associated with establishing the diagnosis and rebreeding or replacement costs.[5] Seropositivity is also associated with increased risk of stillbirth and increased risk of retained placenta. Losses associated with epidemic abortion have been estimated at tens (20–85) of millions of dollars to the dairy or beef industries in Australasia and the United States.

Although seropositive heifers have been reported to produce less milk than seronegative herdmates, this difference in milk production between seropositive and seronegative animals is not necessarily apparent in herds unaffected by an abortion problem. Study of beef cattle has suggested that seropositivity might be associated with reduction in average daily weight gain, but production performance and carcass measures are not consistently reported to be affected.

PATHOGENESIS

N. caninum has a predilection for fetal chorionic epithelium and fetal placental blood vessels, producing a fetal vasculitis and inflammation and degeneration of the chorioallantois, and widespread necrosis in the placentome.[6] Tachyzoites penetrate host cells and are located in a parasitophorous vacuole. They can be found in macrophages, monocytes, vascular endothelial cells, fibroblasts, hepatocytes, renal tubular cells, and in the brain of infected animals. With neuromuscular disease, cranial and spinal neural cells are infected. Cell death is caused by the replication of tachyzoites (during endodyogeny).

CLINICAL FINDINGS

Abortion is the cardinal clinical sign observed in infected **cows**.[2,3] Fetuses may die in utero, or can be reabsorbed, mummified, stillborn, born alive but diseased, or born clinically normal but infected. Cows that are infected can have **decreased milk production** in the first lactation, producing approximately 1 L less of milk per cow per day than uninfected cows, are prone to abort, and have a higher risk of being culled from the herd at an early age.

In addition to the occurrence of early abortion, the disease in beef herds is associated with the birth of live-born, premature, **low birthweight** calves. Depending on the degree of prematurity, these calves can be kept alive with intensive care during the neonatal period.

Most congenitally infected calves are born alive without clinical signs. Occasionally, congenital infection can be manifest with ataxia, loss of conscious proprioception, paralysis, and/or other **neurologic deficits** in new-born calves,[2] but most congenitally infected calves appear as clinically normal and, surprisingly, some evidence suggests that congenital infection does not necessarily have a detrimental effect on calf health and survival.[3]

N. caninum infection has been demonstrated in the nervous system of a **horse** with progressive debilitation, followed by a sudden onset of neurologic disease with paraplegia. It appears to be a rare cause of

neurologic disease in horses, but should be considered in the differential diagnosis of equine protozoal myeloencephalitis.

CLINICAL PATHOLOGY

Serologic testing can be conducted using IFAT or ELISA, and there appears to be good agreement in results between the two tests. ELISA using recombinant protein appears to have a higher diagnostic specificity and sensitivity than using whole-tachyzoite lysates.[7] IFAT is commonly used and achieves a relatively high diagnostic specificity and sensitivity for the detection of maternal infection.[7] The persistence of serum antibody titers following infection is uncertain, and they might fluctuate during pregnancy. A positive titer in a cow that has aborted indicates exposure but not causality. IgG avidity patterns have been used to predict the duration of infection. Diagnosis can also be conducted by detecting anti-*N. caninum* antibody or genomic DNA of *N. caninum* in **fetal pleural fluid or sera**.[7]

NECROPSY FINDINGS

Gross findings are not specific and the fetus may be fresh, autolyzed, or in early stages of mummification; in the placenta, the cotyledons are usually necrotic.[10] The brain may be autolyzed, but should still be submitted for examination as well as the heart, liver, and placenta, if available. Histologic findings commonly relate to **multifocal nonsuppurative encephalitis, myocarditis hepatitis, and/or placentitis** Liver lesions may be more prominent in epizootic abortions. IHC or PCR can be used to detect tachyzoites or their DNA in tissues (particularly in the brain).[7] IHC can be specific, but insensitive for identifying *Neospora* in the placenta; therefore, maternal serology should be used in conjunction.

TREATMENT

There is no treatment that can be used to curtail an ongoing abortion epidemic. Possible drug therapies are generally not considered an option because of likely unacceptable milk and meat residues and withdrawal problems.

DIFFERENTIAL DIAGNOSIS

Serology and/or polymerase chain reaction can confirm infection in individual cows.

Because of the high prevalence of infection, and the occurrence of congenital infection, care must be taken in extrapolating the results of a single positive diagnosis to problems of abortion. The high rate of natural congenital infection means that evidence of infection in an aborted fetus is not proof of causation of abortion, and fetal examination should be coupled to serologic examination of aborting and nonaborting animals in the herd to assess statistical differences.

- Other causes of abortion in cattle
- Weak calf syndrome

CONTROL

All efforts should be made to exclude the possibility of dog **fecal contamination** of cattle feed and water and of the grazing environment.[4] **Placentas, aborted fetuses, and dead calves** should be removed immediately and disposed of so that the definitive host and cattle cannot gain access to them.

Congenitally infected cows are at high risk of abortion, and abortion rates in infected herds can be substantially reduced by **culling** infected animals.[2-4] Congenitally infected calves can be identified by testing precolostral blood samples using a specific and sensitive serologic test and culled at a young age. If precolostral blood sampling is not feasible, examination of sera at 6 months of age should identify infected calves, with positive titers indicating either congenital infection or postnatal infection. Calves introduced into a herd should be seronegative.

It is possible that strategic therapy of pregnant cows with an appropriate antiprotozoal drug could abort the infection. This could be effective in beef cattle, but would probably not be legal or appropriate in lactating dairy cattle.

Although evidence for increased risk for *Neospora* abortion caused by immunosuppression resulting from concurrent infection with BVD virus is equivocal, control of BVD infections should be a component of anti-neosporosis control.

There has been a considerable effort to develop vaccines against neosporosis.[8,9] An inactivated tachyzoite vaccine was approved in the United States for use in pregnant cows. There are no controlled studies on its efficacy in mitigating the effects of bovine neosporosis in dairy cattle. Vaccination of dairy cattle may interfere with a herd test and cull policy.

DOURINE (*MALADIE DU COIT*)

SYNOPSIS

Etiology *Trypanosoma equiperdum.*

Epidemiology Venereal disease of horses, mules, and donkeys, endemic in southern and northern Africa, Asia, and possibly South and Central America.

Clinical signs Primary genital signs, secondary cutaneous signs, and tertiary nervous signs and emaciation.

Lesions Edematous swelling and later, depigmentation of external genitalia, emaciation, anemia, and subcutaneous edema.

Differential diagnosis list

- Nagana
- Surra
- Coital exanthema
- Equine infectious anemia.
- Purulent endometritis

Treatment Chronic cases unresponsive to trypanocides and may become carriers. Treatment is thus not recommended.

Control Elimination of reactors, control of breeding and movement of animals in affected regions or countries.

ETIOLOGY

Trypanosoma equiperdum belongs to the *brucei* group, subgenus *Trypanozoon,* but occurs only as long, slender, and monomorphic form. It may be more appropriately referred to as *T. brucei equiperdum.* Unlike *T. brucei. brucei,* it has lost part of its kinetoplast DNA (hence dyskinetoplastic). The parasite is morphologically indistinguishable from *T. evansi* in blood smears. *T. equiperdum* is the only pathogenic trypanosome that does not require an arthropod vector for its transmission. It resides more in extra vascular tissue fluid than in blood.

EPIDEMIOLOGY

Occurrence

Dourine is endemic in Asia, Africa, southeastern Europe, and Central America. It has been eradicated from North America, and strict control measures have reduced the

incidence to a low level in most parts of Europe. It occurred in Italy in 2011.[1] The disease is endemic in parts of Ethiopia and Namibia and is rarely reported in other parts of sub-Saharan Africa. It has not been reported in Latin America for over 20 years. It is possible that lack of reporting in some countries may be caused by very strict international regulations that tend to discourage official notification of the disease. All Equidae are susceptible, and natural infection is known to occur only in horses, mules, and donkeys. In Ethiopia, the disease is more prevalent during the breeding season from June to September.[2]

Measures of Disease Occurrence

In most countries, dourine now occurs only sporadically; its prevalence has declined generally because the horse is no longer that important militarily, economically, and agriculturally, and because of strict control measures in many countries. A recent survey of 237 horses from an endemic area of Ethiopia showed that infection rates varied with the method of examination.[3] The rates were 4.6% based on standard parasitologic methods, 27.6% on serology, and up to 47.6% on DNA detection by PCR. This was the first time in more than 30 years that a fresh strain of *T. equiperdum* was isolated from clinical cases of dourine. Case mortality varies; in Europe, it may be as high as 50% to 70%, but it is much lower elsewhere, although many animals may have to be destroyed as a means of control.

Methods of Transmission

Natural transmission occurs only by coitus, but infection can also be acquired through intact oral, nasal, and conjunctival mucosae in foals at birth. The source of infection may be an infected stallion or mare actively discharging trypanosomes from the urethra or vagina, or an uninfected male acting as a physical carrier after serving an infected mare. The trypanosomes inhabit the urethra and vagina but disappear periodically so that only a proportion of potentially infective matings result in infection. Invasion occurs through intact mucosa, and no abrasion is necessary.

Risk Factors

T. equiperdum is incapable of surviving outside the host. Like other trypanosomes, it also dies quickly in cadavers. Some animals, especially donkeys and mules, may be clinically normal but act as carriers of the infection for many years. Because the disease does not require an arthropod vector for its transmission, and in view of the extensive movement of horses across continents that now takes place, the risk of infection, though small, is present in every country, as with any other venereal disease. Thoroughbred horses are more susceptible than indigenous horses, and donkeys tend to show more chronic signs.

Immune Mechanisms

Infected animals produce antibodies to successive antigenic variants, as in *T. brucei*. Recovered animals often become carriers. Blood from infected horses is rarely infective to other horses, and the disease is not easily transmitted to ruminants under experimental conditions. Humans are not affected.

Biosecurity Concerns

There are none except when animals have to be moved internationally.

PATHOGENESIS

T. equiperdum shows a remarkable tropism for the mucosa of genital organs, the subcutaneous tissues, and the peripheral and CNSs. Trypanosomes deposited during coitus penetrate the intact genital mucosa, multiply locally in the extracellular tissue space, and produce an edematous swelling that may later undergo fibrosis. Subsequent systemic invasion occurs, and localization in other tissues causes vascular injury and edema, manifested clinically by subcutaneous edema. Invasion of the peripheral nervous system and the spinal cord leads to incoordination and paralysis.

CLINICAL FINDINGS

The severity of the clinical syndrome varies depending on the strain of the trypanosome and the general health of the horse population. The disease in Africa and Asia is much more chronic than in South America or Europe and may persist for many years, often without clinical signs, although these may develop when the animals' resistance is lowered by other disease or malnutrition.

The incubation period varies between 1 and 4 weeks, but could extend to more than 3 months in some animals. Initial signs may not be recognized until the breeding season. The ensuing disease will manifest genital signs in the primary stage, cutaneous signs in the secondary stage, and nervous signs in the tertiary stage.

In stallions, the **initial signs** are swelling and edema of the penis, scrotum, prepuce, and surrounding skin, extending as far forward as the chest. Paraphimosis may occur, and inguinal lymph nodes are swollen. There is a moderate mucopurulent urethral discharge. In mares, the edema commences in the vulva and is accompanied by a profuse fluid discharge, hyperemia, and sometimes ulceration of the vaginal mucosa. The edema spreads to the perineum, udder, and abdominal floor. In Europe, the disease is more severe; genital tract involvement is often accompanied by sexual excitement and more severe swelling.

In the **secondary stage**, cutaneous urticaria-like plaques, 2 to 5 cm in diameter, develop on the body and neck and disappear within a few hours up to a few days. These so-called silver dollar spots are pathognomonic for dourine but are not always present and are uncommon in endemic areas. Succeeding crops of plaques may result in persistence of the cutaneous involvement for several weeks.

Progressive anemia, emaciation, weakness, and nervous signs that appear at a variable time after genital involvement characterize the **tertiary stage**. Stiffness and weakness of the limbs are evident and incoordination develops, progressing terminally to ataxia and paralysis. Marked atrophy of the hindquarters is common, and in all animals there is loss of condition, in some to the point where extreme emaciation necessitates destruction. Lack of coordination of the hind legs, swelling of the external genitalia, and emaciation were the most common clinical signs in horses suspected to have dourine in Ethiopia.

CLINICAL PATHOLOGY

Trypanosome detection is difficult, but should be attempted in edema fluid, subcutaneous plaques, and vaginal or urethral washings or blood in early stages. Inoculation of blood into laboratory rodents is not as helpful as with other members of the *brucei* group.

An efficient CFT is available and was the basis for a successful eradication program in Canada. However, the test does not distinguish between members of the *brucei* group. Other serologic tests that can be used include the IFAT, the capillary agglutination test for trypanosomes, and the ELISA, but the CFT remains the most reliable. Serologic tests do not distinguish between members of the *brucei* group; hence they are of limited value in areas where *T. brucei* or *T. evansi* is endemic, even when monoclonal antibodies are used. In recent interlaboratory ring trials to evaluate serologic methods for dourine diagnosis, 9 out of 22 laboratories observed a false-positive result with a known *T. evansi*-positive serum, whether by CFT or IFAT.[4] However, diagnosis can be made based on serologic tests and characteristic clinical signs under the right epidemiologic setting.[2]

PCR has been used to detect trypanosome DNA and is an indication of an active infection, unlike serologic tests that detect past and current infections. Still, the PCR test cannot yet distinguish *T. equiperdum* from *T. evansi* or *T. brucei*.[5,6]

With the recent isolation of new strains of *T. equiperdum* from clinical cases in Ethiopia,[3] the first in 4 decades worldwide, there is hope that new internationally recognized tests for the diagnosis of dourine will be developed soon.

NECROPSY FINDINGS

Emaciation, anemia, and subcutaneous edema are always present, and edema of the external genitalia may be evident or the external genitalia may have healed, leaving the characteristic depigmented scars of permanent leukodermic patches. Lymph nodes

are enlarged, and there is softening of the spinal cord in the lumbosacral region.

Histologic lesions consist of lymphoplasmacytic infiltration in the spinal nerves, ganglia, and meninges of the lumbar and sacral regions and in affected skin and mucosa. Trypanosomes can be found in sections of the skin and genital mucosa during the primary and secondary phases of the infection. Affected lymph nodes show nonspecific lymphoid hyperplasia.

DIFFERENTIAL DIAGNOSIS

The full clinical syndrome is diagnostic, when present, because no other disease has the clinical and epizootiologic characteristics of dourine. However, when the full clinical picture is not developed, other diseases like nagana, surra, coital exanthema, equine infectious anemia, and purulent endometritis should be considered. With one exception, all recent reports of the disease have been based on clinical signs, serology, and detection of trypanosome DNA, but not on parasitologic detection.

TREATMENT

TREATMENT AND CONTROL

None is recommended.

Many trypanocidal drugs have been used in the treatment of dourine, but results are variable, chronic cases in particular are unresponsive to treatment. The main drawback is that treated animals may remain inapparent carriers and could continue to spread the disease or complicate serologic tests. Nevertheless, in Ethiopia, treatment of experimentally infected horses with Cymelarsan at 0.25 mg/kg BW was found to be effective for both acute and chronic cases.[7]

Berenil (diminazene) at 7 mg/kg BW as a 5% solution injected IM, with a second injection of half the dose 24 hours later, or suramin (10 mg/kg IV for two to three treatments at weekly intervals), or quinapyramine sulfate (3–5 mg/kg in divided doses injected subcutaneously) have been tried in the past.

CONTROL

In dourine-free countries, an embargo should be placed on the importation of horses from countries in which the disease is endemic, unless the animals have been properly tested and found negative. Eradication on an area or herd basis is by the application of the CFT, along with strict control of breeding and movement of horses. Positive reactors are disposed of, and two negative tests not less than a month apart can be accepted as evidence that the disease is no longer present. Castration or neutering of infected animals is not adequate because mating can still occur.

Toxic Agents Primarily Affecting the Reproductive System

ESTROGENIC SUBSTANCES

ETIOLOGY

Poisoning occurs either accidentally or intentionally from administration of a number of different products. Supplementation may be by addition to the feed, but is usually by subcutaneous implants. Many of them are used as growth promotants to increase weight gain and feed efficiency in animals.[1] Estrogen in some form can be found in the following four categories of growth promotants:

- Endogenous hormones (estradiol-17-β, progesterone, testosterone)[1,2]
- Synthetic hormones (ethinylestradiol, others)[1]
- Xenobiotics (zearalenone [α-zearalanol; zeranol], trenbolone)[1,3]
- Miscellaneous (diethylstilbestrol and related compounds such as hexestrol and dienestrol)[1]

EPIDEMIOLOGY

Occurrence

Poisoning by estrogenic substances occurs in the following circumstances:

- Natural substances such as genistein present in plants and as zearalenone in fungi[1,3]
- Dietary supplements for fattening cattle[1]
- Overdosage of medications used in clinical infertility cases
- Pigs fed hexestrol implants in capon necks
- Cattle fed on chicken litter from farms on which estrogens are used as supplements.

Risk Factors

Animal Risk Factors

Steers implanted with an estrogen at a standard dose rate may respond in an exaggerated manner and show signs of toxicity. Estradiol implants are reputed to be associated with more of these problems than zeranol.

Environmental Risk Factors

Estrogens from treated animals are found in the environment in water and animal manure and may act as endocrine disrupters. Water treatment plants are able to remove most of the estrogens, but animal manure is not regulated in the many parts of the world unless it is discharged into a water supply.[4-6]

Farm Risk Factors

Pasture may be contaminated by manure from cattle treated orally or by subcutaneous implants with estrogenic substances that pass significant amounts in the feces.[2,6] Ensilage made from the pasture may also be contaminated.

Human Risk Factors

Estrogenic substance administration as a management tool is regarded unfavorably in many countries because of the risk of intoxication occurring in humans eating contaminated meat. Their use is banned in some and strictly controlled in others. In one small study, a palpable mammary tumor was observed in a rat implanted with a 12-mg zeranol pellet.[3] The presence of environmental zearalenone has been proposed as a link to early puberty and anabolic growth effects in young girls.[7]

PATHOGENESIS

Signs and lesions are the direct result of amplification of the pharmacologic effects of the substances.

CLINICAL SIGNS

Idiopathic Female Estrogenism

In addition to the toxic effects associated with estrogens in specific plants, increased estrogenic activity is also encountered in mixed pasture, generally only at certain times and on particular fields. Clinically the effects are those of sterility, some abortions, swelling of the udder and vulva in pregnant animals and virgin heifers, and endometritis with a slimy, purulent vaginal discharge in some animals. Estrous cycles are irregular. In milking cows, there is depression of the milk yield, reduction in appetite, and an increase in the cell count of the milk.

Male Estrogenism

Steers in feedlots may exhibit excessive mounting by other steers, sometimes to the point of causing death. Head injuries caused by head-to-head butting, frequent bawling, stampedes, and pawing the ground to the point of hole-digging are other reported signs. These problems tend to pass off after a short time. Preputial prolapse may be a problem in *Bos indicus* cattle. Experimental feeding of zeranol to young bulls is associated with retardation of testicular and epididymal development.

Nymphomania in Cows

Larger doses of stilbestrol, usually administered accidentally to cows, may be associated with prolapse of the rectum and vagina and elevation of the tail head caused by relaxation of the pelvic ligaments. Susceptibility to fracture of the pelvic bones and dislocation of the hip are common sequelae. Nymphomaniac behavior in such animals results in other skeletal injuries, especially fracture of the wing of the ilium.

Swine Estrogenism

Common clinical signs include weight loss, decreased feed efficiency, straining, prolapse of the rectum, incontinence of urine, anuria, and death.[8] Estrogens such as zearalenone ingested by sows after day 11 to 13 of the estrous cycle can be associated with retention of corpora lutea and a syndrome of anestrus or pseudopregnancy, which typically persists for 45 to 60 days postestrus. This effect may occur at zearalenone concentrations of 3 to 10 ppm in the diet. Pregnant sows given zearalenone postbreeding may have failure of implantation and early fetal abortion.

Urethral Obstruction

Heavy mortalities have occurred in feeder lambs after the use of implants of estrogens as a result of prolapse of the rectum, vagina, and uterus, together with urethral obstruction by calculi. The calculi consist largely of desquamated epithelial and inflammatory cells that form a nidus for the deposition of mineral; the desquamation is probably stimulated by the estrogen. Also, urethral narrowing caused by the estrogen facilitates complete obstruction by the calculi.

CLINICAL PATHOLOGY

High blood levels of estrogens are characteristic. In swine, the syndrome of anestrus associated with zearalenone will be accompanied by elevated progesterone concentrations caused by the retention of corpora lutea.

NECROPSY FINDINGS

Enlargement and vascular engorgement of accessory sex organs, especially in neutered animals, are characteristic. Uterine enlargement and keratinization of vaginal epithelium may be detected, and in mature female swine there may be persistent multiple retained corpora lutea. Swine also show inflammation and necrosis of the rectal wall, enlargement of the kidneys, thickening of the ureters and distension of the bladder, and gross enlargement of the prostate and seminal vesicles. Histopathology on jejunum obtained from pigs treated with low doses of zearalenone and T-2 toxin showed normal crypts and villi but decreased numbers of goblet cells and acidophilic granulocytes in the mucous membrane and numerous plasma cells in the intestinal epithelium.[8]

PHYTOESTROGEN TOXICOSIS

SYNOPSIS

Etiology Ingestion of plants that produce estrogen (phytoestrogens) resulting in a number of reproductive problems.

Epidemiology Pastures dominated by specific strains of legumes, in lush growth mode, or hay or silage made from such pasture, are associated with problems if exposure is prolonged. Sheep are much more susceptible than cattle.

Clinical pathology Positive estrogen assay in blood.

Lesions

Live animals: Severe flock infertility in sheep; prolongation of estrus periods, interestrus periods shortened.

Postmortem: Ewes show cystic endometrial degeneration.

Diagnosis confirmation Laboratory assay of feed, blood, and tissue; the appearance of genital pathology at necropsy, or with a uterine biopsy or laparoscopy.

Treatment None.

Control Grazing management, use of low-phytoestrogen cultivars.

ETIOLOGY

Important estrogenic substances found in plants and fungi include the following:

- Plants
  - Coumestans (coumestrol, 4-methoxycoumestrol, repensol, trifoliol)[1]
  - Isoflavones (daidzein, formononetin, genistein, biochanin A, glycitein)[2,3]
  - Isoflavan (equol, a metabolite of daidzein)[3]
- Fungi (resorcylic acid lactones [zearalenone])[4]

Compared with pharmaceutical agents, these substances have low estrogenic activity, but they are associated with serious clinical effects because of the high concentrations they reach in some plants and daily intake over long periods. The coumestans are most common in plants of the *Medicago* genus; isoflavones are most common in the *Trifolium, Baptisia,* and *Cytisus* genera. Only *Medicago* and *Trifolium* spp. are of any importance to animals. Those likely to contain sufficient amounts to be associated with disease are

Fusarium (variety of species); contains zearalenone[4]
Glycine max (soybean; contains coumestans and isoflavones; affects pigs)
Medicago sativa (alfalfa, lucerne; contains coumestans; affects cattle, sheep)
Trifolium alexandrinum (isoflavones)
T. alpestre (alpestrine clover; contains isoflavones)
T. pratense (red clover; contains isoflavones; affects sheep)[1]
T. repens (white clover, Ladino clover; contains coumestans)[1]
T. subterraneum (subterranean clover; contains isoflavones; affects sheep).

EPIDEMIOLOGY

Occurrence

Animals on pasture are at the greatest risk, but poisoning can also occur on diets containing prepared feeds such as soybean (*Glycine max*) meal, or moldy feed containing *Fusarium* fungi.

Risk Factors

Animal Factors

Phytoestrogen toxicosis is clinically important only in sheep. Cattle are generally considered to be less sensitive than sheep.[1,5,6] For example, cows can ingest large amounts of estrogens (over 40 g per day per cow) in red clover without showing any reduction in reproductive efficiency. Horses usually graze the toxic pasture without ill effects.

Massive reproductive wastage has been experienced in sheep on pastures dominated by such plants as *Trifolium subterraneum,* and the death rate from dystocia and prolapse of the uterus can also be high. The most common abnormality is a failure to conceive, even with multiple matings, and the flock breeding status worsens progressively, with the lambing percentage falling from a normal 80% down to 30%. Sheep eating a lot of estrogenic clover in the spring can become temporarily infertile, but are normally fertile again by the usual breeding season in the autumn. However, ingestion of the plant in several successive years is associated with "permanent clover disease"—infertility from which ewes do not recover. Under these conditions sheep farming becomes unprofitable, and large areas of country have been made unsuitable for sheep raising because of this disease.

Human Factors

Various phytoestrogens have been found in foods of animal origin (eggs, milk, meat, fish, and seafood). Equol was found in several foods, including eggs, milk, and meat.[7] Not all phytoestrogens are harmful and many of them are have known human health benefits.[8] Many, however, are endocrine disruptors, which means that they can produce adverse health effects as well.

Plant Factors

The estrogenic activity of pastures depends on the degree of domination of the pasture by the toxic plants, the variety of the plant species, and the duration of the animal's exposure to them. Newly sown pastures are usually most toxic because of domination by the sown legume. Pastures deficient in phosphorus are also likely to be clover dominant. High nitrogen fertilizer applications reduce phytoestrogen content. Varieties of *Trifolium subterraneum,* e.g., Yarloop, Dwalganup, Dinninup, and Geraldton, are much more toxic than Bacchus Marsh and Daliak. Pastures containing more than 30% of the first four varieties are likely to be unsafe. In some clovers, e.g., red clover, the estrogen content varies with the season, and is high in early spring, low in midsummer, and high again in the autumn after the hay has been taken off. Insect damage to pasture can increase the estrogen content 10-fold, and bacterial infection (e.g., by *Pseudopezzia medicaginnis,* a leaf-spotting organism on alfalfa) and fungal infection by 100-fold. Plants that have matured in the field and set seed have no estrogenic potency, but the making of potent fodder into hay causes little depression of estrogen content. Clover ensilage can contain high levels of estrogens, and the ensiling process is considered to increase the estrogenic effect of clover 3- to 5-fold.

Trifolium repens (white clover, in contradistinction to Ladino clover), does not have a high content of estrogens.[1] However, when heavily infested with fungi it can contain significant amounts. It is thought that the production of estrogens is a byproduct of the plant's mechanism of resistance to the fungal infection. Ladino clover, a large-growing variety of white clover, may contain large quantities of a highly active estrogen (coumestrol), and when it dominates a pasture and is grazed when the pasture is lush, it may be associated with the cornification of vaginal epithelium and functional infertility in ewes. Three estrogenic compounds have been isolated from *T. pratense* (red clover), and where this plant dominates the pasture a clinical syndrome similar to that associated with subterranean clover may be observed. Ewes grazing on red clover pasture, especially a toxic cultivar of the plant, may have their conception rate at the first mating cycle reduced from 75% to as low as 25%.

PATHOGENESIS

Much of the metabolism of phytoestrogens in ruminants occurs in the rumen as well as in the liver.[1] The differences between sheep and cattle in the ruminal metabolism of these compounds are thought to be the reason for the comparative freedom of cattle from the clinical disease.

The amount of phytoestrogen ingested by a ewe on a highly poisonous pasture may equal her daily estrogen secretion at the peak of her estrous cycle. The effect of the phytoestrogens is exerted mainly on the uterus and ovaries. Structurally, there is hyperplasia and hypertrophy of the epithelium of the uterus, vagina, and cervix, and dysplasia of the granulosa cells of the ovary, with a consequent reduction in secretion of estradiol. Increases in teat size and milk secretion are additional, secondary effects.

The functional abnormality is not one of estrus; in sheep the demonstration and duration of estrus may be normal or depressed, and the defect is one of sperm transport because of changes in the composition of cervical mucus and the structure of cervical glands. The change is to more watery mucus, and this is the basis of a test in affected sheep in which the watery mucus is more readily absorbed by a cottonwood plug inserted in the vagina. The increased weight of the plug is a positive test.

It is possible that a good deal of the infertility seen in ewes on improved clover pasture may be associated with its high estrogen content, in spite of the absence of the more dramatic evidence of hyperestrogenism described earlier. Because it is necessity to use this pasture, a great deal more needs to be known about the seasonal occurrence of the estrogenic substances and the management of sheep grazing the pasture so that the effects of the disease can be minimized.

CLINICAL FINDINGS

Ewes

Clover disease, the severe clinical manifestation of phytoestrogen poisoning, and rarely seen today, includes dystocia, prolapse of the uterus or vagina, severe infertility, and death. The more common and less severe field expression of phytoestrogen poisoning is a significant decrease in fertility rate. It may be temporary with normal reproductive efficiency returning soon after the ewes are moved to clover-free pasture. In ewes exposed to a low level intake of estrogens over a long period, e.g., in excess of two grazing seasons, a process of irreversible "defeminization" may occur. This is a state of permanent subfertility. The estrous cycle is normal, but an abnormally large number of ewes fail to conceive. In affected flocks, there may also be a high incidence of maternal dystocia caused by uterine inertia, or failure of the cervix or vagina to dilate. Affected ewes show little evidence of impending parturition and many full-term fetuses are born dead.

Male Castrates

Wethers may secrete milk, and metaplasia of the prostate and bulbourethral glands is evident. These can be detected at an early stage of development by digital rectal palpation. Continuing hyperplasia and cystic dilatation of these glands is associated with their prolapse in a subanal position, followed by rapid weight loss and fatal rupture of the bladder. Rams usually show no clinical abnormality, and their fertility is not impaired.

Cattle exhibit clinical signs less often than sheep, with experimental reports of decreases in conception and fertilization caused by prolongation of oocyte maturation and decreased sensitivity of the corpus luteum to luteolytic agents.[5,6] Temporary infertility; discharge of cervical mucus; and swelling of the mammary gland, vulva, and uterus have all been recorded in cattle.

Gilts exposed to genistein may develop structural changes and abnormalities in the cervix and uterus.[9]

CLINICAL PATHOLOGY

Laboratory assays are available and essential to diagnosis and monitoring of feed contents of phytoestrogens.[7] Chemical assays are not as sensitive as biologic assessments based on increased size of genitalia in subject animals.

NECROPSY FINDINGS

Severe cystic degeneration of the endometrium is present in the most severe cases. Similar clinical and histopathologic changes have been produced by the daily injection of 0.03 mg of diethylstilbestrol per ewe for a period of 6 months. There is also a long-term change in the cervix with an increased incidence of cervicitis and a histologically observable transformation to a uterine-like

appearance. In ewes on a long-term intake of toxic pasture, the lesions include elevation of the tail head, partial fusion of the vulvar labia, and clitoral hypertrophy.

Diagnostic confirmation of phytoestrogen poisoning requires laboratory assay of feed, blood, and tissue, and the appearance of genital pathology at necropsy, or with a uterine biopsy, or laparoscopy.

DIFFERENTIAL DIAGNOSIS

Differential diagnosis list

- Overdose of pharmaceutical preparation as part of a program to improve fertility in a herd.
- Overdose of an implant or feed additive with a growth stimulant that has estrogenic capability.

TREATMENT

Administration of testosterone is a logical response to poisoning but appears to be an unlikely commercial proposition.

CONTROL

Avoidance of high estrogenic activity strains of the respective plants, grazing management to avoid dangerous pasture at the most toxic part of the season, and dilution of the estrogen intake by providing additional and alternative feeds, are all used to control the disease. Prevention of clover disease can only be achieved by proper management of sheep and pasture to avoid ingestion of excessive amounts of estrogens. Vaccination with a phytoestrogen-immunogenic protein conjugate has produced good levels of antibodies, but has not been successful in preventing the problem. Careful management of flocks on estrogenic pasture can significantly improve reproductive output.

ZEARALENONE TOXICOSIS

SYNOPSIS

Etiology Zearalenone is an estrogenic mycotoxin produced primarily by fungus in the genus *Fusarium,* which is the causative agent. *F. graminearum* is the species most responsible for animal reproductive problems, but *F. cerealis, F. culmorum, F. cookwellense, F. equiseti,* and *F. semitectum* are contaminants of moldy maize, wheat, oats, and barley grain and cause issues as well.

Epidemiology Global issue with zearalenone found in a variety of cereals and foodstuffs in many countries.

Clinical pathology None in particular; progesterone levels may be decreased.

Lesions Associated with hyperestrogenism and include abortions, stillbirths, mammary gland enlargement and secretions, vulvar edema, and vaginitis in females as well as testicular atrophy and mammary gland enlargement in males.

Diagnostic confirmation Presence of zearalenone and/or metabolites in feces, urine, and serum; presence in feedstuffs.

Treatment Remove animals from contaminated feed and correct prolapses.

Control Keep moisture content of stored grain below 15%–16%; feed contaminated grains to less susceptible animals.

ETIOLOGY

Zearalenone is a nonsteroidal estrogenic mycotoxin produced primarily by fungi in the genus *Fusarium. F. graminearum* is the species most responsible for animals' reproductive problems, but *F. cerealis, F. culmorum, F. cookwellense, F. equiseti,* and *F. semitectum* are contaminants of moldy maize, wheat, oats, and barley grain and are associated with toxicosis.[1,2] Swine are most commonly affected, but cases have occurred in sheep and cattle[3,4] and more rarely in horses.[5]

EPIDEMIOLOGY

Occurrence

The fungi that produce zearalenone primarily colonize corn, but they also infect other cereal grains such as barley, wheat, and oats.[1,2] Zearalenone has also been detected in a number of other plants including rice, sorghum, millet, and soybeans. Most typically, contamination occurs from high moisture during storage; field contamination has been reported but occurs less often. Zearalenone has been detected in pastures in New Zealand, which has been associated with infertility in ewes.[6] Contamination of food and animals is considered a global problem because zearalenone has been found in Africa, Asia, Australia, Europe, North America, and South America.[2]

Risk Factors

Animal Risk Factors

Swine of all ages, but especially prepubertal gilt, are the most sensitive to the effects of zearalenone. The primary effects are reproductive and depend on the dose and time of administration in relationship to the animal's estrous cycle.[5,6]

Farm Risk Factors

Elevated levels of zearalenone in the feed are primarily associated with improper storage and not contamination in the field.[2]

Human Risk Factors

There is considerable concern that humans, especially young girls, will be adversely affected by zearalenone in cereal products, milk and milk-based products, and meats. In Europe, 32% of mixed cereal samples from nine countries were found to be contaminated with zearalenone. Zearalenone is excreted in milk and present in some concentration in meats in animals with high intake, but currently the risk to humans is thought to be low.[2]

PATHOGENESIS

Zearalenone is rapidly absorbed following an oral exposure, with an estimated uptake of 80% to 85%.[1,2] In swine, it can be detected in the serum within about 30 minutes after ingestion.[2] Distribution is primarily to the adipose tissue and the ovary and uterus. The liver is the main site of metabolism, but other tissues such as the intestine, kidney, ovary, and testis are metabolic sites.[1] Two different biotransformation pathways have been proposed and likely play a role in the susceptibility `of different species.[1,5] Zearalenone is either conjugated with glucuronic acid or hydroxylated to α- and β-zearalenol.[1,5] In swine, the preferred route is conjugation with conversion to primarily α-zearalenol.[1,4,5] Sheep are similar to swine but cattle convert to β-zearalenol, a less estrogenic metabolite.[4] Excretion is biliary in most species with significant enterohepatic recirculation occurring.[1]

Zearalenone crosses cell membranes and binds to cytosolic 17β-estradiol receptors. Once this occurs, it is translocated into the nucleus where it binds to estrogen-responsive elements and stimulates mRNA synthesis resulting in estrogen-like effects.[1,3]

CLINICAL FINDINGS

Swine

Pigs of all ages are affected, including piglets nursing on sows, which themselves show no signs of estrogenism. The most significantly affected are the 6 to 7-month-old gilts. Vulvovaginitis, including swelling of the vulva to three to four times normal size, enlargement of mammary glands, a thin catarrhal exudate from the vulva, and increased size and weight of the ovaries and uterus, is the severest form

of the poisoning.[3,6] Prolapse of the vagina is common (up to 30% of affected pigs) and there is prolapse of the rectum in some pigs (5%–10%). The toxin reduces serum progesterone levels in sows, but the administration of progesterone to affected gilts does not counteract the estrogenic effects. The syndrome is indistinguishable from that produced by long-term overdosing with diethylstilbestrol. Signs appear 3 to 6 days after feeding of moldy grain commences and disappear soon after the feeding stops. The mortality rate is high because of the secondary development of cystitis, uremia, and septicemia.

The more important manifestation of the poisoning may be infertility, including absence of estrus, high levels of stillbirth, neonatal mortality, and reduced litter size. Small fetal size, fetal malformations, splayleg and hindlimb paresis, pseudopregnancy, and constant estrus are also recorded.[3]

Zearalenone in male pigs can induce feminizing characteristics; suppress libido; and decrease spermatogenesis, testicular weights, and serum testosterone concentrations.[2]

Ruminants

In cattle, the effect of zearalenone is largely on conception rate, and the rate of services per conception may rise, but the overall effect is less than in sows. Milk production may be decreased.[2] Behavioral estrus occurs at times unrelated to ovarian cycles and in late pregnant cows. There is idiopathic vaginitis. Symmetric enlargement of the mammary glands is recorded in prepubertal dairy heifers feeding on fungus-infected corn. Estrogenic disturbances are also suspected in sheep. Abortion is suspected to occur, and mild vulvovaginitis and hypertrophy of the uterus are recorded. Experimental feeding of zearalenone to lactating cows and ewes does result in minor contamination of their milk sufficient to produce hyperestrogenism in a lamb sucking a poisoned ewe.

Horses

Zearalenone toxicosis is rarely reported in horses.[1] A recent study using equine ovarian cultured granulosa cells demonstrated that zearalenone may play a role in some equine reproductive disorders.[5]

CLINICAL PATHOLOGY

Zearalenone and its metabolites can be identified in urine, plasma, and feces by high-performance liquid chromatography[7] and in feedstuffs by liquid chromatography mass spectrometry and a rapid immunoassay.[8,9] In 2003, 16 countries limited the amount of allowable zearalenone in maize and cereals; the allowable concentration varies from 50 to 1000 µg/kg depending on the country.[5]

NECROPSY FINDINGS

On necropsy, there are nonspecific findings other than expected changes associated with estrogen-related reproductive tract abnormalities. These include changes in ovarian weight with decreased numbers of corpora lutea, increased dead piglets, vaginal and rectal prolapses, vulvar edema and vaginitis in females, and testicular atrophy and mammary gland enlargement in males.[10]

DIFFERENTIAL DIAGNOSIS

Differential diagnosis list

- Accidental overdose of synthetic estrogen substances
- Estrogenic substances
- Phytoestrogens

TREATMENT

Complete recovery follows when the feeding of the affected grain is stopped and no treatment other than surgical repair of the prolapsed organs is attempted.

CONTROL

The moisture content of grains should be kept below 15% to 16% during storage. If contaminated feeds must be used, they should be fed to animals less susceptible to toxicosis. The 2006 EU guidelines for zearalenone in feeds recommend that piglets and gilts do not receive more than 0.1 mg zearalenone/kg BW; sows and fattening pigs no more than 0.25 mg zearalenone/kg BW; and sheep, goats, calves, and dairy cows no more than 0.5 mg zearalenone/kg BW.[10]

MARE REPRODUCTIVE LOSS SYNDROME (EARLY FETAL LOSS, LATE FETAL LOSS, FIBRINOUS PERICARDITIS, AND UNILATERAL UVEITIS)

SYNOPSIS

Etiology Exposure to Eastern tent caterpillars (ETCs; *Malacosoma americanum),* in particular during the spring when the caterpillars are most active.

Epidemiology Occurs primarily in the Ohio River valley, but reported in other states. Risk factors are the presence of black cherry trees on pasture, ETC, and feeding hay on the ground.

Clinical pathology Culture of fetal and placental tissue most commonly results in growth of non–β-hemolytic streptococci and/or *Actinobacillus.*

Lesions Inflammation of the intraamniotic umbilical cord (funisitis), premature placental separation, placental edema, placentitis, diffuse alveolitis, and hemorrhage in a variety of organs.

Diagnostic confirmation Based on the presence of appropriate clinical signs with a history of exposure of affected horses to ETCs.

Treatment Supportive care only.

Control Removal of cherry trees from pasture, spraying ETC nests and pastures with pyrethrin pesticides, keeping horses off pasture or muzzling mares on pasture during active ETC months.

ETIOLOGY

In 2001 an epidemic of early fetal loss (40–80 days; range 40–140 days) and late fetal loss (about 340 days) was recognized in north central Kentucky, southern Ohio, and Tennessee affecting over 3500 mares.[1,2] It occurred again in 2002 but far fewer horses were affected. The epidemic was termed mare reproductive loss syndrome (MRLS). At the same time there was also a marked increase in incidence of birth of weak foals and fibrinous pericarditis and unilateral uveitis in adult horses in the same region.[1-3] Research in horses and pigs confirmed the causative agent as *Malacosoma americanum,* the Eastern tent caterpillar (ETC). Similar episodes of equine abortions, now referred to as equine amnionitis and fetal loss (EAFL), occurred in Australia and have been associated with the *Ochrogaster lunifer,* the processionary caterpillar.[4,5]

EPIDEMIOLOGY

Historically, many epidemiologic studies were performed to determine the source of the epidemic. Several toxins such as fescue, nitrate/nitrite, phytoestrogens, and mycotoxins were examined and ruled out leaving a

strong association between the presence of ETCs (*M. americanum,* black cherry trees (*Prunus serotina*), and feeding horses hay off the ground. Black cherry trees were involved because they are the preferred host tree for ETC and may be a source of cyanide. Black cherry trees (i.e., cyanide) were ruled out as a cause of MRLS, and an association with ETC was examined experimentally. In several different experiments, pregnant horses (50 to 200 days' gestation) were exposed to various forms of ETC and only those mares exposed to live ETC larvae aborted. These were the first studies to reproduce MRLS and demonstrate that ETC could cause pregnancy loss in mares. Further studies demonstrated that the cuticle (setae; hairs) is the structure responsible for the abortigenic activity.[1,2] Culture of the placental fluid or fetal tissues in both early and late losses showed non–β-hemolytic streptococci and *Actinobacillus,* which are bacteria routinely found in the oral cavity of horses.[2,6] Finally, the syndrome was reproduced in pigs with abortions occurring 13 to 16 days after first ingestion.[1] More important, histopathologic examination showed ETC setae imbedded in the gastrointestinal mucosa that were surrounded by microgranulomatous lesions.[1,2,6] A similar pattern was subsequently confirmed in pregnant and nonpregnant mares.

Occurrence

The first well-studied and documented outbreak of abortions occurred from April 26 through mid-June of 2001, with a lower incidence of disease during the same months in 2002. An abortion storm, which may have been related, occurred in Kentucky in 1991 and 1982, but no epidemiologic studies were performed.[1] In 2006, a similar syndrome associated with large numbers of ETC was reported in Florida.[2]

The 2001 to 2002 outbreak caused early fetal loss in 25% to 63% of mares on one-third of farms, 14% to 24% on another third, and 2% to 13% on the remaining one-third. Approximately 21% of mares pregnant at 42 days' gestation were not pregnant when examined at 70 to 90 days' gestation. The expected pregnancy loss rate between 42 days and parturition is 12%. Over 3500 mares (3000 early fetal losses; 500 late fetal losses) aborted during the outbreak.[1,3] The economic losses incurred because of MRLS during 2001 and 2002 are estimated to be $500 million.[1]

Risk Factors

Animal Risk Factors

Risk factors for the disease are the presence of black cherry trees, exposure to ETC (especially the presence of large numbers of caterpillars on pasture), and pasturing or feeding hay to horses at pasture.

For late-term abortion the risk factors include increased amount of time at pasture, less time in stall, feeding concentrate on the ground, increased proportion of feed obtained from pasture, and being fed exclusively in pasture during the final 4 weeks of gestation. All of these factors favor exposure to ETC.

Risk factors for pericarditis include presence of mares or foals with MRLS on the farm, grazing, and exposure to ETC. Risk factors for uveitis have not been defined.

Farm Risk Factors

ETCs are endemic to the eastern United States including the Ohio River valley. Egg masses are laid on many trees in the Rosaceae family including black cherry trees, which are the preferred host. Eggs hatch in the early spring when the cherry trees bud. Local populations of the caterpillars fluctuate dramatically from year to year, but mares are likely exposed to small numbers of the caterpillars every spring. Climatic conditions that favor survival of ETC and synchronize their maturation result in simultaneous hatching of large numbers of eggs. The rapid emergence of large numbers of caterpillars results in abrupt and heavy exposure of horses and consequent development of MRLS. Weather conditions thought to contribute to the 2001 outbreak include a period of low temperatures in March, above normal temperatures in April, and a frost and freeze in late April immediately followed by several warm days.

PATHOGENESIS

The pathogenesis of the diseases associated with MRLS has not been well defined. Based on experimental studies and natural cases, ETC setae are likely involved in the pathophysiology. Two different hypotheses have been proposed:

- Setae lodged in the gastrointestinal submucosa causes inflammation, form microgranulomas, and disrupt the mucosal barrier. Resident bacteria such as *Actinobacillus* spp. penetrate the barrier, resulting in bacteremia and hematogenous spread to the placenta, fetus, pericardium, uvea, and meninges.[1,6]
- Setae or parts of the exoskeleton contain an as yet unidentified toxin that is toxic to the placenta and fetus.[1]

CLINICAL FINDINGS

Early Fetal Loss

This is detected by per rectum uterine examination, either manual or using ultrasonographic visualization of uterine contents, during early pregnancy. Fetal loss occurs after 35 days, conception not being affected, and affected mares do not come into estrus because of the presence of endometrial cups, which do not regress until 100 to 180 days after ovulation.[3]

Mares have no clinically detectable premonitory signs of fetal loss.[1,2] Ultrasonographic examination of the uterus of pregnant mares reveals that the allantoic fluid of fetuses <80 days of age has increased echogenicity on the day of fetal death. Allantoic fluid increases in echogenicity with increasing fetal age, and care should be taken when interpreting this observation.

Late Fetal Loss

Late fetal loss occurs as a late-term abortion (final several weeks of gestation), birth of a stillborn foal at full term, and the birth of a foal that is weak and of reduced viability. The birth of an affected foal is associated with premature placental separation ("red bag" deliveries), foaling while standing, and explosive expulsion of the fetus and placenta. Foals born alive are weak, have sunken eyes, progressive neurologic signs consistent with hypoxia, and have a high death rate (50%) despite intensive care. Severe leukopenia at birth often progresses to leukocytosis at 24 to 48 hours of age. Serum biochemical abnormalities include elevated serum creatinine concentrations, hypoglycemia, and increased serum creatine kinase activity. Bacteria isolated from stillborn foals at necropsy or on culture of blood samples from sick foals are nonspecific organisms, including nonhemolytic streptococci and *Actinobacillus* spp.

Fibrinous Pericarditis

Clinical signs in horses of both genders include tachycardia, pleural effusion, pericardial effusion, ascites, fever, abdominal pain, and sudden death.[1,2] Younger horses (<2 years of age) may be more susceptible to developing pericarditis. There is accumulation of large quantities of pericardial fluid and fibrin deposition on the parietal and visceral pericardial surfaces evident on ultrasonographic examination of the chest. The lungs have ultrasonographic evidence of consolidation consistent with pneumonia in approximately 50% of cases. Pericardiocentesis yields abundant fluid that is light yellow and has a low white blood cell count ($<5 \times 10^9$/L) characterized by well-preserved neutrophils. Horses with a prolonged course of the disease (>2 weeks) can have elevated white cell counts in pericardial fluid secondary to opportunistic infection, usually with *Actinobacillus* spp.[6] Hematologic abnormalities are minimal and characterized by a slight leukocytosis in approximately 50% of cases. Azotemia occurs in horses with severe cardiac tamponade.

Unilateral Uveitis

Clinical signs are acute and unilateral and include corneal edema, exudates in the anterior and posterior chambers, and iris hemorrhage.[1] Progression of the syndrome leads to blindness and global atrophy. There is no age predilection and no organisms have been found on culture.

CLINICAL PATHOLOGY

Culture of fetal and placental tissue most commonly results in growth of non–β-

hemolytic streptococci and/or *Actinobacillus*. *Actinobacillus* spp., along with several other bacteria, has been isolated from fibrinous pneumonia.

Diagnostic confirmation is based on the presence of appropriate clinical signs with a history of exposure of affected horses to ETCs.

DIFFERENTIAL DIAGNOSIS

Differential diagnosis list:
Cyanide toxicosis
Ergot/fescue
Infectious causes of placentitis
Mycotoxicosis
Nitrate toxicosis
Phytoestrogens

NECROPSY FINDINGS

Examination of the placenta, stillborn foals, and foals that die after birth reveals inflammation of the intraamniotic umbilical cord (funisitis), premature placental separation, placental edema, placentitis, diffuse alveolitis, and hemorrhage in a variety of organs. Horses with pericarditis have impressive accumulation of hairy fibrin in the pericardial space with marked thickening of the visceral and parietal pericardium (a hoary heart).

TREATMENT

Treatment of affected foals is primarily supportive in nature. Horses with pericarditis should have the fluid drained to relieve or prevent cardiac tamponade and to minimize the accumulation of fibrin. Pericardial fluid may need to be drained several times, and its accumulation should be monitored ultrasonographically. Administration of broad-spectrum antibiotics should be based on culture and sensitivity of pericardial fluid. Treatment for uveitis is standard and includes atropine, antiinflammatory agents, topical and systemic antibiotics (culture and sensitivity as indicated), and other agents such as cyclosporin or tissue plasminogen activator.

CONTROL

This is based on prevention of ingestion of ETC by horses. Preventing horses from ingesting caterpillars by minimizing access to pasture and feeding hay in stalls is likely to be beneficial.

Other control measures include removing wild or black cherry trees, the favored host species for ETCs, from pastures, hedges, and fence rows; applying pesticides to trees to kill over wintering eggs or, after hatching, caterpillars; installation of barriers to caterpillar migration onto pasture; manual removal of egg tents; installing pheromone traps; and restricting access of mares to pasture.[7,8]

Application of bifenthrin or permethrin, but not 3% horticultural oil, to egg masses (tents) during the winter prevents emergence of caterpillars in the spring. Insecticidal soap or oils sprayed on neonatal caterpillars is minimally effective. Bifenthrin or spinosad are effective against all instars for 7 days when sprayed on foliage. Injection of trunks of cherry trees with dicrotophos or emamectin is effective against all instars, but injection with milbemectin or avermectin is not effective. A spray of 50 mL of 39% permethrin diluted in 4 L of water and applied to a 2-m wide band of pasture outside the fence line kills migrating caterpillars and prevents them obtaining access to pasture. This solution can also be sprayed on the trunks of trees to kill caterpillars as they leave the tree.

EQUINE AMNIONITIS AND FETAL LOSS

EAFL is the name given to a syndrome of abortions that occurred in horses in New South Wales between April and October 2004.[1] Mares from 4 months to term aborted fetuses with signs of inflammatory changes primarily involving the amnion (amnionitis) and amniotic portion of the umbilical cord (funisitis).[2,3] Clinical signs in mares before abortion were minimal.

The syndrome, while occurring several years after the epidemic of MRLS in the United States, had some similarities and caterpillars were looked at as a possible source of the problem. Several caterpillars were examined with the *O. lunifer* (the processionary caterpillar) ultimately causing abortion in two different experimental studies involving early pregnancy and midlate pregnancy.[3,4]

There are some differences between the two syndromes. An infectious agent has been identified in both EAFL and MRLS, but they are not the same bacteria. The predominant bacteria isolated from EAFL cases were environmental coryneforms and gram-negative rods, whereas *Actinobacillus* and non–β-hemolytic streptococci were common isolates from MRLS cases.[2,5] Fibrinous pericarditis and unilateral uveitis affected a number of horses in the MRLS epidemic but did not occur with EAFL.[1] Finally, although devastating, the number of horses involved in the 2004 EAFL outbreak was considerably less than the 2001 to 2002 MRLS epidemic.

PLANTS AND FUNGI (UNKNOWN TOXINS) AFFECTING THE REPRODUCTIVE SYSTEM

PLANTS

Plants Associated With Abortion

- *Iva angustifolia* (narrow-leafed sumpweed)
- *Salvia coccinea* (red salvia)
- *Tanacetum vulgare* (tansy)
- *Verbena bonariensis* (purple top)

Plants Associated With Prolonged Gestation

- *Lysichiton americanus* (skunk cabbage)
- *Salsola tuberculatiformis* (cauliflower saltwort; in ewes it is associated with atrophy of the pituitary, adrenal, and thymus glands of the fetus and prolongation of pregnancy to as long as 213 days).

Plants Associated With Congenital Defects

- *L. americanus* (skunk cabbage; is associated mostly with craniofacial deformity).

FUNGI

Fungi Associated With Reproductive Dysfunction

- *Penicillium roqueforti*, growing on moldy mixed grain and ensilage, is suspected of causing bovine abortion and retained placenta.

- *T. repens* (white clover) does not normally contain estrogens, but when heavily infested with fungi it may contain significant amounts.
- *Ustilago hordei* (barley smut) fungus is thought to be toxic to farm animals; feeding it to experimental animals has been associated with infertility and stillbirths.
- In southeastern Australia a common infertility syndrome, including abortion and fetal mummification, has been ascribed to an onion-like weed, *Romulea rosea.* There is a suspicion that the disease may be caused by a toxin produced by a fungus, *Helminthosporium biseptatum,* which grows on the weed.

Congenital and Inherited Diseases Primarily Affecting the Reproductive System

CHROMOSOMAL TRANSLOCATIONS IN CATTLE

A chromosomal translocation is a mutation occurring when two nonhomologous chromosomes exchange parts, which results in a chromosomal rearrangement. The most common type or translocation is the **reciprocal translocation** (RCP) in which a segment from one chromosome is exchanged with a segment of another nonhomologous chromosome, creating a pair of translocation chromosomes. A particular form of reciprocal translocation is the **Robertsonian translocation (ROB)**. During a ROB participating chromosomes break at their centromeres (center pieces) and the long arms of the two chromosomes merge to form a single chromosome with one centromere and two long arms. At the same time, a new chromosome containing both short arms is also created, which typically only contains nonessential genetic information and is lost during following cell divisions. Chromosomal translocations are identified by the chromosomal series involved. Thus a 1/29 translocation represents a fusion between a chromosome of each of the pairs numbered 1 and 29.

A number of chromosomal rearrangements have been identified in different livestock species over the years and have been associated with clinical conditions such as intersexuality, congenital malformations, and reproductive dysfunction.[1] Some of the translocations that occur endemically in certain regions have been associated with significant economic losses.[2] Several European countries have established cytogenic screening programs to monitor the occurrence of chromosomal translocations in the livestock population.[1] In Italy the incidence of RCP in cattle determined in an official cytogenic screening program was 0.3%, whereas 7.1% of studied animals were carriers of a ROB.[2] By far the most common ROB identified was the so-called translocation 1/29, which is endemic in the region, accounting for 99.6% of all ROBs.[2]

Translocation 1/29 has been identified in many breeds of cattle and has been associated with significant reductions in the fertility of cows bred by artificial insemination services. Early embryonic death occurs in embryos produced by fertilization of affected gametes or fertilization of normal gametes by spermatozoa carrying the 1/29 translocation. There is no abnormality of serving behavior or semen quality. The translocation has been shown to be inherited in most European beef breeds including the Blonde d'Aquitaine, Swedish Red and White, Charolais, Danish Limousin, British Friesian and Red Poll breeds, and in the wild British White cattle. In Bolivian Creole cattle breeds, in the Creole-like cattle, the average frequency was 10.42% with a variation from 0% to 28.2%. In contrast, Yacumeño and Creole-type cattle did not show the centric fusion. The highly significant differences between Creole cattle breeds in relation to the 1/29 translocation could be the consequence of factors such as founder group, genetic drift, and selection. The low frequency observed in the Saavendreño Creole dairy cattle might be caused by breeding under a more intensive system and selection according to milk yield and fertility traits. The frequency of affected animals in a breed may vary between 1% and 20%. Karyotyping and culling of abnormal bulls in most artificial breeding centers has reduced the impact of the defect.

Translocations 1/21, 2/4, 14/20, and **13/2** have also been identified in bulls, the 1/21 in Holstein Friesian cattle, and the latter two seem to be widespread in Simmental cattle. None of them has been linked with a disease, but it is becoming accepted practice not to use such animals for artificial insemination and in some countries to refuse their importation.

A cytogenetic survey of Holstein bulls at a commercial artificial insemination unit to determine the prevalence of bulls with centric fusion and chimeric anomalies found that chimeric fusion is extremely rare in Holstein bloodlines available by artificial insemination in the United States. However, chimeric bulls are more common and reportedly have decreased reproductive performance. Because of the possibility of de novo onset of chimeric fusion at any time, early cytogenetic screening should be encouraged for prospective bulls intended for artificial insemination programs.

Translocation 27/29 is suspected of being associated with reduced fertility in Guernsey cattle. These and other abnormalities of chromosomal structure were detected in an examination of a large number of infertile dairy heifers.

INHERITED PROLONGED GESTATION (ADENOHYPOPHYSEAL HYPOPLASIA)

Prolonged gestation occurs in cattle and sheep in several forms and is usually, although not always, inherited.[1]

The forms of the disease are prolonged gestation with fetal gigantism or prolonged gestation with deformed or normal or small size fetuses. Differential diagnoses include: mistaken breeding date, intrauterine death and fetal mummification, and pituitary abnormalities in the fetus caused by infection by BVD virus, Akabane virus or bluetongue virus, ingestion of *Veratrum californicum,* and genetic abnormalities.[1]

The disease is caused by lack of a functioning fetal hypothalamic-pituitary axis and consequent inability of the fetus to initiate parturition. The result is prolonged gestation and continued growth of the fetus. The hypothalamic-pituitary axis is also critical for survival of the newborn and affected animals are not viable.

PROLONGED GESTATION WITH FETAL GIGANTISM

The inherited disease is recorded in Holstein,[2] Ayrshire, and Swedish cattle with prolongation of pregnancy from 3 weeks to 5 months. The cows may show marked abdominal distension, but in most cases the abdomens are smaller than one would expect. Parturition, when it commences, is without preparation. Udder enlargement, relaxation of the pelvic ligaments, and loosening and swelling of the vulva do not occur, and there is also poor relaxation of the cervix and a deficiency of cervical mucus. Dystocia is usual and cesarean section is advisable in Holstein cattle, but the Ayrshire calves have all been reported as having been born without assistance. The calves are very large (48 to 80 kg BW) and show other evidence of postterm growth, with a luxuriant hair coat and large, well-erupted teeth that are loose in their alveoli, but the birthweight is not directly related to the length of the gestation period.

The calves exhibit a labored respiration with diaphragmatic movements more evident than movements of the chest wall. They invariably die within a few hours in a hypoglycemic coma. At necropsy there is adenohypophyseal hypoplasia and hypoplasia of the adrenal cortex and the thyroid gland. The progesterone level in the peripheral blood of cows bearing affected

calves does not fall before term as it does in normal cows.

PROLONGED GESTATION WITH CRANIOFACIAL DEFORMITY

This form of the disease has been observed in Guernsey, Jersey, and Ayrshire cattle. It differs from the previous form in that the fetuses are dead on delivery, show gross deformity of the head, and are smaller than the normal calves of these breeds born at term. In Guernsey cattle the defect has been shown to be inherited as a single recessive character, and it is probable that the same is true in Jersey cattle. The gestation period varies widely with a mean of 401 days.

Clinical examination of the dams carrying defective calves suggests that no development of the calf or placenta occurs after the seventh month of pregnancy. Death of the fetus is followed in 1 to 2 weeks by parturition unaccompanied by relaxation of the pelvic ligaments or vulva or by external signs of labor. The calf can usually be removed by forced traction because of its small size. Mammary gland enlargement does not occur until after parturition.

The calves are small and suffer varying degrees of hypotrichosis. There is hydrocephalus and in some cases distension of the gut and abdomen caused by atresia of the jejunum. The bones are immature and the limbs are short. Abnormalities of the face include cyclopian eyes, microphthalmia, absence of the maxilla, and the presence of only one nostril. At **necropsy** there is partial or complete aplasia of the adenohypophysis. The neural stalk is present and extends to below the diaphragm sellae. Brain abnormalities vary from fusion of the cerebral hemispheres to moderate hydrocephalus. The other endocrine glands are also small and hypoplastic.

The disease has been produced experimentally in ewes by severe ablation of the pituitary gland, or destruction of the hypothalamus, or section of the pituitary stalk in the fetus and by adrenalectomy of the lamb or kid. Infusion of adrenocorticotropic hormone into ewes with prolonged gestation caused by pituitary damage produces parturition but not if the ewes have been adrenalectomized beforehand.

PROLONGED GESTATION WITH ARTHROGRYPOSIS

A form of prolonged gestation, which occurs in Hereford cattle and is thought to be inherited, is accompanied by arthrogryposis, scoliosis, torticollis, kyphosis, and cleft palate.

Prolonged gestation is also reported in **Belgium Blue cattle** and appears to have a genetic component. Affected calves were not grossly abnormal.[1]

INHERITED INGUINAL HERNIA AND CRYPTORCHIDISM

Inguinal hernias and cryptorchidism in pigs have been considered to be inherited defects for many years, but the evidence is uncertain.

INGUINAL HERNIAS

Inguinal hernias of pigs have been shown to be inherited in some breeds (e.g., Duroc and Landrace), but not in others (e.g., Yorkshires). The genetic basis has been investigated in Large White pigs and Landrace pigs and the candidate genes narrowed to a region on SSC13 (Sus scrofa chromosome) between 34 and 37 Mb.[1] In Pietrain pigs, genes involved in collagen metabolism (homeobox A10 [HOXA10] and matrix metalloproteinases 2 [MMP2]) and one gene encoding zinc finger protein multitype 2 (ZFPM2; important in the development of diaphragmatic hernia) were significantly associated with hernias.[2]

Cryptorchidism

Evidence suggesting the inheritance of cryptorchidism in swine, sheep, horses, and Hereford cattle and hermaphroditism in swine is also available.

Cryptorchidism is a common congenital anomaly in pigs, and a genome-wide association study of Large White and Landrace pigs localizes the associated gene or genes to candidate genes to SSC8 (Sus scrofa chromosome) between 65 and 73 Mb.[1]

Cryptorchidism is common in equids, and there is concern that it might be hereditary.[3] Unilateral cryptorchidism is overrepresented in Percherons, American Saddle Horses, and American Quarter Horses among hospital admissions for cryptorchid castration and has an incidence of 15% among Friesian colt foals.[4] Approximately 9% of the ~600 Icelandic Horse yearling stallions did not have both testes in the scrotum.[5] The likelihood of cryptorchidism in yearlings was significantly influenced by farm and time period of birth. Heritability estimates for cryptorchidism ranged from 0.12 to 0.32 (standard error [SE] 0.08–0.12) on the observable scale, and from 0.35 to 0.96 (SE 0.24–0.40) when transformed to the underlying continuous scale.[5] Cryptorchidism in horses appears to be inherited with a polygenic pattern of transmission, although analysis of microsatellite markers of 24 affected horses did not reveal significant associations with allelic or genotypic frequencies.[6]

19 Perinatal Diseases

Introduction

This chapter considers the principles of the diseases that occur during the first month of life in animals born alive at term. Diseases causing abortion and stillbirth are not included. The specific diseases discussed are presented separately under their own headings.

The inclusion of a chapter on diseases of the newborn, and at this point in the book, needs explanation. The need for the chapter arises out of the special sensitivities that newborns have:

- Their immunologic incompetence
- Their dependence on adequate colostrum containing adequate antibodies at the right time
- Their dependence on frequent intake of readily available carbohydrate to maintain energy
- Their relative inefficiency in maintaining normal body temperature, upward or downward

All of these points require emphasis before proceeding to the study of each of the body systems.

There are no particular aspects of a clinical examination that pertain only to or mostly to neonates. The same clinical examination as is applied to adults is used, with additional, careful examination for congenital defects and diseases, which may involve the umbilicus, the liver, the heart valves, the joints and tendon sheaths, the eyes, and the meninges, and for birth-related trauma (e.g., rib fracture, joint luxation, distal limb fracture).

Because there is a much greater susceptibility to infectious disease, dehydration, and death, diagnosis and treatment must be reasonably accurate and rapid. Supportive therapy in the form of fluids, electrolytes and energy, and nursing care are especially important in the newborn to maintain homeostasis.

Perinatal and Postnatal Diseases

One of the difficulties in the study of perinatal and postnatal diseases is the variation in the type of age classification that occurs between publications, which makes it difficult to compare results and assessments. The term *perinatal* is usually used to describe morbidity or mortality that occurs at birth and in the first 24 hours of life. The term *neonatal* is usually used to describe morbidity or mortality between birth and 14 days. However, there is variation in the use of these terms. To ensure that our meanings are clear, we set out in the following section what we think is the most satisfactory classification of all the diseases of the fetus and the newborn, which is adapted from a scheme proposed for lambs. The importance of this type of classification is in the assessment of risk for a given type of disease and in the prediction of likely causes that should be investigated by further examinations. This approach is not of major importance in the assessment of disease in an individual animal, although it is of importance in helping establish the priority in diagnostic rule-outs. The classification is, however, of considerable value in the approach to perinatal morbidity and mortality in large flocks or herds, where an assessment of the age occurrence of morbidity and mortality can guide subsequent examinations to the probable group of cases, with optimal expenditure of investigative capital.

GENERAL CLASSIFICATION

FETAL DISEASES

Fetal diseases are diseases of the fetus during intrauterine life, for example, prolonged gestation, intrauterine infections, abortion, fetal death with resorption or mummification, and goiter.

PARTURIENT DISEASES

Parturient diseases are diseases associated with dystocia, causing cerebral anoxia or fetal hypoxemia, and their consequences and predispositions to other diseases; injury to the skeleton or soft tissues and maladjustment syndrome of foals are also included here.

POSTNATAL DISEASES

Postnatal diseases are divided into early, delayed, and late types:

- **Early postnatal disease** (within 48 hours of birth). Deaths that occur during this period are unlikely to be caused by an infectious disease unless it has been acquired congenitally. Most diseases occurring in this period are noninfectious and metabolic (e.g., hypoglycemia and hypothermia as a result of poor mothering, hypothermia as a result of exposure to cold, low vigor in neonates as a result of malnutrition). Congenital disease will commonly manifest during this period but may sometimes manifest later. Infectious diseases are often initiated during this period, but most manifest clinically at a later age because of their incubation period; some (e.g., navel infection, septicemic disease, and enterotoxigenic colibacillosis) have a short enough incubation to occur during this period.
- **Delayed postnatal disease** (2 to 7 days of age). Included in this category are desertion by the mother, mammary incompetence resulting in starvation, and diseases associated with increased susceptibility to infection as a result of failure in the transfer of colostral immunoglobulins (the predisposing causes to these occur in the first 12 to 24 hours of life). Examples include colibacillosis, joint ill, lamb dysentery, septicemic disease, and most of the viral enteric infections in young animals (e.g., rotavirus and coronavirus).
- **Late postnatal disease** (1 to 4 weeks of age). There is still some influence of hypogammaglobulinemia, with late-onset enteric diseases and the development and severity of respiratory disease in this period, but other diseases not directly associated with failure of transfer of immunoglobulins, such as cryptosporidiosis, white muscle disease, and enterotoxemia, start to become important.

PERINATAL DISEASE—GENERAL EPIDEMIOLOGY

Diseases of the newborn and neonatal mortality are a major cause of economic loss in livestock production. In cattle, sheep, and pigs, the national average perinatal mortalities exceed by far the perinatal mortality experienced in herds and flocks with good management. In these species the identification of the management deficiencies that are the cause of a higher-than-acceptable mortality in a herd or a flock is a most important long-term responsibility of the practicing veterinarian and, in most instances, is more important than the identification of the causal agent or the short-term treatment of individual animals with neonatal disease. In contrast, in horses, the individual is of extreme importance, and the primary thrust is in the treatment of neonatal disease.

All animals must be born close to term if they are to survive in a normal farm environment. Minimal gestational ages for viability (in days) for each of the species are as follows:

- Calf—240
- Foal—311
- Lamb—138
- Piglet—108
- Cria—295

LAMBS

Mortality Rates

Neonatal lamb mortality is one of the major factors in impairment of productivity in sheep-raising enterprises around the world, and nearly half of all preweaning lamb deaths occur on the day of birth.[1] Mortality can obviously vary with the management system (intensive versus extensive lambing, highly supervised versus minimally supervised, variations in the provision of shelter, etc.) and according to whether there is a particular disease problem in a given flock. Nonselective mortality surveys have shown population mortality rates in lambs, from birth to weaning, that vary from 10% to 30%, and there are flocks that may exceed this upper figure in the face of a major problem. In well-managed flocks, neonatal mortality is less than 10% and in some is below 5%.

Major Causes

The major cause of neonatal mortality in lambs is noninfectious disease. Many studies have explored the causes for neonatal lamb mortality, which are broadly categorized as follows:[2]

- Death related to birth process
- Failure of neonatal adaptation to postnatal life
- Infectious disease
- Functional disorders
- Predation

Fetal Disease

Infectious abortion can cause considerable fetal, parturient, and postnatal mortality in infected flocks, but it is a relatively minor cause of perinatal mortality overall. In contrast to other large animal species, abortion storms in sheep are often accompanied by significant mortality in liveborn animals. Many agents associated with abortion in ewes produce placentitis and cause abortion in late pregnancy. This frequently results in the birth of liveborn growth-retarded and weak lambs that die during the first few days of life. Any investigation of perinatal mortality in sheep should also consider the presence of agents causing abortion, although abortion and the birth of dead lambs is always prominent in abortion outbreaks.

Parturient Disease

Stillbirth occurs largely as a result of prolonged birth and fetal hypoxemia. Prolonged birth and dystocia are particular problems in large single lambs. Higher rates of stillbirth can also occur in flocks that are in poor condition. Prolonged birth is a major risk factor for subsequent postnatal disease.

Postnatal Disease

Starvation and hypothermia are common causes of death of neonatal lambs that can result from decreased vigor, pain or trauma after a difficult delivery, failure to adapt to postnatal life, or infectious disease. A number of studies have consistently identified **low birth weight** as the single most important factor associated with lamb mortality.[1,2] Other common factors associated with the mortality rates of neonatal lambs are litter size (which cannot entirely be attributed to lower birth weight of twins), lamb sex (with males having higher mortality than females), and lamb behavior.[1] Management practices that have been found to reduce lamb mortality include winter feeding of pregnant ewes and housing at lambing.[2]

Birth Weight

Birth weight is determined by the nutrition and genetics of the ewe and by litter size, which is also determined by the parity and genetics of the ewe. Reflecting these influences, most surveys of neonatal mortality in lambs show the following characteristics:

- A significant association between the body condition score or **nutrition of the late pregnant ewe** and perinatal mortality
- A relation between **birth weight** and mortality (depending on the breed, a birth weight of less than 2.5 to 3.0 kg has increased risk for death)
- A higher mortality in lambs from **primiparous ewes**[1]
- A pronounced effect of **litter size**, with mortality in lambs born as triplets being higher than in those born as twins, which in turn is higher than that in lambs born as singles

Lambs with low birth weight are born with fewer body reserves, are less vigorous at birth, and take longer to stand (and thus to reach the teat and ingest colostrum). They are also more susceptible to hypothermia because of higher body surface relative to body mass, lower body fat content, and lower thermogenic capacity as a result of lower muscle mass.

The association between birth weight and lamb mortality has a U-shaped pattern, with the lowest mortality rates with normal birth weight and increasing mortality rates with both decreasing and increasing birth weight. An increase in mortality in large-birth-weight lambs born as singles has been associated with increased risk for dystocia.

Environmental Factors

Environmental factors of temperature, wetness, and wind can greatly affect lamb mortality rates; their influence varies according to the management system.

The identification of the determinants of mortality just described is of more than academic value because almost all can be modulated by the identification of **at-risk groups** and the adjustment of management procedures or by the identification and mitigation of adverse environmental factors.

Infectious Disease

Infectious disease can be important in some flocks but commonly contributes to lamb mortality from 2 days of age on. The major infectious diseases of lambs that cause mortality are enteritis and pneumonia. Their prevalence varies with the management system—enteric disease and liver abscess are more common in shed lambing systems than with lambing at pasture. Risk for pneumonia is greatest in very light or heavy lambs and in lambs from maiden ewes and ewes with poor milk production.

Other Factors

Other factors can be important in individual flocks or regions. Lambs found dead or missing may account for significant losses in some conditions, such as mountain or hill pastures. **Predation**, or predation injury, is an important cause of loss in some areas of the world and, depending on the region, can occur from domestic dogs, coyotes, birds, or feral pigs. **Poor mothering** and an inability of the ewe to gather and bond to both lambs in the case of twins can be a problem in Merinos and can cause permanent separation of lambs from the ewe and subsequent death from starvation.

Management at lambing can also influence the patterns of mortality. Intensive stocking at the time of lambing allows increased periparturient supervision and tends to reduce the incidence of stillbirths and lamb mortality related to parturition. It can furthermore ensure the early feeding of colostrum to weak lambs. On the other hand, it can result in a greater occurrence of mismothering associated with the activities of "robber" ewes and may increase lamb mortality related to infectious disease.[3] Mortality rates can differ between breeds, and lambs from crossbred dams may have higher survival rates.

Recording Systems

Simple systems for recording, determining, and evaluating the major causes of lamb mortality in a flock, for determining the time of death in relation to birth, and for relating the deaths to the weather and management system are available. These systems of examination are effective in revealing the extent of lamb losses and the areas of management that require improvement, and they are much more cost-effective than extensive laboratory examinations, which may give little information on the basic cause of the mortality. More intensive examination systems that combine these simple examinations with selected biochemical indicators of determinant factors are also available.

DAIRY CALVES

Mortality Rates

Mortality rates of neonatal calves reported in the literature are often subdivided into **perinatal mortality,** which frequently—but not consistently—includes stillborn calves, and **postnatal mortality,** which in most cases includes calf mortalities occurring from 48 or 72 h onward to several months of age. Comparing numbers from different studies is difficult not only because of different definitions of the perinatal and postnatal periods, but also because some studies include all births, whereas others only include births of heifer calves.

Perinatal Mortality Rates

Perinatal mortality rates for dairy calves reported from countries with a developed dairy industry range from 2% to 10%, with a consistently increasing trend over the past decades.[4,5] The majority of perinatal deaths, approximately 75%, are considered to occur in the first hour of life, with the remainder occurring either before parturition (approximately 10%) or between 1 and 72 h after birth (approximately 15%).[4] Mortality rates in dairy calves in the first 24 h of life are between 6.5% and 9.7%.[6,7]

Neonatal Mortality Rates

Studies reporting neonatal mortality rates in calves, defined as mortality from day 3 of life on, are difficult to compare because different time ranges are considered, and some studies include all calves, whereas others only include heifer calves. In a recent U.S. study including 1138 births, a mortality rate of 4.6% for the period until 135 days of life was reported; a French study based on over 3 million calvings determined a mean mortality rate of 4.2% for the period between 3 and 30 days for the years 2005/2006.[8,9] In general, mortality rates for the perinatal period (0 to 48 h) tend to be higher than mortality rates for neonatal calves (from 3 days on), which underscores how critical the perinatal period is for the newborn calf.

Mortality rates for unweaned dairy heifers in the United States were surveyed repeatedly between 1996 and 2007 and were found to have declined from 10.8% in 1996 to 7.8% in 2007.[10]

Fetal Disease/Abortion

Abortion is a term generally used to describe the expulsion of a dead fetus from 45 to 265 days of gestation. A large dairy survey conducted in the United States in 2007 estimated that approximately 4.5% of all pregnant dairy heifers and cows had aborted in 2006.[13] The majority of these have no diagnosed cause.

Major Causes

Perinatal Mortality

The exact cause of death in the perinatal period, which often includes stillborn and weakborn calves, frequently remains undetermined. Epidemiologic studies investigating the risk factors for perinatal mortality in dairy calves have identified a number of genetic and nongenetic factors that are consistently associated with perinatal mortality.[4,7,11,12] Dystocia has consistently been identified as the single most important factor associated with perinatal mortality. Reported odds ratios (ORs) vary widely (2.7 to 14.6), but suggest that calves requiring assisted delivery have a 2.7 to 14.6 higher risk of death in the perinatal period than spontaneously born calves.[4] Other factors contributing to perinatal mortality include **lactation number** (calves born from heifers being more likely to die in the first hours of life than calves from multiparous cows), **birth weight** (calves with a birth weight of less than 20 kg and over 60 kg being at increased risk),[7] and **days of gestation** (calves born before 272 days of gestation being 6.7 times more likely to die than calves born between 272 and 302 days of gestation).[7] The OR for the death of a **twin calf** in the perinatal period was estimated at 13.4 times greater compared with singleton calves.[4]

Calving-associated anoxia may be an important contributing factor in these deaths.

Postnatal Mortality

Mortalities of neonatal dairy calves in the first days and weeks of life are attributable in large part to diarrheal disease. In a large survey conducted in the United States in 2007, diarrhea was by far the most common cause of death in unweaned dairy heifers, accounting for 56.5% of all deaths in that age category.[13] Other causes included respiratory problems (22.5%), undetermined causes (7.8%), lameness or injury (1.7%), and navel or joint infections (1.6%).[13]

Postnatal Disease

Calves are at highest risk for death in the first 2 weeks of life and especially in the first week. Septicemic and enteric diseases are most common during this period, with respiratory disease being more common after 2 weeks of age. **Failure of transfer of passive immunity** is a major determinant of this mortality.[14] The economic significance of neonatal disease can be considerable, and the occurrence of disease as a calf can also subsequently affect days-to-first-calving intervals and long-time survival in the herd. Death also causes a loss of genetic potential, both from the loss of the calf and the reluctance of the farmer to invest in higher-priced semen in the face of a calf mortality problem.

Meteorologic or **seasonal influences** may have an effect on dairy calf mortality rate,

and this can vary with the region.[4,7] In cold climates during the winter months, an increase in mortality may be associated with the effects of cold, wet, and windy weather, whereas in hot climates there may be an increase in mortality during the summer months in association with heat stress.

Management

Management is a major influence, and in well-managed dairy herds, calf mortality usually does not exceed 5% from birth to 30 days of age. Risk factors for disease morbidity and mortality in dairy calves relate to the **infection pressure** to the calf and factors that affect its **nonspecific** and **specific resistance** to disease. It is generally recognized that mortality is associated with the **type of housing** for calves, calving facilities, the person caring for the calves, and attendance at calving.[4] Thus calves that are born in separate calving pens have a lower risk of disease than those born in loose housing or stanchion areas, and the value of good colostrum feeding practices is apparent. Studies on the role of calf housing and the value of segregated rearing of calves in reducing infection pressure generally show beneficial health results.

The quality of management will be reflected in rates of failure of transfer of passive immunity and will also affect the infection pressure on the calf during the neonatal period. Quality of management is very hard to measure but is easily recognized by veterinary practitioners.

The epidemiologic observations that calf mortality is lower when females or family members of the ownership of the farm manage the calves, rather than when males or employees perform these duties, is probably a reflection of this variation in quality of management and suggests that owner managers and family members may be sufficiently motivated to provide the care necessary to ensure a high survival rate in calves. Even so, calf health can be excellent with some hired calf-rearers and very poor with some owner calf-rearers.

BEEF CALVES

Mortality Rates

Mortality in beef herds is usually recorded during the period from birth to weaning and has ranged from 3% to 7% in surveys, with higher rates in calves born to heifers; significantly higher mortality can occur in herds with disease problems. In a survey conducted in the United States in 2007, a perinatal mortality rate (including stillbirths) of 2.9% and a postnatal mortality rate (for the period from birth to weaning) of 3.5% was determined.[15] The majority of this mortality occurs within the first week of life, and most of it occurs in the parturient or immediate postnatal period as a result of prolonged birth or its consequences.

Major Causes

Dystocia resulting in death is common, and dystocial calves, twin-born calves, and calves born to heifers are at greater risk for postnatal disease. Enteric and respiratory diseases occur in outbreaks in some years, and very cold weather can result in high loss from hypothermia. In a 2007 survey conducted in the United States, beef calf mortality before weaning was found to be attributable to birth-related problems in 25.7%, to weather-related causes in 25.6%, to undetermined causes in 18.6%, to digestive tract problems (including diarrhea) in 14.0%, and to respiratory tract problems in 8.2% of all deaths.[15] Diarrhea and other infectious diseases become the most important cause of death in calves from their third day of life on.

Fetal Disease

Abortion rates appear to be lower than in dairy cattle, usually less than 1%. The majority of these are not diagnosed as to cause, but of those that are, infectious abortion is the most common diagnosis.

Parturient Disease

Accurate prospective and retrospective studies have shown that 50% to 60% of the parturient deaths in beef calves are associated with slow or difficult birth and that the mortality rate is much higher in calves born to heifers than from mature cows. **Dystocial birth** can lead to injury of the fetus and to hypoxemia and may not necessarily be associated with fetal malposition. **Birth size** is highly heritable within all breed types of cattle, and perinatal mortality will vary between herds depending on their use of bulls with high ease-of-calving ratings in the breeding of the heifer herd. Milk fever and overfatness at calving are other preventable causes of mortality. Selective intensive supervision of calving of the heifer herd can also result in a reduction of perinatal mortality.

Postnatal Disease

Scours and pneumonia are the next most important causes of mortality in beef calves, followed by exposure to extremely cold weather or being dropped at birth into deep snow or a gully.[15] The incidence of diarrhea is greatest in the first 2 weeks of life, and there is considerable variation in incidence between herds. However, explosive outbreaks of diarrhea or exposure chilling can be significant causes of mortality in certain years. The purchase of a calf for grafting, often from a market, is a significant risk for introduction of disease to a herd.

The **body-condition score** of the dam can influence calf mortality; dams with high condition scores have a higher risk for dystocial mortality, and those with low scores have a higher risk for infectious disease. Mortality from diarrhea is often higher in calves born to heifers, possibly because heifers are more closely congregated for calving supervision or because of a higher risk for failure of transfer of passive immunity in this age group. Congenital abnormalities can be an occasional cause of mortality in some herds.

PIGLETS

Mortality Rates

Preweaning mortality rates in commercial pig farms reported from different parts of the world range between 11% and 20%, with more than 30% of the mortality occurring in the first 24 hours and more than 50% in the first 4 days of life.[16-18] Mortality increases as the mean litter size increases and as the mean birth weight of the piglets decreases. In most herd environments, the minimal **viable weight** is approximately 1 kg. The mean number of piglets weaned is related to the size of the litter up to an original size of 14 and increases with parity of sows up to their fifth farrowing. Preweaning mortality is negatively correlated with herd size and farrowing crate utilization, and it is positively correlated with the number of farrowing crates per room. The use of farrowing crates was found to reduce neonatal mortality by 50% in some studies, mainly as a result of decreased frequency of crushing of piglets by the sow.

Major Causes

Surveys of neonatal mortality in piglets have repeatedly indicated that the most important causes of death in piglets from birth to weaning are noninfectious in origin.[16,17,19] The major causes are **starvation and crushing** (75% to 80%; although these may be secondary to, and the result of, hypothermia), congenital abnormalities (5%), and infectious disease (6%). The major congenital abnormalities are congenital splayleg, atresia ani, and cardiac abnormalities. Infectious diseases may be important on certain individual farms but do not account for a major cause of mortality.

Fetal Disease

Fetal disease rates in most herds are low unless there is an abortion storm or poor control of endemic infections such as parvovirus. In contrast to other species, the majority of abortions are diagnosed and are infectious.

Parturient Disease

Stillbirths account for 4% to 8% of all deaths of piglets born, and 70% to 90% are type II or intraparturient deaths, in which the piglet was alive at the beginning of parturition.[16] The viability of newborn piglets can be accurately evaluated immediately after birth by scoring skin color, respiration, heart rate, muscle tone, and ability to stand. Stillbirths are more commonly born in the later birth orders of large litters, and it is a relatively

common practice for sows to be routinely given oxytocin at the time of the birth of the first piglet to shorten parturition. Controlled trials have shown that although oxytocin administration at this time will result in a significant decrease in farrowing time and expulsion intervals, there is a significant increase in fetal distress, fetal anoxia, and intrapartum death and an increase in piglets born alive with ruptured umbilical cords and meconium staining.

Postnatal Disease

The large percentage of mortality caused by **crushing** and trampling likely includes piglets that were starved and weak and thus highly susceptible to being crushed. The estimated contribution of crushing and starvation to neonatal mortality varies from 19% to 58% of liveborn mortality.[16] The body-condition score of the sow at the time of farrowing, the nursing behavior of the sow, the sow's ability to expose the teats to all piglets, and the sucking behavior of the piglets also have a marked effect on survival.

Cold stress is also an important cause of loss, and the provision of a warm and comfortable environment for the newborn piglet in the first few days of life is critical.[17] The lower critical temperature of the single newborn piglet is 34°C (93°F). When the ambient temperature falls below 34°C (93°F), the piglet is subjected to cold stress and must mobilize glycogen reserves from the liver and muscles to maintain deep body temperature. The provision of heat lamps over the creep area and freedom from draughts are two major requirements.

Management

Minimizing the mortality rate of newborn piglets will depend on management techniques, which include the following:

- Proper selection of the breeding stock for teat numbers, milk production, and mothering ability
- The use of farrowing crates and creep escape areas to minimize crushing injuries
- Surveillance at farrowing time to minimize the number of piglets suffering from hypoxia and dying at birth or a few days later
- Batch farrowing, which allows for economical surveillance
- Fostering to equalize litter size
- Cross-fostering to equalize nonuniformity in birth weight within litters
- Improvement in the thermal comfort of the piglets
- Supplemental iron
- Artificial rearing with milk substitutes containing purified porcine gammaglobulin to prevent enteric infection

FOALS

Mortality Rates

Foals are usually well supervised and cared for as individual animals. Neonatal death is less frequent than in other species, but equivalent rates of morbidity and mortality occur on some farms. Infectious disease is important, along with structural and functional abnormalities that are undoubtedly better recognized and treated than in any of the other large animal species. In a large survey of thoroughbred mares in the United Kingdom, only 2% of newborn foals died, only 41% of twins survived, and 98% of singles survived. In contrast, a mortality rate of 22% between birth and 10 days was recorded in an extensively managed system. A recent retrospective study from Ireland determined a foal mortality rate of 5% during the first 12 months; 64.7% of deaths occurred during the first 30 days, and 82% of all deaths occurred within the first 6 months of life.[20]

Major Causes

Fetal Disease

Fetal disease is a major cause of loss; in one study, infections accounted for approximately 30% of abortions. In a retrospective study of 1252 fetuses and neonatal foals submitted for postmortem examination over a 10-year period in the United Kingdom, equine herpes virus and placentitis accounted for 6.5% and 9.8% of the diagnoses, respectively. The placentitis occurred in late gestation, was concentrated around the cervical pole and lower half of the allantochorion, and was associated with ascending chronic infections of bacteria or fungi resident in the lower genital tract.

Parturient Disease

Neonatal asphyxia, dystocia, umbilical cord abnormality, congenital abnormalities, and musculoskeletal trauma are important causes of foal mortality. A retrospective study from Ireland found that 45.5% of all deaths that occurred in the first 30 days of life were attributable to congenital abnormalities, 18.2% to the perinatal asphyxia syndrome, and 18.2% to musculoskeletal trauma.[20] In a UK study, umbilical cord disorders accounted for 38.8% of the final diagnoses. Umbilical cord torsion usually resulted in death of the fetus in utero, but the long cord/cervical pole ischemia disorder resulted in intrapartum death and a fresh fetus with lesions consistent with acute hypoxia.

Twins are at higher risk for spontaneous abortion.

Postnatal Disease

Postnatal disease causing mortality from birth to 2 months of age includes lack of maturity (36%), structural defect (23%), birth injury (5%), convulsive syndrome (5%), alimentary disorder (12%), generalized infection (11%), and other (miscellaneous; 9%). Of the **infectious diseases**, gastrointestinal and septicemic diseases have the greatest importance. Whereas in the past many of these conditions would have been fatal, significant advances in the science of equine perinatology were made in the 1980s and 1990s, and protocols for the treatment of neonatal disease have been developed that are based on equivalents in human medicine. These have proved of value in the management and treatment of prematurity, immaturity, dysmaturity, and neonatal maladjustment syndromes in newborn foals and in enteric and septicemic diseases. Different levels of intensive care have been defined, starting from those that can be applied at the level of the farm and increasing in sophistication, required facilities, and instrumentation to those that are the province of a specialized referral hospital. Early follow-up studies indicate that this approach is of considerable value in foals with neonatal disease and that most surviving foals become useful athletic adults.

NEW WORLD CAMELID CRIAS

Mortality Rates

Mortality of newborn llamas and alpacas is low compared with other production animal species, which in part because New World camelids (NWCs) are frequently kept as companion animals and receive better attention and more intensive treatment in cases of disease. Preweaning mortality rates for llama and alpaca crias are in the range of 2% to 6%, with the great majority of deaths occurring in the first week of life.[21,22]

Major Causes

Fetal Disease

Abortion and fetal loss after 100 days of gestation have been estimated to occur in 5% of all pregnancies in NWCs.[23] Common noninfectious causes for abortion include stress (e.g., related to transport), nutritional deficiencies, and iatrogenic administration of PGF2α or glucocorticoids. Documented infectious causes for abortion include toxoplasmosis, brucellosis, chlamydiosis, listeriosis, leptospirosis, and neosporosis.[23]

Parturient Disease

Perinatal mortality of crias is strongly associated with the course of parturition and the age of the dam at birth. Dystocia and assisted birth clearly increase the risk for postnatal morbidity and perinatal and postnatal mortality in NWC crias, as in other species.[21]

Postnatal Disease

The great majority of preweaning mortality occurs in the first week of life, and hypothermia and starvation were determined to be the most common causes of death. Low birth weight was found to considerably increase the risk of perinatal death, as was young age of the dam. Primiparous dams 2 to 3 years old give birth to lighter calves than do older dams and are considered to produce less

colostrum, and of inferior quality, than their multiparous herd mates. Small crias have more difficulties standing and getting sufficient amounts of colostrum and lose more body heat because of greater body surface relative to body mass, and thus they are at increased risk of starving to death or of developing perinatal or postnatal diseases.[21] A difficult parturition negatively affects perinatal vitality and thereby considerably increases the risk for postnatal morbidity and mortality.[22]

PERINATAL DISEASE—SPECIAL INVESTIGATION OF ANY NEONATAL DEATHS (ILLNESS)

The following protocol is a generic guide to the investigation of deaths of newborn animals. It will require modification according to the species involved.

1. Determine the duration of pregnancy to ensure that the animals were born at term.
2. Collect epidemiologic information on the problem. Where possible, the information should include the following:
   - What is the abnormality?
   - What are the apparent age at onset and the age at death?
   - What clinical signs are consistently associated with the problem?
   - What is the prevalence and proportional risk in particular groups (maternal, paternal, nutritional, vaccinated, etc.)?
   - What is the parity of the dam that gave birth to the animal, and what proportional risk does this reflect within the group?
   - What is the birth history of affected animals? Are births supervised, and if so, what is the frequency of observation and what are the criteria for intervention? What is the proportional risk associated with prolonged birth?
   - Is there an effect of litter size, and what is the health of the other littermates?
   - Was there any difference in management of the dams of the affected animals compared with the group as a whole?
   - What is the farm policy for feeding colostrum?
   - What were the environmental conditions during the past 48 hours? (In housed animals, the quality of the environment should be measured objectively.)
3. Conduct a postmortem examination of all available dead neonates. The determination of body weight is essential, and measures of **crown–rump length** can also give an indication of gestational age. In order of precedence, the purpose of the postmortem examination is to determine:
   - The time of death in relation to parturition (e.g., fetal disease, parturient disease, early or delayed postnatal death). This can be determined from the state of the lungs, the nature of the severed end of the umbilical artery and the presence of a clot, the state of the brown-fat deposits, whether the animal has walked, and whether it has suckled before death.
   - The possibility that animals born alive have died because of cold stress, hypoglycemia, and starvation. An indication can be obtained from an examination of the brown-fat reserves and observation of the presence or absence of milk in the gastrointestinal tract and fat in the intestinal lymphatics. The presence of subcutaneous edema in the hind limbs is also relevant.
   - The possible presence of birth injury or trauma. In addition to examination of the ribs and liver for trauma and the presenting areas for subcutaneous edema, the brain should be examined for evidence of hemorrhage.
   - The presence of infectious disease. If necessary, samples can be submitted for examination.
   - The presence of congenital disease
4. If abortion is suspected, specimens of fetal tissues and the placenta are sent for laboratory examination. Examinations requested are pathologic and microbiological for known pathogens for the species of animal under consideration.
5. A serum sample should be collected from the dam for serologic evidence of teratogenic pathogens, followed by another sample 2 weeks later. Samples from unaffected dams should also be submitted. A precolostral serum sample from affected animals may assist in the diagnosis of intrauterine fetal infections.
6. Investigate management practices operating at the time, with special attention to clemency of weather, feed supply, maternalism of dam, and surveillance by the owner—all factors that could influence the survival rate. Where possible, this should be performed using objective measurements. For example, in calf-rearing establishments, the efficacy of transfer of colostral immunoglobulins should be established by the bleeding of a proportion of calves and actual measurement, food intake should be established by actual measurement, and so forth.

Perinatal Disease—Congenital Defects

SYNOPSIS

Etiology Genetic, infectious, toxic, and physical causes are recognized for some defects, but the etiology of most is not known.

Continued

Epidemiology Low but significant incidence in all animals; epidemiology depends on cause.

Clinical findings Congenital defects can be structural or functional; clinical signs depend on organ system(s) affected.

Clinical pathology Specific serologic and biochemical tests can be used in the diagnosis and control of some congenital disease and, if available, are detailed under specific disease headings.

Necropsy findings Specific to the particular problem.

Diagnostic confirmation Abnormalities of structure or function that are present at birth are obviously congenital defects; they may or may not be inherited, and inherited defects may or may not be manifest at birth; genome analysis for inherited defects.

Control Avoidance of exposure to teratogenic agents; vaccination for some teratogenic infections; identification of carriers for genetic defects.

ETIOLOGY

Congenital disease can result from defective genetics or from an insult or agent associated with the fetal environment. A neonate with a congenital defect is an adapted survivor from a disruptive event of a genetic or environmental nature or of a genetic–environmental interaction at one or more of the stages in the sequences of embryonic and fetal development.

Genetic abnormalities may result in a wide spectrum of disorders that can vary from severe morphologic malformations to the presence of inborn errors of metabolism in animals that may be born apparently normal and develop disease later in life.

Susceptibility to injurious **environmental agents** depends on the nature and the severity (dose size and duration of application) of the insult and decreases with fetal age. Before attachment, the zygote is resistant to teratogens but susceptible to chromosomal aberrations and genetic mutations. Agents that disrupt blastula and gastrula stages and that interfere with normal apposition of the uterine mucosa are usually embryotoxic and induce early embryonic death.

The period during which an **organ system** is being established is a particularly critical period for that system, and different teratogens, if applied at that time, can produce similar defects. One example is the complex of arthrogryposis and cleft, which can occur in the calves of cattle grazing certain species of lupine, in calves infected in utero with Akabane virus, and as an inherited disease in Charolais calves.

Many noninherited congenital defects in animals occur in "**outbreaks**," which is a reflection of the exposure of the pregnant herd to a virus, poisonous plant, or other teratogen during a period of fetal susceptibility. Because this occurs in early pregnancy, it is often very difficult to determine the nature of this exposure at the time the animals are born.

Some teratogens are quite **specific** in the defect that they produce, and their action may be limited to a single species; a tentative diagnosis as to cause can be based on this association. Others produce a wide variety of abnormality that may also occur with other teratogens, and cause is less obvious.

The exact etiology of most congenital defects is unknown. Influences that are known to produce congenital defects are presented here.

Chromosomal Abnormality and Inheritance

Most chromosomal abnormalities are associated with poor fertility and early embryonic death. A few are structural or numerical aberrations of chromosomes. The importance of chromosomal abnormality to congenital defects in farm animals has not been studied extensively, but a study of 55 aborted and stillborn calves found 6 with an abnormal chromosome component. Chromosomal abnormality is usually associated with multiple deformations. Most chromosomal abnormalities are mutant genes, and the majority are inherited as recessive traits. There are many examples among domestic animals.

Viral and Other Infections

Members of the Bunyaviridae (Akabane virus, Cache valley virus, and Rift Valley fever virus), *Orbivirus* (bluetongue virus, epizootic hemorrhagic disease virus, and Chuzan virus), and *Pestivirus* (bovine virus diarrhea virus, border disease virus, and hog cholera virus) families; Japanese B encephalitis virus; and Wesselsbron virus are recognized teratogens. Other viruses also can result in fetal death without malformation. Examples are as follows:

- Akabane virus—this infection of pregnant cattle, sheep, and goats causes arthrogryposis, microencephaly, and hydrocephalus. Infection of, and disease of, the fetus depends on the stage of pregnancy and the fetus's immunologic status. In cattle infected between 76 and 104 days of pregnancy, hydranencephaly predominates; arthrogryposis predominates with infections between 104 and 173 days of gestation, and poliomyelitis predominates after 173 days. In sheep the window of susceptibility for congenital defects is between 30 and 50 days.
- Cache valley virus—congenital infection of lambs with Cache valley virus produces disease very similar to that produced by Akabane virus in cattle. The period of susceptibility for congenital defects is 36 to 45 days of pregnancy.
- Rift Valley fever virus infection of pregnant sheep results in placentitis and abortion, but attenuated vaccine strains produce arthrogryposis and brain defects.
- Bluetongue virus—vaccination of ewes with attenuated vaccine virus between days 35 and 45 of pregnancy causes a high prevalence of porencephaly in lambs. Natural infections of sheep (50 to 80 days of gestation) and cattle (60 to 120 days of gestation) can result in fetal death and resorption or the birth of stillborn animals, weakborn animals, and animals with hydrocephalus, hydranencephaly, and, occasionally, arthrogryposis. Similar defects are produced by Chuzan, Aino, and Kasba virus infections.
- Bovine viral diarrhea—infection with cytopathogenic strains before 100 days can result in abortion and mummification, cerebellar hypoplasia, and optic defects, including cataracts, retinal degeneration, and hypoplasia and neuritis of the optic nerves. Other defects are brachygnathia, curly coats, abortion, stillbirth, and mummification. Infection of the bovine fetus between 45 and 125 days of gestation with a noncytopathic biotype of the virus can result in the development of a persistently viremic and immunotolerant calf that is carried to term, is born alive, remains persistently viremic, and may later develop mucosal disease.
- Border disease virus—the window of susceptibility is from 16 to 90 days of gestation, and, depending on the fetal age at infection and the presence of a fetal immune response, fetal infection may result in fetal death, growth retardation, the birth of persistently infected lambs, or lambs born with hypomyelinogenesis, hydranencephaly, and cerebellar dysplasia. Coat defects may also be seen.
- Hog cholera virus—vaccination of sows with modified vaccine virus between days 15 and 25 of pregnancy produces piglets with edema, deformed noses, and abnormal kidneys. Natural infection with field virus can cause reproductive inefficiency and cerebellar hypoplasia in piglets.
- An unidentified virus is associated with the AII type of congenital tremor in pigs.
- Congenital infection with Wesselsbron virus and with Rift Valley fever is

recorded as producing central nervous system disease in cattle and sheep.
- Japanese B encephalitis virus in pigs can result in abortion or in the birth of weak, mummified, or stillborn piglets and live piglets with neurologic abnormalities. The window of susceptibility is from 40 to 60 days of gestation.
- Pseudorabies virus infection of the pregnant sow can result in myoclonia congenita in piglets.
- Viral, bacterial, and protozoal agents that produce abortion in animals can also produce intrauterine growth retardation and the birth of weakborn neonates that are highly susceptible to mortality in early life.

Nutritional Deficiency

Many congenital defects in animals are known to be caused by deficiencies of specific nutrients in the diet of the dam. Examples are as follows:
- Iodine—goiter and increased neonatal mortality are caused in all species; prolonged gestation occurs in horses and sheep. Congenital musculoskeletal lesions are seen in foals (congenital hypothyroid dysmaturity syndrome). Deficiency may result from a primary deficiency or be induced by nitrate or *Brassica* spp. Syndromes are also produced by iodine excess, often associated with feeding excess seaweed or seaweed products.
- Copper—enzootic ataxia in lambs can result from either to a primary copper deficiency or a secondary deficiency in which the availability of copper is interfered with by other minerals (e.g., molybdenum and iron).
- Manganese—chondrodystrophy and limb deformities in calves
- Vitamin D—neonatal rickets
- Vitamin A—eye defects, harelip, and other defects in piglets
- Vitamin E and/or selenium—congenital cardiomyopathy and muscular dystrophy
- Congenital cobalt deficiency is reported to reduce lamb vigor at birth and to increase perinatal mortality because of impaired immune function in the lamb. A similar effect on immune function in neonatal lambs and calves has been proposed with copper deficiency.
- Malnutrition of the dam can result in increased neonatal mortality and is suspected in the genesis of limb deformities and in congenital joint laxity and dwarfism in calves.
- Vitamin A deficiency induced by feeding potato tops or water with high nitrate content has been associated with congenital blindness in calves.

Poisonous Plants

The teratogenic effects of poisonous plants have been reviewed in detail. Some examples are as follows:
- *Veratrum californicum* fed to ewes at about the 14th day of pregnancy can cause congenital cyclopia and other defects of the cranium and brain in lambs, in addition to prolonged gestation. When fed at 27 to 32 days of pregnancy, it can produce limb abnormalities. Tracheal stenosis has been produced by feeding at 31 to 33 days of gestation. The alkaloid cyclopamine is the teratogenic substance.
- "Crooked-calf disease" is associated with the ingestion of *Lupinus* sp. during pregnancy. This is a major problem on some rangelands in western North America. There are approximately 100 species of *Lupinus* in Canada and the United States, but the disease has been mainly associated with *L. sericeus*, *L. leucophyllus*, *L. caudatus*, and *L. laxiflorus.* These species are thought to be toxic because of their content of anagyrine, but some piperidine alkaloids may also produce the disease. The disease has been reproduced by feeding anagyrine-containing lupines to pregnant cattle between 40 and 90 days of gestation, but it can occur with later feeding in natural grazing. The syndrome is one of arthrogryposis, torticollis, scoliosis, and cleft palate.
- *Astragalus* and *Oxytropis* spp. locoweeds cause limb contracture in calves and lambs, in addition to fetal death and abortion.
- Tobacco plants—ingestion of *Nicotiana tabacum* (burley tobacco) and *Nicotiana glauca* (tree tobacco) by sows between 18 and 68 days of gestation, with peak susceptibility between 43 and 55 days, can cause limb deformities in their piglets. The teratogen is the piperidine alkaloid anabasine. Cleft palate and arthrogryposis have also been produced experimentally in the fetuses of cattle and sheep fed *N. glauca* during pregnancy, but the plant is not palatable, and thus this is an unlikely cause of natural disease.
- *Conium maculatum*, poison hemlock, fed to cows during days 55 to 75 of pregnancy, to sheep in the period of 30 to 60 days of pregnancy, and to sows in the period of 30 to 62 days of pregnancy will cause arthrogryposis, scoliosis, torticollis, and cleft palate in the fetuses. Cattle are most susceptible. The piperidine alkaloids coniine and coniceine are responsible.
- *Leucaena leucocephala* (or mimosine, its toxic ingredient) causes forelimb polypodia (supernumerary feet) in piglets when fed experimentally to sows.
- Fungal toxicosis from the feeding of moldy cereal straw has been epidemiologically linked to outbreaks of congenital spinal stenosis and bone deformities associated with premature closure of growth plates in calves.

Farm Chemicals

Certain farm chemicals are associated with teratogenic effects, including the following:
- Some benzimidazoles (parbendazole, cambendazole, oxfendazole, albendazole netobimin) are important teratogens for sheep, producing skeletal, renal, and vascular abnormality when administered between 14 and 24 days of pregnancy.
- Methallibure, a drug used to control estrus in sows, causes deformities in the limbs and cranium of pigs when fed to sows in early pregnancy.
- Apholate, an insect chemosterilant, is suspected of causing congenital defects in sheep.
- The administration of trichlorfon to pregnant sows can result in the birth of piglets with cerebellar hypoplasia and congenital trembles.
- Organophosphates have been extensively tested and found to be usually nonteratogenic. A supposed teratogenic effect is probably more a reflection of the very common usage of these substances in agriculture (see the discussion in the section on poisoning by organophosphates).
- Griseofulvin given to a mare in the second month of pregnancy is suspected of causing microphthalmia and facial bone deformity in a foal.

Physical Insults

Physical insults can also result in fetal abnormalities; examples are as follows:
- Severe exposure to beta or gamma irradiation (e.g., after an atomic explosion) can cause a high incidence of gross malformations in developing fetuses.
- Rectal palpation of pregnancy using the amniotic slip method between 35 and 41 days of pregnancy in Holstein Friesian cattle is associated with atresia coli in the calf at birth, but there is also a genetic influence. It is probable that the cause is palpation-induced damage to the developing colonic vasculature.
- Hyperthermia applied to the dam experimentally causes congenital deformities, but this appears to have no naturally occurring equivalent. The most severe abnormalities occur after exposure during early pregnancy (18 to 25 days in ewes). Disturbances of central nervous system development are the most common. Defects of the spinal

cord manifest themselves as arthrogryposis. and exposure of ewes to high temperatures (42° C, 107.5° F) causes stunting of limbs; the lambs are not true miniatures because they have selective deformities, with the metacarpals selectively shortened. The defect occurs whether nutrition is normal or not. Hyperthermia between 30 and 80 days of pregnancy in ewes produces growth retardation in the fetus. Developmental abnormalities have been reproduced experimentally in explanted porcine embryos exposed to environmental temperatures similar to those that may be associated with reproductive failure resulting from high ambient temperatures in swine herds.

Environmental Influences

Currently, there is considerable interest in the possible teratogenic effects of human-caused changes in the environment. The concern is understandable because the fetus is a sensitive biological indicator of the presence of noxious influences in the environment. For example, after an accidental release of polybrominated biphenyls, much of the angry public commentary related to the probable occurrence of congenital defects. The noxious influences can be physical or chemical. In one examination of the epidemiology of congenital defects in pigs, it was apparent that any environmental causes were from the natural environment; human-caused environmental changes, especially husbandry practices, had little effect. A current concern in some regions is an apparent increase in congenital defects thought to be associated with exposure to radiofrequency electromagnetic fields associated with mobile telephone networks, but there are few hard data.

EPIDEMIOLOGY

Individual abnormalities differ widely in their spontaneous occurrence. The determination of the cause of congenital defects in a particular case very often defies all methods of examination. Epidemiologic considerations offer some of the best clues, but they are obviously of little advantage when the number of cases is limited. The possibility of inheritance playing a part is fairly easily examined if good breeding records are available. The chances of coming to a finite conclusion are much less probable. The determination of the currently known teratogens has mainly been arrived at following epidemiologic studies suggesting possible causality followed by experimental challenge and reproduction of the defect with the suspected teratogen.

An expression of the **prevalence** of congenital defects is of very little value unless it is related to the size of the population at risk, and almost no records include this vital data. Furthermore, most of the records available are retrospective and based on the number of cases presented at a laboratory or hospital.

Reported prevalence rates of 0.5% to 3.0% for calves and 2% for lambs are comparable with the human rate of 1% to 3%. A much higher rate for animals of 5% to 6% is also quoted. A study of over 3500 cases of abortion, stillbirth, and perinatal death in horses found congenital malformations in almost 10%. A very extensive literature on congenital defects in animals exists, and a bibliography is available.

Some breeds and families have extraordinarily high prevalence rates because of intensive inbreeding. The extensive use, by artificial insemination, of certain genetics can result in a significant increase in the occurrence and similar nature of congenital defects when the bulls are carriers of genetic disease. The use of bulls that were carriers for complex vertebral malformation syndrome, for example, resulted in an approximately threefold increase in the presence of arthrogryposis, ventricular septal defect, and vertebral malformations in Holstein Friesian calves submitted to diagnostic laboratories in the Netherlands between 1994 and 2000.

Checklists of recorded defects are included in the Further Reading section.

PATHOGENESIS

The pathogenesis of many of the congenital defects of large animals is poorly understood, but it is apparent that the disease produced by each teratogen is likely to have its own unique pathogenesis. Congenital defects in large animals include defects induced from structural malformations, from deformations, from the destruction of tissue by extraneous agents, and from enzyme deficiencies, or from a combination of these.

Structural Malformations and Deformations

Structural malformations result from a localized error in morphogenesis. The insult leading to the morphogenic error takes place during organogenesis and thus is an influence imposed in early gestation. **Deformations** occur where there is an alteration in the shape of a structure of the body that has previously undergone normal differentiation. Deforming influences apply later in the early gestational period, after organogenesis.

Deformation is the cause of arthrogryposis and cleft palate produced by the piperidine alkaloids from *Conium maculatum* and *Nicotiana* spp. and by anagyrine from *Lupinus* spp., which produce a chemically induced reduction in fetal movements. Ultrasound examination of the normal fetus shows that it has several periods of stretching and vigorous galloping during a 30-minute examination period. In contrast, the fetus that is under the influence of anagyrine has restricted movement and lies quietly, often in a twisted position. Restricted fetal limb movement results in arthrogrypotic fixation of the limbs, and pressure of the tongue on the hard palate when the neck is in a constant flexed position inhibits closure of the palate. In experimental studies there is a strong relation between the degree and duration of reduced fetal movement, as observed by ultrasound, and the subsequent severity of lesions at birth.

Restriction in the movement of the fetus, and deformation, can also result from teratogens that produce damage and malfunction in organ systems, such as the primary neuropathy that occurs in the autosomal-recessive syndrome in Charolais cattle and the acquired neuropathy in Akabane infection, both of which result in arthrogryposis through absence of neurogenic influence on muscle activity.

It has been suggested, with some good evidence, that the etiology and pathogenesis of congenital torticollis and head scoliosis in the equine fetus are related to an increased incidence of transverse presentation of the fetus. Flexural deformities of the limbs are also thought to be a result of errors in fetal positioning and limited uterine accommodation, which may be further complicated by maternal obesity. Abnormal placental shape may also be important in the genesis of skeletal deformations.

Viral Teratogenesis

Viral teratogenesis is related to the susceptibility of undifferentiated and differentiated cells to attachment, penetration, and virus replication; the pathogenicity of the virus (cytopathogenic versus noncytopathogenic strains of bovine viral diarrhea); the effects that the virus has on the cell; and the stage of maturation of immunologic function of the fetus at the time of infection. Viral infections can result in prenatal death, the birth of nonviable neonates with severe destructive lesions, or the birth of viable neonates with growth retardation or abnormal function (tremors, blindness). The gestational age at infection is a major influence. In sheep infected with border disease virus between 16 and 90 days of gestation, the occurrence of the syndromes of early embryonic death, abortion, and stillbirth and the birth of defective, small, and weak lambs are related to the fetal age at infection. Certain viruses cause selective destruction of tissue and of organ function late in the gestational period, and the abiotrophies are examples of selective enzyme deficiencies. The pathogenesis of the viral diseases is given under their specific headings in later chapters.

Inherited Congenital Defects

A number of **inherited congenital defects**, some of which are not clinically manifest until later in life, are associated with specific

enzyme deficiencies. Examples are maple syrup urine disease (MSUD), citrullinemia, factor XI deficiency in cattle, and the lysosomal storage diseases. Inherited lysosomal storage diseases occur when there is excessive accumulation of undigested substrate in cells. In mannosidosis, the disease occurs as a result of an accumulation of saccharides caused by a deficiency of either lysosomal α-mannosidase or β-mannosidase. In GM_1 gangliosidosis, disease is caused by a deficiency of β-galactosidase; in GM_2 gangliosidosis, the cause is a deficiency of hexosaminidase.

The age at development of clinical signs and their severity are dependent on the importance of the enzyme that is deficient, the biochemical function and cell type affected, and, in storage disease, the rate of substrate accumulation. Factor XI deficiency is manifest with bleeding tendencies, but the condition is not necessarily lethal. In contrast, calves with citrullinemia and MSUD develop neurologic signs and die shortly after birth, whereas the onset of clinical disease can be delayed for several months with α-mannosidosis.

CLINICAL AND NECROPSY FINDINGS

The intention is to give details of the clinical signs of all the congenital defects here, but some general comments are necessary. Approximately 50% of animals with congenital defects are **stillborn**. The defects are usually readily obvious clinically. Diseases of the nervous system and musculoskeletal system rate high in most published records, which may be related to the ease with which abnormalities of these systems can be observed. For example, in one survey of congenital defects in pigs, the percentage occurrence rates in the different body systems were as follows:

- Bones and joints, 23%
- Central nervous system, 17%
- Special sense organs, 12%
- Combined alimentary and respiratory tracts (mostly cleft palate and atresia ani), 27%
- Miscellaneous (mostly monsters), 9%
- Genitourinary and abdominal wall (hernias), each 5%
- Cardiovascular system, 3%

In a survey of congenital defects in calves, the percentage occurrence rates were as follows:

- Musculoskeletal system, 24%
- Respiratory and alimentary tracts, 13%
- Central nervous system, 22%
- Abdominal wall, 9%
- Urogenital, 4%
- Cardiovascular, 3%
- Skin, 2%
- Others, 4%
- (Anomalous-joined twins and hydrops amnii accounted for 20%.)

In a survey of foals, the approximate percentage occurrence rates were as follows:

- Musculoskeletal system, 50%
- Respiratory and alimentary tracts, 20%
- Urogenital, 9%
- Abdominal wall, 6%
- Cardiovascular, 5%
- Eye, 5%
- Central nervous system, 5%

Contracted foal syndrome and craniofacial abnormalities were the most common congenital defects in a study of stillbirth and perinatal death in horses.

Many animals with congenital defects have more than one anomaly. In pigs, for example, the average is two, and considerable care must be taken to avoid missing a second and third defect in the excitement of finding the first. In some instances, the combinations of defects are repeated often enough to become specific entities. Examples are microphthalmia and cleft palate, which often occur together in piglets, and microphthalmia and patent interventricular septum in calves.

There are a number of defects that cannot be readily distinguished at birth and others that disappear subsequently. It is probably wise not to be too dogmatic in predicting the outcome in a patient with only a suspicion of a congenital defect or one in which the defect appears to be causing no apparent harm. A specific instance is the newborn foal with a cardiac murmur.

Sporadic cases of congenital defects are usually impossible to define etiologically, but when the number of affected animals increases, it becomes necessary and possible to attempt to determine the cause.

CLINICAL PATHOLOGY

The use of clinical pathology as an aid to diagnosis depends on the disease that is suspected and its differential diagnosis. The approach varies markedly with different causes of congenital defects: **specific tests** and procedures are available for some of the viral teratogens, for congenital defects associated with nutritional deficiencies, and for some enzyme deficiencies and storage diseases, and the specific approach for known teratogens is covered in the individual diseases section.

When an unknown viral teratogen is suspected, precolostral blood samples should be collected from the affected neonates and also from normal contemporaries that are subsequently born in the group. Precolostral serum can be used for investigating the possible fetal exposure of the group to an agent, and the buffy coat or blood can be used for attempted virus isolation. IgG and IgM concentrations in precolostral serum may give an indication of fetal response to an infecting agent even if the agent is not known and there is no serologic titer to known teratogenic agents.

Enzyme-based tests have been used to virtually eradicate carriers of α-mannosidosis in cattle breeds in Australia and New Zealand, and DNA-based tests are used to detect and eliminate the carriers of such diseases as generalized glycogenosis in cattle.

DIFFERENTIAL DIAGNOSIS

- The diagnostic challenge with congenital defects is to recognize and identify the defect and to determine the cause.
- Syndromes of epidemic disease resulting from environmental teratogens are usually sufficiently distinct that they can be diagnosed on the basis of their epidemiology combined with their specific clinical, pathologic, and laboratory findings and on the availability of exposure.
- Congenital defects occurring sporadically in individual animals pose a greater problem. There is usually little difficulty in defining the condition clinically, but it may be impossible to determine the cause. With conditions where there is not an obvious clinical diagnosis, an accurate clinical definition may allow placement of the syndrome within a grouping of previously described defects and suggest possible further laboratory testing for further differentiation.

The examination for cause of an unknown congenital defect is usually not undertaken unless more than a few newborn animals in a herd or area are affected in a short period of time with similar abnormalities. A detailed epidemiologic investigation will be necessary, which will include the following:

- Pedigree analysis. Does the frequency of occurrence of the defect suggest an inherited disease, or is it characteristically nonhereditary?
- Nutritional history of dams of affected neonates and alterations in usual sources of feed
- Disease history of dams of affected neonates
- History of drugs used on dams
- Movement of dams during pregnancy to localities where contact with teratogens may have occurred
- Season of the year when insults may have occurred
- Introduction of animals to the herd

The major difficulty in determining the cause of nonhereditary congenital defects is the long interval of time between when the causative agent was operative and when the animals are presented, often 6 to 8 months. Detailed clinical and pathologic examination of affected animals offers the best opportunity in the initial approach to determine the etiology based on the presence of lesions that are known to be caused by certain teratogens.

INTRAUTERINE GROWTH RETARDATION

Intrauterine growth retardation is a special form of congenital defect. It is a failure to grow properly, in contrast to a failure to gain body weight, and occurs when the developmental age is less than the chronologic (gestational) age. **Runt** is a common colloquial agricultural term. Normal fetal growth rate is determined by genetic and epigenetic factors, and cross-breeding experiments suggest that fetal size is regulated by the embryonic/fetal genotype and also is an effect of maternal genotype. Litter size has an effect on birth weight in all species, most likely through effects on the placental delivery of nutrients and removal of waste products relative to total fetal mass. A **genetic** association with intrauterine growth retardation has been shown in Japanese Black calves.

There is a strong positive association between placental mass and fetal size at birth in all species, and the majority of cases of growth retardation result from inadequate placentation, disturbance in utero of placental blood flow, or placental pathology.

ETIOLOGY

There are a number of different etiologies.

Heat stress to ewes in the final third of pregnancy will result in intrauterine growth retardation, but the condition is not as severe as when ewes are exposed in the second third of pregnancy, which is the period of placental growth. Hyperthermia results in a redistribution of blood away from the placental vascular bed and a decrease in cotyledon mass, with consequent reduction in birth weight. The degree of growth restriction is directly related to the degree of hyperthermia to which the ewe is exposed and her heat tolerance. The growth retardation affects fetal weight more than fetal length, and although there is some reduction in the growth of the brain, it is relatively less than that of the internal organs, resulting in an increased brain : liver weight ratio at birth.

Viral infections, such as border disease and bovine virus diarrhea in ruminants and parvovirus in pigs, produce growth-retarded neonates, as do bacterial and other infections that result in placentitis.

Inadequate placentation is the cause of runt piglets. Runts are smaller and thinner and have disproportionately larger, domed heads compared with normal pigs. A deficiency in specific **trace elements** is suspect in some field cases of growth retardation in ruminants, but there is no evidence for deficient trace-element nutrition in runt pigs.

Inadequate nutrition can result in growth retardation in utero. Growth retardation can be produced in fetal pigs, lambs, and calves by **maternal caloric undernutrition**. Nutritional restriction in ewes reduces the number of placental lactogen receptors that mediate amino acid transport in fetal liver and glycogen synthesis in fetal tissue, leading to depletion of fetal liver glycogen stores. This has been postulated as a possible cause of the fetal growth retardation that accompanies maternal caloric undernutrition; runt pigs have a reduced metabolic rate and lower skeletal muscle respiratory enzyme activity. This deficiency persists after birth; runt pigs have a lower core temperature and a lessened ability to increase their metabolic rate and heat production in response to cold.

Paradoxically, **overnourishing the adolescent ewe** will also result in placental growth restriction and in utero growth retardation. This effect is most evident in the second third of pregnancy. This syndrome is accompanied by the birth of lambs with a shorter gestational age, commonly reduced by 3 days. It is thought that the fetal hypoxia and hypoglycemia that accompany placental insufficiency might stimulate the maturation of the fetal hypothalamic–pituitary–adrenal axis, initiating early parturition. The growth of those lambs that survive initially lags behind that of normal lambs, but there is compensatory growth and no difference in weight at 6 months of age.

Measurements that can be used to determine the presence of growth retardation in a **dead fetus** include crown–rump (anal) length, brain weight, body weight, ratios of brain to body weight, long-bone weight, and appendicular ossification centers. Formulas are available to determine the degree of growth retardation.

In the **live animal** the presence of radiodense lines in long bones and the examination of closure of ossification centers can provide evidence for prior stressors in pregnancy that induce fetal growth retardation, such as malnutrition or infection of the dam, that may not be found by other examinations.

Intrauterine growth retardation is accompanied by an impaired cellular development of tissues, such as the small intestine and skeletal muscle, and disproportionately large reductions in the growth of some organs, such as the thymus, spleen, liver, kidney, ovary, and thyroid. There is an associated impairment of thermogenesis, immune function, and organ function at birth. In lambs there is impaired development of secondary wool follicles.

The **survival** of fetuses with growth retardation requires special nutritional care and the provision of adequate heat; this topic is discussed in the section on critical care for the newborn. In large piggeries that practice batch farrowing, the survival of runts can be significantly improved by the simple practice of fostering them together in one litter on one sow so that they do not have to compete with larger-birth-size and more vigorous pigs, by ensuring adequate colostrum intake and adequate environmental warmth, and by feeding using a stomach tube in the first few hours of life, if indicated.

Physical and Environmental Causes of Perinatal Disease

Neonatal animals are newborns. The definition of a neonate is not precisely defined in terms of age of the animal and likely will vary from species to species dependent on the ability of the newborn to survive relatively independently and on the maturity or degree of postnatal development. Most farm mammals can be considered neonates until they are 2 weeks of age.[1]

The health of neonates is determined by factors that influence their growth and development in utero and their capacity to adapt to extrauterine life. Neonates affected by intrauterine conditions that impede their normal development (intrauterine growth retardation or premature birth) might not be prepared for the rapid and extensive physiologic changes needed to survive after birth. Furthermore, conditions experienced by the newborn can adversely affect its health and well-being; key among these factors are adequate nutrition, transfer of passive immunity from the dam, a thermoneutral environment or protection from the adverse effects of

excessive cold or heat, and protection from risk of injury.

PERINATOLOGY

Clinical care of the newborn animal in large animal veterinary medicine has traditionally started at the time of birth, but there is a growing recognition of the importance of antenatal and parturient events to the subsequent viability of the neonate.[2] This has been particularly recognized by equine clinicians and has led to the clinical concept of perinatology. One purpose of perinatology is to expand the care of the neonate into the antenatal and parturient period through the use of measurements that reflect fetal health or that can predict risk to fetal viability. Measures that can be used are still being developed and evaluated, but the following discussion includes those that have apparent value.

HEART RATE

Fetal heart rate recorded by electrocardiography (ECG) or by ultrasound can be used as a measure of fetal viability, for the detection of twins, and as a monitor for fetal distress during parturition.[3] The fetal heart rate of foals declines during gestation (Fig. 19-1) to approximately 60 to 80 beats/min near to term, and that of fetal calves is approximately 110 beats/min during the final 2 weeks of gestation.[4]

It has been suggested that a base heart rate of 80 to 92 beats/min with baseline variations of 7 to 15 beats/min and occasional accelerations above this is normal for the fetal heart rate of equids, and that bradycardia is evidence of abnormality. Continued monitoring traces may be needed to assess fetal distress.

Cardiac arrhythmia is common at the time of birth and for the first few minutes following and is thought to result from the transient physiologic hypoxemia that occurs during the birth process.

An alternative to fetal ECG monitoring is use of per rectum or percutaneous ultrasonography to detect carotid or peripheral pulse rates in foals and calves.[4,5]

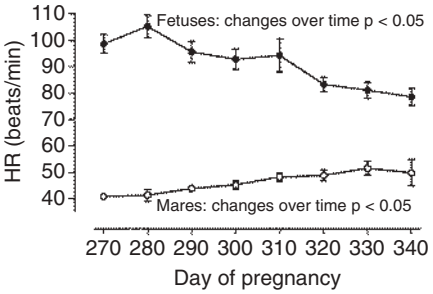

Fig. 19-1 Heart rate of mare and fetus from 270 days of gestation until foaling. The heart rate of the mare increases, whereas that of the foal declines, as the duration of gestation increases. (Reproduced from Nagel et al., 2011.[16])

ULTRASOUND EXAMINATION

The fetus can be examined by **ultrasound** to establish the presentation, the presence of twins, the heart rate, the presence and quality of fetal movement, the presence of placentitis, placental thickness, the presence of echogenic particles in the amniotic fluid, the depth of allantoic and amniotic fluid, and an estimate of body size from the measurement of the aortic and orbit diameters.[3,5-8] Measurements of fetal heart rate, fetal aortic diameter (an indicator of fetal size and, if measured near parturition, fetal birth weight),[8] uteroplacental contact, maximal fetal fluid depths, uteroplacental thickness, and fetal activity have allowed the development of objective measures to assess fetal well-being (Fig. 19-2).[6]

Clinicopathologic examination of samples of the **amniotic fluid** for the determination of pulmonary maturity and other measures of foal health is limited because there is a considerable risk for abortion and placentitis, even with ultrasound-guided amniocentesis, and the technique is not recommended for routine clinical use.

PREMATURITY

The average gestational length for mares is 343 days (range, 307 to 381), with the duration of gestation being longer for mares foaling later in the spring and for mares giving birth to a male foal (344 versus 341 days for a filly foal, respectively). There is no effect of breed of the mare or her age on gestational length.[9] Approximately 95% of mares were found to foal between 320 and 360 days of gestation, with 1.1% foaling at less than 320 days. Death rates were 8.3%, 3.6%, and 4.8% for foals born at less than 320 days, 320 to 360 days, and more than 360 days of gestation, respectively.[9] The difference was not statistically significant, but the number of foals born at less than 320 days was small (12), and this could have masked a statistical difference in case fatality rates. No foal lived if it was born at less than 311 days of gestation. Foals born at less than 320 days of gestational age are considered premature, and those born at less than 310 days are at significant risk for increased rate of death.[10]

Dystocia is associated with increased morbidity and case fatality rate in foals. Stage II labor lasting longer than 40 minutes is associated with increased risk of stillbirth (16×), death after birth (8×), and illness in the foal (2×).[9]

Similar data are available for cattle. For instance, in 41,116 calvings of Japanese Black cattle, there were 1013 stillbirths (2.46%) and 3514 dystocias (8.55%). Stillbirth rates were greater for those born at 301 or more days of pregnancy (OR: 1.049 [1.035 to 1.062]) and at 270 or fewer days of pregnancy (OR: 2.072 [2.044 to 2.101]) compared with those at between 281 and 290 days of pregnancy.[11] Among Holsteins, Jerseys, and crossbreds, gestation length was ~275 days, with male calves having a gestation length 1.2 days longer. The percentage of stillbirths was 6.6% across all observations, with 9.6% among first-parity dams and 5.1% among multiparous dams.[12]

Traditionally, external signs have been used to predict a premature foaling, and the common signs used are the enlargement of the udder, milk flow, and the occurrence of vaginal discharge. Causes of early foaling include bacterial or fungal placentitis and twin pregnancy. Several **assays** are used as alternate methods of determining whether foaling is imminent and if problems are present.

Plasma **progestogen** concentrations in mares decline in pregnancy to reach a low around 150 days of gestation. Plasma progestogen cannot be used to accurately predict the time of foaling, and a single sample is not diagnostic. There is a strong correlation between the presence of plasma progestogen concentrations above 10 ng/mL before a gestational age of 310 days and the presence of placental lesions, and a rapid drop in concentration to below 2 ng/mL that persists for more than 3 days indicates impending abortion. Current research is examining the profiles of individual progestogens during pregnancy to determine whether the profile of any progestogen can be used as a predictor of fetal distress.

There is considerable interest in predicting the time of parturition in mares. Recognition that significant changes occur in udder secretions during the last week of gestation, including a drop in pH on the day of foaling and increases in concentrations of calcium and potassium and declines in levels of sodium and chloride, has led to the development of several relatively simple tests.[13] These tests include measurement of the refractive index, pH, and calcium concentration of udder secretions during the week before anticipated parturition. Samples can be analyzed for calcium carbonate concentration using a water hardness kit, for pH with pH test paper, and for refractometry index with a Brix or similar refractometer. The positive predictive value (PPV) of parturition occurring within 72 hours and the negative predictive value (NPV) within 24 hours for calcium carbonate concentration (≥400 μg/g) were 94% and 98%, respectively.[14,15] The PPV within 72 hours and the NPV within 24 hours for the pH test (≤6.4) were 98% and 99%, respectively. The PPV within 72 hours and the NPV within 24 hours for the Brix test (≥20%) were 73% and 97%, respectively. The high negative predictive value of measurement of calcium concentrations (by either method) and pH provides a way of determining when the mare is not likely to foal within the next 24 hours.[14]

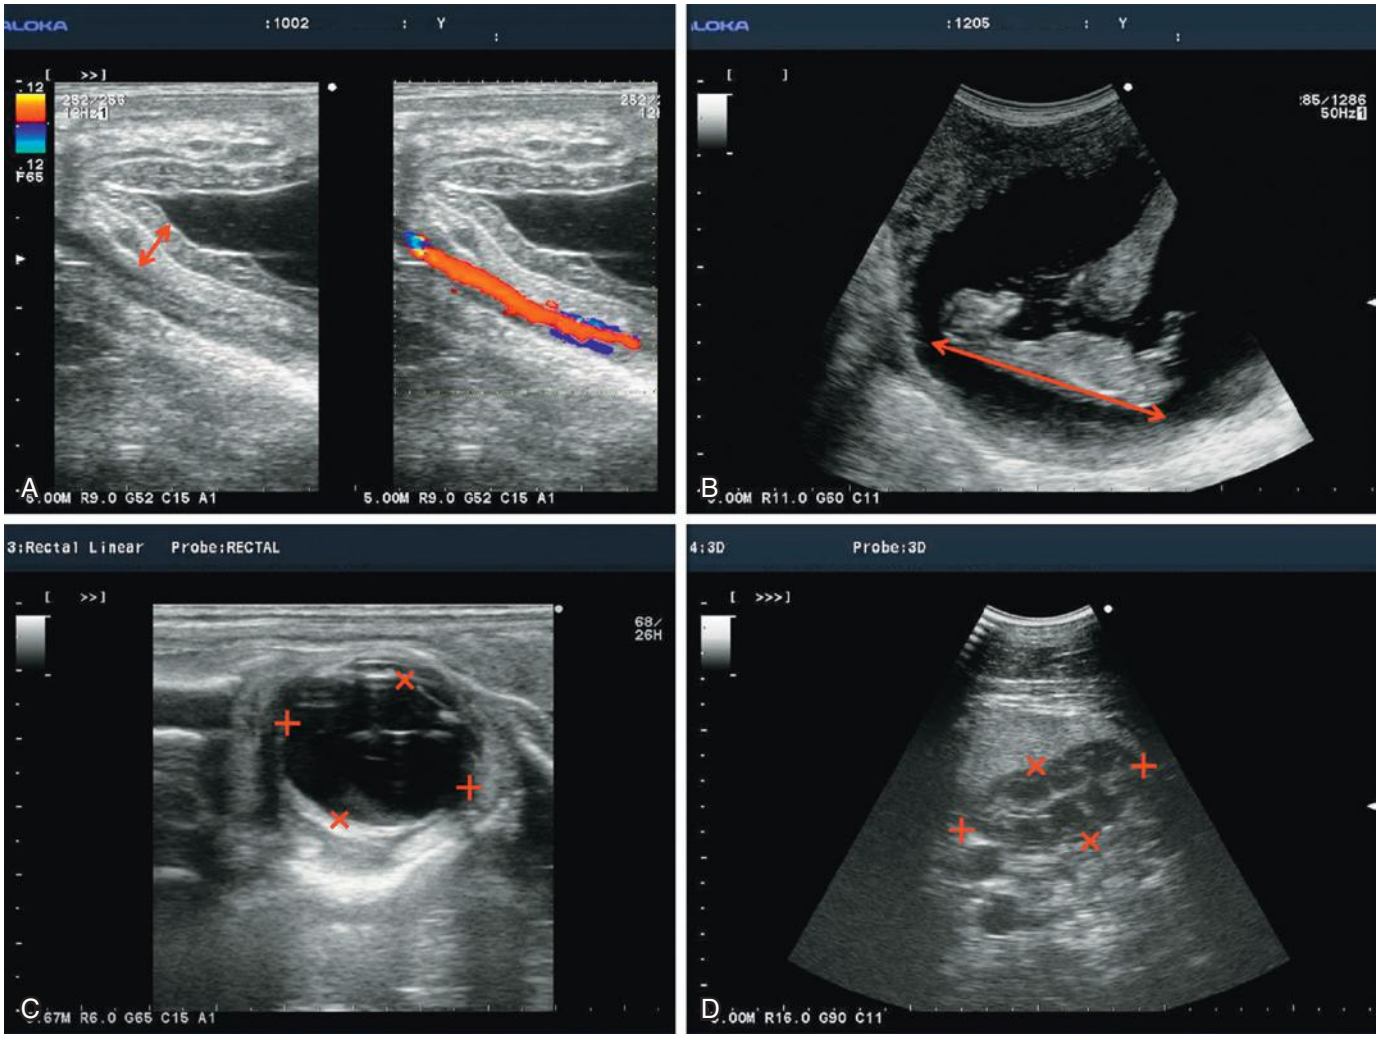

Fig. 19-2 Measurement of ultrasonographic indices of pregnant mare. **A,** Transrectal images in the ventral part of the uterine body, near the cervix. Headers show the combined thickness of the uterus and placenta (CTUP). **B,** Transrectal image of crown rump length (CRL) (header). **C,** Transrectal image of fetal eye orbit. Eye length (=) and width (×) measurements are shown. Eye length is measured from the maximum length of the inner margins of the vitreous body, and eye width is measured from the margin of the anterior portion of the capsule of the lens to the inner margin of the optic disc. **D,** Transabdominal image of the fetal abdomen at the level of the kidney. Kidney cross-sectional length (=) and width (×) measurements are shown. (Reproduced with permission from Murase et al., 2014.[6])

PREMATURITY AND DYSMATURITY OF FOALS

Foals that are born before 300 days are unlikely to survive, and foals born between 300 and 320 days of gestation are considered premature but can survive (see earlier discussion).[1] **Premature foals** are characterized clinically by low birth weight, generalized muscle weakness, poor ability to stand, lax flexor tendons, weak or no suck reflex, lack of righting ability, respiratory distress, short and silky haircoat, pliant ears, soft lips, increased passive range of limb motion, and sloping pastern axis. Radiographs may show incomplete ossification of the carpal and tarsal bones and immaturity of the lung, and there may be clinical evidence of respiratory distress. **Full-term foals** born after 320 days of gestation but exhibiting signs of prematurity are described as **dysmature.**

Premature foals have hypoadrenal corticalism. They are neutropenic and lymphopenic at birth and have a narrow neutrophil-to-lymphocyte ratio. In premature foals older than 35 hours the neutrophil count can be used to predict survival, and foals that remain neutropenic after this time have a poor prognosis. Premature foals also have low plasma glucose, low plasma cortisol, and a blood pH of less than 7.25. An extensive collaborative investigation of equine prematurity has been conducted, and information on foal metabolism and guidelines for laboratory and clinical assessment

of maturity are available.[2] Foals that are born with clinical abnormalities suggestive of intrauterine growth retardation, prematurity, or dysmaturity are more likely to have an abnormal placenta and have higher serum concentrations of creatinine.[3]

The **placenta** is critical to the fetus in the antenatal period, and pregnancies involving placental lesions commonly result in foals that suffer premature-like signs at whatever stage they are delivered.[3,4] Placental edema, placental villous atrophy, and premature separation of the placenta are significant causes of fetal ill-health and delayed development.[5]

Precocious lactation of the mare can be associated with placentitis. The examination of the placenta for evidence of placentitis and for the presence of larger-than-normal avillous areas should be part of normal foaling management. There is a high correlation between both allantochorionic weight and area and foal weight in normal placentas. Normal placentas had a low association with subsequent perinatal disease in the foals.[3,4] In contrast, abnormal placental histology was associated with poor foal outcome (three normal foals from 32 abnormal placentas). Edema, sacculation, and strangulation are other abnormalities and can be associated with microscopic deposits of minerals within the lumen of placental blood vessels.

PARTURIENT INJURY AND INTRAPARTUM DEATH

During parturition extreme mechanical forces are brought to bear upon the fetus, and these can result in direct traumatic damage or can impair fetal circulation of blood by entrapment of the umbilical cord between the fetus and the maternal pelvis, which can lead to hypoxemia or anoxia and death of the fetus during the birth process. Neonates that suffer birth trauma and anoxia but survive are at risk for development of signs of neurologic disease, have reduced vigor, are slower to suck, and are at increased risk for postnatal mortality.[1]

In all species, but in ruminants in particular, the **condition of the dam** can have a marked influence on the prevalence of birth injury and its consequences. The effect is well illustrated in sheep, where the two extremes of condition can cause problems. Ewes on a high plane of nutrition produce a large fetus and also deposit fat in the pelvic girdle, which constricts the birth canal, predisposing to dystocia. Conversely, thin ewes may be too weak to give birth rapidly. **Pelvic size** can influence the risk of birth injury, and ewe lambs and heifers mated before they reach 65% of mature weight are at risk. **Pelvimetry** is used to select heifers with adequate pelvic size for breeding, but the accuracy and validity of this method are seriously questioned. **Breed** is also a determinant of length and ease of labor and the subsequent quickness to time to first suckle.

TRAUMA AT PARTURITION

Traumatic injuries can occur in apparently normal births, with prolonged birth, and as a result of dystocia, which may or may not be assisted by the owner. Incompatibility in the sizes of the fetus and the dam's pelvis is the single most important cause of dystocia, and birth weight is the most important contributing factor. In cattle, expected progeny difference (EPD) estimates for calf birth weight are good predictors of calving ease. In foals, calves, and lambs the chest is most vulnerable to traumatic injury, but there is the chance of vertebral fracture and physical trauma to limbs with excessive external traction.[2]

Fractured ribs are common in foals and can lead to laceration of the lungs and heart and internal hemorrhage.[3] **Rupture of the liver** is common in some breeds of sheep and can also occur in calves and foals. A retrospective study of rib and vertebral fractures in calves suggests that most result from excessive traction and that, as a result, smaller dystocial calves are more at risk. **Vertebral fractures** occur as the result of traction in calves with posterior presentations and in calves with hip lock. Trauma is a major cause of neonatal mortality in piglets, but it occurs in the postparturient phase and is associated with being overlain or stepped on by the sow. It is possible that the underlying cause of crushing mortality in piglets is hypothermia.

Intracranial hemorrhage can result in damage to the brain. A high proportion (70%) of nonsurviving neonatal lambs at birth or within 7 days of birth have single or multiple intracranial hemorrhages, with the highest incidence being in lambs of high birth weight.[4] Similar lesions have been identified in foals and calves, but they are not a common finding in foals with neonatal maladjustment syndrome. Experimentally controlled parturition in ewes showed that duration and vigor of the birth process affected the severity of intracranial hemorrhages, and further studies indicated that these birth-injured lambs had depressed feeding activity and that they were particularly susceptible to death from hypothermia and starvation.

Birth anoxia associated with severe dystocia in cattle can result in calves with lower rectal temperatures in the perinatal period than normal calves and a decreased ability to withstand cold stress. Intracranial hemorrhage, especially subarachnoid hemorrhage, occurs in normal full-term deliveries as the result of physical or asphyxial trauma during or immediately following delivery.

In a prolonged birth, **edema** of parts of the body, such as the head and particularly the tongue, may also occur. Edema occurs particularly in the calf and the lamb, possibly because of less close supervision at parturition, and also because the young of these species can sustain a prolonged birthing process for longer periods than the foal without their own death or death of the dam. The edema can interfere with subsequent sucking, but the principal problem relative to neonatal disease is the effect of the often prolonged hypoxia to which the fetus is subjected. There is interference with the placental circulation and failure of the fetus to reach the external environment. The hypoxia may be sufficient to produce a stillborn neonate, or the neonate may be alive at birth but not survive because of irreparable brain damage. Intrapartum deaths resulting from prolonged parturition occur in piglets.

FETAL HYPOXIA

Hypoxemia and hypoxia can occur as a result of influences during the birth process or because of pulmonary immaturity in premature births. The most common causes are dystocia, interrupted or restricted blood flow through the umbilical vein (carrying oxygenated blood to the fetus) and artery, and placental lesions, including premature separation of the placenta during labor, that reduce the effective surface area of the placenta in contact with the endometrium.[1] Intrapartum hypoxemia of the fetus resulting from **prolonged parturition** is common, particularly in calves born to first-calf beef heifers, and is presumed to be associated with the greater case fatality rate and morbidity in foals born after stage 2 labor of greater than 40 minutes.[2] Prolonged duration of parturition in ewes increases the risk of asphyxia (90× for each 10-min increase), decreases the viability score of lambs, and increases the latency to suckle the udder. Twin-born lambs were found to have a 16-fold greater risk of asphyxia.

Transient tachypnea occurs immediately after birth and is normal. **Prolonged tachypnea**, with flaring of the nostrils, open-mouth breathing, exaggerated rib retraction, and paradoxical breathing patterns, is highly suggestive of primary pulmonary abnormality. Failure of respiration can occur at this stage and creates an urgent need for resuscitation measures. In the foal, **body position** can have a major effect on arterial oxygen tension. A foal that is unable to stand or to right itself from lateral recumbency is at risk

from atelectasis and should be assisted to lie in sternal recumbency to stand. Hypoxia and hypercapnia resulting from mismatching of ventilation and perfusion are accentuated by prolonged recumbency.

Placental dysfunction or restriction of blood flow in the umbilical vessels during the second stage of labor can result in fetal hypoxia and death. Blood flow in umbilical vessels is reduced during uterine contractions and ceases during stage 2 labor in cattle as the calf's head appears at the vulva and just before delivery of the calf.[1] Before this stage, blood flow in the umbilical vein is significantly lower in acidotic than in nonacidotic calves, indicating impairment of oxygen delivery to the fetus and development of increased blood lactate concentrations.[1]

Fetal capillary blood pH and oxygen and carbon dioxide tensions can be measured during parturition, as is common practice in human obstetrics.[3] Fetal blood is collected from capillaries in the front feet as they project from the vulva by making a small incision (nick) in the skin and collecting blood into a capillary tube, which is then sealed before blood-gas analysis.[3] In 38 calves, some of which were born as a result of relieved dystocia or cesarean section, fetal capillary blood-gas values and pH (mean ± standard deviation [SD]) during the final 30 minutes of stage 2 labor were as follows: pH = 7.30 ± 0.10 (min 6.99, max 7.43), P_{O_2} = 19.5 ± 9.4 mm Hg, P_{CO_2} = 55.9 ± 26.0 mm Hg, HCO_3^- = 26.0 ± 4.4 mm Hg, base excess = −0.9 ± 5.3 mM/L, and oxygen saturation = 21.9 ± 16.6.[3] These compare with the following values in capillary blood obtained after recovery from birth in healthy calves: pH = 7.37 ± 0.11, P_{O_2} = 58.4 ± 17.0 mm Hg, P_{CO_2} = 38.1 ± 13.2 mm Hg, HCO_3^- = 20.8 ± 4.9 mm Hg, base excess = −3.2 ± 4.4 mM/L, and oxygen saturation = 82.4 ± 14.9%.[3] Similarly, jugular vein blood collected from 79 **lambs** immediately after birth (before onset of regular breathing) had the following values: pH = 7.21 ± 0.09 (range, 6.99 to 7.41), P_{O_2} = 18.4 ± 9.8 mm Hg (4 to 53), P_{CO_2} = 65.4 ± 12.5 mm Hg (29.6 to 103.7), HCO_3^- = 26.5 ± 4.0 mm Hg (13.9 to 35.4), base excess = −1.3 ± 5.1 mM/L (−16 to 9), and oxygen saturation = 21.2 ± 16.6% (0 to 85).[4] Both normal calves and lambs are acidotic, hypoxemic, and hypercapnic during birth as a result of impaired placental blood flow, and prolonged duration of stage 2 of parturition likely exacerbates this hypoxia and increases morbidity and fatality rate.[1]

A similar syndrome has been produced experimentally by clamping the umbilical cord of the bovine fetus in utero for 6 to 8 minutes, followed by a cesarean section 30 to 40 minutes later. Calves born following this procedure may die within 10 to 15 minutes after birth or survive for up to 2 days. During the experimental clamping of the umbilical cord, there is a decline in the blood pH, P_{O_2}, and standard bicarbonate levels and an increase in P_{CO_2} and lactate levels. There is also increased fetal movement during clamping and a release of meconium, which stains the calf and the amniotic fluid. Those that survive for a few hours or days are dull and depressed, cannot stand, and have poor sucking and swallowing reflexes, and their temperature is usually subnormal. They respond poorly to supportive therapy. A slight body tremor may be present, and occasionally tetany and opisthotonus occur before death. Calves that are barely able to stand cannot find the teats of the dam because of uncontrolled head movements. At necropsy of these experimental cases, there are petechial and ecchymotic hemorrhages on the myocardium and endocardium, there is an excess of pericardial fluid, and the lungs are inflated. When the experimental clamping lasts only 4 minutes, the calves usually survive.

Meconium staining (brown discoloration) of the coat of the newborn at birth is an important indicator that it has suffered hypoxia during or preceding the birth process,[5,6] and such neonates merit close supervision in the early postnatal period. In lambs, severe hypoxia during birth results in death within 6 days of birth. **Neurologic lesions** in lambs that died between birth and 6 days of age include hemorrhages in the meninges, brain congestion and edema, neuronal ischemic necrosis, intraparenchymal hemorrhages in the medulla oblongata and cervical spinal cord, parasagittal cerebral necrosis, and periventricular leukomalacia.[7] Edema was more severe in the brain than in other regions of the central nervous system. Ischemic neurons first appeared 24 hours postpartum, increased linearly in number between 48 hours and 5 days postpartum, and had a laminar distribution in the cerebral cortex, indicating a hypoxic-ischemic encephalopathy.[7] No significant lesions were found in anteparturient deaths or in those aged between 7 and 16 days. Lesions in the central nervous system can explain most deaths at birth and within 6 days of birth. The lesions were hypoxic-ischemic and appeared to be related to birth injury in some cases.[7] Similar lesions are not found in foals with neonatal maladjustment syndrome (see page 1871).

Fetal anoxia associated with **premature expulsion** of the **placenta** occurs in all species. Anoxia occurs in all parities of cow and with little relation to calving difficulty, although malpresentation is a predisposing factor. Prepartum diagnosis in cattle is hindered by the low prevalence of prepartum vaginal hemorrhage, and the majority of fetuses die during the birth process. The placenta is expelled with the fetus. **Premature separation** of the placenta ("red bag") occurs in foals and is an emergency that requires immediate attention. Premature placental separation occurs in approximately 1.6% of births and is associated with a case fatality rate of 18% in the foals.[2]

In all species the prevention of intrapartum hypoxia depends on the provision of surveillance. Universal surveillance is usually not practical for species other than the horse, and in cattle, for example, it tends to concentrate on the group at most risk so that surveillance, and assistance if necessary, is provided for first-calf heifers at the time of calving. Heifers that do not continue to show progress during the second stage of parturition should be examined for evidence of dystocia, and obstetric assistance should be provided if necessary.

The treatment and care of foals with this syndrome is described in the section on critical care of the newborn later in the chapter. The monitoring, treatment, and care of agricultural animals with this syndrome should follow the same principles but is usually limited by the value of the animal and the immediate access to a laboratory. Measures such as the time from birth to sternal recumbency, the time from birth to standing, and the time from birth to first suckle have been used to grade calves and identify those that might require intervention and treatment, but the best method of evaluation is an assessment of muscle tone. There is no effective practical treatment for calves affected with intrapartum hypoxia other than the provision of ventilation, as for the foal, and the correction of the acidosis. The airway should be cleared, and if physical stimulation of ventilation gives no response, then mechanical ventilation should be attempted. The practice of direct mouth-to-mouth ventilation assistance should be strongly discouraged, especially in lambs, because of the risk from zoonotic disease agents. Doxapram hydrochloride has been used in calves to stimulate respiration, but without demonstrated efficacy.

HYPOTHERMIA IN NEWBORNS

The environment of the neonate has a profound effect on its survival. This is especially true for lambs and piglets, in which hypothermia and hypoglycemia are common causes of death. Hypothermia can also predispose to inadequate milk intake, including colostrum, and increase the risk and severity of infectious disease. A fuller description, including hypothermia affecting adults, is provided under "Hypothermia" in Chapter 5.

LAMBS

Cold stress and resultant death rates of lambs is an important animal welfare issue.[1] Lambs

are very susceptible to cold, and hypothermia is an important cause of mortality in the early postnatal period.[2] **Cold stress** to neonatal lambs is attributable to heat loss resulting from one or more of the factors of low ambient temperature, wind, and evaporative cooling. The healthy newborn lamb has a good ability to increase its metabolic rate in response to a cold stress by shivering and nonshivering thermogenesis (brown adipose tissue). The energy sources in the neonatal lamb are liver and muscle glycogen, brown adipose tissue, and, if it nurses, the energy obtained from colostrum and milk. The ingestion of colostrum can be essential for early thermogenesis in lambs, especially twin lambs.

The **critical temperature** (the ambient temperature below which a lamb must increase metabolic heat production to maintain body temperature) for light-birth-weight lambs is 31° C to 37° C (88°–99° F) in the first days of life.

The risk of death from hypothermia is highest in lambs of small birth size. **Heat production** is a function of body mass, whereas **heat loss** is a function of body surface area. Large-birth-size lambs have a greater body mass in relation to surface area and are thus more resistant to environmental cold stress. In contrast, small-birth-size lambs, with a smaller body mass relative to surface area, are more susceptible to chilling. The dramatic nature of this relationship was shown in early studies on cold stress and survival in lambs many years ago. Birth weight is lower in twins and triplets and in the progeny of maiden ewes. Susceptibility is also influenced by maternal nutrition in pregnancy (see the next section) because this can both influence placental mass, birth weight, and the energy reserves of the neonate and also affect the activity of the ewe at parturition, and the resultant poor mothering behavior and mismothering can result in starvation in the lamb.

Lambs are particularly susceptible to cold stress during the first 5 days of life. During this period hypothermia can result from heat loss in excess of summit metabolism or from depressed heat production caused by intrapartum hypoxia, immaturity, and starvation.

Heat loss is a function of the surface area available for convective, conductive, and evaporational heat loss; ambient temperature; wetness of the skin (fleece); and wind speed. These factors can be described mathematically as follows:

$$\begin{aligned} &\textit{Chill index}\ (kJ/m^2/hr) \\ &= 481 + (11.7 + 3.1 * V) * (40 - T) \\ &\quad - (418 * [1 - e^{-0.04Ra}]), \end{aligned}$$

where temperature (T), rain (Ra), and wind speed (V) are considered and are related to mortality rate in newborn lambs (Fig. 19-3).

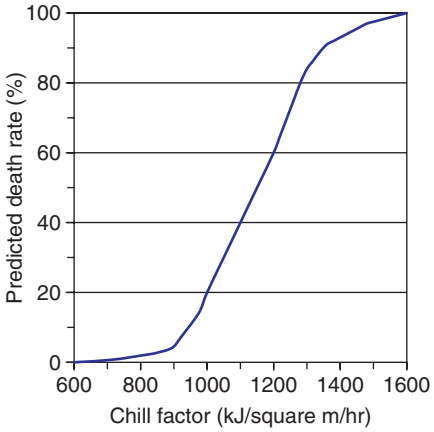

Fig. 19-3 Predicted death rate for neonatal lambs as a function of wind chill. (Data generated from LambAlive. Horizon Agriculture [www.hzn.com.au/lambalive.php] and courtesy of Dr. John Larsen, University of Melbourne.[6,7])

Heat Loss in Excess of Summit Metabolism

Low-birth-weight lambs born into a cool environment where there is wind are especially susceptible because of the evaporative cooling of fetal fluids on the fleece. For a small newborn lamb, the evaporative cooling effect of a breeze of 19 km/h (12 mph) at an ambient temperature of 13° C (55° F), common in lambing seasons in many countries, can be the equivalent of a cold stress equivalent to 25° C (77° F). The heat loss in these circumstances can exceed the lamb's ability to produce heat (summit metabolism), and progressive hypothermia and death result. Hypothermia as a result of heat loss in excess of summit metabolism can also occur when there is rain or just with cold and wind. Death occurs primarily in the first 12 hours of life.

Hypothermia From Depleted Energy Reserves

Hypothermia occurring in lambs after 12 hours of age is usually a result of depletion of energy reserves in periods of cold stress; milk is the sustaining energy source. There are three major causes of hypothermia from depleted energy reserves.

One of the early manifestations of developing hypothermia is the **loss of sucking drive**; severe cold stress and developing hypothermia can result in behavioral changes that cause low milk intake and subsequent depletion of energy reserves.

The second important cause is **mismothering**; the third is related to **birth injury**. Most researched measures of maternal behavior, temperament, and lambing difficulty are poorly correlated genetically with lamb survival.[3] Dystocia-related hypoxia is associated with acidemia, a reduction in summit metabolism, and disturbance in thermoregulation and can result in hypothermia. Birth-injured lambs, usually large single-born lambs, have depressed sucking and feeding activity, and actions to increase the birth weight of lambs above a certain point are likely to be counterproductive.[4] The relationship between mortality of lambs and birth weight is a U-shaped curve, with smaller and larger lambs at increased risk of death.[2]

In lambs that have hypothermia associated with heat loss in excess of summit metabolism, heat is required for **therapy**, but in lambs with starvation hypothermia the administration of glucose is also necessary. Glucose is administered intraperitoneally at a dose of 2 g/kg body weight using a 20% solution. Following the administration of the glucose, the lambs should be dried with a towel if wet and rewarmed in air at 40° C (104° F). This can be done in a warming box using a radiant heater as the heat supply. Care should be taken to avoid hyperthermia. Careful attention must be given to the nutrition of the lambs after rewarming; otherwise, relapse of hypothermia will occur. A feeding of 100 to 200 mL of colostrum will also be beneficial, but lambs should not be fed before they are normothermic because aspiration pneumonia is a risk. Experimental hypothermia in lambs has shown little direct long-term pathologic effect.

In most countries the selection of time of lambing is dictated by nutritional considerations and the seasonality of the ewes' sexual behavior, and lambing occurs at a time of year when cold stress is likely. The **control** of loss from hypothermia in newborn lambs requires supervision at lambing and protection from cold. Shed lambing will reduce cold-stress loss. The provision of shelter in lambing paddocks is effective at reducing mortality rate and in increasing profitability.[5] The site is important because birth sites in lambing paddocks are not randomly distributed, and there is variation in the preferred sites between breeds. Some ewes will seek shelter at lambing, but many ewes in wool will not. In some flocks, sheep are shorn before lambing in an attempt to force this shelter-seeking trait.

Experimentally, there is a strong relationship between breed and the degree of hypothermia produced. There is also convincing evidence that rearing ability is heritable in sheep, that some of this relates to traits within the newborn lamb, and that a significant reduction in neonatal mortality associated with susceptibility to hypothermia could be achieved with a genetic approach.

Lambs are also susceptible to **hyperthermia,** and thermoregulation is not efficient at high environmental temperatures. Heat prostration and some deaths can occur in range lambs when the environmental temperature is high, especially if lambs have to perform prolonged physical exercise and if there is an absence of shade.

CALVES

Hypothermia as a result of environmental influence is less common in full-term healthy calves than in lambs, but mortality rates have been shown to increase with decreasing ambient temperature and increasing precipitation on the day of birth. The **critical temperature** for neonatal calves is much lower than that for lambs, approximately 13°C (55°F), and *Bos taurus* calves are more resistant to cold stress than are *Bos indicus.*

Experimentally produced hypothermia in calves causes little overt injury except for peripheral damage to exterior tissues. During cooling there can be significant peripheral hypothermia before any marked reduction in core body temperature. Calves have a remarkable ability to resist and overcome the effects of severe cold temperatures. However, there is a relationship between the occurrence of cold weather and calf deaths, including those resulting from "weak-calf syndrome," and deficiencies in thermoregulation occur in animals born prematurely and in dystocial calves. As in lambs, dystocia will reduce teat-seeking activity and sucking drive, and dystocial calves have lower intakes of colostrum, lower body temperatures, and decreased ability to withstand cold stress.

Rewarming of hypothermic calves can be by radiant heat, but immersion in warm water produces a more rapid response and with minimal metabolic effort. The prevention of hypothermia requires the provision of shelter from wet and wind for the first few days of life. Cows can be calved in a shed; alternatively, sheds for calves can be provided in the fields. Beef calves will use shelters in inclement weather; these may not improve their health status, although they are in common use.

PIGLETS

Hypothermia from heat loss and hypothermia/hypoglycemia from starvation are major causes of loss in neonatal pigs. Newborn piglets have a reasonably good ability to increase their metabolic rate in response to cold stress, but they have limited energy reserves, especially limited brown adipose tissue, and they consequently rely on a continual intake of milk for their major energy source, sucking approximately every hour. Young pigs have a good ability for peripheral vasoconstriction at birth, but surface insulation is deficient because at this age there is no subcutaneous layer of fat. The **critical temperature** for young pigs is 34°C (93°F).

Thermoregulation is inefficient during the first 9 days of life and is not fully functional until the 20th day. Newborn piglets must be provided with an external heat source in the first few weeks of life. The body temperature of the sow cannot be relied upon for this, and the preferred air temperature for neonatal pigs is 32°C (89.5°F) during the first day and 30°C (86°F) for the first week. In contrast, the preferred temperature for the sow is about 18°C (64°F). A **separate environment** (creep area) must be provided for the piglets. Provided that there is an adequate ambient temperature to meet the requirements of the piglets and good floor insulation, hypothermia will not occur in healthy piglets of viable size unless there is a failure of milk intake.

Birth anoxia, with resultant reduced vigor, reduced teat-seeking activity, and **risk for hypothermia**, occurs particularly in later-birth-order pigs in large litters from older sows. Failure of milk intake can also occur with small-birth-size piglets and is influenced by litter size, low number of functional teats relative to litter size, and teat-sucking order.

FOALS

There have been few studies on thermoregulation in foals, but the large body mass in relation to surface area renders healthy newborn foals, like healthy calves, relatively resistant to cold. Also, foals are less likely to be born in a hostile environment than are other farm animals. Significant foal mortality from hypothermia as a result of starvation and exposure can occur in extensively managed herds, and dystocia, low birth weight, and poor mothering are contributing factors.

Sick and **premature foals** can have difficulty in maintaining body temperature in normal environments, and the metabolic rates of sick foals and premature foals are approximately 25% lower than those of healthy foals.

The relatively larger ratio of surface area to mass, lower energy reserves, and lower insulation of the coat of premature foals, coupled with the lower metabolic rate, place them at particular risk for hypothermia. **Dystocial foals** also have lower metabolic rates, but dysmature foals appear to thermoregulate normally. Methods of investigation that allow postmortem differentiation of placental insufficiency, acute intrapartum hypoxemia, inadequate thermogenesis, and starvation as causes of mortality in foals are available.

Hypothermia should be suspected in premature foals when the rectal temperature falls below 37.2°C (99°F) and should be corrected with external warmth, rugging, or moving to a heated environment. If fluids are being administered, they should be heated to normal body temperature.

MATERNAL NUTRITION AND THE NEWBORN

There is increasing evidence that the maternal environment for a fetus affects lifelong characteristics of offspring and the subsequent generation of offspring ("grandchildren"). Although the effects of the maternal environment on the development of offspring are complex and involve factors such as maternal nutrition and health during gestation, birth weight of the fetus, sex of the fetus, quality of lactation by the dam, and environmental conditions, there is now solid evidence of epigenetic effects ("programming") in determining the growth and productivity of offspring in domestic species, and reviews are available.[1-4] It is now well understood that factors such as maternal nutrition can have long-lasting effects on an animal's health and productivity and that these effects can be transmitted to progeny separate from changes in the genotype (DNA composition).[2] This phenomenon, recognized in human medicine,[5] is well documented in pigs and cattle[6,7] and has risen to have considerable economic importance as part of the Australian Lifetime Wool project.[8-10] The concept is that early life (including in utero) environmental conditions cause epigenetic changes that can persist for the life of the individual and that can be transmitted to offspring.

Epigenetic changes involve methylation of cytosine in cytosine-guanine dinucleotides and alteration of histones in genetic material such that the accessibility of DNA for transcription is reduced or eliminated. The result is that methylated genes are silenced and not transcribed. Methylation of DNA and histones thereby affects the phenotype of the animal because the changes are transmitted during mitosis to daughter cells. Epigenetic effects can be cell and organ specific and can be transmitted to offspring.

An associated phenomenon important to animal breeding is the concept of imprinted genes. Genomic imprinting is a phenomenon in mammals in which the father and mother contribute different epigenetic patterns to the fetus. A limited number of monoallelic expressed genes exert their effect in a parent-of-origin-specific manner through specific genomic loci in the parents' germ cells. For these genes, expression is restricted to one of the two parentally inherited chromosomes. Imprinted chromosomes are silenced, allowing the other chromosome to be expressed, which is referred to as maternally expressed/paternally imprinted or paternally expressed/maternally imprinted.[1] Although the number of genes that can imprint is limited, many of these genes encode for proteins that regulate a wide variety of biological processes, including embryonic and neonatal growth,

metabolism, and behavior.[1] Understanding of this process has followed observations on abnormalities in animals born as a result of assisted reproductive technologies (including in vitro fertilization and somatic-cell nuclear transfer cloning) that alter methylation of chromosomes in gametes.[1,11] (See "Disorders of Cloned Offspring," page 1870).

Fetal programming describes the lifelong effects of in utero exposure of the fetus to various conditions.[2] Experimental maternal undernutrition during gestation adversely affects intermediate energy metabolism in lambs tested at ~20 weeks of age, evident as lower insulin secretory capacity and greater tissue insulin sensitivity.[12] Some of the effects of in utero exposure to the fetus could have lifelong effects on attributes important for agricultural productivity. This has been demonstrated for sheep in the Lifetime Wool project, in which numerous studies have revealed the importance of providing optimal nutrition and body condition for ewes for both the ewes' productivity and the lifetime productivity of their lambs.[13,14] The body weight profile of Merino ewes determines the fleece weight and fiber diameter of their progeny, with an optimal weight profile of the ewe resulting in higher fleece weight and finer wool in the progeny.[8] It does not appear that nutrition of the ewe affects milk production by her daughter and, therefore, live weight at weaning of the ewe's daughter's progeny.[15]

There is interest in fetal programming and epigenetics for horses, but currently there are no practical implications, although these can be anticipated.[3,4]

Effects on both the dam and the fetus can occur from overfeeding or underfeeding of the dam,[9] and there can be effects from the influences of trace-element deficiencies or toxic substances. Severe **undernutrition** of the dam can affect fetal size and its thermogenic rate, with consequences as described earlier. Prepartum protein restriction has the greatest effect. Severe undernutrition of the dam can also lead to weak labor and increased rates of dystocia and can limit the development of the udder. Colostrogenesis may be impaired, with a greater risk of infectious disease in the neonate, and milk production may be significantly reduced or delayed, with a risk of starvation.

Most information is available for the effects of nutrition of the pregnant ewe on fetal growth rate, udder development, the availability of energy in the body reserves of fetuses at term, and the amount and energy content of colostrum. In sheep, maternal nutrition can have a significant influence on fetal growth rate and placental size.[16] The underfeeding of hill sheep in late pregnancy markedly reduces the term weight of the udder and the prenatal accumulation and subsequent rates of secretion of colostrum. A low plane of nutrition in late pregnancy results in a marked decrease in fetal body-lipid and brown-fat reserves, a marked reduction in the total production of colostrum, and a reduction in the protein concentration in colostrum during the first 18 hours after parturition. However, exposure of late pregnant ewes to cold by shearing increases lamb birth weight and lamb brown-fat reserves.

Inadequate nutrition can also result in in utero growth retardation. Growth retardation can be produced in fetal pigs, lambs, and calves by **maternal caloric undernutrition**. Nutritional restriction in ewes reduces the number of placental lactogen receptors that mediate amino acid transport in fetal liver and glycogen synthesis in fetal tissue, leading to depletion of fetal liver glycogen stores. This has been postulated as a possible cause of the fetal growth retardation that accompanies maternal caloric undernutrition. Runt pigs have a reduced metabolic rate and lower skeletal muscle respiratory enzyme activity. This deficiency persists after birth; runt pigs have a lower core temperature and a lessened ability to increase their metabolic rate and heat production in response to cold. Paradoxically, **overnourishing the adolescent ewe** will also result in placental growth restriction and in utero growth retardation. This effect is most evident in the second third of pregnancy. This syndrome is accompanied by the birth of lambs with a shorter gestational age, commonly reduced by 3 days. It is thought that the fetal hypoxia and hypoglycemia that accompany placental insufficiency might stimulate the maturation of the fetal hypothalamic–pituitary–adrenal axis, initiating early parturition.

Maximum lamb survival is achieved at intermediate lamb birth weights, and the **nutritional management** of the pregnant ewe in fecund flocks is very important. Ewes with multiple lambs can be selected using ultrasound and fed separately from those with singles. Pregnant maiden ewes should also be fed to their separate requirements. The recommendation is for a body-condition score of 3.0 to 3.5 at mating, with a fall of 0.5 in score during the second and third months of pregnancy and a subsequent rise in score to 3.55 to the point of lambing, and with a distinct weight gain in late pregnancy. Equivalent condition scores are also appropriate for other species.

Toxic substances and trace-element deficiencies can result in increased risk for fetal and neonatal mortality and are discussed under those headings. Of particular significance is the agalactia, prolonged gestation, and fetal distress at birth seen in mares fed grain contaminated with ergot (*Claviceps purpurea*) and in mares grazing tall fescue (*Festuca arundinacea*) containing the endophyte fungus *Acremonium coenophialum*.

POOR MOTHER–YOUNG RELATIONSHIP

Any examination of neonatal mortality suspected of being caused by hypothermia, starvation, or infection as a result of failure of transfer of passive immunity, and even trauma by crushing in piglets, must take into account the possibility that poor mothering and a poor mother–young bond could be the primary cause. Inadequate maternal care leads to rapid death of the newborn under extensive conditions where there is no human intervention to correct the problem.[1] The defect is most likely to be on the side of the dam, but it may originate with the offspring, especially in those that are hypothermic.[2] A poor relationship may be genetic or nutritional, and, on the part of the offspring, it may be the result of birth trauma.

For both the dam and the young, there is a much greater chance of establishing a good bond if the animal has been reared in a group rather than as an individual. Because sight, smell, taste, and hearing are all important in the establishment of seeking and posturing to suckle activity by the dam and seeking, nuzzling, and sucking activity by the offspring, any husbandry factor that interferes with the use of these senses predisposes to mortality. Weakness of the offspring as a result of poor nutrition of the dam, harassment at parturition by overzealous attendants, and high growth of pasture are obvious examples. Poor mother–young relationship can be a problem in cattle, pigs, and sheep, and occasionally in horses, especially with extensive foaling practices. In pigs a poor mother–young relationship may be developed to an intense degree in the form of farrowing hysteria, which is dealt with under that heading. In sheep a poor mother–young relationship can be a significant contributor to neonatal death from starvation, especially

Table 19-1 Scoring system for assessing vigorousness of newborn lambs[2]

Score	Description
1	Does not stand for at least 40 min; little or no teat-seeking drive; does not appear alert or active
2	Attempts to stand after 30 min; low teat-seeking drive and tendency to follow ewe; shows some alertness but not very active; does not appear coordinated in attempts
3	Shakes head within 30 s; attempts to stand within 15 min; seeking teat within 10 min of standing; follows ewe but distracted by other moving objects; generally alert and active; coordination may be lacking
4	Attempts to stand within 10 min of birth; seeking teat within 5 min of standing; strong tendency to follow ewe; alert and active and well-coordinated movements
5	Attempts to stand within 5 min of birth; follows ewe closely; very alert and active

Table 19-2 Definitions for lamb behaviors[2]

Behavior	Definition
Shakes head	Lamb raises and shakes head
To knees	Lamb rolls onto chest, gathers legs under it, and pushes front half of the body up off the ground
Attempts to stand	Lamb supports bodyweight on at least one foot
Stands	Lamb stands unsupported on all four feet for > 5 s
Reaches udder	Lamb approaches ewe and nudges her in the udder region
Unsuccessful suck	Lamb places head under ewe in contact with the udder, but either fails to grasp the teat or releases it without sucking
Sucks	Lamb hold teat in its mouth and appears to be sucking with appropriate mouth and head movements, may be tail-wagging, remains in this position for > 5 s

in highly strung breeds such as the Merino, which have a higher mismothering rate than do Romney ewes.[2,3]

Bonding occurs rapidly after birth, although there is some minor variation between species, with bonding starting within a few minutes of birth in sheep but taking up to 2 to 3 hours in some horses, for example. The strength of bonding also appears to vary between species. The bonding of the dam to the neonate is usually quite specific, although this can be modulated by management systems, and the neonate may be less selective and will often attempt to suck other dams. With sheep lambed under intensive lambing practices, this can lead to high rates of mismothering and subsequent abandonment, when preparturient "robber" ewes adopt lambs from multiple births. A high degree of shepherding is required to minimize loss in these management systems, whereas in extensive systems a strong bonding is established if the ewe and lamb are allowed to remain relatively undisturbed on the lambing site for 6 hours. A scoring system is available to allow objective assessment of the vigor of newborn lambs (Tables 19-1 and 19-2).

There is evidence of genetic and parental (sire) effects on the ability of lambs to follow the dam and to avoid mismothering. These effects appear to be modest. [2,4,5]

Vaginal cervical stimulation and the central release of oxytocin are thought to be important in initiating maternal behavior, although caudal epidural anesthesia for delivery does not effect mothering or bonding. Sucking is also a major determinant. Recognition is olfactory and auditory and mediated by the release of neurotransmitters.

Bonding is often slower with primiparous dams and is also delayed where there is postpartum pain. A failure of bonding leads to rejection and abandonment of the neonate.

Maternal care is also important to neonatal survival, and there is significant difference in litter mortality from crushing and injury among sows related to sow behavior and their response to piglet distress calls. A description of normal and abnormal behavioral patterns of the mare and foal is available, and techniques for fostering have been described.

TEETH CLIPPING OF PIGLETS

It is necessary to shorten the needle teeth of the upper and lower jaw of the newborn pig using a clean pair of sharp nail clippers or a grinding wheel. It is essential to practice good hygiene or infection of tooth roots can occur, leading to local inflammation and infection with the possibility of abscessation associated with *Fusobacterium* and *Trueperella*. It is not done before 6 hours of age because it will interfere with the absorption of colostrum. It is done to prevent damage to the sow's teats or to other piglets before 7 days after birth. Damage to the sow's teats will cause pain and reluctance to allow suckling. Damage to other piglets may interfere with the establishment of the "pecking order" in the litter.

Failure of Transfer of Passive Immunity (Failure of Transfer of Colostral Immunoglobulin)

The acquisition and absorption of adequate amounts of colostral immunoglobulins is essential to the health of ruminant, porcine, and equine neonates because they are born virtually devoid of circulating immunoglobulin. **Failure of passive transfer** (FPT) has been a commonly used term to describe the transfer of passive immunity (immunoglobulins, specifically IgG1 in colostrum) from the dam to the neonate. The process by which colostral immunoglobulin is absorbed is far from passive; it is an active and focused activity. Accordingly, FPT provides an incorrect summary of this process, and **failure of transfer of passive immunity** (**FTPI**) provides a more accurate descriptive term. Adequate antibody transfer is the cornerstone of all neonatal preventive health programs, but FTPI remains an important problem particularly affecting the dairy industry. Educational campaigns targeting dairy producers have been launched in the past decades, and, encouragingly, the prevalence of FTPI in dairy heifers in the United States decreased from over 40% in 1992 to 19% in 2007.[1]

Much of the description that follows refers to the calf because more studies on transfer of passive immunity have been conducted in calves. However, most of the information is applicable to the other species; where there are differences, these are mentioned.

NORMAL TRANSFER OF IMMUNOGLOBULINS

Immunoglobulins in colostrum are present in different concentrations. The major immunoglobulin in colostrum is IgG. IgG consists of two fractions, IgG_1 and IgG_2, which contribute 80% and 5% to 10%,

respectively, to the total colostral immunoglobulin concentration. IgM and IgA each account for approximately 5% of the colostral immunoglobulin content. IgG is concentrated in colostrum by an **active, selective, receptor-mediated transfer** from the blood of the dam across the mammary secretory epithelium. This transfer to colostrum begins approximately 4 to 6 weeks before parturition and results in colostral IgG concentrations in first milking colostrum that are several-fold higher than maternal serum concentrations. This active IgG transfer ceases suddenly at the onset of lactation, presumably in response to increased prolactin secretion around parturition.[2] IgA and IgM are largely derived from local synthesis by the mammary gland rather transfer from plasma.

Following ingestion by the newborn, a significant proportion of these immunoglobulins is transferred across the epithelial cells of the small intestine during the first few hours of life and transported via the lymphatic system to the blood. Immunoglobulins in blood are further varyingly distributed to extravascular fluids and to body secretions depending on the immunoglobulin class.

These absorbed immunoglobulins protect against systemic invasion by microorganisms and septicemic disease during the neonatal period. Unabsorbed immunoglobulins and immunoglobulins resecreted into the gut play an important role in protection against intestinal disease for several weeks following birth. FTPI has unequivocally been associated with increased morbidity and mortality and reduced growth rates of neonates. Adequate immunoglobulin supply at birth is associated with higher first- and second-lactation milk production and decreased risk of culling during the first lactation.[5]

In foals, FTPI presents a significant risk for the development of illness during the first 3 months of life.

Lactogenic Immunity

The IgG concentration in milk falls rapidly following parturition in all species, and immunoglobulin concentrations in milk are low (Table 19-3). In the sow, the concentration of IgA falls only slightly during the same period, and it becomes a major immunoglobulin of sows' milk. IgA is synthesized by the mammary gland of the sow throughout lactation and serves as an important defense mechanism against enteric disease in the nursing piglet. IgA in milk is an important mucosal defense mechanism in piglets, whereas in the calf there is little IgA in milk, but some enteric protection is provided by colostral and milk IgG and IgG derived from serum that is resecreted into the intestine.

FAILURE OF TRANSFER OF PASSIVE IMMUNITY

FTPI is the major determinant of septicemic disease in most species. It also modulates the occurrence of mortality and severity of enteric and respiratory disease in early life and performance at later ages.

In terms of the modulation of disease, there can be no set cut-point for circulating immunoglobulins because this cut-point will vary according to the farm, its environment, infection pressure, and the type of disease. Values are given as guidelines. **FTPI in calves** has been defined as a **serum IgG concentration below 1000 mg/dL (10 mg/mL)** when measured between 24 hours and 7 days of age. With **foals**, the equivalent IgG cutoff concentrations **for FTPI** and **partial FTPI are given as 400 mg/dL** and **800 mg/dL**, respectively. Although a serum IgG concentration above 400 mg/dL might be adequate for healthy foals kept in a clean environment with minimal pathogen exposure, a concentration above 800 mg/dL is considered optimal.[6] For **New World camelid crias,** a cut-point value for the serum IgG concentration **of 1000 mg/dL** measured at around 36 hours of life has been recommended.[7]

Rates of FTPI in dairy calves can vary widely between farms, but they were estimated to be in the range of 20% in a recent nationwide survey conducted in the United States.[1] In beef calves FTPI rates tend to be lower; a recent Canadian study reported the incidence of FTPI, defined as serum IgG concentrations below 800 mg/dL, of 6% and a rate of marginal transfer of passive immunity (800 mg/dL < IgG < 1600 mg/dL) of 10%.[8] Failure rates in foals reported in the literature are approximate 13% to 16%. Rates in lambs are also comparatively low, and the incidence of FTPI in crias has been estimated to be around 10%.[7]

In animals that are **fed colostrum artificially**, risk for FTPI is primarily dependent on the amount or mass of immunoglobulin present in a feeding of colostrum, the time after birth that this is fed, the efficiency of its absorption from the digestive tract, and possibly also the degree of bacterial contamination.[1] The mass of immunoglobulins fed is determined by the concentration of immunoglobulin in the colostrum and the volume that is fed. Feeding trials with calves suggest that a **mass of at least 150 g** of IgG is required in colostrum fed to a 45-kg calf to obtain adequate (≥1000 mg/dL IgG) colostral immunoglobulin concentrations in serum.

In animals that **suck colostrum naturally**, such as foals, risk for FTPI is primarily dependent on the concentration of immunoglobulin in the colostrum, the amount that is ingested, and the time of first suckling. Inadequate colostral immunoglobulin concentration and delay in ingestion of colostrum are the two important factors in FTPI in foals.

DETERMINANTS OF TRANSFER OF COLOSTRAL IMMUNOGLOBULINS

1. Amount of immunoglobulin in colostrum fed:
   a. *Volume* of colostrum fed
   b. *Concentration* of immunoglobulins in colostrum
2. Amount of colostrum actually suckled or fed
3. Rate of abomasal or gastric emptying after colostrum ingestion
4. Efficiency of absorption of immunoglobulins by neonate
5. Time after birth of suckling or feeding
6. Time of collection of colostrum after calving (with artificial colostrum feeding)
7. Degree of bacterial contamination of colostrum

Table 19-3 Failure of transfer of passive immunity;[1] concentrations and relative percentage of immunoglobulins in serum and mammary secretions of cattle and pigs

		CONCENTRATION (mg/ml)			TOTAL IMMUNOGLOBULIN (%)		
Animal	Immunoglobulin	Serum	Colostrum	Milk	Serum	Colostrum	Milk
Cow	IgG_1	11.0	75.0	0.59	50	81	73
	IgG_2	7.9	2.9	0.02	36	5	2.5
	IgM	2.6	4.9	0.05	12	7	6.5
	IgA	0.5	4.4	0.14	2	7	18
Sow	IgG	21.5	58.7	3.0	89	80	29
	IgM	1.1	3.2	0.3	4	6	1
	IgA	1.8	10.7	7.7	7	14	70

Determinants of Immunoglobulin Concentration in Colostrum

Nominal concentrations of immunoglobulin in the first milking colostrum of cows and sows are shown in Table 19-4.[1] Current conventional wisdom posits that **high-quality bovine colostrum** should contain **at least 50 g/L IgG**,[2] and that 3 L of high-quality colostrum should be fed as soon as possible after birth.[3,4] This strategy will provide the needed 150 g of colostral IgG. There can be substantial variation in the concentration of immunoglobulin in colostrum in all species, and the ingestion of a "normal" amount of colostrum that has low immunoglobulin concentration may provide an insufficient amount of immunoglobulin for protection. In a study of over 900 first-milkings colostrum from Holstein Friesian cows, only 29% of the colostrum samples contained a sufficiently high concentration of immunoglobulin to provide 100 g IgG in a 2-L volume. The equivalent percentages for 3- and 4-L volume feedings were 71% and 87%, respectively.

It is apparent that variation in colostral immunoglobulin concentration can be a cause of FTPI. Some causes of this variation are the following:

- The concentrations of immunoglobulin in colostrum fall dramatically after parturition. The concentrations in second-milking colostrum are approximately half those in the first milking, and by the fifth postcalving milking, concentrations approach those found during the remainder of lactation. A similar situation exists with **horses**. The mean concentrations of IgG in colostrum of mares 3 to 28 days before foaling is greater than 1000 mg IgG/dL, whereas at parturition the mean concentrations may vary from 4000 to 9000 mg/dL. The concentrations decrease markedly to 1000 mg/dL in 8 to 19 hours after parturition.
- The immunoglobulin concentration of colostrum decreases after calving even when the cow is not milked. It is important that this colostrum be **milked as soon as possible after parturition.** Colostrum that is collected 6 hours or later after calving has a significantly lower concentration than that collected 2 hours after calving. In a study documenting the effect of time since parturition on colostral IgG concentration, it was observed that colostral IgG concentration decreased by 3.7% during each subsequent hour after calving because of postparturient secretion of IgG-poor milk by the mammary glands.
- Colostrum from cows or mares that have been **premilked** to reduce udder edema or from dams that **leaked colostrum** before parturition have low immunoglobulin concentrations, and alternate colostrum should be fed for immunoglobulin transfer.
- In cattle, **dry periods** of less than 30 days may result in colostrum of lower immunoglobulin concentration.
- **Premature foaling** or the **induction of premature parturition** using long-acting corticosteroids in cattle can result in colostrum with low immunoglobulin concentration and/or low volume.
- In cattle, average colostral immunoglobulin concentrations are higher in cows in third or higher **lactation groups** compared with younger cows. However, colostrum from all lactation numbers can produce adequate immunoglobulin mass. There is no scientific basis for not feeding first-milking colostrum from first-lactation cows.
- Larger-volume first-milking colostrum tends to have lower immunoglobulin concentrations than smaller-volume colostrum, presumably as a result of dilution.
- Immunoglobulin concentrations were found to be higher in the early temporal fractions of a single milking of first-milking colostrum. This might suggest that segregation of the first portion of the first-milking colostrum could provide colostrum with higher immunoglobulin concentration for feeding.
- There are **breed differences** in the concentration of immunoglobulins in first-milking colostrum. In **cattle**, beef breeds have higher concentrations. Many dairy breeds, including Holstein Friesian, produce colostrum of relatively low immunoglobulin concentration, and a significant proportion of calves that suckle cows of these breeds ingest an inadequate mass of immunoglobulin. Channel Island breeds have a greater concentration of immunoglobulin in colostrum that Holstein Friesians. **Breed differences** are also seen in **horses**, with Arabian mares having higher colostral immunoglobulin concentrations than Standardbreds, which in turn are higher than those of Thoroughbreds. Breed differences also occur in **sheep**, with higher concentrations in meat and wool breeds than dairy breeds.
- Heat **stress** to cattle in the latter part of pregnancy results in lower colostral immunoglobulin concentrations.
- Colostral volume but not colostral immunoglobulin concentration is reduced in mastitic quarters, and it is unlikely that mastitis is a major determinant of the high rate of FTPI in dairy calves. Colostrum from cows with clinical mastitis should nonetheless not be fed because it may contain pathogens in large amounts and has unphysiologic composition.
- The **pooling of colostrum** in theory could avoid the variation in immunoglobulin concentration of individually fed colostrum and could provide a colostrum that reflects the antigenic experience of several cattle. In practice, colostrum pools from Holsteins invariably have low immunoglobulin concentrations because high-volume, low-concentration colostrum dilutes the concentration of the other samples in the pool. If pools are used, the diluting influence of low-immunoglobulin-concentration, high-volume colostrum should be limited by restricting any individual cow's contribution to the pool to 9 kg (20 lb) or less. However, pooling increases the risk of disease transmission because multiple cows are represented in a pool and the pool is fed to multiple calves. This can be important in the control of Johne's disease, bovine leukosis, *Mycoplasma bovis*, *E. coli*, and *Salmonella* spp.
- **Bacterial contamination** of colostrum can have a negative effect on transfer of passive immunity. The current recommendation is that fresh colostrum should contain less than 100,000 cfu/mL total bacteria count and less than 10,000 cfu total coliform count.[2] One study found that 85% of colostrums sampled from 40 farms in the United States exceeded this threshold. Colostrum that is to be fed or stored should be collected with appropriate preparation and sanitation of the cow and of the milking equipment used on fresh cows.
- **Pasteurization of colostrum** either at 63° C (145° F) for 30 min or 72° C (162° F) for 15 s was shown to reduce colostrum IgG concentration by at least 30% and to thicken or congeal the colostrum. In contrast, **pasteurization at 60° C (140° F) for 60 min** was found to affect neither colostral IgG concentration nor fluid characteristics while eliminating or at least significantly decreasing the content of major pathogens, including *Mycobacterium avium subps. paratuberculosis*, *M. bovis*, *E. coli*, and *Salmonella* spp.
- **Old mares** (older than 15 years) may have poor colostral immunoglobulin concentration.

Volume of Colostrum Ingested

Dairy Cows

The volume of colostrum that is fed has a direct influence on the mass of immunoglobulin ingested at first feeding. The average volume of colostrum ingested by nursing Holstein Friesian calves in the first 24 hours of life is reported as 2.4 L, but there is wide variation around this mean. In **natural suckling** situations, calves may fail to ingest

adequate colostrum volumes before onset of the closure process and therefore absorb insufficient colostral immunoglobulin. Early assisted suckling may help avoid this. In dairy calves the volume of colostrum that is ingested can be controlled in **artificial feeding systems** using nipple bottle feeders or esophageal tube feeders. **Bucket feeding** of colostrum is not recommended because training to feed from a bucket can be associated with erratic intakes.

The **traditional recommendation** for the volume of colostrum to feed at first feeding to calves is 2 L (2 quarts). However, only a small proportion of first-milking colostrum from Holsteins contains a sufficiently high concentration of immunoglobulin to provide 100 g IgG in a 2-L volume, and higher volumes of colostrum are required to achieve this mass intake. Some calves fed with a **nipple bottle** will drink volumes greater than 2 L, but others will refuse to ingest even 2 L of colostrum in a reasonable period of time, and calf rearers may lack the time or patience to persist with nipple bottle feeding until the required volume has been ingested by all calves.

Larger volumes of colostrum can be fed by an **esophageal feeder,** and single feedings of large volumes of colostrum (3.5 to 4.0 L per 45 kg of body weight) result in the lowest percentage of calves with FTPI by allowing calves fed colostrum with relatively low immunoglobulin concentrations to receive an adequate immunoglobulin mass before closure. Feeding this volume by an esophageal feeder causes no apparent discomfort to a minimally restrained calf and was not found to negatively affect intestinal IgG absorption compared with voluntary intake of the same (large) volume.[10] There is nonetheless some debate around the recommendation to systematically tube feed neonatal calves because of animal welfare concerns. In several European countries animal welfare legislation prohibits force-feeding of animals without medical indication.[20]

Beef Cows

With beef breeds very effective colostral immunoglobulin transfer is achieved with natural sucking. This is thought to be a result of the greater vigor at birth exhibited by these calves and the higher immunoglobulin concentrations in beef colostrum, requiring a smaller volume intake to acquire an adequate mass. **Natural sucking** will give an adequate volume intake, and there is no need to artificially feed colostrum unless the dam is observed to refuse nursing or the calf's viability and sucking drive are compromised. The **yield of colostrum** and colostral immunoglobulins in beef cows can vary widely, and range beef heifers may produce critically low volumes of colostrum. Differences in yield can be attributed to breed or to nutritional status, although undernutrition is not an effect unless it is very severe.

Ewes

Colostrum yield is high in ewes in good condition at lambing, but it may be low in ewes with condition scores of 1.5 to 2.0.

Sows

In sows there is also very effective colostral immunoglobulin transfer with natural sucking, and piglets average an intake of 5% to 7% of body weight in the first hour of life. There is between-sow variation in the amount of colostrum, and there can be a large variation in colostrum supply from teat to teat, which may explain variable health and performance. During farrowing and for a short period following, colostrum is available freely from the udder, but thereafter it is released in ejections during mass suckling. A strong coordinated sucking stimulus is required by the piglet for maximum release of colostrum, and this requires that the ambient temperature and other environmental factors be conducive to the optimum vigor of the piglets. Small-birth-weight piglets, **late-birth-order** piglets, and piglets sucking posterior teats obtain less colostrum.

All Species

In all species a low-volume intake may also occur because of the following factors:

- Poor **mothering behavior**, which may prevent the newborn from sucking; occurrence of disease; or milk fever
- Poor **udder and/or teat conformation** so that the newborn cannot suck normally or teat seeking is more prolonged. Udder-to-floor distance is most critical, and low-slung udders can account for significant delays in intake. Bottle-shaped teats (35-mm diameter) also significantly reduce intake.
- Delayed and **inadequate colostral intake** frequently accompanies perinatal asphyxia or acidemia because of the greatly decreased vigor of the calf in the first few hours of life. Perinatal asphyxia can occur in any breed and is greatly increased by matings resulting in fetal–maternal disproportion and dystocia.
- The newborn may be weak, traumatized, or unable to suck for other reasons; a **weak sucking drive** can be a result of congenital iodine deficiency, cold stress, or other factors.
- Disease of the periparturient dam, such as clinical hypocalcemia in cattle or the mastitis metritis agalactia complex in sows, may preclude adequate colostrum intake by offspring.
- Failure to allow newborn animals to ingest colostrum may occur under some management systems.

Efficiency of Absorption

After ingestion of colostrum by the newborn, colostral immunoglobulins are absorbed from the small intestine, by a process of pinocytosis, into the columnar cells of the epithelium. In the newborn calf this is a very rapid process, and immunoglobulin can be detected in the thoracic duct lymph within 80 to 120 minutes of its being introduced into the duodenum. The **period of absorption** varies between species and with immunoglobulin class. The mechanism by which absorption ceases is not well understood, but it may be related to replacement of the fetal enterocyte. The region of maximum absorption is in the lower small intestine, and peak serum concentrations are reached by 12 to 24 hours in all species. Absorption is not limited to immunoglobulin, and **proteinuria** during the first 24 hours of life is associated with the renal excretion of low-molecular-weight proteins such as β-lactoglobulin.

Feeding Methods, "Closure of the Gut," and Immunoglobulin Absorption

Under normal conditions complete loss of the ability to absorb immunoglobulin (closure of the gut) occurs by 24 to 36 hours after birth in all species, and there is a significant reduction in absorptive ability (as much as 50% in some studies but minimal in others) by 8 to 12 hours following birth. The **time from birth to feeding** is a crucial factor affecting the absorption of colostral immunoglobulin in all species, and any delay beyond the first few hours of life, particularly after 8 hours, significantly reduces the amount of immunoglobulin absorbed.

The recommendation is that all neonates should be fed colostrum within the first 2 hours of life.

Natural Sucking

Natural sucking is the desired method of intake of colostrum and is the most efficient, but it is influenced by the sucking drive and **vigor** of the neonate at birth. Newborns that suck colostrum can achieve very high concentrations of colostral immunoglobulin, and the efficiency of absorption is best with this feeding method. However, in dairy calves natural sucking is commonly associated with a high rate of FTPI because of **delays in sucking** coupled with low intake. Rates of FTPI in calves allowed to obtain colostrum via voluntary nursing reported in the literature can be as high as 40% to 60%.[1] Many factors influence the occurrence of delayed sucking, but calf vigor and birth-related asphyxia are the most important. Parity of the dam, conformation of the udder, and breed were also found to be significantly associated with the rate of FTPI. One older study reported that 46% of all calves born to multiparous cows had failed to nurse within 6 hours of birth compared with 11% of calves of primiparous cows.[11] Jersey calves have better rates of successful transfer of passive immunity with natural sucking than do Holsteins Friesians.

Artificial Feeding

In contrast, when calves are **fed colostrum artificially**, minimal delays from birth to the time of colostrum feeding occur, and maximal colostrum immunoglobulin absorption results. In breeds such as Holstein Friesians, where colostral immunoglobulin concentrations tend to be low and maximal efficiency of absorption is necessary, the logical way to minimize risk of FTPI is to feed the maximum volume of colostrum that is well tolerated within the first few hours of life. The published literature consistently reports higher calf serum IgG concentrations and a lower rate of FTPI in response to larger colostrum feeding volumes.[2,10,12]

Other Influences

Even with the best available on-farm colostrum-selection methods, **large colostrum-feeding volumes are essential** to minimize the risk of FTPI in breeds with relatively low colostral immunoglobulin concentrations. The method is particularly advantageous where time constraints of other farm activities limit the time available for calf feeding. The major detrimental influence on absorptive efficiency of immunoglobulin is **delayed feeding after birth**. Other factors that may affect absorptive efficiency include the following:

- **Perinatal asphyxia or acidemia** may have both direct and indirect effects on colostral immunoglobulin transfer. Asphyxia has a major effect on subsequent sucking drive, and acidemic calves ingest far less colostrum than calves with more normal acid–base status at birth. In carefully controlled colostrum feeding studies, a significant negative correlation between the degree of hypercapnia and the efficiency of absorption of colostral immunoglobulin in the first hours of life was demonstrated. However, this effect was only transient because there was no difference in serum IgG concentration at the time of gut closure between normoxic and hypoxic calves.
- In one early study, a **mothering effect** was reported in which calves remaining with their dams absorbed colostral immunoglobulin more efficiently than calves removed immediately to individual pens. However, other studies have shown much smaller or no effects of mothering using similar experimental designs. The different results of these studies have not been reconciled.
- There can be **seasonal** and **geographic** variations in transfer of immunoglobulin in calves, although these are not always present on farms in the same area, and their cause is unknown. Where seasonal variation occurs in temperate climates, the mean monthly serum IgG concentrations are lowest in the winter and increase during the spring and early summer to reach their peak in September, after which they decrease. The cause is not known, but a decrease in sucking drive is observed in colder months and may contribute. In subtropical climates, peak levels occur in the winter months, and low levels are associated with elevated temperatures during the summer months. **Heat stress** in late pregnancy will reduce colostral immunoglobulin concentration, but high ambient temperature is a strong depressant of absorption, and the provision of shade will help to obviate the problem.
- The efficiency of absorption may be decreased in **premature calves** that are born following induced parturition using long-acting corticosteroids; in contrast, medical **induction of parturition** with short-acting corticosteroids in cattle does not interfere with the efficiency of absorption of immunoglobulins in calves.
- The absorption of small volumes (1 to 2 L) fed by an esophageal feeder is usually suboptimal and inferior to the absorption after sucking the same small volume.[10] This effect may at least in part be attributable to retention of some colostrum in the immature forestomaches for several hours. The calf will feel satiated and not inclined to suck naturally for the next few hours.
- A **trypsin inhibitor** in colostrum may serve to protect colostral IgG from intestinal degradation. It varies in concentration between colostrums. The addition of a trypsin inhibitor to colostrum improves immunoglobulin absorption.
- In a study of **mare-associated determinants of FTPI** in foals (based on serum Ig measurements), there was a trend to increase rates of FTPI in foals from mares aged over 12 years, but no significant association with age, parity, or gestational age of foals over 325 days was found. There was an association with season, with a lower incidence in the late spring compared with foals born earlier in the year and with a foal score based on a veterinary score of foal health and "fitness."

Traditionally it has been considered that the **movement** of animals, either the dam just **before parturition** or the newborn animal during the first few days of life, is a special hazard for the health of the calf. The postulated reason is that the dam may not have been exposed to pathogens present in the new environment and thus not have circulating antibodies against these pathogens. The newborn animal may be in the same position with regard to both deficiency of antibodies and exposure to new infections. Although this may be the case in some situations, the developing practice of contract-rearing of dairy heifers away from the farm to be brought back as close-up springers and the practice of purchase of close-up heifers on the farm are not associated with appreciable increase in mortality in their calves.

Decline of Passive Immunity

Colostral antibody concentrations in blood fall quickly after birth and have usually disappeared by 6 months of age. In the **foal**, they have fallen to less than 50% of peak level by 1 month of age and to a minimum level between 30 and 60 days. This is the point at which naturally immunodeficient foals are highly susceptible to fatal infection.

In **calves**, the level of IgG declines slowly and reaches minimum values by 60 days, in contrast to IgM and IgA, which decline more rapidly and reach minimum values by approximately 21 days of age. The half-lives for IgG, IgM, and IgA in calves are approximately 20, 4, and 2 days, respectively, and the half-lives of IgGa, IgGb, IgG(T), and IgA in foals are approximately 18, 32, 21, and 3.5 days, respectively.

Immunologic competence is present at birth, but endogenous antibody production does not usually reach protective levels until 1 month, and maximum levels are not reached until 2 to 3 months of age. The endogenous production of intestinal IgA in the piglet begins at about 2 weeks of age and does not reach significant levels until 5 weeks of age.

Foals that acquire low concentrations of immunoglobulins from colostrum may experience a transitory hypogammaglobulinemia at several weeks of age as the levels fall and before autogenous antibodies develop. They are, as expected, more subject to infection than normal.

OTHER BENEFITS OF COLOSTRUM

In addition to its immunoglobulin content, colostrum contains considerably more protein, fat, vitamins, and minerals than milk and is especially important in the transfer of fat-soluble vitamins. It has **anabolic effects,** and lambs that ingest colostrum have a higher summit metabolism than colostrum-deprived lambs. Colostrum also contains growth-promoting factors that stimulate DNA synthesis and cell division, including high concentrations of insulin-like growth factor (IGF)-1.

Colostrum contains approximately 1×10^6 leukocytes/mL, and several hundred million are ingested with the first feeding of colostrum. In calves, 20% to 30% of these are lymphocytes and cross the intestine into the circulation of the calf. It is postulated that they have importance in the development of neonatal resistance to disease, but there is little tangible evidence. Calves fed colostrum depleted of leukocytes are thought to be more poorly protected against neonatal disease than those fed normal colostrum.

ASSESSMENT OF TRANSFER OF PASSIVE IMMUNITY

Because of the importance of transfer of colostral antibodies to the health of the neonate, it is common to quantitatively estimate the levels of immunoglobulins, or their surrogates, in colostrum and in serum to predict risk of disease and to take preventive measures in the individual or to make corrective management changes where groups of animals are at risk.

Assessment in the Individual Animal

When samples are taken from an individual animal to determine the risk for infection, sampling is undertaken early so that replacement therapy can be given promptly if there has been inadequate transfer. IgG is detectable in serum 2 hours following a colostrum feeding and **sampling at 8 to 12 hours** after birth will give a good indication of whether early sucking has occurred and has been effective in transfer. This type of monitoring is commonly performed in foals and camelid crias.[7,13] There are a number of different tests that can be used; some are quantitative and others semiquantitative. In calves, sampling may be undertaken for similar reasons, but the cost of replacement therapy is limiting.

Assessment Tests on Serum

Sampling to **monitor** the efficacy of a farm policy for feeding and handling colostrum, to evaluate the passive immunity status in **calves to be purchased,** or to determine the **rates of FTPI** in investigations of neonatal disease can be conducted at any time in the first week of life after 24 hours with most tests. Numerous tests are currently available, some of which directly measure serum IgG concentration and some of which estimate the IgG concentration based on the serum concentration of the total globulin or other protein fractions.

Radial Immunodiffusion

The radial immunodiffusion (RID) is based on the precipitation of antigen and antibody to an insoluble precipitin complex and thus directly measures IgG concentration in serum or plasma. The RID is considered the reference method to measure serum/plasma IgG, but it takes at least 24 h to perform and thus longer than is desirable for most clinical purposes. In a recent study two commercial RID test kits for calves were compared, and a large bias and wide limits of agreements between the two tests were found, which has raised questions about the reliability of the results.[21]

Lateral-Flow Immunoassay

The lateral-flow immunoassay is a calf-side test directly measuring IgG in serum or plasma with reportedly high sensitivity and specificity. Although the test can be performed on-site and results are available within 20 min, it only provides a pass/fail result using a cutoff value of 10 mg/mL.[2]

Turbidimetric Immunoassay

The turbidimetric immunoassay (TIM) is commercially available and can be run on a handheld chemistry analyzer to be used with bovine serum. In a preliminary study conducted at the University of Minnesota, the test was found to be more accurate than indirect tests such as serum refractometry.

Zinc Sulfate Turbidity Test

The zinc sulfate turbidity test is based on a selective precipitation reaction of the salt with high molecular weight proteins such as immunoglobulin (not specifically IgG). The test is commonly used with a test solution containing 200 mg/L zinc sulfate but was found to have poor specificity and would only classify 69% of tested calves correctly. Increasing the zinc sulfate concentration from 200 to 350 mg/L considerably improved the specificity and positive predictive values of the test, but this test modification is not widely used.[15] Another inconvenience is that hemolyzed blood samples will give artificially high readings, and the reagent must be kept free of dissolved carbon dioxide.

Sodium Sulfite Precipitation Test

The sodium sulfite precipitation test is based on the selective precipitation of high-molecular-weight proteins with sodium sulfate at different concentrations. Test solutions of 14%, 16%, and 18% sodium sulfite are commonly used, and the development of turbidity at a certain concentration allows for a crude estimate of the serum immunoglobulin concentration; the lower the concentration at which turbidity occurs, the higher is the concentration of immunoglobulin. Particularly the use of the 14% and 16% sodium sulfite solutions was found to result in an unacceptably high percentage of calves being misclassified as FTPI while having adequate serum immunoglobulin concentrations.[15]

Serum γ-Glutamyltransferase Activity

Serum γ-glutamyltransferase (GGT) activity has been used as a surrogate for determining the efficacy of transfer of passive immunity in calves and lambs (not in foals). GGT activity is high in the colostrum of ruminants (but not horses), and serum GGT activity in calves and lambs that have sucked or been fed colostrum is 60 to 160 times greater than normal adult serum activity and correlates moderately well with serum IgG concentrations. The half-life of GGT from colostrum is short, and serum GGT activity falls significantly in the first week of life. Serum GGT values equivalent to a serum IgG concentration of 10 mg/mL are 200 IU/L on day 1 of life and 100 IU/L on day 4. Serum GGT concentrations less than 50 IU/L indicate FTPI.

Serum Total Protein

Measuring total protein concentrations in serum or plasma with a refractometer is a practical, rapid, and inexpensive method to estimate the immunoglobulin concentration by extrapolating it from the total protein concentration. Despite the indirect nature of the test, there is a reliable correlation between the refractometer reading and total immunoglobulin concentration measured by RID. In healthy calves a serum total protein of 5.5 g/dL or greater is associated with adequate transfer of passive immunity.

Serum total protein has a good predictive value for fate of the newborn, and the facile and practical nature of the test and its predictive ability commend it for survey studies in calves and lambs but not foals. Cut-points will vary with the environment and the infection pressure to the calves. The sensitivity of the test is maximal using a cut-point of 5.5 g/dL, and the specificity is maximal at a cut-point of 5.0 g/dL. Because serum total protein concentration measured by refractometry can result in an incidental misclassification of an individual calf, this test is primarily recommended as a screening tool to assess the colostrum management on a herd level, but not as diagnostic tool for an individual animal. Herd screening could be conducted by testing a minimum of 12 calves on a farm between 24 hours and 7 days old. At least 80% of tested calves should have serum protein concentrations above 5.5 g/dL to consider the colostrum management satisfactory at the herd level.

Serum total protein concentration can also be estimated using the same Brix refractometer used for measuring colostral IgG concentration, with an appropriate adjustment factor.[14]

Glutaraldehyde Coagulation Test

The glutaraldehyde test was initially introduced to identify hypergammaglobulinemia in adult cattle with chronic inflammatory disease. The semiquantitative test is based on a clotting reaction of glutaraldehyde in the presence of high immunoglobulin concentration, where the time to clot formation is negatively correlated with the serum IgG.[16] A modified glutaraldehyde coagulation test is also available for the detection of hypogammaglobulinemia in neonatal calves, but it is less accurate.[15] The test may yield false-positive results with hemolysis and is difficult to quantitate.

Latex Agglutination Test

A commercial latex agglutination test is available for horses. It is rapid and provides semiquantitative results, but results were reported to be inconsistent.

ELISA Snap-Test

ELISA snap-tests are foal-side immunologic tests directly measuring IgG in a

semiquantitative manner. Test kits are commercially available for foals and have been available for calves. In foals the available snap-tests were found to be rapid and accurate.

Monitoring Colostrum

Brix Refractometry

The most accurate and practical way to ensure that an adequate colostral mass is fed is to test the colostrum using a Brix refractometer (the digital version is preferred). This instrument was designed for use in food processing but was adapted in the late 1970s to provide a low-cost test of colostrum quality. A Brix refractometer value of 21% or 22% or higher indicates acceptable colostrum (same value for fresh or frozen samples; approximately equivalent to a colostral IgG concentration of 50 g/L); colostrum with a value below 21% or 22% should be discarded.[17,18]

Specific Gravity

Specific gravity, determined by refractometry, can be used as a measure of the immunoglobulin content of colostrum. In **mares** the concentration of immunoglobulin in colostrum is highly correlated with the specific gravity of the colostrum, which in turn is highly correlated with the serum immunoglobulin levels achieved in foals. Temperature-corrected measurements are most accurate. Measurement of colostrum specific gravity provides a rapid and easy method of identifying foals likely to be at a high risk for FTPI and the need to provide them with colostrum of a higher Ig content. To prevent FTPI, it is recommended that the colostral specific gravity should be equal to or greater than 1.060, and the colostral IgG concentration should be a minimum of 3000 mg/dL.

In **cattle** the relation of specific gravity of colostrum to colostral immunoglobulin concentration is linear but is better in Holstein Friesian than in Jersey cows. The measurement is simple, but there is a correction for temperature, and air trapped in colostrum taken by a milking machine can give a false reading if the measurement is taken too quickly after milking. The cut-point recommended to distinguish moderate from excellent colostrum has been set at 1.050, approximating an IgG concentration of 50 g/L, and is based on the amount of immunoglobulin required for a 2-L (2-quart) feeding. Specific gravity is not a perfect surrogate for immunoglobulin concentration with cattle colostrum. It has good negative prediction, but it will falsely pass 2 out of 3 colostrums that have unacceptably low immunoglobulin concentrations. An analysis of first-milking colostrum in midwestern U.S. dairies found that specific gravity differed among breeds and was influenced by month of calving, year of calving, lactation number, and protein yield in previous lactation and that it was more closely associated with colostrum protein concentration ($r = 0.76$) than IgG_1 concentration ($r = 0.53$).

Glutaraldehyde Test

This test for mare colostrum is available commercially and is reported to have a high predictive value for colostrums that contain more than 38 mg/mL of IgG and have a specific gravity greater than 1.060.

ELISA

Recently a cow-side immunoassay kit has become available commercially in the United States. The kit provides a positive or a negative response, with the cut-point being a concentration of 50g/L of IgG in colostrum, and has accuracy sufficient to recommend its use for rejection of colostrums with low immunoglobulin concentration.

CORRECTION OF FAILURE OF TRANSFER OF PASSIVE IMMUNITY

Oral Therapy

Oral therapy can be considered in individual animals (generally foals and crias), provided that FTPI—or the risk thereof—is diagnosed and the treatment is administered before gut closure (i.e., not later than 18 h of life). For foals, oral administration of at least 0.5 L frozen equine colostrum of good quality (specific gravity > 1.060) that has been properly stored and thawed is recommended. Alternatives include colostrum substitutes containing lyophilized IgG or good-quality bovine colostrum. The latter option is probably the least effective and requires at least 4 L of good-quality (specific gravity >1.050) colostrum.

Parenteral Immunoglobulins

Blood transfusion is commonly used in food animal practice, and the method is described elsewhere in this text. Fresh plasma from a random donor or purified hyperimmune plasma that is commercially available for foals and crias in some countries are alternatives. Large amounts are required to obtain the required high serum concentrations of immunoglobulins, and intravenous infusion can be accompanied by transfusion-type reactions.

AVOIDANCE OF FAILURE OF TRANSFER OF PASSIVE IMMUNITY

With all species, with the exception of dairy calves, the common practice is to allow the newborn to suck naturally. The policy for avoidance of FTPI with naturally sucking herds should be to provide supplemental colostrum by artificial feeding of those neonates with a high risk for FTPI, based on the risk factors detailed earlier. In the dairy calf, rates of FTPI with natural sucking are so high that many farms opt to remove the calf at birth and feed colostrum by hand to ensure adequate intake.

Colostrum

Colostrum can be stripped from the dam and fed fresh, or the neonate can be fed stored (banked) colostrum.

Colostrum for Banking

With **dairy cows**, first-milking colostrum from a cow with a first-milking yield of less than 10 kg should be used. The temptation for the farmer is to store the leftover from the feeding of large-volume colostrum. The leftover colostrum should not be used because it has a high probability of containing a low immunoglobulin concentration.

Colostrum from **mares** should have a specific gravity of 1.060 or more, and 200 mL can be milked from a mare before the foal begins sucking.

Storage of Colostrum

Colostrum can be kept at **refrigerator temperature** for approximately 1 week without significant deterioration in immunoglobulins; bacteria counts, however, may reach unacceptably high levels (above 100,000 cfu/mL) after 2 days in refrigerated milk.[2] Addition of potassium sorbate in a 0.5% final solution impairs bacterial growth for several days.[2] The addition of 5 g of propionic or lactic acid per liter extends the storage life to 6 weeks, but, more commonly, colostrum is frozen for storage. **Frozen colostrum**, at −20° C (−4° F), can be stored for at least 1 year, and there is no impairment in the subsequent absorption of immunoglobulins. Frozen colostrum should be stored in flat plastic bags in the amount required for a feeding, which facilitates thawing. **Thawing** should be at temperatures below 55° C (131° F). Higher temperatures and microwave thawing result in the deterioration of immunoglobulins and antibodies in frozen colostrum and frozen plasma.

Pasteurization of Colostrum

There are several indications for pasteurization of colostrum. This procedure can be a suitable instrument in a program for the control of specific infectious diseases, such as paratuberculosis, salmonellosis, or *M. bovis* infection, but it can also be useful to ameliorate calf health by improving colostrum quality and reducing the exposure of the neonate to pathogens. On-farm pasteurization of bovine colostrum for 60 min at 60° C (140° F) results in elimination or at least significant reduction of bacterial contamination without impairing fluid characteristics or availability of IgG for intestinal absorption.[9] One recent study reported significantly higher serum IgG concentrations at 24 h of life when calves were fed pasteurized colostrum compared with calves receiving the same quality and amount of raw colostrum.[19] The authors attributed this effect to reduced bacterial interference with intestinal IgG absorption. Pasteurization extends the shelf life of refrigerated colostrum without

additives to 8 to 10 days when stored in clean, sealed containers.

Cross-Species Colostrum

Colostrum from another species can be used to provide immunologic protection when same-species colostrum is not available. Bovine colostrum can be fed to a number of different species. Although absorption of immunoglobulin occurs and significant protection can be achieved, the use of cross-species colostrum is not without risk, and the absorbed immunoglobulin has a short half-life. Bovine colostrum has been successfully used for many years to improve the survival rate of hysterectomy-produced artificially reared pigs. It has also been used as an alternate source of colostral antibody for rearing goats free of caprine arthritis–encephalitis (CAE). Colostrum from some cows can result in the development of hemolytic anemia, occurring at around 5 to 12 days of age, in lambs and kids because the IgG of some cows attaches to the red cells and their precursors in bone marrow, resulting in red cell destruction by the reticuloendothelial system. Bovine colostrum can be tested for "antisheep" factors by a gel precipitation test on colostral whey, but this test is not generally available. Bovine colostrum can provide some protection to newborn foals against neonatal infections, and protection appears to result from factors in addition to the immunoglobulins, which have a short half-life in foals.

Colostrum Supplements

In recent years there has been a move to develop supplements or even replacements for colostrum to feed calves. These have been attempted using IgG concentrated from bovine colostrum, milk whey, eggs, or bovine serum. The search for colostrum substitutes or colostrum replacers has been prompted by the problem of the variability of IgG concentration in natural colostrum. It has also been prompted by possible limitations of availability of high-quality colostrum on dairy farms as a result of discarding colostrum from cows that test positive for diseases that can transmit through colostrum, such as paratuberculosis, bovine leukosis, and *M. bovis.*

There is evidence that the inclusion of **colostrum replacer (CR)** or **colostrum supplement (CS)** products can impair the efficiency of colostral immunoglobulin, and if they are fed, they should be fed after normal colostrum rather than mixed into the colostrum. It has been proposed that the distinction between a colostrum supplement and a colostrum replacer should be the immunoglobulin mass contained in the product, with a colostrum supplement containing less than 100 g IgG per dose and a colostrum replacer having sufficient immunoglobulin mass in a dose to result in a serum IgG concentration greater than 10 mg/mL following a feeding. Furthermore, CR products are formulated to provide adequate protein, energy, minerals, and vitamins to completely replace colostrum, which is not the case for CS supplement products. When fed as the sole source of immunoglobulin to colostrum-deprived calves, CS products achieve circulating concentrations of immunoglobulin that are lower than those achieved by natural colostrum containing equivalent amounts of immunoglobulin.

A large mass of immunoglobulin is required for acquisition of adequate serum immunoglobulin concentrations. Calves fed a colostrum replacement containing a high mass (250 g) of an IgG derived from bovine serum and fed at 1.5 and again at 13.5 hours after birth achieved equivalent serum IgG concentrations to calves fed normal colostrum and showed no difference in gain or health parameters during the first 4 weeks of life. However, the performance of commercially available products for IgG supplementation varies greatly, with many of them faring badly. The choice of a specific product should therefore be based on the availability of convincing data supporting the efficacy of the product in question.

The use of colostrum replacers should be limited to situations where sufficient amounts of colostrum of adequate quality are unavailable. There can be little justification for more widespread use, particularly because there are limited independent health-related publications documenting their efficacy. Also, as mentioned earlier, in addition to immunoglobulin, natural colostrum contains various substances important to neonatal physiology.

Lacteal-Secretion-Based Preparations

Colostrum supplements prepared from whey or colostrum are available commercially in many countries. Depending on the manufacturer, they contain varying amounts of immunoglobulin, but significantly less than first-milking colostrum. The amount of immunoglobulin contained varies, but the recommendations for feeding that accompany these products indicate that they will supply approximately 25% or less of the immunoglobulin required to elevate calf serum IgG concentrations above 1000 mg/dL. There is a further problem in that the immunoglobulins in products made from colostrum or whey are poorly absorbed, and trials assessing their ability to increase circulating immunoglobulins when fed with colostrum have generally shown little improvement and no improvement in health-related parameters.

Bovine-Serum-Based Preparations

Colostrum supplements prepared from bovine serum are also available commercially, but regulations governing the feeding of blood or blood products to calves (risk reduction for bovine spongiform encephalopathy) may limit their availability in some countries. The absorption of immunoglobulin from these bovine-serum-derived commercial products appears better than from milk-protein-derived products, and consequently they are also marketed as colostrum replacers.

The IgG in a commercially available bovine serum colostrum replacer has been shown to be effectively absorbed when fed to newborn lambs. The feeding of 200 g of IgG in the first 24 hours of life resulted in a mean plasma concentration of 1800 mg/dL.

Administration of Colostrum

Foals

Foals should be allowed to suck naturally. The specific gravity of the mare's colostrum can be checked at foaling; if this is less than 1.060, supplemental colostrum may be indicated. Foals that do not suck, or that have serum IgG concentrations less than 400 mg/dL at 12 hours of age, or that require supplementation for other reasons, should be fed colostrum with a specific gravity of 1.060 or more at an amount of 200 mL at hourly feedings.

Dairy Calves

Assisted Natural Sucking

Leaving the newborn dairy calf with the cow is no guarantee that the calf will obtain sufficient colostrum, and a high proportion of dairy calves fail either to suck early or to absorb sufficient immunoglobulins from ingested colostrum. This problem can be alleviated to some extent by **assisted natural sucking,** but this can fail because not all calves requiring assistance are detected. An alternate approach is to milk 2 L of colostrum from the dam, bottle feed each calf as soon after birth as possible, then leave the calf with the cow for 24 hours and allow it to suck voluntarily. Although this will not be as effective as a system based entirely on artificial feeding of selected colostrum, it is an approach that is suitable for the smaller dairy farm.

Artificial Feeding Systems

With **artificial feeding systems**, the calf is removed from the dam at birth and fed colostrum by hand throughout the whole absorptive period. Nipple bottle feeding can be used, with 2 L of colostrum given every 12 hours for the first 48 hours of life. The first feeding is usually milked from the cow by hand, and the remaining feedings are from the colostrum obtained from the cow after the first machine milking. With care and patience, this system can result in good transfer of passive immunity in all calves except those born to dams that have very low concentrations of immunoglobulin in their colostrum. Unfortunately, with Holstein Friesians this can be a significant percentage. An extension of this system is to bottle feed at the same frequency but to feed stored

colostrum selected for its superior immunoglobulin content. Bottle feeding of newborn calves requires considerable **patience**, and its success is very much dependent on the calf feeder and on the availability of the feeder's time when faced with a calf that has a slow intake.

Where the diligence of the calf feeders is poor, or where there is a time constraint on their availability, the feeding of a large volume of colostrum (4 L to a 45 kg calf) by **esophageal feeder** at the initial feeding immediately after birth can be a successful practice. The **large-volume feeding** also allows the delivery of an adequate mass of immunoglobulin with colostrum that has low immunoglobulin concentrations without impairing the intestinal IgG absorption rate compared with voluntary intake of the same large amount of colostrum.[10] The practice usually uses stored colostrum, and the feeding can be achieved within a few minutes. It can be supplemented by bottle feeding of a second feeding at 12 hours of life.

The practice of feeding stored colostrum as the sole source of colostrum is limited to larger dairy herds, but it does allow the selection of superior colostrum for feeding, with selection based on weight and specific gravity as detailed earlier.

Beef Calves

Beef calves should be allowed to suck naturally, and force-feeding of colostrum to beef breeds should not be practiced unless there is obvious failure of sucking. Where colostrum is required, as with weak beef calves, calves with edematous tongues, and calves that have been subjected to a difficult birth, it can be administered with an esophageal feeder or a stomach tube.

Lambs

Lambs are allowed to suck naturally, but there can be competition between siblings for colostrum; one large single lamb is capable of ingesting, within a short period of birth, all the available colostrum in the ewe's udder. Lambs require a total of 180 to 210 mL colostrum/kg body weight during the first 18 hours after birth to provide sufficient energy for heat production. This amount will usually provide enough immunoglobulin for protection against infections. **Supplemental feeding** of colostrum may be advisable for lambs from multiple birth litters, lambs that lack vigor, and those that have not nursed by 2 hours following birth. This can be done with a nipple bottle or an esophageal feeder.

Piglets

Colostral supplementation is not commonly practiced with piglets. An immunoglobulin dose of 10 g/kg body weight on day 1 followed by 2 g/kg on succeeding days for 10 days is sufficient to confer passive immunity on the colostrum-deprived pig.

Clinical Assessment and Care of Critically Ill Newborns

The following discussion focuses on care and treatment of critically ill foals, although the principles are applicable to any species. The increasing availability of secondary and tertiary care for ill newborns has allowed the development of sophisticated care for newborns of sufficient emotional or financial value.[1] This level of care, at its most intensive, requires appropriately trained individuals (both veterinarians and support staff) and dedicated facilities. True intensive care of newborns requires 24-hour monitoring. The following discussion is not a comprehensive guide to intensive care of newborns, but is rather an introduction to the general aspects of advanced primary or basic secondary care. Sophisticated interventions, such as mechanical ventilation and cardiovascular support, are mentioned but not discussed in detail.

CLINICAL EXAMINATION

Initial assessment of an ill newborn should begin with collection of a detailed history, including length of gestation, health of the dam, parturition, and behavior of the newborn after birth, including the time to stand and to commence nursing activity. Physical examination should be thorough, with particular attention to those body systems most commonly affected. A form similar to that in Figure 19-4 is useful in ensuring that all pertinent questions are addressed and that the physical examination is comprehensive.

Examination of ill neonates should focus on detection of the common causes of disease in this age group: sepsis, either focal or systemic; prematurity or dysmaturity; metabolic abnormalities (such as hypoglycemia or hypothermia); birth trauma; diseases associated with hypoxia; and congenital abnormalities. Detailed descriptions of these conditions are provided elsewhere in this chapter.

Sepsis

Sepsis is an important cause of illness in neonates that can manifest as localized infections without apparent systemic signs, localized infections with signs of systemic illness, or systemic illness without signs of localized infection.[2]

Localized infections without signs of systemic illness include septic synovitis or osteomyelitis and omphalitis. Signs of these diseases are evident on examination of the area affected and include lameness, distension of the joint, and pain on palpation of the affected joint in animals with synovitis or osteomyelitis and an enlarged external umbilicus with or without purulent discharge in animals with infections of the umbilical structures. Specialized imaging and hematologic and serum biochemical examinations (see following discussion) are useful in confirming the infection.

Systemic signs of sepsis include depression, failure to nurse or reduced frequency of nursing, somnolence, recumbency, fever or hypothermia, tachypnea, tachycardia, diarrhea, and colic, in addition to any signs of

Fig. 19-4, cont'd

localized disease. Fever is a specific, but not sensitive, sign of sepsis in foals. The presence of petechia in oral, nasal, ocular, or vaginal mucous membranes, the pinna, or coronary bands is considered a specific indicator of sepsis, although this has not been documented by appropriate studies. A similar comment applies for injection of the scleral vessels. A scoring system (the sepsis score) has been developed to aid in the identification of foals with sepsis.

The **sepsis score** was developed with the intention of aiding identification of foals with sepsis, thereby facilitating appropriate treatment. A table for calculation of the sepsis score (the modified sepsis score) is provided in Table 19-11. Foals with a score of 12 or greater are considered to be septic, with a sensitivity of 94% in the original report. However, more recent studies, including one of 1095 foals, have found the sensitivity and specificity of the sepsis score to be less than the original report. The modified sepsis score detected sepsis with a sensitivity of 56% and a specificity of 73% using a cutoff value of 11 or more. A cutoff value of 7 yielded a sensitivity of 84% and specificity of 42%.[3] These recent studies are broadly consistent with earlier studies that demonstrate that the sepsis score has limited sensitivity (67%, 95% CI 59% to 75%) and specificity (76%, 95% CI 68% to 83%) in foals less than 10 days of age. Similarly, 49% of 101 foals with positive blood cultures had a sepsis score of 11 or less, indicating a low specificity of the test. The low to moderate sensitivity of the sepsis score for detection of sepsis or bacteremia means that many foals with sepsis are incorrectly diagnosed as being nonseptic (i.e., a high false-negative rate), whereas a moderate to low specificity means that the false-positive rate might be excessive, with a number of foals being considered septic when they are not. This is an important shortcoming of the test because accurate and prompt identification of foals with sepsis is assumed to be important for both prognostication and selection of treatment. The sepsis score might be useful in some situations, but its shortcomings should be recognized when using it to guide treatment or determine prognosis.

Prematurity and Dysmaturity

Detection of **prematurity** is important because it is a strong risk factor for development of other diseases during the immediate postpartum period. The detection of prematurity is often based on the length of gestation. However, the duration of gestation in Thoroughbred horses varies considerably, with 95% of mares foaling after a gestation of 327 to 357 days. The generally accepted "average" gestation is 349 days, with fillies having shorter gestations than do colts (348 versus 350 days) and gestation length declining by approximately 20 days, from 360 to 340 days, in Standardbred mares in New Zealand.[4] Ponies have a shorter gestation (333 days, range 315 to 350 days). Therefore a diagnosis of prematurity should be based not just on gestational age but also on the results of physical, hematologic, and serum biochemical examination of the newborn. Factors helping in the determination of prematurity are listed in Table 19-4. Foals that are immature (premature) at birth typically have low birth weight and small body size, a short and silky hair coat, and laxity of the

Table 19-4 Criteria to assess stage of maturity of the newborn foal

Criterion	Premature	Full term
Physical		
Gestational age	320 d	Normally > 330 d
Size	Small	Normal or large
Coat	Short and silky	Long
Fetlock	Overextended	Normal extension
Behavior		
First stand	>120 min	<120 min
First stand	>3 h	<3 h
Suck reflex	Poor	Good
Righting reflexes	Poor	Good
Adrenal activity		
Plasma cortisol values over first 2 h postpartum	Low levels (<30 ng/mL)	Increasing levels (120–140 ng/mL) at 30–60 min postpartum
Plasma ACTH values over first 2 h postpartum	Peak values (≈650 pg/mL) at 30 min postpartum and declining subsequently	Declining values from peak (300 pg/mL at birth)
Response to synthetic ACTH1-24 (short-acting Synacthen), dose 0.125 mg IM	Poor response shown by a 28% increase in plasma cortisol and no changes in neutrophil:lymphocyte ratio	Good response shown by a 208% increase in plasma cortisol and widening of neutrophil:lymphocyte ratio
Hematology		
Mean cell volume (fl)	>39	<39
White blood cell count ($\times 10^9$/L)	6.0	8.0
Neutrophil:lymphocyte ratio	<1.0	>2.0
Carbohydrate metabolism		
Plasma glucose levels over first 2 h postpartum	Low levels at birth (2–3 mmol/L), subsequently declining	Higher levels at birth (4.1 mmol/L), maintained
Plasma insulin levels over first 2 h postpartum	Low levels at birth (8.6 µU/mL), declining	Higher levels at birth (16.1 µU/mL), maintained
Glucose tolerance test (0.5 mg/kg body weight IV)	Slight response demonstrated by a 100% increase in plasma insulin at 15 min postadministration	Clear response demonstrated by a 250% increase in plasma insulin at 5 min postadministration
Renin–angiotensin–aldosterone system		
Plasma renin substrate	Higher and/or increasing levels during 15–60 min postpartum	Low (<0.6 µg/mL) and declining levels during 15–30 min postpartum
Acid–base status (pH)	<7.25 and declining	>7.3 and maintaining or rising

IM, intramuscularly; IV, intravenously.

flexor and extensor tendons. The cranium is rounded, and the pinnae lack tone (droopy ears). The foals are typically weak and have trouble standing, which is exacerbated by laxity of the flexor tendons and periarticular ligaments. **Dysmature** (postmature) foals are typically large, although they can be thin, and have a long hair coat and flexure tendon contracture. These signs are consistent with prolonged gestation combined with inadequate intrauterine nutrition. Healthy foals stand approximately 65 min (interquartile range, 45 to 100 minutes) after birth.[4] Examination of the placenta, either by ultrasonographic examination before birth or by direct examination, including histologic and microbiologic testing, after birth is useful in identifying abnormalities that have significance for the newborn.

Hypoxia

Hypoxia during late gestation, birth, or the immediate postpartum period has a variety of clinical manifestations depending on the tissue or organ most affected. Signs of central nervous system dysfunction are often assumed to be a result of cerebral hypoxia during birth, although neonatal maladjustment syndrome does not appear to be related to hypoxia (see "Neonatal Maladjustment Syndrome," page 1871). Other signs suggestive of peripartum hypoxia include colic and anuria.

Hypoglycemia

Foals that are hypoglycemic because of inadequate intake, such as through mismothering, congenital abnormalities, or concurrent illness, are initially weak, with rapid progression to somnolence and coma.

Endocrine Abnormalities

Abnormalities in endocrine function of foals are common and often associated with risk of death.[1,5-10] Septic foals have higher serum ACTH, cortisol, and ACTH:cortisol ratios, and higher serum parathyroid hormone concentrations (but not calcitonin concentrations) than do healthy foals of the same age.[5,6] Septic foals have lower insulin and IGF-1 and higher ghrelin, growth hormone, and glucagon concentrations than do healthy foals.[7,8] Arginine vasopressin concentrations are higher in septic foals.[9] Plasma adrenomedullin concentrations are highest in sick foals (both septic and nonseptic) and might be a useful marker of foal health.[10] Critically ill foals may also have evidence on nonthyroidal illness syndrome (see "Diseases of the Thyroid," Chapter 17).[11]

DIAGNOSTIC IMAGING

Radiographic and ultrasonographic examination of neonates can be useful in determining maturity and the presence of abnormalities. Prematurity is evident as failure or inadequate ossification of cuboidal bones in the carpus and tarsus. Radiographs of the thorax should be obtained if there is any suspicion of sepsis or pneumonia because thoracic auscultation has poor sensitivity in detecting pulmonary disease in newborns. The severity of abnormalities in the lungs of foals detected by radiographic examination is related to prognosis, with foals with more severe disease having a worse prognosis for recovery. Abdominal radiographs may be useful in determining the site of gastrointestinal disease (see discussion of foal colic).

Ultrasonography is a particularly useful tool for examination of neonates, in large part because their small size permits thorough examination of all major body cavities. Ultrasonography of the umbilical structures can identify omphalitis and abscesses of umbilical remnants and, when available, is indicated as part of the physical examination of every sick neonate.

Examination of the **umbilical structures** can reveal evidence of infection, congenital abnormalities, and urachal tears. Examination of the umbilicus can be achieved using a 7.5-mHz linear probe (such as that commonly used for reproductive examination of mares), although sector scanners provide a superior image. Examination of the umbilical structures should include examination of the navel and structures external to the body wall, the body wall, the umbilical stump as it enters the body wall and separates into the two umbilical arteries, the urachus and apex of the bladder, and the umbilical vein. The size and echogenicity of each of these structures should be determined. For foals less than 7 days of age, the intraabdominal umbilical stump should be less than 2.4 cm in diameter, the umbilical vein less than 1 cm, and the umbilical arteries less than 1.4 cm (usually < 1 cm). Examination of these structures should be complete: the umbilical vein should be visualized in the umbilical stump and then followed as it courses along the ventral abdominal wall and into the liver; the umbilical arteries should be visualized in the umbilical stump and then as they separate from that structure and course over the lateral aspects of the bladder; the urachus should be visualized from the external umbilical stump through the body wall and as it enters the bladder.

Abnormalities observed frequently in the umbilical structures include overall swelling, consistent with omphalitis; gas shadows in the urachus or umbilical stump, which are indicative of either a patent urachus allowing entry of air or growth of gas-producing bacteria; and the presence of flocculent fluid in the urachus, vein, or artery, which is consistent with pus. Urachal tears can be observed, especially in foals with uroperitoneum.

Ultrasonographic examination of the **abdomen** is useful in identifying abnormalities of gastrointestinal function and structure, including intestinal distension or thickening of the intestinal wall. Thickness of the wall of the intestinal tract of healthy Standardbred foals of less than 5 days of age are as follows (95% predictive interval): 1.6 to 3.6 mm for the stomach, 1.9 to 3.2 mm for the duodenum, 1.9 to 3.1 mm for the jejunum, 1.3 to 2.2 mm for the colon, and 0.8 to 2.7 mm for the cecum.[12] Intussusceptions are evident as "donut" lesions in the small intestine, but evaluation of the clinical importance of these findings should be considered in the context of the foal. Intussusceptions are detected in a large proportion of healthy neonatal foals as incidental findings.[12] Gastric outflow obstruction should be suspected in foals with a distended stomach evident on ultrasonographic examination of the abdomen. Herniation through the umbilicus or inguinal ring can be confirmed by ultrasonographic examination.[13] Uroperitoneum is readily apparent as excessive accumulation of clear fluid in the abdomen. Hemorrhage into the peritoneum can be detected as accumulation of echogenic, swirling fluid. Accumulation of inflammatory fluid, such as in foals with ischemic intestine, is detected by the presence of flocculent fluid.

Ultrasonographic examination of the **chest** can reveal the presence of pleural abnormalities, consolidation of the lung (provided that the consolidated lung is confluent with the pleura), accumulation of fluid in the pleural space (hemorrhage secondary to birth trauma and fractured ribs, inflammatory fluid in foals with pleuritis), pneumothorax (usually secondary to lung laceration by a fractured rib), or congenital abnormalities of the heart.

Advanced imaging modalities, such as **computed tomography (CT) and magnetic resonance imaging (MRI)**, are available at referral centers and are practical in foals and other neonates because of the small size of the animals. These modalities are useful in detection of intrathoracic and intraabdominal abnormalities, including abscesses, gastrointestinal disease, and congenital abnormalities. MRI is particularly useful for diagnosis of diseases of the brain and spinal cord.

CLINICAL PATHOLOGY

Serum Immunoglobulin Concentration

Serum or plasma immunoglobulins are associated with the risk of death in hospitalized foals. Foals with serum IgG concentration less than or equal to 4.0 g/L were 4.7 (95% CI 2.6 to 8.5) times as likely to die as were foals with a concentration greater than 8 g/L. Foals with an IgG of greater than 4 g/L and less than 8 g/L were 3.7 (2.0 to 6.8) times as likely to die as were foals with concentrations above 8 g/L.[14]

Serum immunoglobulin G (IgG) concentration, or its equivalent, must be measured in every ill or at-risk newborn and should be repeated every 48 to 96 hours in critically ill neonates. A variety of tests are available for

rapid detection of FTPI in foals and calves. Although measurement of serum IgG concentration is ideally performed by the gold standard test, a radial immunodiffusion, this test requires at least 24 hours to run, whereas the stall-side or chemistry analyzer tests can be run in a few minutes. The sensitivity and specificity have been determined for a number of these rapid tests. Overall, most tests have high sensitivity (>80%), meaning that the few foals that have low concentrations of IgG are missed, but poor specificity (50% to 70%), meaning that many foals that have adequate concentrations of immunoglobulin are diagnosed as having inadequate concentrations. The exact sensitivity and specificity depend on the test used and the concentration of immunoglobulin considered adequate. The high sensitivity and low specificity of most of the available rapid tests result in a number of foals that do not need a transfusion receiving one. However, this error is of less importance than that of foals that should receive a transfusion not receiving one.

Serum or plasma concentrations of IgG should be measured after approximately 18 hours of age, and preferably before 48 hours of age—the earlier FTPI is recognized, the better the prognosis for the foal. Foals that ingest colostrum within the first few hours of birth have minimal increases in serum IgG concentration over that achieved at 12 hours of age, suggesting that measurement of serum IgG concentration as early as 12 to 18 hours after birth is appropriate. This early measurement of serum IgG concentration could be especially important in high-risk foals. The oldest age at which measurement of serum IgG is useful in foals is uncertain, but depends on the clinical condition of the foal. Typically, immunoglobulin concentrations of foals that have adequate concentrations of IgG within the first 24 hours reach a nadir at about 6 weeks of age and then rise to concentrations similar to adults over the next 2 to 3 months.

Hematology

It is important to recognize that the hemogram of neonates differs from that of older animals (Table 19-5) because these differences can affect the clinical assessment of the animal. The hematologic and serum biochemical values of foals and calves can vary markedly during the first days and weeks of life, and it is important that these maturational changes are taken into account when assessing results of hematologic or serum biochemical examination of foals. Hematologic examination can reveal evidence of hemolytic disease, bacterial or viral infection, or prematurity/dysmaturity (Table 19-4). Repeated hemograms are often necessary to monitor for development of sepsis and responses to treatment.

Foals with **sepsis** can have a leukocyte count in the blood that is low, within the reference range, or high. Approximately 40% of foals with sepsis have blood leukocyte counts that are below the reference range. Most foals with sepsis (approximately 70%) have segmented neutrophil counts that are below the reference range, with fewer than 15% of foals having elevated blood neutrophil counts. Concentrations of band cells in blood are above the reference range in almost all foals with sepsis. Some foals born of mares with placentitis have a very pronounced mature neutrophilia without other signs of sepsis; these foals typically have a good prognosis. Lymphopenia is present in foals with equine herpervirus-1 septicemia or Arabian foals with severe

Table 19-5 Hematologic values of normal foals and calves

combined immunodeficiency. Thrombocytopenia occurs in some foals with sepsis. Hyperfibrinogenemia is common in foals that have sepsis, although the concentration might not be above the reference range in foals examined early in the disease.

Hyperfibrinogenemia is common in foals born of mares with placentitis and reflects systemic activation of the inflammatory cascade even in foals that have no other evidence of sepsis. Serum amyloid A concentrations are above 100 mg/L in foals with sepsis. Septic foals also have blood concentrations of proinflammatory cytokines, and of plasma C-reactive protein,[15] that are higher than those in healthy foals. Plasma haptoglobin concentrations are not different between surviving and nonsurviving foals and are only minimally lower in foals with sepsis than in nonseptic hospitalized foals.[15] Indices of coagulation are prolonged in foals with sepsis, and concentrations of antithrombin and protein C antigen in plasma are lower than in healthy foals. These abnormalities indicate that coagulopathies are common in septic foals.

Prematurity is associated with a low neutrophil:lymphocyte ratio (<1.5:1) in blood and red cell macrocytosis (Table 19-4). A neutrophil:lymphocyte ratio above 2:1 is considered normal. Premature foals that are not septic can have low blood neutrophil counts but rarely have immature neutrophils (band cells) or toxic changes in neutrophils.

Serum Biochemistry

Care should be taken in the interpretation of the results of serum biochemical examinations because normal values for newborns are often markedly different from those of adults, and they can change rapidly during the first days to weeks of life (Table 19-6). Serum biochemical examination can reveal electrolyte abnormalities associated with renal failure, diarrhea, and sepsis. Elevations in serum bilirubin concentration or serum enzyme activities may be detected. As a minimum, blood glucose concentrations should be estimated using a chemical strip in depressed or recumbent newborns.

Markedly elevated serum **creatinine** concentrations are not uncommonly observed in foals with no other evidence of renal disease. The elevated serum creatinine in these cases is a consequence of impaired placental function during late gestation, with the consequent accumulation of creatinine (and probably other compounds). In foals with normal renal function, which most have, the serum creatinine concentration should decrease to 50% of the initial high value within 24 hours. Other causes of high serum creatinine concentration that should be ruled out are renal failure (dysplasia, hypoxic renal failure) and postrenal azotemia (uroperitoneum).

Blood or plasma **l-lactate concentrations** are useful indicators of the presence and severity of systemic disease that impairs oxygen delivery to tissue (hypoxemia, poor perfusion, anemia) or use by tissue (endotoxemia), but it is not specific for any one disease or group of diseases, with the exception that septic foals have higher concentrations than do nonseptic foals.[16-19] However, the difference between septic and nonseptic foals (4.8 [range, 0.6 to 37) and 3.3 [range, 0.3 to 21] mmol/L) is not sufficiently different to make it useful in an individual animal.[20] Blood lactate concentrations of healthy foals are greatest at birth to 12 hours of age and then decline.[16] Blood lactate concentrations of foals that do not survive their acute illness do not decline in response to therapy,[16] and risk of death increases by 1.1 for each mmol/L increase in blood lactate concentration of foals at time of admission to a veterinary hospital.[17,20] Serial measurement of blood lactate concentrations and calculation of an "area-under-the-curve" measure also provides useful information related to risk of death, but not the cause of the disease.

Sepsis is usually associated with hypoglycemia, although septic foals can have normal or elevated blood glucose concentrations. Hypoglycemia is attributable to failure

to nurse, whereas hyperglycemia indicates loss of normal sensitivity to insulin. Indicators of renal, hepatic, or cardiac (troponin) damage can increase in foals with sepsis, causing organ damage or failure. Foals with sepsis tend to have elevated concentrations of cortisol in serum.

Prematurity is associated with low concentrations of cortisol in plasma or serum and minimal increase in response to intramuscular administration of 0.125 mg of exogenous ACTH (corticotropin). Plasma cortisol concentration of normal full-term foals during the first 24 hours of life increases from a baseline value of approximately 40 ng/mL to over 100 ng/mL 60 minutes after ACTH administration, whereas plasma cortisol concentrations in premature foals do not increase from values of slightly less than 40 ng/mL. At 2 and 3 days of age, plasma cortisol concentrations of full-term foals increase twofold after ACTH administration, albeit from a lower resting value, but do not increase in premature foals. Blood glucose concentrations of premature foals are often low, probably because of inability to nurse.

Blood Gas

Arterial blood pH, P_{CO_2}, and P_{O_2} should be measured to determine the newborn's acid–base status and the adequacy of respiratory function. Foals with hypoxemia are five times more likely to have pulmonary radiographic abnormalities. Prolonged lateral recumbency of foals compromises respiratory function, and arterial blood samples should be collected with the foal in sternal recumbency. Repeated sampling may be necessary to detect changes in respiratory function and to monitor the adequacy of oxygen supplementation or assisted ventilation.

Blood Culture

Identification of causative organisms of sepsis in foals can aid in prognostication and potentially in selection of therapy, although there does not appear to be a relation between antimicrobial sensitivity of organisms isolated from blood, as determined by Kirby–Bauer testing, and survival of foals. Anaerobic and aerobic blood cultures should be performed as early in the disease process as possible, and preferably before initiation of antibiotic treatment, although antimicrobials should not be withheld from a newborn with confirmed or suspected sepsis to obtain a result from blood culture. Strict aseptic technique should be used when collecting blood for culture. Blood cultures should also be collected if there is a sudden deterioration in the newborn's condition.

Gram-negative enteric bacteria are the most common isolates from blood of newborn foals, with *E. coli* the most common isolate. *A. equuli* is also a common isolate from foals. There are important differences in diseases produced by the various organisms, with foals with *A. equuli* septicemia being twice as likely to die, seven times more likely to have been sick since birth, six times more likely to have diarrhea, five times more likely to have a sepsis score of more than 11, and three times more likely to have pneumonia than foals with sepsis associated with other bacteria.

A problem with blood culture is the time needed to obtain either interim or final results because this can delay detection of infection or decisions to use focused antimicrobial therapy. Use of real-time polymerase chain reaction (PCR) to detect bloodstream infection of foals will likely supplement conventional blood culture in foals.[21]

Other Body Fluids

Synovial fluid should be submitted for aerobic and anaerobic culture, Gram stain, and cytologic examination when signs of synovitis, such as lameness, joint effusion, or joint pain, are present.

Analysis of cerebrospinal fluid (CSF) is indicated in newborns with signs of neurologic disease. Samples of CSF should be submitted for cytologic examination, measurement of total protein concentration, Gram stain, and bacterial culture.

Urinalysis may provide evidence of renal failure (casts) or urinary tract infection (white blood cells).

Abdominal fluid should be collected in foals with abdominal pain or distension and should be submitted for cytologic examination and, if uroperitoneum is suspected, measurement of creatinine concentration.

TREATMENT

The principles of care of the critically ill newborn farm animal are as follows:

- The newborn should be kept in a sanitary environment to minimize the risk of nosocomial infections.
- Systemic supportive care should be provided to maintain homeostasis until the newborn is capable of separate and independent existence.
- There should be frequent and comprehensive reevaluations of all body systems to detect signs of deterioration and allow early correction.
- Provision should be made to ensure adequate passive immunity (serum or plasma IgG concentration > 8 g/L) to reduce the risk of secondary infections or to treat existing infections. Transfer of passive immunity should be evaluated using laboratory methods that measure serum or plasma IgG concentration.

The level of care provided depends on the value of the animal and the available facilities, personnel, and expertise. Newborns of limited financial worth are usually treated on the farm, whereas valuable foals and calves can be referred for specialist care. Referral of sick neonates to institutions and practices with expertise in provision of critical care to newborns should be timely and prompt and, when necessary, should be recommended on the first visit.

Nursing Care

The sophistication of care for critically ill newborns depends on the facilities and personnel available, with intensive management requiring dedicated facilities and trained personnel available 24 hours a day. The minimum requirement for providing basic care of ill newborns is a sanitary area in which the newborns can be protected from environmental stress. Often this means separating the newborn from its dam.

Excellent nursing care is essential for maximizing the likelihood of a good outcome. Critically ill animals might benefit from constant nursing care. Strict attention must be paid to maintaining the sanitary environment to minimize the risk of nosocomial infections. The newborn should be kept clean and dry and at an ambient temperature in its thermoneutral zone. Bedding should prevent development of decubital ulcers. Foals should be maintained in sternal recumbency, or at least turned every 2 hours, to optimize their respiratory function.

Correction of Failure of Transfer of Passive Immunity

Colostral Immunoglobulin

Ideally, adequate transfer of passive immunity is achieved by the newborn nursing its dam and ingesting an adequate amount of colostrum containing optimal concentrations of immunoglobulins, principally IgG (IgGb) in foals. Foals need approximately 2 g of IgG per kilogram of body weight to achieve a plasma concentration of 2000 mg/dL (20g/L); therefore a 45-kg foal needs approximately 90 g of IgG to attain a normal serum IgG concentration (or approximately 40 g to achieve a serum IgG concentration of 800 mg/dL [8 g/L]). Assuming that colostrum contains on average 10,000 mg/dL (100 g/L), foals must ingest at least 1 L of colostrum to obtain sufficient immunoglobulin. Because colostral IgG concentration varies considerably (from 2000 to 30,000 mg/dL), specific recommendations regarding the quantity of colostrum to be fed to neonatal foals cannot be made with certainty. However, colostrum with a specific gravity of more than 1.060 has an IgG concentration of more than 3000 mg/dL (30 g/L), suggesting that foals should ingest at least 1.5 L to achieve serum IgG concentrations above 800 mg/dL (8 g/L).

Critical Plasma IgG Concentrations in Foals

There is some debate as to what constitutes a critical serum or plasma IgG concentration. Foals that ingest an adequate amount of colostrum typically have serum immunoglobulin concentrations during the first week of life greater than approximately 2000 mg/dL (20 g/L). Both 400 mg/dL

(4 g/L) and 800 mg/dL (8 g/L) have been recommended as concentrations below which foals should be considered to have increased likelihood of contracting infectious disease, but recent evidence strongly supports the use of 800 mg/dL (8 g/L) as the minimal concentration in hospitalized foals. However, on a well-managed farm the serum IgG concentration was not predictive of morbidity or mortality among foals, suggesting that serum immunoglobulin concentration in some populations of foals is not an important risk factor for infectious disease. The foals in this study were from an exceptionally well-managed farm. Other researchers have found that foals with serum IgG concentration below 800 mg/dL (8 g/L) are at markedly increased risk of subsequent development of infectious disease, including sepsis, pneumonia, and septic arthritis. It is likely that there is no single concentration of IgG in serum that is protective in all situations, and the concentration of IgG in serum that is desirable in an individual foal depends on the risk factors for infectious disease of that foal. Our opinion is that a minimum serum IgG in foals free of disease and housed in closed bands on well-managed farms is 400 mg/dL (4 g/L). For foals at increased risk of disease—for instance, those on large farms with frequent introduction of animals and foals that are transported or housed with foals with infectious disease—the minimum advisable serum IgG concentration is 800 mg/dL (8 g/L). Foals that have infectious disease should have serum IgG concentrations of at least 800 mg/dL, and it might be advantageous for these foals to have even higher values, as indicated by the enhanced survival of foals with septic disease administered equine plasma regardless of their serum IgG concentration. This therapeutic advantage could be because of the additional IgG or because of other factors included in the plasma. Transfusion of plasma to sick foals improves neutrophil function, an important advantage given that oxidative burst activity of neutrophils from septic foals is reduced compared with that in healthy foals.

Plasma Transfusion

The ability of foals to absorb macromolecules, including immunoglobulins, declines rapidly after birth, being 22% of that at birth by 3 hours of age and 1% of that at birth by 24 hours of age. Consequently, by the time that FTPI is recognized, it is no longer feasible to increase serum IgG concentrations by feeding colostrum or oral serum products. Foals should then be administered plasma or serum intravenously. The **amount of plasma** or serum to be administered depends on the target value for serum IgG concentration and the initial serum IgG concentration in the foal. For each gram of IgG administered per kilogram of body weight of the foal, serum IgG concentration increases by approximately 8.7 mg/dL (0.87 g/L) in healthy foals and 6.2 mg/dL (0.62 g/L) in sick foals. To achieve serum IgG concentrations above 800 mg/dL (8 g/L) in foals with serum IgG concentrations below 400 mg/dL (4 g/L), they should be administered 40 mL/kg of plasma containing at least 20 g/L of IgG. Similarly, foals with serum IgG concentrations above 400 mg/dL (4g/L) but below 800 mg/dL (8 g/L) should be administered 20 mL/kg of plasma. For 45-kg foals, these recommendations translate to administration of 1 or 2 L of plasma, respectively.

The ideal product for transfusion into foals with FTPI is **fresh frozen plasma** harvested from horses that are Aa and Qa antigen-negative and that do not have antibodies against either or both of these red blood cell antigens (see the discussion of neonatal isoerythrolysis). The donor horses should have been vaccinated against the common diseases of horses and have tested negative for equine infectious anemia. Good-quality commercial products specify the minimum concentration of IgG in the plasma. Concentrated serum products that do not need to be frozen until use are available. These are much more convenient for field use than are plasma products that must be frozen until immediately before transfusion. However, the IgG concentration of these products is often not specified, and the manufacturer's recommendations for dosing often result in administration of inadequate amounts of immunoglobulin. Serum products can produce adequate concentrations of IgG in foals, but the dose is usually two to three times that recommended by the manufacturer. An adequate dose of concentrated serum products is approximately 1 L for some products. The crucial point is that it is not the volume of plasma or serum that is administered that is important, but rather the quantity of immunoglobulin delivered to the foal. A total of 20 to 25 g of IgG is required to raise the serum IgG concentration of a 50-kg foal by 400 mg/dL (4 g/L).

Plasma should be administered intravenously; oral administration is likely to be wasteful, especially in foals more than a few hours old. Frozen plasma should be thawed at room temperature or by immersion in warm (<37° C, 100° F) water. Thawing by immersion in water at temperatures higher than body temperature can cause denaturation and coagulation of proteins, with loss of efficacy of transfused immunoglobulins. Plasma should never be thawed or warmed using a microwave because this denatures the proteins.

Administration of plasma should be intravenous; intraperitoneal administration, such as used in pigs or small ruminants, has not been investigated in foals. The thawed plasma should be administered through a jugular catheter using a blood administration set containing a filter (160- to 270-µm mesh) to prevent infusion of particulate material. Strict asepsis should be used. The foal should be adequately restrained for the procedure, with some active foals needing moderate tranquillization. Premedication with antihistamines or nonsteroidal antiinflammatory drugs is usually not necessary. The plasma should be infused slowly at first, with the first 20 to 40 mL administered over 10 minutes. During this period the foal should be carefully observed for signs of transfusion reaction, which is usually evident as restlessness, tachycardia, tachypnea, respiratory distress, sweating, or urticaria. If these signs are observed, the transfusion should be stopped, and the foal should be reevaluated and treated if necessary. If no transfusion reactions are noted during the first 10 minutes, the infusion can then be delivered at 0.25 to 1.0 mL/kg/min (i.e., about 1 L/h for a 50-kg foal). Rapid infusion can result in acute excessive plasma volume expansion, with the potential for cardiovascular and respiratory distress.

Serum IgG concentration should be measured after the infusion to ensure that an adequate concentration of IgG has been achieved. Serum IgG can be measured as early as 20 minutes after the end of the transfusion.

Nutritional Support

Provision of adequate nutrition is essential to the recovery of ill newborns. Healthy newborn foals have estimated energy requirements of 500 to 625 kJ/kg/d (120 to 150 kcal/kg/d) and consume approximately 20% of their body weight as milk per day. Measurements of foal energy expenditure using indirect calorimetry reveal expenditure of ~60 to 80 kcal/kg/d in healthy foals, which is reduced to ~50 kcal/kg/d for critically ill foals.[22]

The best food for newborns is the dam's milk, and newborns that are able to do so should be encouraged to nurse the dam. However, if the foal is unable to nurse or the dam is not available, then good-quality milk substitutes should be used. Soy and other plant-protein-based milk replacers are not suitable for newborns. Commercial products formulated for foals, calves, and lambs are available. Human enteral nutrition products supplying 0.7 to 1 kcal/mL (2.8 to 4.1 kJ/mL) can also be used for short-term (several days to a week) support of foals.

It is preferable to provide enteral, rather than parenteral, nutrition to ill newborns with normal or relatively normal gastrointestinal function. Sick neonatal foals should initially be fed 10% of their body weight as mare's milk, or a suitable replacer, every 24 hours, divided into hourly or 2-hour feedings. If the foal does not develop diarrhea or abdominal distension, then the amount fed can be increased over a 24- to 48-hour period to 20% to 25% of the foal's body weight (or 150 kcal/kg/day; 620 kJ/kg/day). Newborns can be fed by nursing a

bottle or bucket or via an indwelling nasogastric tube such as a foal feeding tube, stallion catheter, human feeding tube, or enema tube. Every attempt should be made to encourage the newborn to nurse its dam as soon as the newborn can stand. Adequacy of nutrition can be monitored by measuring blood glucose concentrations and body weight.

Parenteral nutrition (PN) can be provided to newborns that are unable to be fed by the enteral route. This can be achieved by administration of various combinations of solutions containing glucose (dextrose), amino acids, and fat. A commercial product that does not include lipid has been used successfully for up to 12 days in foals. One product that has been used successfully for foals is a solution of amino acids (5%), dextrose (25%), and electrolytes (Clinimix E; Baxter Healthcare Corporation, Deerfield, IL). Lipid emulsion is not added to the preparation. Additional multivitamin supplements including calcium gluconate (provided 2.5 mmol/L), magnesium sulfate (6 mEq/L), B-vitamin complex (thiamine 12.5 mg/L; riboflavin 2 mg/L; niacin 12.5 mg/L; pantothenic acid 5 mg/L; pyridoxine 5 mg/L; cyanocobalamin 5 µg/L), and trace elements (zinc 2 mg/L; copper 0.8 mg/L; manganese 0.2 mg/L; chromium 8 µg/L) are added. Administration is through a catheter, a single-lumen 14-gauge over-the-wire catheter (Milacath), inserted in the jugular vein with its tip placed in the cranial vena cava. A double-T extension set is used to allow concurrent constant-rate infusion of isotonic crystalloid fluids and intravenous administration of medication in one line and PN solution in the other. An infusion pump is used for continuous-rate infusion of the solutions. The PN solution should be prepared under aseptic conditions just before administration and used for only a period of 24 hours after preparation. A 0.22-µm filter is included in the administration line to remove all bacteria, glass, rubber, cellulose fibers, and other extraneous material in the PN solution. The filters and administration sets are changed with each new bag of PN solution.

The rate of PN infusion is determined based on the weight and physical and metabolic condition of the foal. The general protocol is based on the assumption that sick foals expend approximately 50 kcal/kg body weight per day (basal rate).[22] The PN is started at half the basal rate for 12 hours, increasing to the basal rate over 24 to 48 hours, and then in some foals increased slowly to 75 kcal/kg/d if tolerated by the foal. The clinical condition of the foal is assessed frequently. Blood glucose concentrations should be measured every 6 to 8 hours during the introduction and weaning of PN until the blood glucose concentration is stabilized. Insulin can be administered during hyperglycemic crises (≫250 mg/dL) at a dose of 0.1 to 0.4 U/kg regular insulin intramuscularly, but this is rarely needed. When a constant rate of PN is achieved, glucose concentrations should be measured every 8 to 12 hours, depending on the clinical condition of the foal. Foals are weaned off the PN as their clinical condition improves, and enteral feeding is gradually increased. The rate of PN is halved every 4 to 12 hours if blood glucose concentration is stable until half the basal rate is obtained, at which time the infusion is discontinued if the foal is bright, alert, and nursing well.

PN is supplemented with isotonic fluid therapy administered intravenously. The fluid rate and composition are determined based on clinical condition, packed cell volume, total protein, and serum electrolyte concentrations (Na, Cl, Ca, K and HCO_3). The composition and rate are adjusted to maintain normal hydration and electrolyte and acid–base status. During the period that foals receive PN, enteral feeding is initially withdrawn, and the foals are muzzled or separated from the mare. Beginning 24 hours after the institution of PN, 20 to 40 mL of mare's milk ("trophic" feeding) is administered enterally every 4 hours. The trophic feeding provides nutrition to enterocytes and stimulates production of lactase in the small intestine in preparation for resumption of enteral feeding. As the foals are weaned off the PN, enteral feedings are gradually increased from small trophic feeding every 4 hours to allowing the foal to nurse from the mare for 2 to 5 minutes every 2 hours and eventually unrestricted nursing from the mare.

Antimicrobial Treatment

Normal newborns are at risk of acquiring life-threatening bacterial infections, and the risk increases when they do not ingest adequate colostrum in a timely fashion or are subjected to environmental stresses (see the discussion on neonatal infection). Newborns in which bacterial infection is suspected and those at high risk of developing an infection, such as sick newborns with FTPI, should be administered antimicrobials. Antimicrobial therapy should not be delayed pending the results of bacterial culture and antimicrobial sensitivity testing.

The choice of antimicrobial is determined by the likely infecting agent and clinical experience with antimicrobial susceptibility of local strains of pathogens. In general, broad-spectrum antimicrobials are chosen because it is almost impossible to predict, based on clinical signs, the nature of the infecting agent and its antimicrobial susceptibility. Although *Streptococcus* spp. were historically reported to be the cause of most infections in neonatal foals, currently infections of neonatal foals are usually a result of gram-negative organisms, including *E. coli*, *Klebsiella* spp., and *Salmonella* spp. Because of the wide variety of infecting agents and their varying antimicrobial susceptibility, it is possible to make only general recommendations for antimicrobial therapy of neonates. A frequently used antimicrobial regimen is an aminoglycoside (gentamicin or, more commonly, amikacin) and penicillin. Some commonly used drugs and their doses are listed in Table 19-7. Dosage of antimicrobials in foals differs somewhat from that of adults, and the pharmacokinetics of drugs in normal foals are often different from those of the same drug in sick foals. Consequently, higher dosages administered at prolonged intervals are often indicated in sick foals, especially when concentration-dependent drugs such as the aminoglycosides are used.

The response to antimicrobial therapy should be monitored, using physical examination and clinical pathology data, on at least a daily basis. Failure to improve should prompt a reconsideration of the therapy within 48 to 72 hours, and a worsening of the newborn's condition may necessitate changing the antimicrobial sooner than that. The decision to change antimicrobial therapy should be guided, but not determined, by the results of antimicrobial sensitivity testing of isolates from the affected newborn. These antimicrobial susceptibility patterns should be determined locally because the results can vary geographically, although results of studies are published.[23,24] The utility of antimicrobial sensitivity testing in determining optimal antimicrobial therapy for foals has not been determined, although it is likely that, as with mastitis in cows, sensitivity to antimicrobials determined by the Kirby–Bauer method will not be useful in predicting efficacy.

Fluid Therapy

Fluid therapy of newborns differs from that of adult animals because of important differences in fluid and electrolyte metabolism in newborns. The following guidelines are suggested:

- **Septic shock**—sequential boluses of 20 mL/kg delivered over 5 to 20 minutes with reevaluation after each bolus. Usually, 60 to 80 mL/kg is the maximum dose before use of pharmacologic support of blood pressure is considered. Care should be taken to avoid fluid overload, and the foal should be reevaluated after each bolus and the need for continued fluid therapy determined. Continuous infusion of fluid is not indicated.
- **Maintenance support**—this should be determined based on the ongoing losses and the clinical status of the animal. However, general recommendations are as follows:
  - First 10 kg of body weight—100 mL/kg/d
  - Second 10 kg of body weight—50 mL/kg/d

Table 19-7 Antimicrobials used in neonatal foals

Antimicrobial	Dose and route	Frequency	Comments
Amikacin sulfate	25 mg/kg, IM or IV	24 h	Excellent Gram-negative activity, potentially nephrotoxic. Use with a penicillin.
Amoxicillin trihydrate	25 mg/kg, PO	6–8 h	Variable absorption decreasing with age. Limited Gram negative spectrum.
Amoxicillin–clavulanate	15–25 mg/kg, IV	6–8 h	Enhanced Gram-negative spectrum.
Amoxicillin sodium	15–30 mg/kg, IV or IM	6–8 h	Limited Gram-negative spectrum. Use with an aminoglycoside. Safe.
Ampicillin sodium	10–20 mg/kg, IV or IM	6–8 h	Limited Gram-negative spectrum. Use with an aminoglycoside. Safe.
Ampicillin trihydrate	20 mg/kg, PO	6–8 h	Limited Gram-negative spectrum. Variable absorption decreasing with age.
Cefotaxime sodium	15–25 mg/kg, IV	6–8 h	Use for bacterial meningitis. Expensive.
Cefoperazone sodium	20–30 mg/kg, IV	6–8 h	Use for *Pseudomonas* spp. infections.
Cefpodoxime proxetil	10 mg/kg PO	8–12 h	Broad spectrum and well absorbed by foals after oral administration.
Ceftazidime sodium	20–50 mg/kg, IV	6–8 h	Third-generation cephalosporin. Save for refractory infections.
Ceftiofur sodium	10 mg/kg, IV over 15 min	6 h	Broad spectrum. Note higher dose than used in adults.
Chloramphenicol palmitate	50 mg/kg, PO	6–8 h	Broad spectrum, bacteriostatic. Human health risk. Restricted use.
Chloramphenicol sodium succinate	50 mg/kg, IV	6–8 h	Broad spectrum, bacteriostatic. Human health risk. Restricted use.
Ciprofloxacin	5 mg/kg, IV	12 h	Broad spectrum. Potentially toxic to developing cartilage.
Enrofloxacin	5–7.5 mg/kg, PO or IV	12–24 h	Broad spectrum. Potentially toxic to developing cartilage.
Gentamicin sulfate	12 mg/kg, IV or IM	36 h	Good Gram-negative spectrum. Nephrotoxic. Use with a penicillin. Dose should be decreased to 6.6 mg/kg IV or IM every 24 hours for foals > 2 weeks of age.
Metronidazole	15–25 mg/kg, IV or PO	8–12 h	Active against obligate anaerobes and protozoa only.
Oxytetracycline	5 mg/kg, IV	12 h	Variable Gram-negative activity. Safe. Cheap. High and prolonged dose protocols have the potential to result in discoloration of the teeth.
Procaine penicillin G	20,000–40,000 IU/kg, IM	12 h	Very limited Gram-negative activity. Muscle soreness. Cheap.
Sodium or potassium penicillin G	20,000–40,000 IU/kg, IV or IM	6 h	Limited Gram-negative activity. Use with an aminoglycoside.
Pivampicillin	15–30 mg/kg, IV or IM	8 h	Ampicillin prodrug.
Ticarcillin sodium	50 mg/kg, IV	6 h	Active against Gram-negative organisms. Expensive.
Ticarcillin-clavulanate	50 mg ticarcillin/kg, IV	6 h	Extended activity. Expensive.
Trimethoprim-sulfonamide	15–30 mg/kg, PO, IV	12 h	Cheap. Broad spectrum. Limited efficacy in treating septicemia in foals.

- Weight in excess of 20 kg—25 mL/kg/d

Neonates with high ongoing losses, such as those with diarrhea or gastric reflux, can have higher fluid requirements.

Care should be taken to prevent administration of **excess sodium** to foals because they have a limited ability to excrete sodium. The recommended intake is 2 to 3 mEq/kg/d, and this includes sodium administered in parenteral fluids. One liter of isotonic sodium chloride provides a 50-kg foal's sodium requirements for 1 day.

A suitable maintenance fluid for foals is isotonic dextrose (5%) with supplemental potassium (10 to 40 mEq/L).

Respiratory Support

Respiratory failure, evidenced by elevated arterial P_{CO_2} and decreased P_{O_2}, may be a result of depressed central activity, weakness of respiratory muscles, or lung disease. Regardless of the cause, should the hypoxemia become sufficiently severe, oxygenation must be improved by increasing respiratory drive, increasing the inspired oxygen tension, or employing mechanical ventilation. Foals should always be maintained in sternal recumbency to allow optimal respiratory function.

Provision of respiratory support should be considered when the arterial P_{O_2} is less than 60 mm Hg (8 kPa) and the arterial P_{CO_2} is more than 60 mm Hg (8 kPa) in a foal in sternal recumbency. Pharmacologic respiratory stimulants have only a very short duration of action and are of limited use. Nasal insufflation of oxygen is achieved by placing a nasopharyngeal tube and providing oxygen at a rate of 5 L/min.

Mechanical ventilation is useful for maintaining oxygenation in foals with botulism, with more than 80% of foals surviving in one small study. However, this intervention requires considerable expertise and sophisticated equipment. The prognosis is much worse for foals with diseases of the lungs that require mechanical ventilation.

Gastroduodenal Ulcer Prophylaxis

Ill neonatal foals are often treated with antacid drugs in an attempt to prevent the development or progression of gastroduodenal ulcers, although the efficacy of this approach is unproven. There is a trend toward not administering antiulcer medications to foals except for those with demonstrated gastric ulceration, in part because of the recognition that critically ill foals often have gastric pH above 7.0, and administration of ranitidine does not affect this pH. (See "Gastric Ulcers in Foals" for further discussion.)

COMMON COMPLICATIONS

Complications of the neonate's disease or its treatment occur frequently:

- Entropion is common in critically ill foals and, although readily treated, can cause corneal ulceration if undetected.
- Aspiration pneumonia occurs in weak foals, often as a result of aggressive bottle feeding or regurgitation of milk around a nasogastric tube.
- Nosocomial infections can be severe and life-threatening and are best prevented by strict hygiene and asepsis.
- Septic synovitis/arthritis occurs as a consequence of bacteremia and should be treated aggressively.
- Omphalitis and omphalophlebitis occur and can be an undetected cause of fever and relapse. These are best detected by ultrasonographic examination of the abdomen.
- Patent urachus, evident as urine at the navel, usually resolves with time and local treatment.
- Uroperitoneum as a result of urachal rupture occurs in critically ill foals and should be suspected in any ill foal that develops abdominal distension.
- Angular limb deformities and excessive flexor tendon laxity occur frequently in ill neonatal foals but usually resolve with minimal symptomatic treatment as the foal recovers its strength.

PROGNOSIS

The prognosis for critically ill neonates depends on many factors, including the

nature and severity of the disease, facilities available for care, and the expertise of the personnel caring for the neonate. There is a consensus that the recovery rate for severely ill foals has improved over the last decade because of provision of better care. There are reports of survival rates of around 80% for foals treated at a specialized intensive care unit. However, the high cost of providing care for these animals has prompted studies to determine outcome, as a means of deciding whether, financially, treatment is warranted. Surviving Thoroughbred foals do not differ from siblings with regard to percentage of starters, percentage of winners, or number of starts, but surviving foals achieve significantly fewer wins and total earnings.[25]

The increased number of foals being treated intensively has resulted in prospective studies of outcome. The prognosis for athletic activity for foals with septic arthritis is poor. Thoroughbred foals with **septic arthritis** have odds of 0.28 (95% CI 0.12 to 0.62; roughly one-quarter of the likelihood) for racing compared with a cohort of healthy foals. Multisystemic disease, in addition to the presence of septic arthritis, decreased the likelihood of racing to one-tenth that of healthy foals (OR 0.12, 95% CI 0.02 to 0.90). Affected foals that survive take almost 40% longer to race for the first time. Approximately 30% to 48% of affected Thoroughbred foals eventually race, compared with approximately 65% of normal foals.

Attempts to determine prognostic indicators for survival of foals have been partially successful, but they tend to be most applicable to the intensive care unit in which they were developed. The common theme is that sicker foals are less likely to be discharged from the hospital alive.

Characteristics of foals that are more likely to survive include ability to stand when first examined, normal birth, white blood cell (WBC) count in blood that is within or above the reference range, lack of dyspnea, normal plasma fibrinogen concentration, and short duration of disease. The odds of a hospitalized neonatal foal surviving can be calculated using the following formula:

$$\begin{aligned} &Logit\,(Probability\ of\ survival) \\ &= -0.3072 - 2.0115\,(Cold\ extremities) \\ &\quad - 0.8166\,(Prematurity) \\ &\quad - 0.7685\,(\geq 2\ Infection/\\ &\quad inflammation\ sites) + 0.9877\,(IgG) \\ &\quad + 1.1331\,(Glucose) + 0.9043\,(WBC) \end{aligned}$$

In addition, the survival odds can be summarized in a much more useful form by the methods shown in Tables 19-8 and 19-9. An app to calculate survival probabilities is available for Android phones.[26]

Table 19-8 Method for calculating survival score in hospitalized neonatal foals[1]

Variables	Score	
Cold extremities	No	Yes
	2	0
Prematurity (<320 days)	No	Yes
	1	0
≥2 infection/ inflammation sites	No	Yes
	1	0
IgG (mg/dL)	<400	≥400
	0	1
Glucose (mg/dL)	<80	≥80
	0	1
WBC × (10^3/μL)	≤4	>4
	0	1
TOTAL SCORE		

Table 19-9 Probability of survival for hospitalized neonatal foals with survival scores calculated according to table 19-8

Total foal survival score	Probability of survival
0	3%
1	8%
2	18%
3	38%
4	62%
5	82%
6	92%
7	97%

STILLBIRTH/PERINATAL WEAK-CALF SYNDROME

SYNOPSIS

Etiology Uncertain; probably multiple etiologies and multifactorial.

Epidemiology Most commonly several cases on a farm; several farms affected in a geographic region in a single season; problem may not occur for several years and then occur as "epidemic" in a region.

Clinical findings Calves may be born weak and unable to stand. More commonly, they are born apparently normal and stand but subsequently collapse with hypothermia and die within a few hours of birth.

Lesions Petechial hemorrhages, subcutaneous edema, and hemorrhage commonly in the subcutaneous tissue of the carpal and tarsal joints.

Diagnostic confirmation Specific to cause.

Treatment Supportive.

Control Specific to cause.

HISTORICAL ASPECTS

A syndrome of newborn calves called *weak-calf syndrome* was first recognized in Montana in 1964. It has been recognized throughout the United States and other countries since then, and it is considered a major economic loss in beef cattle herds. In the earlier descriptions of the syndrome, calves were affected by 10 days of age, and approximately 20% were affected at birth. Morbidity ranged from 6% to 15%. In some herds, sporadic abortions occurred before calving season of the herd began. In some cases, affected calves died within minutes after being born with varying degrees of obstetric assistance.

In calves that survived for a few days, clinical findings included lassitude, depression, weakness, variable body temperature, a reddened and crusty muzzle, lameness, reluctance to stand, enlargement of the carpal and tarsal joint capsules along with periarticular subcutaneous swellings, and a hunched-up back if they stood. Diarrhea occurred in some calves after a few days of illness, but it was not a major clinical finding. Treatment was ineffective, and the case fatality rates ranged from 60% to 80%.

At necropsy, the prominent lesions were hemorrhage and edema of the subcutaneous tissues over the tarsal and carpal joint regions and extending distally. Polysynovitis with

hemorrhagic synovial fluid often containing fibrin was also common. Erosive and hemorrhagic lesions of the forestomaches and abomasum also occurred. Several different pathogens were isolated from these calves, but no consistent relationship between the pathogens and the lesions was ever determined.

In retrospect, the case definitions were not well described, and it is probable that several different diseases of newborn calves were lumped into the enigma of weak-calf syndrome. As more detailed clinical and laboratory examinations of sick newborn calves have been done over the years, some of the causes of the original syndrome have been identified as specific diseases of newborn calves.

Widely ranging clinical and pathologic findings have been associated with weak-calf syndrome. In the most common situation, calves are born weak and die within 10 to 20 minutes after birth; sometimes they live for up to a few days. At necropsy there are no obvious or only few lesions to account for the illness. Calves that are weak after birth because of traumatic injuries associated with dystocia or other significant lesions can be accounted for according to the nature and severity of the lesions. Reports from Northern Ireland in recent years indicate that in dairy herds the incidence of weak-calf syndrome has ranged from 10% to 20% of all calves born. Field observations in problem herds found that the gestation period is of normal duration, but parturition is usually prolonged, with the first and second stages of labor lasting 24 hours. Affected calves usually are born alive but are unable to sustain breathing following birth. Despite resuscitation efforts, they commonly die within 10 minutes, often accompanied by prominent uncoordinated movements of the limbs. Some calves are stillborn, and whether or not this is a variation of the syndrome is uncertain. In a report from the United Kingdom, the syndrome occurred in calves born from heifers and was characterized by failure to breathe at birth or breathing with difficulty, and/or failing to move after birth, and failure to suck. The term *stillbirth/perinatal weak-calf syndrome* has been suggested as more appropriate.

Dummy-Calf Syndrome

A variation of weak-calf syndrome is dummy-calf syndrome, which has been reported in the southern United States. Affected calves appear normal at birth and are generally alert, but they lack the instinct or the desire to seek the teat or suck after birth and for up to several hours later. The syndrome may occur in calves of any birth weight. The incidence has been highest in purebred Brahman females, but it has also occurred in Aberdeen Angus, Hereford, Chianina, and Brown Swiss breeds of cattle. Field observations indicate that affected calves did not stand for up to 1 to 2 hours after birth to initiate teat-seeking behavior. Dummy calves appear to lack the sensitivity to teat-seek, and if they fail to locate a teat by about 4 to 5 hours after birth, they commonly lose the sucking reflex and then require intensive nursing care by bottle feeding to initiate sucking. In calves that fail to suck and ingest colostrum, hypothermia, hypoglycemia, and neonatal infections are common complications. Concurrently, the dam loses interest in the calf and may abandon it.

ETIOLOGY AND EPIDEMIOLOGY

The etiology of weak-calf syndrome is unclear, but several epidemiologic observations have suggested some possible causes. These include the following:

- Fetal infection near term
- Underdevelopment because of nutritional inadequacy of the maternal diet during pregnancy
- Placental insufficiency
- Maternal dietary deficiencies of selenium and vitamin E
- Hypothyroidism
- Traumatic injuries associated with dystocia and excessive force during obstetric assistance
- Fetal hypoxia from prolonged parturition

Fetal Infections

Fetal infections in the last few days before term can result in stillbirth or weak calves that may die within hours or days after birth. In one series of 293 weak calves in Northern Ireland, **leptospiral infection** was present in 25% of the calves. Calves in which leptospiral antigen was detected in the placenta were significantly lighter by an average of 6 kg to 10 kg than calves with no antigen in the placenta. Calves infected with *Leptospira* in utero were more likely to be infected by *T.* (formerly *Arcanobacterium) pyogenes* or *Bacillus* species, and infection of the placenta is associated with a lower body weight. The adrenal gland, lung, and placenta are the most useful tissues to examine for leptospiral antigen.

Bovine viral diarrhea (BVD) virus infection has been identified in several herds with high occurrence rates of weak-calf syndrome. Effects of intrauterine infection with this virus will depend on the stage of pregnancy at which infection occurs, but birth of stillborn, weak, or dummy calves certainly warrants taking this differential into consideration (see also "Bovine Viral Diarrhea").

An unidentified type of adenovirus has been associated with weak-calf syndrome on a large dairy farm in Israel. At birth the calves were reluctant to suck or drink colostrum and were force-fed colostrum with an orogastric tube. Affected calves were weak at birth and unable to rise without assistance; when forced to move they walked stiffly, suggestive of polyarthritis. An adenovirus was detected in the feces, synovial fluid, and aqueous humor of affected calves.

Maternal Nutritional Deficiency Causing Fetal Underdevelopment

Hypothyroidism as a result of iodine deficiency in the pregnant dam has been considered on the basis of thyroid hyperplasia in some calves. Analysis of the laboratory data from 365 calves that died from the stillbirth/perinatal weak-calf syndrome in Ireland found some differences between calves with abnormal versus normal thyroid glands. Glands weighing more than 30 g were probably abnormal. Abnormal glands were heavier, constituted a greater percentage of the calf's body weight, and had a lower iodine concentration. A higher proportion of calves with an abnormal thyroid gland had uninflated lungs and pneumonia. Abnormal thyroid glands had a lower selenium concentration in the kidneys.

Hypothyroidism as a result of iodine deficiency can be caused by either inadequate dietary iodine supply or the presence of goitrogens in feed. Goitrogens are substances that impair thyroid hormone synthesis, either by inhibiting iodine uptake (cyanogenic goitrogens) or by inhibiting organic binding of iodine by the thyroid glands (goitrogens of the thiouracil type).[1]

However, the experimental reproduction of iodine deficiency in pregnant heifers by feeding an iodine-deficient diet over the last 4 to 5 months of pregnancy resulted in clinicopathologic changes and pathologic changes in the thyroid glands of both the heifers and their calves, but all calves in the iodine-deficient group were born clinically normal.

Because selenium plays a role in the function of the thyroid glands, selenium deficiency can cause hypothyroidism despite adequate dietary iodine supply. **Maternal dietary deficiency of selenium** in pregnant cattle has also been examined, but field trials have failed to show any protective effect from the parenteral administration of pregnant cattle with selenium. The parenteral administration of both selenium and iodine to pregnant cattle did not have any effect on the incidence of the syndrome between treated and untreated herds; the incidences were 7.9% and 7.4%, respectively.

A general nutritional inadequacy in the maternal diet can result in underdevelopment of the fetus and the birth of smaller-than-normal calves, but the deficiency usually must be grossly inadequate. A clinical trial showed that feeding a protein-restricted ration (7% crude protein) during the last trimester of pregnancy resulted in 11.4% lower birth weights than in control animals and in compromised thermogenic ability of the newborn calves, which has been proposed as a contributing factor to perinatal mortality of calves.[2] Another study

reported a selective decrease in absorption of colostral IgG_1 and IgG_2 from the gut in calves from heifers fed protein-deficient diets during the last trimester of pregnancy, which implies a higher risk for FTPI in these calves.[3]

Placental Insufficiency

Intrauterine growth retardation associated with feto-placental dysfunction has been described in Japanese Black beef calves.[4] Affected calves were weak when born at term and were underweight compared with normal calves. Anemia as a result of bone marrow dysfunction was present in affected calves and presumably was associated with intrauterine growth retardation. Thymic hypoplasia is another common finding in Japanese Black calves that died during the perinatal period, which also has been attributed to intrauterine growth retardation and is thought to contribute to perinatal weak-calf syndrome, which has a high occurrence rate in this breed.[4,5] There is some evidence that an immune inadequacy based on T-lymphocyte function may be associated with weak-calf syndrome in Japanese Black calves, which could be related to the thymic hypoplasia because the thymus is the site of T-cell maturation.

Dams delivering weak calves also had lower serum concentrations of estrone sulfate during late pregnancy than those of normal calves, suggesting a feto-placental dysfunction. The dysfunction was influenced by sires and maternal families.

Fetal Hypoxemia

Fetal hypoxemia resulting from prolonged parturition or dystocia may be a cause or contributing factor to weak-calf syndrome. Various predisposing factors can cause prolonged interference with fetal blood or oxygen supply, which can result in death during delivery or shortly after.

Examination of blood-gas values in newborn calves has shown that a prolonged parturition or delivery terminated by forced extraction results in a severe acidemia as a result of oxygen deprivation and ensuing anaerobic glycolysis with lactate accumulation in combination with hypercapnia, resulting in respiratory acidosis. As blood pH drops, first vitality is reduced, subsequently vital organs such as the brain are damaged, and ultimately the fetus dies.

The bovine fetus appears relatively susceptible to hypoxia and hypercapnia, which has been studied experimentally by clamping the umbilical cords of fetuses for 4 to 8 minutes, at 24 to 48 hours before expected birth, followed by a cesarean section 30 to 40 minutes later. Calves born following this procedure may die in 10 to 15 minutes after birth or survive for only up to 2 days. Under these experimental conditions, fetuses can survive anoxia for 4 minutes, but most will die following 6 or 8 minutes of anoxia.[6] During the clamping there is also increased fetal movement and a release of meconium that stains the calf and the amniotic fluid. Those that survive for a few hours or days are dull and depressed, cannot stand, and have poor sucking and swallowing reflexes, and their temperatures are usually subnormal. They respond poorly to supportive therapy. Some calves whose umbilical cords were clamped for 4 minutes were born weak and made repeated efforts to raise their heads and move onto the sternum, but they were unable to maintain an upright position for long. These calves become hypothermic and dull, and their sucking and swallowing reflexes are present but weak. These calves are usually too weak to suck the cow even when assisted, and they commonly develop diarrhea and other complications.

Dystocia and Traumatic Injuries at Birth

Over 50% of perinatal mortality is generally attributed to dystocia, and dystocia may be an important contributing factor to weak-calf syndrome because of fetal hypoxia or traumatic injuries associated with obstetric assistance.[7] In a study of 13,296 calvings over a period of 15 years in two research herds in Montana, calf mortality as a result of dystocia accounted for the single largest loss category through the first 96 hours postpartum. Reported ORs vary widely (2.7 to 14.6), but they suggest that calves requiring assisted delivery had a 2.7 to 14.6 higher risk of death in the perinatal period than spontaneously born calves.[8] At necropsy of the calves that died as a result of dystocia, the findings included a froth-filled trachea, nonfunctional lungs, bruises, contusions, hemorrhages, bone fractures, and joint dislocations. It was concluded that the provision of adequate obstetric assistance at the right time could have reduced the mortality associated with dystocia.

Traumatic injuries of calves at birth are caused primarily by the mechanical influence of traction during delivery and can result in asphyxia and a high perinatal mortality rate. Excessive traction is the most important cause of rib and vertebral fractures in the calf during dystocia. A series of 235 calves that died perinatally were examined by necropsy to determine the possible causes of death related to dystocia. Most of the parturitions were protracted and needed veterinary assistance, and 58% of the calves had pathologic evidence of asphyxia. Calves delivered by extraction had pathologic evidence of asphyxia more often than those born unassisted or delivered by cesarean section. Intrapulmonary amniotic material may be present in the lungs, representing evidence of perinatal respiratory distress. The aspiration of small amounts of amniotic fluid with or without meconium is common in calves and is not associated with hypoxemia, respiratory acidosis, or failure of passive transfer.

Premature Expulsion of Placenta

Premature expulsion of the placenta has been associated with perinatal calf mortality. Field observations indicate that the majority of affected fetuses die of fetal hypoxia during stage 2 of calving. The most significant risk factor associated with premature expulsion of the placenta was fetal malpresentation and malposture. Prolongation of the second stage of parturition allows for sufficient detachment of the placenta for it to occupy the posterior part of the genital tract. The placenta is frequently expelled together with the calf. In one series of cases, there was no significant relationship between the occurrence of premature expulsion of the placenta and parity, calving difficulty, previous calving history, or sex of the calf.

NECROPSY FINDINGS

All calves that die should be examined by necropsy to identify possible causes. It is important to establish if there is one disease complex or several different diseases of newborn calves.

In the weak-calf syndrome described in Northern Ireland, at necropsy many calves had petechial hemorrhages in the thymus gland, on the ventricular epicardium, and in the parietal pleura and endocardium. These lesions were similar to those present in animals that died of acute terminal asphyxiation. The gasps made in response to asphyxia in utero result in amniotic fluid being inhaled into the respiratory tract. In one study, 84% of stillborn calves had these lesions of asphyxia. It is well established that asphyxiation during birth is a major factor in intrapartum stillbirth in piglets and contributes to early postnatal mortality. Froth may be present in the caudal trachea of some calves that die within 10 to 20 minutes after birth.

Varying degrees of subcutaneous edema of the head and/or bruising of the rib cage are also common. Fractures of the ribs are common, accompanied by intrathoracic hemorrhage. Vertebral body fractures occur commonly at the thoracolumbar region and may be accompanied by intraabdominal hemorrhage. The lungs may be inflated normally, partially inflated, or not inflated. Severe bruising and hemorrhage occur around the costochondral junctions, at the sternal extremities of the costal cartilages, and over the sternum and shoulder regions. In some cases, the traumatic lesions are severe and may involve primarily the right side of the rib cage. Severe subcutaneous hemorrhage and edema may be present over the carpal and fetlock joints as a result of the pressure applied by the obstetric chains or ropes.

In the syndrome described in the United States, the lesions either appeared at birth or developed in the first few weeks of life. At necropsy the prominent lesions are marked edema and hemorrhages of the subcutaneous tissues over the carpal and tarsal joints

and extending distally down the limbs. The synovial fluid may be tinged with blood and contain fibrinous deposits. Erosions or ulceration of the gastrointestinal tract, petechial hemorrhage of internal organs, involution of the thymus gland, and hemorrhages in skeletal muscle have also been present.

The weak-calf syndrome described in Japanese Black calves was associated with atrophy of the red bone marrow and thymic hypoplasia.[9] Degeneration of brainstem nerve cells, attributed to protracted hypoxia, was also noticed.

Samples for confirmation of diagnosis include the following:

- Bacteriology—fetal liver, lung, stomach content, adrenal gland; placenta (culture); special detection techniques for *Leptospira* antigens
- Histology—fixed placenta, lung, spleen, brain, liver, kidney; maternal caruncle (light microscopy, Immunohistochemistry)

DIFFERENTIAL DIAGNOSIS

Determination of the cause of weak-calf syndrome in a herd is often difficult because the limits of the case definition cannot be determined. Several risk factors may interact to contribute to the disease. The most common definition is a calf that is alive at birth, appears normal otherwise, but either fails to breathe or breathes for less than approximately 10 minutes and then dies. If they survive for several hours or a few days, affected calves are usually in sternal recumbency, depressed, reluctant to stand unassisted, reluctant to walk, and not interested in sucking. They may not respond favorably to supportive therapy.

Case definition

When an epidemic of the disease is encountered, an epidemiologic investigation of the herd is necessary in an attempt to identify possible risk factors.

The patterns of occurrence should be determined:

- Is the problem more common in calves born to heifers than cows? In some situations, the owner may provide more surveillance for the calving heifers and less for the mature cows, with a consequent greater incidence of weak calves born from the cows.
- Is there any evidence that parturition is prolonged in the heifers or the cows? If so, what are the possible reasons?
- How long are heifers and cows in the herd allowed to calve unassisted before obstetric assistance is provided?
- Is it possible that some nutritional, management, or environmental factor is interfering with normal parturition?
- Is the condition more common in male or female calves, and what are the relative birth weights?
- How soon after birth are the calves affected?
- What is the course of the illness after the first clinical abnormalities are noted?
- Is the serologic herd status regarding specific infectious diseases known (e.g., *leptospirosis*, BVD, bluetongue)?
- The veterinarian should make every effort to clinically examine a representative number of affected calves.

TREATMENT

Calves born weak, unable to stand, lacking the instinct to seek the teat, or lacking a suck reflex need intensive care, including force-feeding of colostrum and the provision of warm surroundings to prevent hypothermia and other complications. Affected calves must be assisted to suck the dam normally. Bottle feeding for a few days may be necessary until the calf becomes strong enough to suck the dam on its own.

CONTROL AND PREVENTION

Control and prevention of weak-calf syndrome is based on empirical observations, beginning with insuring **adequate nutrition of the dam** to avoid any possible nutritional factors affecting neonatal calf vitality. The provision of **adequate surveillance at calving time** and competent obstetric assistance when necessary is also crucial to avoid prolonged parturition and fetal hypoxia in calves.

When epidemics of the disease are occurring, the surveillance of calving must be intensified, and it may be necessary to intervene with obstetric assistance earlier than usual. Determination of the cause may require that the veterinarian attend several calvings, make detailed clinical examinations of the length of parturition, and observe the parturition process and the health of the calves at birth.

DISEASES OF CLONED OFFSPRING

The successful cloning of domestic animals using somatic-cell nuclear transfer has resulted in birth of offspring with a high frequency of clinical abnormalities. Cloning of livestock and horses is achieved by transfer of nuclear material from the cell of an adult animal to the enucleated egg of an animal of the same species (somatic-cell nuclear transfer), with subsequent implantation of the resulting embryo in a surrogate dam and birth of a live, viable offspring. However, the use of nuclear material from somatic cells of adult animals, and from fetal cells, frequently does not result in normal development of the embryo and placenta.

The abnormal development in cloned embryos is a consequence of altered methylation of the genome in transferred nuclear material. This applies particularly for imprinted genes, which are those genes for which only one copy is expressed in the embryo, compared with nonimprinted genes for which both parental copies of the gene are expressed. The lower frequency of expression of imprinted genes (i.e., only one copy, paternal or maternal) is a result of methylation of DNA or chromatin proteins that makes the DNA inaccessible for transcription.[1] Imprinting is a form of epigenetic control of gene expression. To date, 132 imprinted genes have been identified in mice, but only 25, 21, and 14 in cattle, pigs, and sheep, respectively.[1] Imprinted genes encode proteins involved in regulation of many cell processes, including embryonic and neonatal growth and development.[1,2]

In normal reproduction, the paternal genome is demethylated during passage through the oocyte and fusion with the maternal genome. Consequently, the methylation marks of the two genomes (paternal and maternal) are different at the end of the cleavage process. Transfer of somatic nuclear material into an enucleated oocyte results in exposure of both genomes to the active demethylating process in the cytoplasm of the oocyte and uniform or variable demethylation of both genomes. The loss of these parent-specific epigenetic markers results in widespread dysregulation of imprinted genes and subsequent abnormalities in the placenta, fetus, and newborn. Imprinting marks (methylation) are erased during early development, and reprogramming of somatic-cell nuclei used in cloning and these abnormalities in epigenetic control of expression of imprinted genes result in biallelic expression of imprinted genes.[3] The loss of epigenetic control of imprinted genes causes at least some of the abnormalities common in cloned ruminants, including large-offspring syndrome (LOS).[3]

A small proportion of transferred blastocysts develop in viable animals. For cattle, of 134 recipients that received blastocysts, 50

were pregnant 40 days after blastocyst transfer, and 23 had full-term pregnancies. For all species studied, fewer than 3% of cloned embryos result in birth of viable animals. Abnormalities in the placenta and newborn cloned animals are reported for cattle and sheep, but are less frequently reported, if at all, for pigs and equids (horses and mules). Factors influencing the risks of abnormalities in newborns include the source of the nuclear material, type of in vitro culture media, coculture with somatic cells, hormonal treatments, and manipulation of the embryo.[1,4] The frequency of birth of live animals born after somatic-cell nuclear transfer from well-differentiated tissue (e.g., fibroblasts) or fetal somatic cells is lower than after nuclear transfer from embryonic cells (7%, 15%, and 34%, respectively).

The cause of placental, fetal, and neonatal abnormalities is abnormal expression of imprinted genes as a consequence of transfer of nuclear material from differentiated somatic cells,[5] conditions and media used for maintenance and culture of cytoplasts and blastocysts, and techniques used for handling cells.[3,6-8] The key abnormality is loss of methylation of imprinted genes contributed by each parent, with subsequent biallelic expression of these genes. There is debate about which epigenetic or genetic abnormalities underlay the development of placental and fetal abnormalities. Aberrant hypomethylation of IGF-2 and CDKC1C genes has been identified in calves with LOS and results in biallelic expression in the liver and placenta of affected animals.[1] Abnormalities in embryologic development of vasculature is identifiable early during embryogenesis in calves and might be the defect underlying pulmonary, circulatory, and umbilical abnormalities in cloned calves.[9] Furthermore, there is decreased expression of genes in the lungs of cloned goats that do not survive compared with those of healthy kids. Compared with normal goats of the same age from conventional reproduction, expression of 13 genes (BMP4, FGF10, GHR, HGFR, PDGFR, RABP, VEGF, H19, CDKNIC, PCAF, MeCP2, HDAC1, and Dnmt3b) decreased in transgenic cloned goats that died at or shortly after birth.[6] Expression of eight genes (FGF10, PDGFR, RABP, VEGF, PCAF, HDAC1, MeCP2, and Dnmt3b) decreased in fetal death of transgenic cloned goats.[6] A comprehensive list of genes known to be involved in embryogenesis and fetal and placental growth and a description of the effect of decreased expression of these genes are available.[10]

Clinical findings in cloned calves and lambs include abortion, placental abnormalities, large birth size, poor extrauterine viability, respiratory disease, cardiovascular abnormalities, and neurologic disease compatible with neonatal encephalopathy. LOS is confined to ruminants and is characterized by overgrowth, evident as abnormally high birth weight, enlarged tongue, umbilical hernias, and hyporglycemia.[3] Abortion occurs after day 90 of gestation in 30% to 50% of pregnancies in cattle, resulting from transfer blastocysts containing transferred nuclear material. Abnormalities, including hydroallantois, are present in approximately 25% of advanced pregnancies. **Placental abnormalities** include hydroallantois, a reduction in the number of placentomes (from a normal value of approximately 100 to as few as 26 to 70 in cloned calves), abnormally large placentomes (140 g in cloned calves versus 33 g in conventional calves), and edema of the placenta.[10] Maternal retention of the placenta is common and occurs in most cows. Duration of gestation is probably longer in cloned calves, although the frequent delivery of cloned calves by cesarean section makes assessment of gestational duration difficult. Cloned calves are heavier than conventional calves, often by as much as 25%, a well-recognized part of the **large-offspring syndrome** that affects calves born as a result of reproductive manipulation, including in vitro fertilization. Viability of cloned calves that are born alive (commonly by cesarean section) is less than that of conventional calves; only approximately two-thirds of cloned calves born alive survive more than 1 month, although others have reported better survival. Similar results are reported for horses.

A high proportion of cloned calves have **clinically detectable abnormalities** at or soon after birth, including sepsis, neonatal encephalopathy, respiratory failure, umbilical abnormalities, anemia, flexure contracture, abdominal distension, and renal dysfunction. Respiratory failure is a common finding and might reflect persistent fetal circulation or inadequate surfactant production, as evidenced by the high pulmonary artery pressures and signs consistent with patent ductus arteriosus.[11] Left heart failure, which can also cause pulmonary hypertension, is reported in cloned calves. Umbilical abnormalities are evident as abnormal umbilical cord structure (multiple arteries and veins) and large size, with a high risk of hemorrhage from the umbilical cord after birth. Cloned calves have higher body temperatures than do conventional calves.

Of 27 cloned calves delivered alive, 7 were bradypneic or apneic at birth, 5 had flexural limb deformities, and at least 23 had enlarged umbilical cords. The calves were acidotic at birth as a result of both respiratory and lactic acidosis. Calves had normocytic hypochromic anemia, stress leukogram (leukocytosis, neutrophilia, and lymphopenia), and hypoproteinemia (with both hypoalbuminemia and hypoglobulinemia) and had increased serum creatinine concentration.[12] Three of the calves did not develop other clinical signs and were considered healthy after birth, whereas 22 had at least one important clinical abnormality detected during the week after birth. Twelve of the calves developed omphalitis. Fourteen of the calves died or were euthanised.[12]

Hematologic abnormalities include anemia and decreased mean corpuscular volume. Biochemical abnormalities include hypoxemia, azotemia, and hypoglycemia. Plasma leptin and IGF-2 concentrations are higher, and thyroxine lower, in cloned calves. Serum cortisol and adrenocorticotropic hormone (ACTH) stimulation tests do not differ between cloned and conventional calves. Cloned calves can mount normal immune responses.[13] Failure of transfer of passive immunity can occur if calves are unable to suckle or are not administered colostrum or plasma.[12]

Necropsy examination reveals placentomegaly, presence of excess pleural and peritoneal fluid, hepatomegaly, interstitial pneumonia or pulmonary consolidation and alveolar proteinosis, right ventricular dilation, and hepatocellular vacuolation.

Treatment is supportive and directed toward correcting hypoxemia and providing nutritional, fluid, and environmental support (see earlier discussion).

There are currently no recognized methods for preventing these abnormalities, but incremental improvements in methodology and culture techniques will continue to result in fewer cloned offspring with these abnormalities.

EQUINE NEONATAL MALADJUSTMENT SYNDROME (NEONATAL ENCEPHALOPATHY, DUMMY FOAL, BARKERS, AND WANDERERS)

This is a syndrome of foals less than 36 hours of age characterized by a spectrum of changes in mentation ranging from failure

to suckle, abnormal behavior, and seizures through coma in otherwise apparently healthy foals. The syndrome is defined by the clinical abnormalities and not by a common etiology.

ETIOLOGY

The clinical signs associated with this syndrome can be produced by a number of diseases, each of which has its particular etiology. Diseases that contribute to this syndrome include antenatal, natal, or postnatal hypoxia;[1] a range of congenital abnormalities (hydrocephalus, hydrencephalus,[2] and such); metabolic disorders;[3] placental abnormalities;[4] intracranial hemorrhage; prematurity; and thoracic trauma. Fetal or perinatal hypoxia has achieved some prominence as a cause of neonatal maladjustment syndrome in the absence of consistent demonstration of lesions of hypoxia on histopathologic examination of foals. There are isolated cases in which histologic evidence of hypoxia exists, but these are the exception rather than the rule. Finally, most foals with neonatal maladjustment syndrome improve rapidly and completely recover within several days—a clinical course not expected with neonatal or perinatal asphyxia in other species.

Recent evidence implicates a role of neuroactive progestagen derivatives in the etiopathogenesis of neonatal maladjustment syndrome.[5,6] Plasma concentrations of these neuroactive steroids in foals are high immediately after birth and decline rapidly in healthy foals, but not in foals with neonatal maladjustment syndrome.[5] Foals with neonatal maladjustment syndrome and foals with other illness have higher concentrations of progestagen derivatives than do healthy foals.[5] Plasma concentrations of progestagen derivatives decline in sick foals that do not have neonatal maladjustment syndrome, but not in foals with the syndrome.[5] Progestagen derivatives include progesterone, pregnenolone, androstenedione, dehydroepiandrosterone, and epitestosterone.[5] Evidence from other species and limited experimental evidence in foals indicate that allopregnanolone infusion induces changes in mental status that mimic those seen in foals with neonatal maladjustment syndrome.[6] It is proposed that a subset of foals with signs of neonatal maladjustment syndrome have disease attributable to persistence of the fetal hypothalamic–pituitary–adrenal axis after birth.

EPIDEMIOLOGY

The disease is sporadic and occurs worldwide, with an annual **incidence** in foals of less than 1%.[7] Foals of either sex and of any breed born to mares of any age or reproductive history can be affected. The **case fatality rate** is very low for appropriately treated foals without other systemic illness.

PATHOGENESIS

Hypoxia resulting from intracranial vascular accidents, asphyxia at birth, or placental insufficiency before birth damages the central nervous system, causing a wide variety of signs of neurologic dysfunction.

A proposed pathogenesis for foals with persistently high plasma concentrations of progestagen derivatives after birth is failure of the foal's hypothalamic–pituitary–adrenal axis to rapidly adjust to extrauterine life.[6] In utero, foal movement and activity is suppressed, presumably at least in part by high concentrations of neuroactive progestagens. At birth in healthy foals there is a rapid reduction in concentration of these hormones coincident with increases in activity of the foal. Progestagen derivatives, some of which can cross the blood–brain barrier, modulate the activity of the $GABA_A$ receptor and at high concentrations completely inhibit its activity, providing a potential explanation for the somnolence and other signs displayed by foals with neonatal maladjustment syndrome and high plasma progestagen concentrations.[5]

Neurologic abnormalities and a failure to nurse result in a failure of the transfer of maternal immunoglobulins, which predisposes the foal to septicemia and hypoglycemia. Failure to nurse also results in hypoglycemia and malnutrition.

CLINICAL SIGNS

Foals that are abnormal at birth can display a range of behavioral abnormalities, from lack of suckle reflex to convulsions with extensor rigidity. The placenta of affected foals is often abnormal, or there is a history of prolonged parturition. Affected foals either do not develop or lose the suck reflex, have no affinity for the mare, and are unable to locate the udder or teat. Aimless wandering and a characteristic "barking" vocalization are sometimes present. Recumbent foals struggle wildly and in an uncoordinated fashion to stand. Convulsing foals usually display opisthotonos with extensor rigidity. Other signs of convulsive activity include facial twitching and grimacing, nystagmus, rapid blinking, sucking, chewing, and drooling. Between episodes foals are usually depressed or somnolent. Affected foals display little or no interest in the mare. Convulsing foals are tachypneic, tachycardic (>180 bpm), and hyperthermic (>39° C, 102° F) during and immediately after convulsions. It is important to recognize that the severity of clinical signs varies from very mild (foals are often described by owners as being a bit slow or dimwitted) through to grand mal seizures.

Foals that are normal at birth can develop signs by 24 hours of age. The signs are similar to those described previously, with the exception that the foals are initially able to ambulate. It is important to realize that healthy newborn foals lack a menace reflex, have a hypermetric gait and intention tremor, and become flaccid when restrained. The reflex response of healthy foals to restraint by a handler placing one arm under the foal's neck and another around the buttocks and squeezing is to become "floppy" and somnolent.[6] Foals restrained in this way become immobile, lie down, and have an increased pain threshold during restraint.[6]

Affected foals can take days to weeks to recover completely. Blind foals that do not have ocular lesions can take as long as 4 to 6 weeks to regain vision.

Ancillary testing is not usually indicated unless the foal fails to respond after approximately 7 days. At that time, CT or MRI examination of the brain might be indicated to detect congenital anomalies such as hydrocephalus. Examination of CSF should be performed in any foal with signs of central nervous system dysfunction in the presence of fever or other signs of sepsis.

CLINICAL PATHOLOGY

There are no routine hematologic or serum biochemical abnormalities characteristic of the disease, although it is prudent to conduct such examinations to eliminate other diseases; common characteristics are as follows[3]:

- Affected foals usually have **failure of transfer** of maternal immunoglobulins (serum IgG < 400 mg/dL).
- They may be **hypoglycemic** (<80 mg/dL, 4 mmol/L).
- **Cerebrospinal** fluid is often normal, although it may contain red blood cells or appear xanthochromic as a result of bleeding.

Detection of **biomarkers of brain injury** has been investigated. Plasma concentrations of **ubiquitin C-terminal hydrolase** (UCHL1) are higher (6.57, range 2.35 to 11.9 ng/mL) in foals with signs of neonatal maladjustment syndrome (defined as neonatal hypoxic-ischemic encephalopathy in the study) than in healthy foals (2.52, range 1.4 to 4.01 ng/mL).[8] The sensitivity and specificity for diagnosis of neonatal maladjustment syndrome based on a cutoff of ubiquitin C-terminal hydrolase concentrations in plasma of 4.01 ng/mL were 70% and 94%, respectively.[8]

Measurement of **plasma progestagen concentrations** of foals with signs of neonatal maladjustment syndrome might prove to be useful in diagnosis of the disease. Foals with high concentrations of progestagens could be treated appropriately, and those with low or normal concentrations could be further investigated for other diseases such as intracranial hemorrhages or hydrocephalus.

DIAGNOSTIC CONFIRMATION

Definitive diagnosis of the disease is difficult and is based on exclusion of other diseases that can cause similar signs and, at necropsy, demonstration of intracranial lesions consistent with the disease.

NECROPSY FINDINGS

Gross changes are typically limited to diffuse pulmonary congestion with a variable degree of atelectasis. In cases in which dystocia has been a contributing factor, fractured ribs and foci of subcutaneous edema and hemorrhage are sometimes noted. Occasionally, macroscopic cerebral hemorrhages are visible. Histologically, the key findings are hemorrhagic foci within the brain and areas of ischemic necrosis in the cerebral cortex. Meconium and other components of aspirated amniotic fluid accompanied by atelectasis and a mild inflammatory response may be present within the lung. In less affected foals the brain lesions are restricted to hemorrhage, cerebral swelling, and edema. Some affected foals subject to necropsy examination have evidence of intracranial vascular accidents, but it must be recognized that this is a biased sample; many foals recover from the disorder. Affected foals that are euthanized for financial or management reasons often have no detectable lesions in the brain.

Samples for Postmortem Diagnostic Confirmation

Samples for postmortem diagnostic confirmation include formalin-fixed brain, including cerebral cortex, cerebellum, and brainstem, and lung for light microscopic examination.

DIFFERENTIAL DIAGNOSIS

The disease must be differentiated from other diseases that cause neurologic or behavioral abnormalities in foals, including sepsis; renal, hepatic, or gastrointestinal disease, which can occur secondary to fetal hypoxia; hydrocephalus; hypoglycemia; meningitis; neonatal isoimmune hemolytic anemia; and prematurity, dysmaturity, or immaturity (Table 19-10).

TREATMENT

The principles of treatment are as follows:

- Control of convulsions
- Treatment of cerebral edema and hemorrhage
- Correction of FTPI
- Nutritional support and general nursing care

The management of affected foals is mainly supportive and is a time-consuming and labor-intensive endeavor. Provision of nutritional support, treatment of failure of transfer of maternal immunoglobulins, and nursing care are discussed in detail in the section "Principles of Care of the Critically Ill Neonate."

For other than emergency treatment of seizures, in which **diazepam** (0.1 to 0.4 mg/kg, intravenously, as required) or **midazolam** (0.05 to 0.1 mg/kg IV, as required) are useful, **phenobarbital** (phenobarbitone), **phenytoin,** and **primidone** are the drugs of choice for long-term control of seizure activity. Phenobarbital is administered initially at a dose of 9–20 mg/kg intravenously in 30 mL of isotonic saline infused over 15 to 30 minutes. Maintenance therapy is a similar dose intravenously (7–9 mg/kg IV over 20 min every 8–12 hours) or a lower dose (1–5 mg/kg) orally, every 8 hours, and the dose is adjusted

Table 19-10 Differential diagnosis of comatose ("sleeper") neonatal foals

Disease	Epidemiology	Clinical findings	Clinical pathology	Lesions	Treatment and prognosis
Septicemia	*E. coli, Klebsiella* spp., *Streptococcus* spp., *Salmonella* spp., *Actinobacillus suis,* Equine herpesvirus-1. Failure of transfer of passive immunity.	Abrupt onset of depression, fever, failure to nurse, and recumbency. Later diarrhea, pneumonia, and joint distension.	Culture of organism from blood or lesions (joints, lungs, feces).	Consistent with septicemia. Pneumonia. Septic synovitis, arthritis, and osteomyelitis.	Broad-spectrum antibiotics, supportive care (see "Principles of Providing Care to the Critically Ill Neonates"). Guarded to poor prognosis.
Isoimmune hemolytic anemia	Incompatible mating of Aa + or Qa + stallion with negative mare.	Normal at birth. Subsequent depression, cessation of nursing, exercise intolerance, icterus, and anemia. Hemoglobinuria in severe cases.	Positive Coombs' test to demonstrate immunoglobulin on foal's red cells. Dam's colostrum agglutinates or lyses foal red cells.	Anemia, icterus. Death from anemic hypoxia.	Transfusion of washed dam's red blood cells or of compatible donor (check dam's plasma with donor's red cells). Fair prognosis.
Uroperitoneum	Ruptured bladder, urachus or ureteral defect. Colts 1–3 days of age. Foals of either sex with other systemic diseases.	Normal at birth. Onset of abdominal distension, mild colic, depression, and recumbency. May urinate small volumes.	Peritoneal fluid has high creatinine concentration. Hyperkalemia, hyponatremia, and hypochloremia.	Uroperitoneum. Rupture bladder, urachus or ureter.	Surgical correction AFTER drainage of abdomen and resolution of hyperkalemia with intravenous dextrose or 0.9% NaCl. Good prognosis with appropriate care.
Hypoglycemia	Failure to nurse. Rejection by mare. Mare has no milk (agalactia).	Normal at birth, repeated attempts to nurse. Gradual onset (hours) of weakness and depression.	Low blood glucose concentration (<60 mg/dL, 3 mmol/L).	None. No food in stomach.	Excellent response to feeding or intravenous glucose.
Neonatal maladjustment syndrome	Sporadic.	Onset of abnormal behavior, recumbency, failure to nurse or orient to mare. Aimless wandering and vocalization.	None characteristic. Frequently failure of transfer of passive immunity.	Usually none apparent. Occasional intracranial vascular accidents.	Supportive care (see "Principles of Providing Care to Critically Ill Neonates"). Good prognosis.
Congenital defects	Sporadic.	Depends on nature of cardiac, gastrointestinal, or central nervous system defect.	None.	Consistent with defect.	Usually no treatment. Poor prognosis depending on defect.

to provide control of seizures while minimizing the degree of sedation. Because of the long elimination half-life of phenobarbital in foals (~200 hours) and the transient nature of the disease, once seizure control is achieved, administration of phenobarbital can be discontinued. Drug concentrations will be at or above the target concentration (5 to 30 µg/mL) for several days after the final dose. **Phenytoin** (5 to 10 mg/kg intravenously or orally initially, then 1 to 5 mg/kg every 4 hours) or **primidone** (20 to 40 mg/kg orally every 12 to 24 hours, to effect) are also used to control convulsions.

Definitive demonstration of the presence of cerebral edema or intracranial hemorrhage is impossible without sophisticated imaging devices, such as MRI or CT. However, treatment is often initiated on the basis of clinical signs. None of the treatments has demonstrated efficacy, and some are controversial. **Dimethyl sulfoxide** (DMSO) is given intravenously at 0.5 to 1 mg/kg once or twice daily for 3 days as a 10% solution. **Mannitol** (0.25 g/kg, intravenously as a 20% solution) may be effective in treating cerebral edema, but it is contraindicated if intracranial hemorrhage is present. **Glucocorticoids** (dexamethasone, 0.2 to 1 mg/kg, or prednisone, 1 to 2 mg/kg) might reduce intracranial inflammation and swelling. They might be contraindicated in foals with sepsis.

Magnesium sulfate (0.05 mg/kg per hour for 1 hour, then 0.025 mg/kg/h intravenously for up to 48 hours) is often administered to foals with suspected hypoxic encephalopathy in an attempt to minimize neuronal damage. There is no objective evidence of its efficacy in foals.

Foals with respiratory depression can be administered **caffeine** (10 mg/kg orally once and then 3.0 mg/kg orally q 24 hours). There is objective evidence of the lack of efficacy of this treatment in improving survival or decreasing arterial carbon dioxide tension in foals with a diagnosis of neonatal hypoxia-ischemia.[9] Adverse effects include agitation, hyperesthesia, tachycardia, and convulsions.

Good nursing care is critical in affected foals, and a concerted and persistent effort should be made to encourage the foal to nurse the mare. Encouraging the foal to nurse can be frustrating for the handler and mare, but should be done regularly, about every 4 hours, and preferably when the foal is hungry. Affected foals often begin to nurse quite suddenly. Foals should be provided with nutritional support, such as with mare's milk administered by indwelling nasogastric tube, until they are able to suckle.

Affected foals can require up to 4 to 6 weeks to recover completely, although most do so within 1 week of birth, and hasty decisions regarding euthanasia should not be made without recognition of the sometimes long time required for complete recovery.

CONTROL

Prevention of hypoxia in neonates by close monitoring of the health of the mare and of parturition may reduce the incidence of the disease.

Neonatal Infectious Diseases

SYNOPSIS

Etiology Common infections for each animal species are listed under "Etiology" in the discussion. Most etiologies are bacterial, but some are viral.

Epidemiology Commonly predisposed by management and environmental factors and difficult delivery that increase the exposure risk and load and decrease the resistance of the neonate.

Clinical findings Depending on the pathogen and portal of entry, local infection or septicemia with following localization can occur; signs can be specific for the agent and the affected organ(s).

Clinical pathology White blood cell and differential counts, toxic change, serum immunoglobulin concentrations, blood gas analysis, acute-phase protein concentrations, blood culture.

Necropsy findings Specific to disease.

Diagnostic confirmation Specific to disease.

Treatment Treatment may include antimicrobial therapy, correction of acid–base disturbance, fluid and electrolyte therapy, blood or plasma transfusion, antiinflammatory therapy, and other supportive treatment.

Infection is a common cause of morbidity and mortality in neonates. There are a number of specific infectious pathogens that can cause disease. Other microorganisms normally present in the neonate's environment can become opportunistic pathogens whenever the immunologic status of the neonate is impaired. Maternal immunoglobulins are not transferred transplacentally in ungulates, and the newborns rely on the acquisition of immunoglobulins from colostrum for passive antibody protection.

ETIOLOGY

In domestic farm animals the common infections that can produce disease during the neonatal period are described in the following subsections. (Relative importance and prevalence statistics are not given because these vary from area to area and with differing management systems.)

Calves

- Enteritis associated with enterotoxigenic *Escherichia coli*; *Salmonella* spp.; rotavirus and coronavirus; *Cryptosporidium parvum*; *Clostridium perfringens* types A, B, and C; and occasionally by the virus of infectious bovine rhinotracheitis and bovine viral diarrhea
- Bacteremia and septicemia associated with *E. coli, Listeria monocytogenes, Pasteurella* spp., streptococci, or *Salmonella* spp.

Pigs

- Septicemia with or without localization in joints, endocardium, and meninges associated with *Streptococcus suis, Streptococcus equisimilis, Streptococcus zooepidemicus*, and *L. monocytogenes*
- Bacteremia, septicemia, and enteritis associated with *E. coli*
- Transmissible gastroenteritis, Aujeszky's disease, swine pox, enterovirus infections, and vomiting and wasting disease associated with viruses
- Enteritis associated with *C. perfringens, Campylobacter* spp., rotavirus, and *Coccidia* spp.
- Arthritis and septicemia associated with *Erysipelothrix rhusiopathiae*

Foals

- Septicemia with localization associated with *E. coli, Actinobacillus equuli, Klebsiella pneumoniae, α-hemolytic streptococci, S. zooepidemicus, L. monocytogenes, Rhodococcus equi,* and *Salmonella typhimurium*
- Enteritis associated with *C. perfringens* types A, B, and C; *Clostridium difficile; R. equi; Salmonella spp.; Strongyloides westeri; C. parvum;* and rotavirus.

Lambs

- Septicemia or bacteremia with localization in joints and/or synovia and/or leptomeninges associated with *E. coli, L. monocytogenes,* streptococci, micrococci, *E. rhusiopathiae*, and *Chlamyodophila* spp.
- Enteritis associated with enterotoxigenic *E. coli, Salmonella* spp., rotavirus and coronavirus, and *C. parvum*
- Lamb dysentery associated with *C. perfringens* types B and C

- Gas gangrene of the navel associated with *Clostridium septicum, Clostridium novyi*, and *Clostridium chauvoei*
- Pyemia associated with *Staphylococcus aureus*, *Fusobacterium necrophorum*, and *Trueperella* (formerly *Arcanobacterium) pyogenes*
- Pneumonia, polyserositis, and peritonitis associated with *Pasteurella multocida* and *Mannheimia hemolytica*

The agents listed in the following subsections are recorded as causing neonatal infections but are less common than those listed in the previous subsections and not of as great importance.

Calves

Pseudomonas aeruginosa, *Streptococcus pyogenes, Streptococcus faecalis, S. zooepidemicus, Pneumococcus* spp.; enteritis resulting from *Providencia stuartii, Chlamydophila* spp., *A. equuli*.

Lambs

S. aureus (tick pyemia); enteritis resulting from *E. coli,* rotavirus; pneumonia resulting from *Salmonella abortus–ovis*.

Foals

Enterobacter cloacae, *S. aureus, Pasteurella multocida, P. aeruginosa, T. pyogenes, Serratia marcescens*.

All Species

Nonspecific infections are associated with pyogenic organisms, including *T.* (formerly *Arcanobacterium) pyogenes* and *Fusobacterium necrophorum*; *S. faecalis*, *S. zooepidemicus*, *Micrococcus* spp., and *Pasteurella* spp. occur in all species.

EPIDEMIOLOGY

The occurrence of neonatal disease is broadly influenced by two main factors: the exposure or infection pressure of the infectious agent to the neonate and the ability of the neonate to modulate the infection so that disease does not occur. Some agents are sufficiently virulent in their own right that an exposure can lead to disease. With others, the majority, the defenses of the host must be compromised or the infection challenge must be very high before clinical disease occurs. Management of the neonate has a great influence on both of these factors, and the recognition and correction of these risks is the key to the prevention of neonatal disease in both the individual and the group.

Sources of Infection

Postnatal Infection

The vast majority of infections are acquired by the neonate after birth, directly from the environment into which it is born. The source of infection can be any adult animal present in the maternity area, an infected neonate housed in close proximity, contamination of the environment, or an animal caretaker functioning as mechanical or biological vector. Details for the common neonatal diseases are given under the individual disease headings.

Prenatal Infection

Some bacterial and viral infections that manifest with neonatal disease are acquired in utero and are associated with bacteremia/viremia in the neonate.[1] The majority of these are agents that cause abortion, and neonatal septicemia is only part of the disease spectrum associated with these pathogens. Examples include many of the agents producing abortion in sheep.

Some septicemic infections in **foals**, particularly those associated with *A. equuli*, *S. zooepidemicus*, *Salmonella abortusequi*, and possibly some *E. coli* septicemic infections, are acquired by prenatal infection. If the disease is intrauterine in origin, it reaches the foal's organism via the placenta, probably by means of placentitis resulting from a bloodborne infection or endometritis of the mare.

Viral infections that are acquired in utero are listed in the section on congenital disease.

Routes of Transmission

The **portal of infection** is commonly by oral ingestion, but infection may also occur via aerosol inhalation. Invasive organisms capable of producing bacteremia and septicemia invade through the nasopharynx or through the intestinal epithelium. An alternate route of infection and invasion is via the umbilicus. Routes of **excretion** are via the feces in enteric disease and the nasal secretions, urine, and sometimes the feces in septicemic disease, resulting in contamination of the neonatal environment.

Where neonates are in groups or in close contact, direct transmission by fecal, respiratory secretion, and urine aerosols are common routes for transmission of infection. Neonatal bull calves that are group-housed and that suck one another's navels can transmit infection by this activity.

Risk Factors and Modulation of Infection

Immunity

Neonates are generally more susceptible to infection than their adult counterparts. The calf, lamb, piglet, and foal are born without significant levels of immunoglobulins and possess almost no resistance to certain diseases until after they have ingested colostrum and absorbed sufficient quantities of immunoglobulins from the colostrum. **Failure of transfer of passive immunity** is a major determinant and is discussed under that heading.

Immune Responsiveness

All components of the immune system are present in foals and calves at birth, but the immune system of the newborn animal is less mature than its adult counterpart, at least for the first 30 days of life, and does not respond as effectively to an antigen stimulus.

Immune responsiveness is age-dependent but also varies with the antigen. In colostrum-fed animals, part of the inefficiency of the newborn to produce humoral antibodies following exposure to antigens is the interference from circulating colostral antibody and the downregulation by colostrum of endogenous immunoglobulin production.

Colostrum-deprived calves respond actively to injected antigens and are thought to be immunologically competent at birth with respect to most antigens. Immune competence begins during fetal life, and the age of gestation at which this occurs varies according to the nature of the antigen. The bovine fetus will produce antibodies to some viruses, beginning at 90 to 120 days, and by the third trimester of gestation it will respond to a variety of viruses and bacteria. The lamb will respond to some antigens beginning as early as 41 days and not until 120 days for others. The piglet at 55 days and the fetal foal also respond to injected antigens.

The presence of high levels of antibodies in the precolostral serum of newborn animals suggests that an in utero infection was present, which is useful for diagnostic purposes. The detection of immunoglobulins and specific antibodies in aborted fetuses can be a useful aid in the diagnosis of abortion in cattle.

Exposure Pressure

The exposure pressure is a factor of the cleanliness of the environment of the neonate. The phenomenon of a "buildup of infection" in continual-throughput housing for neonatal animals has been recognized for decades and has been translated to many observations of risk for neonatal disease associated with suboptimal hygiene and stocking density in both pen and paddock birthing areas. Details for the individual species are provided in the section on perinatal disease.

Age at Exposure

With several agents that produce neonatal disease, the age of the neonate at infection and the infecting dose have a significant influence on the outcome. Examples are the importance of age with respect to susceptibility to disease associated with some enteric infections. Disease associated with enteropathogenic *E. coli* and with *C. perfringens* types B and C occurs only in young animals, and if infection can be avoided by hygiene in this critical period, disease will not occur regardless of subsequent exposure. Colostrum-deprived calves show significant resistance to challenge at 7 days of age with strains of *E. coli* that invariably produce septicemic disease if challenged at the time of birth, and isolation of

an immunocompromised neonate is an important factor in its survival. Thus the management of the neonate and its environment is a critical determinant of its health. Age at exposure also varies with the epidemiology of the pathogen, and segregated early weaning is used to reduce transmission of and infection with certain pathogens in pigs.

Animal Risk Factors

Animal risk factors that predispose to infection include those that interfere with sucking drive and colostral intake, such as cold stress and dystocia. These are detailed in the preceding section on perinatal disease.

PATHOGENESIS

The pathogenesis varies with the neonatal infectious disease under consideration and is given for each of these in the special medicine section.

An infection can remain localized at the initial site of infection, as is the case with uncomplicated omphalitis or enterotoxigenic *E. coli* infection, or it can spread by invading the organism (e.g., via the nasopharynx, the gastrointestinal tract, or the umbilical vein or urachus). In the latter case the usual pattern of development is bacteremia followed by **septicemia** with severe systemic signs, or **bacteremia** with few or no systemic signs followed by **localization** in various organs.[2] **Localization** is most common in the joints, producing a suppurative or nonsuppurative arthritis. Less commonly there is localization in the eye to produce panophthalmitis, in the heart valves to cause valvular endocarditis, or in the meninges to produce meningitis.

Secondary lesions often take time to develop, and signs usually appear at 1 to 2 weeks of age. This is especially true with some of the streptococcal infections, in which bacteremia may be present for several days before localization in the joints and meninges produces clinical signs. Bacterial meningitis in newborn ungulates is preceded by bacteremia followed by a fibrinopurulent inflammation of the leptomeninges, choroid plexuses, and ventricle walls, but it does not affect the neuraxial parenchyma. It is proposed that the bacteria are transported in monocytes, which do not normally invade the neuraxial parenchyma.

Dehydration and acid–base and electrolyte imbalance can occur very quickly in newborn animals, whether diarrhea and vomiting (pigs) are present or not, but obviously are more severe when there is fluid loss into the gastrointestinal tract. In gram-negative sepsis the prominent signs are those of endotoxemia.

CLINICAL FINDINGS

The clinical findings depend on which organ systems are affected, the rapidity of growth of the organism, its propensity to localize, and its potential to produce toxemia. Clinical signs are often vague and unspecific in the initial phase of septicemia until the infection localizes and affects one or several organs.[1,2] Organisms that have a low propensity for toxemia present with fever, depression, anorexia, and signs referable to localization. These include endocarditis with a heart murmur; panophthalmitis with pus in the anterior chamber of the eye; meningitis with rigidity, pain, and convulsions; and polyarthritis with lameness and swollen joints. With more virulent organisms there are clinical signs of toxemia and bacteremia, including fever, and advanced stages result in hypothermia, severe depression, obtundation, coma, petechiation of mucosae, dehydration, acidemia, and rapid death.

The clinical and clinicopathologic characteristics of the septicemic foal were detailed in an outbreak of septicemia in colostrum-deprived foals and in the clinical records of 38 septicemic foals admitted to a referral clinic. The major clinical findings included lethargy, unwillingness to suck, inability to stand without assistance but remaining conscious, unawareness of environment and thrashing or convulsing, diarrhea, respiratory distress, joint distension, central nervous system abnormalities, uveitis, and colic. Fever was not a consistent finding.

A **sepsis score** has been developed for foals based on 14 measures related to historical, clinical, and laboratory data (Table 19-11). The score derived from the collective differential scoring of these data has been found to be more sensitive and specific for infection than any parameter taken individually. However, a subsequent study of 168 foals presented to a university hospital found that the sepsis score correctly predicted sepsis in 58 out of 86 foals and nonsepsis in 24 out of 45 foals, resulting in a sensitivity of 67%, a specificity of 75%, a positive predictive value of 84%, and a negative predictive value of 55%, and it was suggested that the score system should be used with care because the low negative predictive value limited its clinical utility.

A sepsis score for calves, based on fecal consistency, hydration, behavior, ability to stand, state of the umbilicus and degree of injection of scleral vessels, and presence of hypoglycemia and abnormal neutrophil cell count, was found to have reasonable predictive value.[3]

The clinical findings specific to individual etiologic agents are given under their specific headings in the special medicine section of this book.

CLINICAL PATHOLOGY

Clinical pathology is used as an integral part of the evaluation of a sick neonate and to help formulate a treatment plan. A major evaluation is to attempt to confirm the presence or absence of sepsis, and this type of evaluation has been developed most successfully in the foal. **Blood culture** is part of this examination, but the time for a positive result limits its value in the acutely ill neonate. Laboratory findings in foals with neonatal sepsis are variable and depend on the severity, stage, and site of infection. **Serial examinations** are commonly used. In examinations relating to the possible presence of septicemia, particular emphasis is placed on the results of the white blood cell and differential counts, the presence of toxic change (toxic granulation and vacuolization), serum immunoglobulin concentrations, arterial oxygen concentrations, the presence of metabolic acidosis, abnormal blood glucose concentrations, and elevated fibrinogen levels.[1,4]

DIFFERENTIAL DIAGNOSIS

- The principles of diagnosis of infectious disease in newborn animals are the same as for older animals. However, in outbreaks of suspected infectious disease in young animals, there is usually a need for more diagnostic microbiology and pathology.
- With outbreaks, owners should be encouraged to submit all dead neonates as soon as possible for a meaningful necropsy examination.
- In addition to postmortem examination, it is necessary to identify the factors that may have contributed to an outbreak of disease in newborn calves, piglets, or lambs, and only detailed epidemiologic investigation will reveal these.

TREATMENT

The first principle is to obtain an etiologic diagnosis if possible. Ideally a drug sensitivity of the causative bacteria should be obtained before treatment is given, but this is not always possible. It may be necessary to choose an **antibiotic** based on the tentative diagnosis and previous experience with treatment of similar cases.

Outbreaks of infectious disease are common in litters of piglets and groups of calves and lambs, and individual treatment is often necessary to maximize survival rate. Supportive fluid and electrolyte therapy and correction of acid–base disturbances are described in detail under "Disturbances of Free Water, Electrolytes, and Acid–Base Balance."

The provision of **antibodies** to sick and weak newborn animals through the use of blood transfusions or serum is often practiced, especially in newborn calves in which the immunoglobulin status is unknown. Whole blood given at the rate of 10 to 20 mL/kg body weight, preferably by the intravenous route, will often save a calf that appears to be in shock associated with neonatal diarrhea. The blood is usually followed by fluid therapy. Serum or plasma can also be given at half the dose rate. The blood should not be taken from a cow near parturition because the circulating immunoglobulins

Table 19-11 Worksheet for calculating a sepsis score for foals less than 12 days of age[1]

Variable	NUMBER OF POINTS TO ASSIGN					Score for this case
	4	*3*	*2*	*1*	*0*	
1. Historical data						
a. Placentitis, vulvar discharge before delivery, dystocia, sick dam, induced parturition		Present			Absent	
b. Gestation length (days)		<300	300–310	311–330	>330	
2. Clinical examination						
a. Petechiation or scleral injection (nontraumatic)		Marked	Moderate	Mild	None	
b. Rectal temperature (° C)			>38.9	<37.8	37.9–38.7	
c. Hypotonia, convulsions, coma, depression			Marked	Moderate	Mild	
d. Anterior uveitis, diarrhea, respiratory distress, swollen joints or open wounds		Present			Absent	
3. Hemogram						
a. Neutrophil count (cells × 10^9/L)		<2.0	2.0–4.0 or 8.0–12.0 >12	4.0–8.0		
b. Band neutrophils (cells × 10^9/L)		>0.2	0.05–0.2		<0.05	
c. Toxic changes in neutrophils	Marked	Moderate	Slight		None	
d. Fibrinogen concentration (g/L)			>6.0	4.1–6.0	4.0	
4. Laboratory data						
a. Blood glucose (mmol/L)			<2.7	2.7–4.4	>4.4	
b. IgG concentration (g/L)	<2.0	2.0–4.0	4.1–8.0		>8.0	
c. Arterial oxygen tension (Torr)		<40	40–50	51–70	>70	
d. Metabolic acidosis (base excess < 0)				Present	Absent	
Total points for this foal						

To calculate the sepsis score, assign foal a score corresponding to the historical physical examination and laboratory data included in the table. A score of 11 or less predicts the absence of sepsis correctly in 88% of cases, whereas a score of 12 or higher predicts sepsis correctly in 93% of cases. For foals less than 12 hours of age that have nursed or received colostrum, assign a value of 2 for the serum immunoglobulin score. If the foal has not nursed, assign a value of 4.

will be low from the transfer into the mammary gland.

Plasma is often incorporated into the therapeutic regimen in foals, both for its immunoglobulin content and for its effect on blood volume and osmotic pressure. Stored plasma can be used. A dose of 20 mL plasma/kg body weight given slowly intravenously is often used, but significantly higher doses are required to elevate circulating immunoglobulins by an appreciable amount. Blood may be collected, the red blood cells allowed to settle, and the plasma removed and stored frozen. The donor plasma should be prescreened for compatibility. Lyophilized hyperimmune equine serum as a source of antibodies may also be fed to foals within 4 hours after birth. Good nursing care is also essential.

Further information on treatment is given in the section on critical care for the newborn later in this chapter.

CONTROL

Methods for avoidance of failure of transfer of passive immunity and the principles for prevention of infectious disease in newborn farm animals follow in this chapter. The control of individual diseases is given under specific disease headings elsewhere in this book.

PRINCIPLES OF CONTROL AND PREVENTION OF NEONATAL INFECTIOUS DISEASES

The four principles of control and prevention of infectious diseases of newborn farm animals are as follows:

- Reduction of risk of acquisition of infection from the environment
- Removal of the newborn from the infectious environment if necessary
- Increasing and maintaining the nonspecific resistance of the newborn
- Increasing the specific resistance of the newborn through the use of vaccines

The application of each of these principles will vary depending on the species, the spectrum of diseases that are common on that farm, the management system, and the success achieved with any particular preventive method used previously.

REDUCTION OF RISK OF ACQUISITION OF INFECTION FROM THE ENVIRONMENT

The animal should be born in an environment that is clean, dry, sheltered, and conducive for the animal to get up after birth, suck the dam, and establish bonding.[1,2] Calving and lambing stalls or grounds, farrowing crates, and foaling stalls should be prepared in advance for parturition. No conventional animal area can be sterilized, but it can be made reasonably clean to minimize the infection rate before colostrum is ingested and during the first few weeks of life when the newborn animal is very susceptible to infectious disease.

With seasonal calving or lambing there can be buildup of infection in the birth area, and animals born later in the season are at greater risk of disease. In these circumstances it may be necessary to move to secondary lambing or calving areas. In northern climates snow may constrict the effective calving area and result in a significant buildup of infection. Buildup of infection pressure must be minimized by a change to a fresh calving/lambing area and by the frequent movement of feed bunks or feed areas. Any system that concentrates large numbers of cattle in a small area increases environmental contamination, and close confinement of heifers and cows around calving time is a known risk factor for calf mortality. With large herds both the cow herd and heifer herd should be broken into as many subgroups as is practical. Extensive systems where cows calve out over large paddocks are optimal, and with more intense systems a group size no larger than 50 has been suggested.

Lambing sheds and calving areas for beef cattle should be kept free of animal traffic during the months preceding the period of

parturition. In dairy herds, maternity pens separate from other housing functions should be provided and cleaned and freshly bedded between calvings. Certainly they should not also be used as hospital pens.

In swine herds, the practice of batch farrowing, with all-in all-out systems of management and disinfection of the farrowing rooms, is essential. Sows should be washed before entry to the farrowing area, and the floor of the farrowing crate should be of the type that minimizes exposure of the piglet to fecal material at birth.

The swabbing of the **navel** with tincture of iodine or chlorhexidine solutions to prevent entry of infection is commonly practiced by some producers and seldom by others. In a heavily contaminated environment it is recommended, although hard evidence supporting the efficacy of this procedure is currently lacking.[1] Severance of the umbilical cord too quickly during the birth of foals can deprive the animal of large quantities of blood, which can lead to neonatal maladjustment syndrome.

When deemed necessary, some **surveillance** should be provided for pregnant animals that are expected to give birth, and assistance provided if necessary. The major objective is to avoid or minimize the adverse effects of a difficult or slow parturition on the newborn and the dam. Physical injuries, hypoxia, and edema of parts of the newborn will reduce the vigor and viability of the newborn and, depending on the circumstances and the environment in which it is born, may lead to disease or even death soon after birth.

When possible, every effort should be made to minimize exposure of the neonate to extremes of temperature (heat, cold, snow). Shelter sheds should be built if necessary.

In beef herds, the practice of purchasing male dairy calves to foster on to cows whose calves have died should be discouraged. If calves are purchased, they should be from a herd whose health status is known to the veterinarian and certainly never through a market. Similarly, colostrum should be obtained from cows within the herd and stored frozen for future use. Colostrum obtained from a different herd presents a biosecurity risk because it can transmit diseases such as bovine enzootic leukemia or Johne's disease. Furthermore, purchased dairy colostrum is commonly second- or third-milking colostrum and of limited immunologic value. The use of a commercial colostrum supplement or replacer is possible, although they have significant limitations.

REMOVAL OF THE NEWBORN FROM THE INFECTIOUS ENVIRONMENT

In some cases of high animal population density (e.g., a crowded dairy barn) and in the presence of known disease, it may be necessary to transfer the newborn to a noninfectious environment temporarily or permanently. Adult cows shedding enteric pathogens are a risk for calf infection. Thus dairy calves are often removed from the dam at birth and placed in individual pens inside or outdoors in hutches and reared in these pens separately from the main herd. This reduces the severity of neonatal diarrhea and pneumonia and risk for mortality compared with calves allowed to remain with the dam. **Individual housing** in hutches is preferred because this avoids navel sucking and other methods of direct-contact transmission of disease. Humans entering these hutches should also practice interhutch hygiene. The prevalence of disease is higher in enclosed artificially heated barns than in hutches. However, despite the well-established value of individual rearing of calves, animal welfare regulations in several countries require that there be visual and tactile contact between calves. The removal of the cow–calf pair from the main calving grounds to a "nursery pasture" after the cow–calf relationship (neonatal bond) is well established, at 2 to 3 days of age, has proved to be a successful management practice in beef herds. This system moves the newborn calf away from the main calving ground, which may be heavily contaminated because of limited space. It necessitates that the producer must plan the location of the calving grounds and nursery pastures well in advance of calving time. Calves that develop diarrhea in the calving grounds or nursery pasture are removed with their dams to a **"hospital pasture"** during treatment and convalescence. The all-in all-out principle of successive population and depopulation of farrowing quarters and calf barns is an effective method of maintaining a low level of contamination pressure for the neonate.

INCREASING THE NONSPECIFIC RESISTANCE OF THE NEWBORN

Following a successful birth, the next important method of preventing neonatal disease is to ensure that the newborn ingests colostrum as soon as possible. With natural sucking the amount of colostrum ingested by the neonate will depend on the amount available, the vigor of the animal, the acceptance by the dam, and the management system used, which may encourage or discourage the ingestion of liberal quantities of colostrum. Beef cows that calve at a condition score lower than 4 (out of 10) are at higher risk of having calves that develop failure of transfer of passive immunity, and the ideal condition score at calving is 5 to 6.

The method of colostrum delivery that is needed to optimize transfer of passive immunity to the dairy calf will vary with the breed of cow, the management level of the farm, and the priority given to calf health. Owner acceptance of alternate feeding systems to natural sucking also is a consideration. The success of the farm policy for the feeding of colostrum is easily monitored by one of the tests described earlier, as is the effect of an intervention strategy.

Newborn male dairy calves are commonly assembled and transported to market or to calf-rearing units within a few days of birth. Studies have repeatedly shown high rates of FTPI in this class of calf. The high rates occur either because the original owner does not bother to feed colostrum to the calf, knowing it is to be sold, or because calves are purchased off the farm before colostrum feeding is completed. The effects of the transportation can have a further deleterious effect on the defense mechanism of the calves, and they are at high risk of disease.

Calf-rearing units should preferably purchase calves directly from a farm with an established policy of feeding colostrum before the calf leaves the farm, and every effort should be made to reduce the stress of transportation by providing adequate bedding, avoiding long distances without a break, and attempting to transport only calves that are healthy. In some countries there is now legislation requiring the feeding of colostrum and limiting the transport of newborn calves.

The honesty of the stated farm colostrum feeding policy can be monitored by testing the calves for their immunoglobulin concentration in serum. Where this is not possible and market calves must be used, the entry immunoglobulin concentration should be tested; the incidence of infectious disease in low-testing calves will be high unless hygiene, housing, ventilation, management and nutrition are excellent. The entry immunoglobulin concentration of calves entering veal or other calf-rearing units is a prime determinant of subsequent health and performance. The "alert" cut-point can be established for an individual farm by monitoring of individual immunoglobulin concentrations and subsequent calf fate.

Following the successful ingestion of colostrum and establishment of the neonatal bond, emphasis can then be given to provision, if necessary, of any special nutritional and housing requirements. Newborn piglets need supplemental heat, and attention must be given to the special problems of intensive pig husbandry. Orphan and weak piglets can now be reared successfully under normal farm conditions with the use of milk replacers containing added porcine immunoglobulins. Heat is often provided to lambs for the first day in pen lambing systems.

Milk replacers for the newborn must contain high-quality ingredients. Calves younger than 3 weeks are less able to digest nonmilk proteins, and the fats best used by the calf are high-quality animal source fats and slightly unsaturated vegetable oils. A 22% crude protein is recommended for milk

replacers comprised only of milk proteins and 24% to 26% in replacers that contain nonmilk protein sources. The level of fat should be at least 15%; higher fat concentration will provide additional energy, which may be required in colder climates. Feeding utensils must be cleaned and disinfected between each feeding if disease transmission is to be minimized.

With animals at pasture, the mustering and close contact associated with management procedures such as castration and docking pose a risk for disease transmission. These procedures should be performed in yards prepared for the purpose—preferably temporary yards erected for this sole purpose in a clean area.

INCREASING THE SPECIFIC RESISTANCE OF THE NEWBORN

The specific resistance of the newborn to infectious disease may be enhanced by vaccination of the dam during pregnancy to stimulate the production of specific antibodies that are concentrated in the colostrum and transferred to the newborn after birth. Vaccination of the dam can provide protection for the neonate against enteric and respiratory disease. Details are given under the specific disease headings in this text. The vaccination of the late fetus in utero stimulates the production of antibody but its practical application has yet to be determined.

COLIBACILLOSIS OF NEWBORN CALVES, PIGLETS, LAMBS, KIDS, AND FOALS

SYNOPSIS

Etiology Pathogenic serotypes of *Escherichia coli:* septicemic, enterotoxigenic (ETEC); enteropathogenic (EPEC); enterohemorrhagic (EHEC), also referred to as verocytotoxigenic (VTEC) or Shiga-toxin-producing (STEC); and necrotoxigenic *E. coli* (NTEC).

Epidemiology Affects newborn calves, piglets, lambs, and goat kids. Risk factors include colostrum deprivation, overcrowding, adverse climatic conditions, and inferior milk replacers. Prevalence of ETEC varies between herds. EHEC (O157:H7) in cattle is not normally associated with clinical disease, but it presents a major zoonotic concern.

Signs Weakness and collapse (septicemia), diarrhea, and dehydration; complications such as meningitis or polyarthritis.

Clinical pathology Isolation of organism from feces or blood; hematology and serum biochemistry to evaluate inflammation and acid–base and electrolyte imbalance.

Lesions Septicemic lesions, dehydration, enteritis.

Diagnostic confirmation Culture of organism and serotyping.

Treatment Antimicrobials, antiinflammatory drugs, fluid and electrolyte therapy.

Control Reduce infection pressure on neonates. Ensure adequate transfer of passive immunity, and vaccinate pregnant dams to induce specific colostrum antibody. Minimize stressors and their effect on neonates.

ETIOLOGY

Colibacillosis is associated with pathogenic serotypes of *E. coli*. For the most part, *E. coli* is a group of harmless bacteria that serve as indicator organisms for fecal contamination and breaches in hygiene. However, several strains have acquired virulence factors, turning them into potentially dangerous pathogens.[1] The prevalence of the different pathogenic serotypes of *E. coli* in farm animals has remained relatively constant for many years. Certain serotypes cause diarrhea and others cause septicemia. Serotypes include the following:

- **Enterotoxigenic *E. coli* (ETEC)** is the most common enteropathogen that causes diarrhea in newborn farm animals. The bacteria cause diarrhea by adhering to enterocytes, colonizing the intestinal mucosa, and **producing enterotoxins**. Enterotoxins cause hypersecretion of electrolytes and water into the small intestine without causing significant morphologic damage or invading tissue.[2]
- **Enteropathogenic *E. coli* (EPEC)** are the **"attaching and effacing"** strains that colonize the small intestine, where they attach tightly to the epithelial cells of the villus and cause typical **attaching and effacing lesions**. They do not produce toxins and seldom invade the intestinal mucosa.
- **Enterohemorrhagic *E. coli* (EHEC)** also cause attaching and effacing lesions and are among the *E. coli* strains capable of producing toxins similar to the one produced by *Shigella dysenteriae* type I. They are therefore also referred to as **Shiga-toxin-producing *E. coli* (STEC).** Because Shiga toxins are detected with the Vero cell-toxicity test, STEC are also known as **verotoxin or verocytotoxin-producing *E. coli* (VTEC).** Shiga toxins may cause anything from mild diarrhea to severe hemorrhagic colitis. In humans EHEC is responsible for the highly fatal hemolytic–uremic syndrome in children.[3] **EHEC are highly prevalent in cattle** but in general do not cause clinical disease in this species, although some Shiga-toxin-producing *E. coli* have been associated with diarrhea in calves. Cattle are the main reservoir of ***E. coli*** O157:H7, one of the important EHEC strains, causing a broad range of clinical disease in humans (see the section on enterohemorrhagic *E. coli* in farm animals and zoonotic implications). Shiga-toxin-producing *E. coli* strains have been associated with edema disease in swine.[2]
- **Necrotoxigenic *E. coli* (NTEC)** strains produce cytotoxic necrotizing factor (CNF)1 or 2. NTEC2 isolates are restricted to ruminants, particularly calves and lambs with diarrhea and septicemia.
- **Septicemic *E. coli*** strains of serogroup 078 are invasive and cause septicemia in calves, piglets, and lambs. Their powerful endotoxins cause endotoxic shock, with a high case fatality rate.

EPIDEMIOLOGY

Occurrence and Prevalence of Infection

The prevalence of colibacillosis has increased in recent years. There are several possible reasons for this, including size of herds, shortage of qualified labor, automated livestock-rearing systems, and increased population density.

Colibacillosis occurs most commonly in newborn farm animals and is a significant cause of economic loss in raising livestock. It is a complex disease in which several different risk factors interact with certain pathogens, resulting in the disease. There are at least two different types of the disease: **enteric colibacillosis** is characterized by varying degrees of diarrhea, dehydration, acidosis, and death in a few days if not treated; **coliform septicemia** is characterized by severe illness and rapid death within hours.

Cattle and Calves

The infection prevalence of **enterohemorrhagic *E. coli***, particularly the *E. coli* O157:H7 strain, has been studied extensively because of concerns with beef and raw milk as source

of foodborne disease in humans. In the United States *E. coli* O157:H7 infection prevalence rates based on positive fecal samples were between 0.2% and 8.4% for cows, 1.6% and 3.0% for heifers, and 0.4% to 40% for calves. Infection prevalence rates reported from Canada, Italy, Japan, and the United Kingdom were 0.3% to 16.1% for cows, 10.0% to 14.1% for heifers, and 1.7% to 48.8% for calves.[4] These numbers underscore the obvious effect of animal age on the epidemiology of infection with *E. coli O157:57*. The **considerable prevalence of this EHEC strain** in cattle has little impact on animal health because EHEC infection in this species is normally not associated with clinical disease, but it presents a **serious public health concern**.

The prevalence of **enterotoxigenic *E. coli*** (ETEC) in diarrheic calves varies widely geographically, between herds, and depending on the age of the animals. The prevalence can be as high as 50% to 60% in diarrheic calves under 3 days of age and only 5% to 10% in diarrheic calves 8 days of age. In some countries the prevalence is only 5% to 8% in diarrheic calves under 3 days of age. Thus **enterotoxigenic colibacillosis is a major cause of diarrhea in calves less than 3 days of age** and is not associated with outbreaks of diarrhea in calves older than 3 days. ETEC infection in calves older than 2 to 3 days will in most cases be associated with a viral infection. The prevalence of ETEC infection is very low or nil in clinically normal calves in herds that have not had a problem with diarrhea. In some beef herds affected with diarrhea in young calves there may be little evidence of infection with enterotoxigenic *E. coli,* and other factors need to be examined.

Piglets

The prevalence of ETEC in diarrheic piglets varies geographically and with herds. In some areas the F5 (K99) pilus was found more frequently than F4 (K88) or F6 (987P), whereas in other regions the F4 pilus is more common. The F4 and F18 pilus adhesins are most commonly associated with postweaning diarrhea of pigs.

Morbidity and Mortality Rates

Calves

In dairy calves raised under intensive and poorly managed conditions the morbidity rate of infection with ETEC may reach 75%, but it is usually about 30%. Case fatality rates vary from 10% to 50% depending on the level of clinical management.

In beef calves the morbidity rates vary from 10% to 50% and the case fatality rates from 5% to 25% or even higher in some years. The population mortality rate in both beef and dairy calves can vary from a low of 3% in well-managed herds to a high of 60% in problem herds in certain years.

Piglets

In piglets the morbidity rate of preweaning diarrhea varies widely between herds, but it averages about 6% of litters, mostly in the first week of life. The morbidity rates increase with increased litter size and decrease with increasing parity of the sow. Losses as a result of stillbirths, traumatic injuries, starvation, and undersize at birth account for a much greater combined total preweaning loss, but colibacillosis accounts for approximately 50% of the gastroenteropathies encountered during the preweaning period.

Postweaning diarrhea (PWD) occurring in the 2 weeks following weaning is one of the economically most important diarrheal diseases in piglets in which colibacillosis plays an important etiologic role.[5] ETEC associated PWD commonly occurs in the immediate postweaning period. Outbreaks can occur suddenly, with mortality rates of 50% and higher. Affected animals can die acutely or show profuse diarrhea for up to 4 days. In uncomplicated cases mortality rates rarely exceed 10%.[5] Postweaning diarrhea of pigs is covered in detail under this heading.

Risk Factors

Several risk factors influence the occurrence of the disease, each one of which must be considered, evaluated, and modified or removed if necessary when investigating the cause of an outbreak so that effective clinical management and control of the disease may be achieved.

Animal Risk Factors

Animal Species

The pathogenesis of colibacillosis involves a number of host factors, of which the presence of specific receptors for adhesins and enterotoxins is probably among the most important.[6] Clinical disease associated with *E. coli* infection is largely dependent on the presence of specific receptors that usually only occur in one or few animal species. because of this receptor specificity of adhesins and enterotoxins, **ETEC strains have considerable species specificity**.[7]

Age and Birth Weight

Diarrhea associated with ETEC occurs in **calves** mainly during the first few days of life, rarely in older calves, and never in adults. Epidemiologic studies of both beef and dairy calves indicate that more than 80% of clinical cases associated with ETEC F5 (K99) occur in calves younger than 4 days of age. The ability of the F5 ETEC to adhere to the small intestinal epithelium of calves decreases continuously from 12 hours of age to 2 weeks of age.[8] The mechanism of this age-related resistance is not well understood, but it may be related to development of resistance to colonization of the small intestine as the calf becomes older. This could be associated with the replacement of villous epithelial cells that occurs in the first few days after birth.

The disease is more common in **piglets** born from gilts than from sows, which suggests that immunity develops with developing age in the sow and is transferred to the piglets. In a survey of approximately 4400 litters of piglets over a period of 4 years in a large piggery, 64% of the litters were treated for diarrhea before weaning, and piglets born to sows under parity 2 were 1.7 times more likely to develop diarrhea before weaning than litters born to sows over parity 3. The susceptibility or resistance to *E. coli* diarrhea in piglets has an inherited basis. The cell surface receptor for the F4 (K88) antigen is inherited in a simple mendelian way, with adherence (*S*) dominant over nonadherence (*s*). Homozygous dominants (*SS*) and heterozygotes (*Ss*) possess the receptor and are susceptible, whereas in the homozygous recessive (*ss*) the receptor is absent and the pigs are resistant. The highest incidence of diarrhea occurs in susceptible progeny born from resistant dams and sired by susceptible sires. Most if not all pigs have intestinal receptors for F5 ($K99^+$) pili and an inheritance pattern similar to F4 (K88) receptors does not exist for F5 receptors.

Immunity and Colostrum

Newborn farm animals are agammaglobulinemic and must ingest colostrum and absorb colostral immunoglobulin within hours of birth to obtain protection against septicemic and enteric colibacillosis. The transfer of immunoglobulin from the dam to the neonate is termed *transfer of passive immunity*. **Failure of transfer of passive immunity** predisposes the neonate to development of infectious diseases (see also the section "Failure of Transfer of Passive Immunity").

Transfer of maternal immunoglobulin to calves depends on three successive processes:

- Formation of colostrum with a high concentration of immunoglobulin by the dam
- Ingestion of an adequate volume of colostrum by the calf
- Efficient absorption of colostral immunoglobulin by the calf

Colostral immunoglobulin is absorbed for up to 24 hours after birth in calves and up to 48 hours in piglets. However, in calves the maximum efficiency of absorption occurs during the first 6 to 12 hours after birth and decreases rapidly from 12 to 24 hours after birth. Following absorption, transfer to the intestinal lumen is a major means of IgG clearance in calves, and this transfer results in antigen-binding antibody in the intestinal lumen. Both blood-derived antibody and lactogenic antibody are significant sources of passive antibodies in the intestinal lumen of the neonatal calf. Maintenance of high concentrations of

milk-derived antibodies in the small intestinal lumen may require more than twice-a-day feedings because antibodies derived from a milk diet are predominantly cleared from the intestinal lumen by 12 hours after feeding. Transfer of passively acquired antibodies from the circulation to the small intestinal lumen is therefore a reasonable hypothesis to explain the strong association between high serum passive immunoglobulin concentrations and reduced morbidity in neonatal calves.

Newborn dairy calves should ingest 80 to 100 g of colostral IgG, and ideally up to 150 g, within a few hours after birth to achieve serum immunoglobulin of 1000 mg/dL.

Environmental and Management Risk Factors

Meteorologic Influences

Although few epidemiologic data are available to support the claim, many veterinarians have observed a relationship between adverse climatic conditions and colibacillosis in both calves and piglets. During inclement weather, such as a snowstorm, a common practice in beef herds is to confine the calving cows in a small area, where they can be fed and watered more easily. The overcrowding is commonly followed by an outbreak of acute calf diarrhea. There is evidence that cold, wet, and windy weather during the winter months and hot, dry weather during the summer months have a significant effect on the incidence of dairy calf mortality.

The risk factors for mortality from diarrhea in beef calves in Alberta, Canada, have been examined. The odds of mortality were increased when the cows and heifers were wintered on the same grounds, when the herd was wintered and calved on the same grounds, and if the cows and heifers were calved on the same grounds. The morbidity and mortality rates from diarrhea during the first 30 days of life increased with an increasing percentage of heifers calving in the herd. Heifers are commonly more closely confined during the calving season for more effective observation and assistance at parturition. This may lead to increased contamination of the environment and the abdominal wall and udder of the heifers. Additional factors in heifers include a higher incidence of dystocia and maternal misbehavior and lower volume and quality of colostrum, all of which can result in weak calves that may not acquire sufficient colostral immunity.

Nutrition and Feeding Methods

Dairy calves fed milk substitutes may be more susceptible to acute undifferentiated diarrhea, some of which may be a result of enteric colibacillosis, compared with those fed cows' whole milk. Extreme heat treatment of the liquid skim milk in the processing of dried skim milk for use as milk substitutes for calves results in denaturation of the whey protein, which interferes with digestibility of the nutrients and causes destruction of any lactoglobulins that are present and may have a protective effect in the young calf.

Irregular feeding practices resulting in dietetic diarrhea may contribute to a higher incidence of enteric colibacillosis in calves. The person feeding and caring for the calves is an important factor influencing calf mortality a result of diarrhea. Although it is generally thought that general or specific nutritional deficiencies, such as a lack of energy, protein, or vitamin A, in the maternal diet predispose to colibacillosis, particularly in calves and piglets, there is no direct evidence that specific nutritional deficiencies are risk factors. However, they probably are, at least in indirect ways, for example, by having an effect on the amount of colostrum available at the first milking after parturition in first-calf heifers underfed during pregnancy.

Standard of Housing and Hygiene

Housing and hygienic practices are probably the most important environmental risk factors influencing the incidence of colibacillosis in calves and piglets, but they have received the least amount of research effort compared with other aspects, for example, control of the disease through vaccination. As the size of herds has increased, and as livestock production has become more intensified, the quality of hygiene and sanitation, particularly in housed animals, has assumed major importance. The disease is much less common when calves are run at pasture or are individually tethered, or penned, on grass.

Source of the Organism and Its Ecology and Transmission

Ingestion is the most likely portal of infection in calves, piglets, and lambs, although infection via the umbilical vessels and nasopharyngeal mucosa can occur. It has been suggested that certain serotypes of *E. coli* may enter by the latter route and lead to the development of meningitis.

In most species, it is assumed that the primary source of the infection is the feces of infected animals, including the healthy dams and neonates, and diarrheic newborn animals, which act as multipliers of the organisms. In some cases, the organism may be cultured from the vagina or uterus of sows whose litters become affected. In pig herds the total number of organisms on each sow is highest in the farrowing barn, decreases when the sow is returned to the breeding barn, and is lowest when the sow is in the gestation barn.

Calves acquire the infection from contaminated bedding and calf pails, dirty calf pens, nearby diarrheic calves, overcrowded calving grounds, and the skin of the perineum and udder of the cow. The organism is spread within a herd through the feces of infected animals and all the inanimate objects that can be contaminated by feces, including bedding, pails, boots, tools, clothing, and feed and water supplies. The organism is one of the first encountered by newborn farm animals, usually within minutes after birth. In cattle, the tonsil can be a reservoir for STEC in healthy animals. It is possible that virulent *E. coli* can be present and may be transferred to calves when they are licked by their dams at birth. The high population density of animals that occurs in overcrowded calving grounds in beef herds and heavily used calving pens in dairy herds and the continuous successive use of farrowing crates without a break for cleanup contribute to a large dynamic population of *E. coli*. The population of bacteria in an animal barn will continue to increase with the length of time the barn is occupied by animals without depopulation, clean-out, disinfection, and a period of vacancy. In some countries where lambing must be done in buildings to avoid exposure to cold weather, the lambing sheds may become heavily contaminated within a few weeks, resulting in outbreaks of septicemic and enteric colibacillosis.

Infected animals are the main reservoir for ETEC, and their feces are the major source of environmental contamination with the bacteria. Passage of the *E. coli* through animals causes a "multiplier effect"; each infected animal excretes many more bacteria than it originally ingested. Diarrheic calves are the most extreme multipliers because they often pass 1 L or more of liquid feces containing 10^{10}/g ETEC within 12 hours, and recovered calves can continue to shed bacteria for several months.

Normal calves and adult cows can serve as reservoirs of infection, and the bacteria can persist in a herd by circulating through animals of all ages. Carrier animals introduced to an uninfected herd are thought to be one of the main causes of natural outbreaks. The duration and amount of shedding probably depend on the degree of confinement, resulting population density, herd immunity, environmental conditions, and perhaps the serotype of the organism.

Pathogen Risk Factors

Virulence Factors of E. coli

Virulence factors of *E. coli* include *pili (fimbriae), enterotoxins (exotoxins), endotoxins,* and *capsules*. The adhesins in the pili of ETEC allow them to adhere to intestinal villous epithelial cells and prevent peristaltic elimination by the gut and to produce enterotoxins.

The virulence factors are relevant to vaccine efficacy. The species-specific adhesin antigens must be identified and incorporated into vaccines, which are given to pregnant females in an attempt to stimulate the production of specific antibody in the

colostrum, which will provide protection against enterotoxigenic colibacillosis. An essential element of vaccine development is the detection of common fimbrial antigens occurring among most pathogenic isolates and able to induce antibodies that block bacterial adhesion. The great diversity of potential pathogenic serotypes encountered in colisepticemia and the failure of serotype-specific antibody to cross-protect against a heterologous challenge in experimental infection have made it difficult to develop vaccines against septicemic colibacillosis.

The major virulence factors of ETEC in calves are the F5 (K99) adhesin antigen and the heat-stable enterotoxin (ST). The colonization in the small intestine of calves by F5 ETEC appears to be site specific, having a predilection for the ileum. Some serogroups also elaborate the F41 adhesin to the F5. Other surface-adhesive antigens, such as Att 25 and F17, have been identified on bovine enteropathogenic and septicemic *E. coli*. The F17a-positive ETEC strains are no longer isolated from diarrheic calves in some countries. It is postulated that the use of a vaccine including O101, K32, and H9 antigens in addition to F5 explains the strongly reduced incidence of the O101:K32:H9, F5 *E. coli* clone. A F4-related fimbrial antigen occurs on some enterotoxigenic and septicemic strains.

Enterotoxins are plasmid-regulated secreted peptides of ETEC bacteria that affect the intestinal epithelium. Two types of enterotoxins are differentiated, large-molecular-weight (88 kDA) heat-labile enterotoxins (LT) and small-molecular-weight heat-stable enterotoxins (ST).[7] LT enterotoxins are predominantly produced by human and porcine ETEC strains, whereas ST enterotoxins are produced by human, porcine, and bovine ETEC strains. The heat-stable enterotoxin from bovine ETEC has been purified and characterized. There is evidence of a form of ST enterotoxin that is common to bovine, porcine, and human strains of ETEC.

Most strains of **septicemic *E. coli*** belong to certain serogroups with virulence properties that enable them to resist the defense mechanisms that would normally eliminate other *E. coli*. **Septicemic strains produce endotoxin**, which results in shock and rapid death, usually in calves that are less than 5 days of age and with FTPI. Isolates of *E. coli* from the blood of critically ill bacteremic calves on a calf-rearing farm in California constituted a heterogeneous group and were found to be aerobactin positive and often resistant to the bactericidal effects of serum. The relative importance of individual serogroups varies between countries. However, it has been established that typeable isolates of *E. coli* from septic calves belong to a relatively small number of serogroups.[9] Strains commonly isolated from calves with septicemia belong to serogroups O78 and O15.[9,10]

Enterohemorrhagic *E. coli* (EHEC) and Shiga-toxin-producing *E. coli* (STEC) are recognized in humans and animals with increased frequency and constitute a major zoonotic concern (see the discussion of enterohemorrhagic *E. coli* in farm animals and zoonotic implications). These organisms are members of O111, O1O3, O5, and O26 serogroups, and none produces enterotoxin, nor do they possess the F5 pili. They produce the potent Shiga toxins or verotoxins SLT1 and SLT2; and some strains, the **attaching and effacing** *E. coli* (**AEEC**), attach to and efface the microvilli of the enterocytes, causing diarrhea and dysentery as a result of hemorrhagic colitis in calves 2 to 5 weeks of age. The effacing (*eae*) gene and the gene coding for the Shiga toxin 1 (*SLT1*) are associated with most isolates of AEEC in cattle. They have been isolated from both diarrheic and healthy sheep and goats.

A study of the onset and subsequent pattern of shedding of STEC O26, O103, O111, O145, and O157 in a cohort of beef calves on a mixed cattle and sheep farm in Scotland found that O26 was shed by 94% of the calves and that 90% of the O26 isolates carried the *vtx1*, *eae*, and *ehl* genes. *E. coli* O103 was the second most commonly shed serogroup of the tested calves, and the pattern of shedding was sporadic and random. There was an absence of shedding of *E. coli* O111, and the prevalence of shedding of O145 was low. Although some shedding of O157 occurred, shedding in calves was sporadic and infrequent. For O26, O103, and O157, there was no association between shedding by calves and shedding by dams within 1 week of birth. For O26 and O103, there was no association between shedding and diarrhea and no significant change in shedding following housing. In a sample of Australian dairy farms, calves as young as 48 to 72 hours had evidence of fecal excretion of STEC, indicating that dairy cattle are exposed to STEC from birth. Calves at weaning are most likely to shed STEC O26 or *E. coli* O157, similar to the prevalence surveys in the northern hemispheres.

Naturally occurring cases of attaching and effacing lesions of the intestines in calves with diarrhea and dysentery and infected with *E. coli* O126:H11, the predominant *STEC* strain in humans, have been described in the United Kingdom. STEC and *eae*-positive non-STEC have been isolated from diarrheic dairy calves 1 to 30 days of age.

E. coli O157 has been isolated from neonatal calves and has been implicated as a cause of diarrhea in calves. The isolates carried various virulence genes, such as *Ehly*, *eae*, *stx1*, and *stx2*. The *Ehly* gene may be a virulence marker for bovine enterohemorrhagic *E. coli* O157 strains. Similar findings have been reported in dairy cattle herds in Brazil. Strains of *E. coli* possessing a subtype beta intimin, normally found in human enteropathogenic *E. coli*, have been found in diarrheic calves in Brazil.

Non-O157 STEC have been isolated from diarrheic calves in Argentina, and the serotypes carried virulence traits associated with increased pathogenicity in humans and cattle. Severe clinical syndromes associated with non-O157 STEC are common in children under 4 years of age and may be associated with diarrheic calves, which shed highly virulent STEC strains and could act as a reservoir and contamination source in these areas.

E. coli O116, a serogroup previously associated with cases of hemolytic–uremic syndrome in humans, has been associated with an outbreak of diarrhea and dysentery in 1- to 16-week-old calves in India. *E. coli* O103:H2, an STEC strain causing disease in humans, has been isolated from calves with dysentery and from a sheep in Australia.

Necrotoxigenic *E. coli* (NTEC), which produce **cytotoxic necrotizing factor (CNF)**, have been isolated from cattle in Northern Ireland and Spain and from diarrheic piglets in England. NTEC1 strains from cattle, pigs, and humans can belong to the same serogroups/biogroups, carry genes coding for adhesions belonging to the same families, and possess other identical virulence-associated properties, and they therefore do not exclude the possibility of cross-infection between humans and farm animals in some cases. In Spain NTEC were detected by tissue culture and PCR in 15.8% of diarrheic dairy calves from 1 to 90 days of age; the majority were NTEC producing CNF2, and the risk increased with age. There was also a strong association between CNF2 and F17 fimbriae. The NTEC, with their associated adhesins and toxins, were present in diarrheic and septicemic calves as early as 1958, and their prevalence seems to be increasing. Their role in causing disease needs further examination.

Most ETEC from **neonatal pigs** belong to the so-called "classical serogroups": O8:K87, O45, O138:K81, O141:K85, O147:K89, O149:K91, and O157:KXVX17. Strains of these serogroups usually express and produce F4 (K88), F5 (K99), F6 (987P), F18 and F41 pilus antigens. With the exception of F18, these pilus antigens mediate adhesion of *E. coli* to ileal villi in neonates, causing profuse diarrhea in unweaned pigs. The F4 and F5 piliated strains are the most common cause of enteric disease in piglets under 2 weeks of age. ETEC strains that produce F6 pili colonize the small intestines and cause diarrhea in neonatal pigs under 6 days of age, but not older pigs. F18, in contrast, is not associated with neonatal colibacillosis in piglets, but together with F4 is the most common adhesin associated with postweaning colibacillosis. There are also some ETEC strains that produce none of the antigens mentioned previously.

F4 produces heat-labile enterotoxin (LT), F5 and F6 do not produce LT, and all three

types produce heat-stable enterotoxin STa in infant mice. Some isolates produce neither LT nor STa but produce enterotoxin in ligated intestinal loops of pigs (STb). Other "nonclassical" strains colonize the small intestine to a certain extent, do not strongly adhere to the intestinal epithelium, and produce enterotoxin and diarrhea in neonatal piglets.

The porcine ETEC strains that induce diarrhea in piglets less than 2 weeks of age but not in older pigs are designated class 2, whereas those strains that induce diarrhea in older pigs are class 1 ETEC. The bovine ETEC strains have several features in common with the porcine class 2 organisms, which include the possession of the 0 antigens 8, 9, 20, or 101; characterization as mucoid colonies; possession of F5 pili; and production of heat-stable enterotoxin. Most ETEC strains of pigs belong to a restricted number of serogroups.

Lambs

Enterotoxigenic strains of *E. coli* can be isolated from the feces of approximately 35% of diarrheic lambs. ETEC strains have also been isolated from the blood of a small percentage of diarrheic lambs. F5 (K99) piliated *E. coli* are associated with outbreaks of diarrhea in lambs under a few days of age. F17 fimbriae *E. coli* have been isolated from diarrheic lambs and kids, but none of the isolates produced any of the toxins normally associated with ETEC strains. Attaching and effacing *E. coli* negative for Shiga toxin but positive for *eae* have been isolated from goat kids affected with severe diarrhea, with a high case fatality rate.

Zoonotic Implications of *E. coli*

Cattle are a major source of EHEC strain O157:H7, which is associated with foodborne disease in humans. (See "Enterohemorrhagic *Escherichia coli* in Farm Animals and Zoonotic Implications.")

PATHOGENESIS

The factors important in understanding the pathogenesis of colibacillosis are the affected species, the age and the immune status of the animal, and the virulence factors of the strain of *E. coli,* particularly its capacity to invade tissues and produce septicemia or to produce an enterotoxin. Diarrhea, dehydration, metabolic acidosis, bacteremia, and septicemia are the major pathogenetic events in the various forms of colibacillosis.

Septicemic Colibacillosis (Coliform Septicemia)

Septicemic colibacillosis occurs in all species as a result of invasive strains of *E. coli* invading the tissues and systemic circulation via the intestinal lumen, nasopharyngeal mucosa, and tonsillar crypts, or umbilical vessels. The intestinal permeability to macromolecules in the newborn piglet may predispose to the invasion of septicemia-inducing *E. coli.* These strains are able to invade extraintestinal tissues, to resist the bactericidal effect of complement in blood, to survive and multiply in body fluids, to escape phagocytosis and intracellular killing by phagocytes, and to induce tissue damage by the release of cytotoxins. Calves and piglets that are deficient in colostral immunoglobulins are highly susceptible to septicemia. Colostrum provides protection against colisepticemia, but it may not prevent diarrhea associated with *E. coli.* Also, colostrum-fed calves are much more resistant to endotoxin than colostrum-deprived calves. Calves, piglets, and lambs that have normal levels of serum immunoglobulins are generally protected from septicemia. The clinical findings and lesions in septicemic colibacillosis are attributable to the effects of endotoxin, which causes shock. The general effects of endotoxin in cattle include hypothermia, decreased systemic blood pressure, tachycardia and decreased cardiac output, changes in WBC counts, alterations in blood coagulation, hyperglycemia followed by hypoglycemia, and depletion of liver glycogen. Animals that recover from septicemia may later develop lesions as a result of local infection of other organs at varying periods of time. Arthritis is a common associated finding in calves, foals, and lambs. Meningitis is common in calves and piglets. Polyserositis as a result of *E. coli* has been recorded in pigs.

Enteric Colibacillosis

Enterotoxigenic Colibacillosis

Enterotoxigenic strains of *E. coli* (ETEC) colonize and proliferate in the upper small intestine and produce enterotoxins, which cause an increase in net secretion of fluid and electrolytes into the gut lumen. The adhesion of *E. coli* to the intestinal epithelial cells is mediated by bacterial pili. The enterotoxigenic form of colibacillosis occurs most commonly in calves and piglets and less commonly in lambs and kids.

The factors that allow or control the colonization and proliferation of these strains and their production of enterotoxin are not well understood. The bacterial fimbriae attach to specific receptor sites on villous epithelial cells, following which the bacteria multiply and form microcolonies that cover the surface of the villi. The capsular polysaccharide of *E. coli* may also be involved in adhesion and colonization. The fimbriae of *E. coli* are strongly immunogenic, a factor that is utilized in the production of vaccines. Because the F5 antigen is only expressed at an environmental pH above 6.5, colonization of the mucosa of the small intestinal tract starts in the ileum, where the intraluminal pH is the highest, and progresses proximally from there.[8] Once established in the gut, ETEC strains start producing and secreting a heat-stable enterotoxin. Similar to the expression of F5, production of enterotoxin is pH dependent, with very limited production at an environmental pH below 7.0.[8] Although this does not appear to have been studied specifically, it can be hypothesized that any factor resulting in an increase of the pH in the gut lumen will facilitate the proliferation of the organism; conversely, lowering the pH may reduce the severity of colibacillosis.

Diarrhea, Dehydration, Metabolic Acidosis, and Electrolyte Imbalance

The production of the enterotoxin results in net secretion of fluid and electrolytes from the systemic circulation into the lumen of the intestine, resulting in varying degrees of diarrhea, dehydration, electrolyte imbalances, acidemia, circulatory failure, shock, and death. The hyperkalemia that is observed in a subset of calves with severe dehydration and acidemia has been associated with cardiac arrhythmias, including bradycardia and atrial standstill.

The effect of the enterotoxin on the gut of calves, piglets, and other species is similar to the effect of cholera enterotoxin in humans and takes place through an intact mucosa. Enterotoxin stimulates mucosal adenylcyclase activity, leading to an increase in cyclic adenosine monophosphate (AMP), which increases intestinal chloride secretion. The increased intraluminal chloride content osmotically drags water into the gut to an amount that exceeds the absorptive capacity of the intestinal mucosa, thereby causing diarrhea. The secretion originates primarily in the intestinal crypts, but the villous epithelium also has a secretory function. The mucosal membrane colonized by ETEC remains morphologically intact. The fluids secreted are alkaline and, in comparison to serum, isotonic, low in protein, and high in sodium and bicarbonate ions. Distension of the abdomen of diarrheic calves may occur, which may be associated with fluid distension of the abomasum and the intestines.

When the disease is confined to the intestine, it responds reasonably well to treatment in the early stages. If death occurs, it is a result of acidemia, electrolyte imbalance, and dehydration. The acid–base and electrolyte changes in piglets 1 to 3 days of age infected naturally and experimentally with ETEC reveal severe dehydration, acidemia, and metabolic acidosis.

Severe metabolic changes can occur in calves with diarrhea. If the disease is progressive, acidemia and metabolic acidosis become more severe as lactic acidosis develops, and severe hypoglycemia may occur. If large amounts of fluid are lost, hypovolemia and shock occur.

Historically, conventional wisdom held that **metabolic acidosis** in diarrheic calves is the result of fecal bicarbonate loss and formation of L-lactate as a result of increased anaerobic glycolysis in dehydrated animals

with decreased tissue perfusion. However, accumulation of L-lactate in neonatal diarrheic calves only appears to occur in calves in their first week of life. Because the relationship between L-lactic acid accumulation and the severity of metabolic acidosis could not be confirmed in clinical cases, it was proposed that exogenous acid supply to the organism must be the major contributor to the so-called **anion-gap acidosis** typically observed in diarrheic calves.[12] The anion gap, defined as the sum of the major cations minus the sum of the major anions, is a measure of "unspecified organic and inorganic acids," of which lactic acid forms a considerable part. It was not until the end of last century that **D-lactic acid accumulation** was first identified as a major contributor to elevated anion gaps in diarrheic calves. In the meantime, several studies confirmed that D-lactic but not L-lactic acidosis is a common occurrence in diarrheic calves. Furthermore D-lactic acidosis was identified as a major contributory factor in calves with high anion-gap acidosis.[12] It is currently assumed that D-lactic acidosis is caused by increased intestinal absorption of this compound in diarrheic calves, where malabsorption results in bacterial fermentation of unabsorbed carbohydrates to D-lactate.[12] Recent retrospective studies suggested that the major driving factor of the acidemia of diarrheic calves was an increase in unmeasured anions, of which lactic acid forms a considerable part. The loss of fluid through the intestinal tract with high sodium and low chloride content is likely to contribute to the so-called strong-ion acidosis. The increase of the total plasma protein concentration that is commonly observed with marked dehydration and resulting in a so-called weak-acid acidosis was found to be a minor contributor to acidemia in diarrheic calves.[13]

The severity and nature of the acidosis in diarrheic calves vary with the age of the calf. Younger calves tend to dehydrate more rapidly and severely than older calves, which may be related to the greater incidence of enterotoxigenic colibacillosis in the young age group. The severity of dehydration, hypothermia, and acidemia is associated with the level of obtundation. Accordingly, the degree of deterioration of the patient's demeanor in combination with the age of the calf are used to predict the severity of acidemia; the more severe the acidemia, the greater the depression.

Conventional wisdom posits that neurologic effects such as ataxia, somnolence, or even coma are primarily caused by severe acidemia or metabolic acidosis, but a series of recent studies unequivocally demonstrated that disturbed neurologic function can better be explained by the frequently observed increase in plasma D-lactate concentration than acidemia/metabolic acidosis per se.[14,15] Experimental studies conducted on euhydrated calves showed that neurologic signs similar to the ones observed in severely diarrheic calves can be reproduced by inducing hyper–D-lactatemia without concomitant acidosis. In contrast, experimentally inducing severe hyperchloremic acidosis in calves did not result in noteworthy effects on the demeanor of treated calves.[16,17]

Hyperkalemia in the Diarrheic Calf

Hyperkalemia is the most prominent electrolyte disturbance recognized in dehydrated diarrheic calves that are severely acidemic. It occurs despite significant net losses of potassium into the gut in diarrheic animals. A recent retrospective study conducted on patients of a teaching hospital revealed an incidence of hyperkalemia in diarrheic calves of 34%.[18] The predominant clinical finding associated with hyperkalemia is bradycardia and arrhythmia that can lead to atrial standstill, with fatal outcome. Although the association between hyperkalemia and acidemia is well established, the underlying mechanism is poorly understood.[19] The long-held mechanism responsible for hyperkalemia in diarrheic calves is directly associated with extracellular acidosis and the electrochemical exchange of K^+ for H^+ across the cell membrane, leading to a shift of potassium from the extracellular to the intracellular space in exchange for H^+ that tends to shift into the opposite direction with increasing extracellular H^+ concentrations. Although widely accepted, this proposed mechanism lacks a sound physiochemical basis because a decrease in plasma pH from 7.4 to 7.0 would increase the extracellular H^+ concentration from 0.000,040 mmol/L to 0.000,100 mmol/L. An equimolar exchange of K^+ for H^+ can therefore only account for an increase of the serum potassium concentration of 0.000,06 mmol/L, an effect that not only is not measurable with current laboratory equipment but also is physiologically irrelevant.[19] An alternative mechanism that has been proposed is impaired activity of Na/K-ATPase in states of acidemia, resulting in impaired transport of potassium into the intracellular space.[19] The previously mentioned retrospective study found the occurrence and the degree of hyperkalemia to be more closely associated to the degree of dehydration than to the decrease in venous blood pH or base excess, suggesting that the impaired ability to excrete potassium through the urinary tract may play a more important role than metabolic acidosis/acidemia in the etiology of hyperkalemia in dehydrated calves.[18]

Hypernatremia in the Diarrheic Calf

Hypernatremia is uncommon in diarrheic calves generally suffering from isotonic or mildly hypotonic dehydration. However, incidental cases of hypernatremia have been reported. It is presumed that mixing errors in the preparation of oral electrolyte solutions to treat diarrhea rather than diarrhea itself is the cause. The experimental oral administration of 1 L of electrolyte concentrate containing 2750 mEq sodium found that calves would willingly consume the solution mixed with milk, and developed signs of hypernatremia within 6 hours of administration.

Effect of Colostral Immunoglobulin Status

An adequate level of serum immunoglobulin can protect calves from death as a result of the effects of diarrhea, but not necessarily from diarrhea. The best protection is provided if both the immunoglobulin levels in the serum and the levels in the colostrum and milk during the first week after birth are high. The immunoglobulin subclasses in the plasma of calves that have received sufficient colostrum are IgG, IgM (and IgM is probably the more important of the two for the prevention of septicemia), and IgA. The serum IgG concentrations of calves under 3 weeks of age dying from infectious disease were much lower than those in normal calves. Of the dead calves, 50% had serum IgG levels that were more than 2 standard deviations below the normal mean, and an additional 35% had concentrations greater than 1 standard deviation below the normal mean. In the intestine, no single subclass of immunoglobulin is known to be responsible for protection against the fatal effects of diarrhea. Individually, each immunoglobulin subclass can prevent death from diarrhea even though calves may be affected with varying degrees of diarrhea. In contrast to the situation in the pig, IgA appears to be least effective.

In pigs, IgA becomes the dominant immunoglobulin in sow colostrum after the first few days of lactation, and this is the immunoglobulin that is not absorbed but is retained in, and reaches a high level in, the gut and plays a major role in providing local protection against enteric colibacillosis in piglets. Porcine colostral IgA is more resistant to gastrointestinal proteolytic enzymes than IgG_2 and IgM. On the other hand, IgG is at a peak concentration in colostrum in the first day after parturition, is readily absorbed by the newborn piglet, and is vital in providing protection against septicemia. Lysozyme in sows' milk may assist in the control of the bacterial population in the gut of the unweaned piglet.

Intestinal Mucosa

In general, ETEC exert their effects by the enterotoxin causing hypersecretion through an intact intestinal epithelium. However, the intraluminal exposure of the jejunum of 3-week-old pigs to sterile crude-culture filtrates from strains of *E. coli* known to produce two types of ST will induce microscopic alterations of the villous epithelium. Focal emigration of neutrophils, especially through the epithelium above aggregated lymphatic follicles; stunting of jejunal and

ileal villi; and adherence of bacteria to jejunal and ileal mucosae are the most consistent findings. These changes are useful in making the diagnosis of enterotoxigenic colibacillosis in calves. Although enterotoxigenic strains are considered to be noninvasive, this does not preclude the possibility that invasion into the systemic circulation may occur, resulting in septicemia, or that septicemic strains may not also be present.

Enzyme histochemistry studies of the small intestinal mucosa in experimental infections of calves with rotavirus and ETEC indicate a marked decrease in enzyme activity in dual infections and a lesser decrease in monoinfections. Increased enzyme activity occurred in parts of the intestinal mucosa that were not affected or only slightly affected by the enteropathogens, which may be an adaptation of the mucosa to maintain absorptive function. Lactose digestion is slightly impaired in calves with mild diarrhea. Calves with acute diarrhea are in a catabolic state and respond with a larger increase of plasma glucose concentration to a given amount of absorbed glucose than do healthy calves.

Fat and carbohydrate malabsorption frequently occurs in diarrheic calves over 5 days of age and contributes to the development of D-lactic acidosis, which has been associated with a strong neurotoxic effect that is presumably responsible for the impaired demeanor of diarrheic calves.

Attaching and Effacing Colibacillosis

Attaching and effacing enteropathogenic *E. coli* can cause naturally occurring diarrhea and dysentery in calves at 18 to 21 days. They do not produce enterotoxin but adhere to the surface of the enterocytes of the large intestine. Affected calves pass bright red blood in the diarrheic feces. The lesions in experimentally infected calves are indistinguishable from those produced by some *E. coli* that are enteropathogenic for humans, rabbits, and pigs. The bovine O118:H16 EHEC strain is able to colonize the intestine of newborn calves, inducing diarrhea 24 hours after challenge and producing attaching and effacing lesions in the small and large intestines.

Synergism Between Enteropathogens

Enterotoxigenic colibacillosis occurs naturally and can be reproduced experimentally using ETEC in calves less than 2 days of age but not in calves 1 week of age. Diarrheic calves older than 3 days of age may be infected with enterotoxigenic F5 (K99) *E. coli* and rotavirus. There is evidence that prior or simultaneous infection of the intestine with rotavirus will enable the *E. coli* to colonize in older calves. Thus there may be synergism between rotavirus and ETEC in calves older than 2 days; this may explain the fatal diarrhea that can occur in calves at 1 week of age, which normally would not be fatal with a single infection. The rotavirus may enhance the colonization of *E. coli*.

The simultaneous experimental infection of neonatal gnotobiotic calves at 24 hours of age with rotavirus and ETEC results in a severe diarrheal disease. The same situation occurs in piglets. However, in both species the effect was considered to be additive rather than synergistic.

Summary of Pathogenesis

Septicemic colibacillosis occurs in newborn animals, and FTPI is the major predisposing factor. Enteric colibacillosis occurs in colostrum-fed animals and is associated with the colonization and proliferation of ETEC, which produce enterotoxin and cause varying degrees of diarrhea, acidemia, and dehydration. Although single infections occur commonly, as in piglet diarrhea, and what was previously described as enteric–toxemic colibacillosis in calves, multiple infections with ETEC and viruses and other agents are more common.

CLINICAL FINDINGS

Calves

Coliform Septicemia

Coliform septicemia is most common in calves during the first 4 days of life and is described as the systemic inflammatory response syndrome (SIRS) to an active infectious process.[20] Most affected calves have low levels of serum IgG because of inadequate transfer of colostral immunoglobulin.[21] The illness is peracute, with the course varying from 24 to 96 hours, with a survival rate of less than 12%. Early clinical signs are vague and nonspecific. Affected animals are weak and obtunded, commonly recumbent, and dehydrated; tachycardia is present, and although the temperature may be high initially, it falls rapidly to subnormal levels when the calf becomes weak and moribund. The suck reflex is weak or absent, the oral mucous membranes are dry and cool, and the capillary refill time may be prolonged. Cold extremities, weak peripheral pulse, and prolonged capillary refill time are common. Scleral injection is common. Diarrhea and dysentery may occur but are uncommon.

The involvement of multiple body systems and organs is characteristic of neonatal septicemia, and careful clinical examination is required to detect abnormalities. If a calf survives the septicemic state, clinical evidence of postsepticemic localization may appear in about 1 week. This includes arthritis, meningitis, panophthalmitis, and, less commonly, pneumonia. In a series of 32 cases of meningitis in neonatal calves, the most frequent clinical findings were lethargy, anorexia, recumbency, loss of the suck reflex, stupor, and coma. Opisthotonos, convulsions, tremors, and hyperesthesia were seen less frequently. The case fatality rate was 100% in spite of intensive therapy, and lesions of septicemia were present at necropsy.

Predictors of Septicemia

The early clinical findings of septicemia in neonatal calves are vague and nonspecific and are often indistinguishable from the findings of noninfectious diseases or those of focal infections such as diarrhea. Positive blood cultures are required for a definitive diagnosis of septicemia, but results are not usually available for 48 to 72 hours, and false negatives are common. Laboratory parameters that have been proposed to identify potentially septic calves include hypoglycemia, left shift of neutrophils, and signs of toxicity of neutrophils.[20]

No single laboratory test has emerged as being completely reliable for the early diagnosis of septicemia in farm animal neonates, and therefore scoring systems and predictive models using obtainable historical, clinical, and clinicopathologic data have been developed.[20] The goal of these mathematical models is to identify septicemic neonates early in the course of disease when appropriate therapy would be most likely to result in a favorable outcome. In a study of diarrheic calves under 28 days of age submitted to a referral clinic for treatment, 31% of the calves were septicemic, based on blood culture. Two models to predict septicemia were used. Clinicopathologic variables associated with an increased risk of septicemia were moderate (1.99 to 5.55 mg/dL) and marked (>5.66 mg/dL) increases in serum creatinine (OR 8.63), moderate to marked toxic changes in neutrophils (OR 2.88), and FTPI (IgG concentrations β 800 mg/dL, globulin β 2 g/dL [OR 2.72], and total serum protein β 5 g/dL). The clinical variables associated with an increased risk of septicemia were age under 5 days (OR 2.58), focal infection (OR 2.45), recumbency (OR 2.98), and weak suck reflex (OR 4.10).

Enteric Colibacillosis

Enteric colibacillosis is the most common form of colibacillosis in newborn calves, primarily 3 to 5 days of age. It may occur in calves as early as 1 day of age and only rarely up to 3 weeks. The clinical severity will vary depending on the number and kind of organisms causing the disease. The presence of a single ETEC may cause a state of collapse usually designated as **enteric toxemia**. In this form of the disease the outstanding clinical signs include severe weakness, coma, subnormal temperature, cold and clammy skin, pale mucosae, wetness around the mouth, collapse of superficial veins, slowness and irregularity of the heart, mild convulsive movements, and periodic apnea. Diarrhea is usually not evident, although the abdomen may be slightly distended, and succussion and auscultation may reveal fluid-splashing sounds suggesting a fluid-filled intestine. The prognosis for these calves is poor, and they commonly die 2 to 6 hours after the onset of signs.

In the more common form of the disease in calves, there is diarrhea in which the feces

are profuse and watery to pasty, usually pale yellow to white in color, and occasionally streaked with blood flecks and very foul-smelling. The dry-matter content of the feces is commonly below 10%. Defecation is frequent and effortless, and the tail and perineum are soiled with feces. The temperature is usually normal in the initial stages but becomes subnormal as the disease worsens. Affected calves may or may not suck or drink depending on the degrees of acidosis, dehydration, and weakness. Calves under 8 days of age may be weak, primarily from the effects of rapid and severe dehydration; in calves older than 8 days the acidemia and metabolic acidosis, a considerable part of which is a result of the accumulation of D-lactic acid, tend to be more severe and make a greater contribution to obtundation and weakness. In the early stages of the disease, the abdomen may be slightly distended as a result of distension of fluid-filled intestines, which can be detected by succussion and auscultation of the abdomen. In some of these calves the diarrhea is not yet obvious but is delayed for several hours, when it can become quite profuse. Mildly to moderately affected calves may be diarrheic for a few days and recover spontaneously with or without treatment. However, 15% to 20% of calves with enteric colibacillosis become progressively worse over a period of 3 to 5 days, gradually become more weak, lose the desire to suck, and progressively appear more obviously dehydrated.

Throughout the course of the diarrhea the degree of dehydration will vary from just barely detectable clinically (4% to 6% of body weight [BW]) to up to 10% to 16% of body weight. The degree of dehydration can be estimated by "tenting" the skin of the lateral portion of the cervical region and measuring the time required for the skin fold to return to normal. In calves with 8% dehydration, 5 to 10 seconds will be required for the skin fold to return to normal; in 10% to 12% dehydration, up to 30 seconds will be required. Recession of the eyeball (enophthalmos) is an alternative method validated to reliably estimate the degree of dehydration in diarrheic calves. Slight sinking of the eyeball without an obvious space between the eyeball and the orbit represents 6% to 8% dehydration, moderate separation of the eyeball from the orbit represents 9% to 12% dehydration, and marked separation of the eyeball from the orbit represents over 12% and up to 16% dehydration. A summary of the relationship between degree of dehydration (% BW), depth of enophthalmos (mm), cervical skin tent duration in seconds, and the state of the mucous membranes and extremities in calves with experimentally induced diarrhea is set out in Table 19-12.[1]

Affected calves can lose 10% to 16% of their original body weight during the first 24 to 48 hours of the diarrhea. The hyperkalemia in calves with neonatal diarrhea has been associated with cardiac rate and rhythm abnormalities, including bradycardia and atrial standstill. Herd outbreaks of the disease in beef calves may last for several weeks, during which time almost every calf will be affected within several days after birth.

Veal calf hemorrhagic enteritis is a fatal syndrome of veal calves characterized by anorexia, fever, diarrhea with mucus-containing feces that become bloody in the later stages, and hemorrhagic diathesis on the conjunctivae and mucous membranes of the mouth and nose. The etiology is unknown; the *E. coli* strains isolated from the feces of affected calves produced enterotoxins and Shiga toxins, but their significance is uncertain.

In some calves between 10 and 20 days of age with a history of diarrhea in the previous several days, from which they have recovered, there will be metabolic acidosis without clinical signs of dehydration. Affected calves are depressed, weak, ataxic, and sometimes recumbent, and they appear comatose. Affected calves respond quickly to treatment with intravenous sodium bicarbonate. A similar syndrome occurs in goat kids.

Lambs and Goat Kids

Although some cases manifest enteric signs, and chronic cases may occur, colibacillosis in lambs is commonly septicemic and peracute. Two age groups appear to be susceptible: lambs 1 to 2 days of age and lambs 3 to 8 weeks old. Peracute cases are found dead without premonitory signs. Acute cases show collapse and occasionally signs of acute meningitis manifested by a stiff gait in the early stages, followed by recumbency with hyperesthesia and tetanic convulsions. Chronic cases are usually manifested by arthritis. The disease in goat kids is similar to that in lambs.

Table 19-12 Degree of dehydration in calves with experimentally induced diarrhea

Degree of dehydration (% BW)	Depth of enophthalmos (mm)	Cervical skin-tent duration (s)	Mucous membranes and extremities
0	None	Less than 2	Moist
2	1	3	Dry
4	2	4	Dry
6	3	5	Dry
8	4	6	Cool extremities
10	6	7	Cool extremities
12	7	>8	Cool extremities
>14	>8	>10	White mucous membranes

Piglets

Coliform Septicemia

Coliform septicemia is uncommon but occurs in piglets within 24 to 48 hours of birth. Some are found dead without any premonitory signs. Usually more than one piglet, and sometimes the entire litter, will be affected. Severely affected piglets seen clinically are weak and almost comatose, appear cyanotic, feel cold and clammy, and have a subnormal temperature. Usually there is no diarrhea. The prognosis for these piglets is poor, and most will die in spite of therapy.

Edema disease is unique form of colibacillosis occurring in piglets between a few days after birth to well after weaning. It is caused by Shiga-toxin-producing *E. coli* strains that induce degenerative angiopathy of small arteries and arterioles.

Enterotoxigenic Colibacillosis

Newborn Piglet Diarrhea

Newborn piglet diarrhea, a form of colibacillosis in piglets, occurs from 12 hours of age up to several days of age, with a peak incidence at 3 days of age. As with the septicemic form, usually more than one pig or the entire litter is affected. The first sign usually noticed is the fecal puddles on the floor. Affected piglets may still nurse in the early stages, but they gradually lose their appetite as the disease progresses. The feces vary from a pasty to watery consistency and are usually yellow to brown in color. When the diarrhea is profuse and watery, there will be no obvious staining of the perineum and hindquarters with feces, but the tails of the piglets will be straight and wet. Sick piglets occasionally vomit, although vomiting is not as prominent as with transmissible gastroenteritis. The temperature is usually normal or subnormal. The disease is progressive; diarrhea and dehydration continue, and the piglets become very weak and lie in lateral recumbency and make weak paddling movements. Within several hours they appear very dehydrated and shrunken, and they commonly die within 24 hours after the onset of signs if not treated. In severe outbreaks the entire litter may be affected and die within a few hours of birth. The prognosis is favorable if treatment is started early, before significant dehydration and acidosis occur.

Postweaning Diarrhea

The postweaning diarrhea (PWD) form of colibacillosis in piglets presents an economically important cause of death of weaned piglets. It is commonly seen within days of

weaning. In peracute cases piglets are found dead with an obviously dehydrated appearance, deeply sunken eyes, and cyanotic extremities. In less acute cases the first sign may be a loss in condition that is largely a result of dehydration. Diarrhea may not be apparent in all cases because fluid may just accumulate in the gut in some animals. If present, diarrhea can be watery to pasty, may contain blood in some instances, and may last between 1 and 5 days (see also "Post-weaning Diarrhea of Pigs").

CLINICAL PATHOLOGY

Culture and Detection of Organism

If septicemia is suspected, blood should be submitted for isolation of the organism and determination of its drug sensitivity. Blood for culture must be taken aseptically and inoculated directly into brain–heart infusion broth. Because of the limited sensitivity to detect bacteremia by a single culture, the blood sample should be repeated a few hours later to enhance recovery rate and confirm septicemia.

The **definitive etiologic diagnosis of enteric colibacillosis** depends on the isolation and characterization of *E. coli* from the intestines and the feces of affected animals. The best opportunity of making a diagnosis is when untreated representative affected animals are submitted for pathologic and microbiological examination. The distribution of the organism in the intestine; determination of the presence of F4 (K88), F5(K99), or F6 (987P) antigens; and the histopathologic appearance of the mucosa contribute to the diagnosis.

The routine culture of feces and intestinal contents for *E. coli* without determining their virulence determinants is of limited value. The laboratory tests used to identify enterotoxigenic F4 (K99) *E. coli* include a direct fluorescent antibody technique with conventional culturing methods and the ELISA, with or without monoclonal antibody, to detect the organism or the enterotoxin in the feces. DNA gene probes specific for genes encoding enterotoxin and adhesins are available and are being used to evaluate *E. coli* isolated from diarrheic animals. Isolates of the organism can also be examined for the presence of toxins using an enzyme immune assay test and latex agglutination test.

Detection of STEC in feces has relied on cytotoxicity testing and DNA hybridization. Several ELISAs are available, and monoclonal antibodies to the Shiga toxins ST1 and ST2 have been used to examine feces from animals. The isolation of *E. coli* O157:H7 has relied on its ability to ferment sorbitol. A sandwich ELISA using monoclonal antibodies to *E. coli* Shiga toxins 1 and 2 for capture and detection is available for detection of STEC in animal feces. A PCR test is also available for detection of ST genes in *E. coli* isolated from cattle, sheep, and pigs affected with diarrhea.

The determination of drug sensitivity of the *E. coli* isolated from the feces of diarrheic calves and piglets is commonly done, but it is of limited value without determining which isolate is enteropathogenic.

Hematology and Serum Biochemistry

A total and differential leukocyte count and remarkable changes in the fibrinogen concentration may indicate the presence of septicemia or severe intestinal infection. However, severely affected calves may not have grossly abnormal hemograms.[21] In enteric disease, the major changes in plasma composition are dehydration, electrolyte imbalance, and metabolic acidosis/acidemia. The total plasma osmolality tends to be decreased.

The packed cell volume and the total protein concentration of the blood will indicate the degree of dehydration, although the increase of total protein in calves with FTPI may underestimate the degree of dehydration. The blood urea nitrogen (BUN) concentration may be increased in severe cases because of inadequate renal perfusion. The blood bicarbonate concentration is markedly reduced, indicating the presence of metabolic acidosis. Decreased blood pH values represent acidemia. Calves with a venous blood pH below 7.0 require immediate parenteral therapy for acidemia. Other serum electrolytes are variable, but there may be a slight decrease in serum sodium and a slight increase in serum chloride. In severely dehydrated animals hyperkalemia may occur, which may result in bradyarrhythmia.[18]

Hematologic abnormalities associated with **septicemia** vary with the stage and severity of the disease. Abnormal neutrophil counts (neutrophilia or neutropenia), a left shift of neutrophils, and signs of toxicity in neutrophils are commonly seen in septic animals.[11,20,21] Hypoglycemia is another common, although certainly not pathognomonic, finding in septic calves.

NECROPSY FINDINGS

In **coliform septicemia** there may be no gross lesions, and the diagnosis may depend on the isolation of the organism from the filtering organs. In less severe cases there may be subserosal and submucosal hemorrhages. A degree of enteritis and gastritis may be present. Occasionally, fibrinous exudates are found in the joints and serous cavities, and there may be omphalophlebitis, pneumonia, and meningitis. The histologic features of such presentations of colibacillosis are those of septicemia and toxemia.

In **enteric colibacillosis** of piglets and calves the carcass appears dehydrated, but the intestine is flaccid and filled with fluid. In calves, the abomasum is usually distended with fluid and may contain a milk clot. Clots are typically absent in calves fed whey milk replacers that do not contain casein. The abomasal mucosa may contain numerous small hemorrhages. In both calves and pigs, the intestinal mucosae may appear normal or hyperemic, and there may be edema of the mesenteric lymph nodes. Mild atrophy or even fusion of jejunal and ileal villi is often seen, but the key microscopic observation is the **presence of bacilli adherent to the brush borders of enterocytes**. Ultrastructurally, there is increased epithelial cell loss from the villus about 12 hours after experimental inoculation of calves with an ETEC.

In calves affected with attaching and effacing *E. coli* there is pseudomembranous ileitis, mucohemorrhagic colitis, and proctitis. Microscopic examination of well-preserved gut segments reveals bacterial adherence, atrophy of ileal villi, and erosion of enterocytes.

In addition to traditional bacteriologic culture techniques, the ETEC may be identified by several tests, including indirect fluorescent antibody (IFA) tests specific for F4 (K88), F5 (K99), and F6 (987P) pilus antigens. The IFA tests can be performed on impression smears or frozen sections of ileal tissue, and the results are available within a few hours. Newer techniques such as DNA gene probes, enzyme immune assays, and latex agglutination tests are now available to identify those isolates that are enterotoxin producers and have adhesin properties.

During severe disease outbreaks it is often necessary to conduct the necropsy examination on diarrheic animals that have been killed specifically for the purpose of obtaining a definitive etiologic diagnosis. The combined use of bacteriologic, parasitologic, and virological methods, together with histologic and immunofluorescent studies of fresh intestinal tissue, will provide the most useful information about the location of the lesions and the presence of enteropathogens. Postmortem autolysis of the intestinal mucosae and invasion of the tissues by intestinal microflora occurs within minutes after death, so gut samples should be collected immediately following euthanasia of the animal.

Samples for Confirmation of Diagnosis

Coliform Septicemia

- Bacteriology—chilled spleen, lung, liver, culture swabs of exudates, umbilicus, meninges (culture)
- Histology—fixed samples spleen, lung, liver, kidney, brain, and any gross lesions

Enteric Colibacillosis

- Bacteriology—chilled segments of ileum and colon (including content; culture and/or FAT, latex agglutination, PCR)
- Histology—fixed duodenum, jejunum, ileum, colon, and mesenteric lymph node

Table 19-13 Possible causes of bacteremia/septicemia and acute neonatal diarrhea in farm animals

Calves	Piglets	Lambs and kids	Foals
Bacteremia/septicemia			
Escherichia coli	*E. coli*	*E. coli*	*E. coli*
Salmonella spp.	*Streptococcus*	*Salmonella* spp.	*Actinobacillus equuli*
Listeria monocytogenes	*L. monocytogenes*	*L. monocytogenes*	*Salmonella abortivoequina*
Pasteurella spp.		*Erysipelothrix rhusiopathiae*	*Salmonella typhimurium*
Streptococcus spp.			*Streptococcus pyogenes*
Pneumococcus spp.			*L. monocytogenes*
Acute neonatal diarrhea			
Enteropathogenic and enterotoxigenic *E. coli*	Enteropathogenic *E. coli*	*Clostridium perfringens* type C	Foal-heat diarrhea
Rotavirus	*Salmonella* spp.	*C. perfringens* type B	Rotavirus
Coronavirus	Transmissible	(lamb dysentery)	*C. perfringens* type B
Bovine torovirus (Breda virus)	gastroenteritis virus	Rotavirus	
Bovine calicivirus	*C. perfringens* type C	Caprine herpesvirus	
Bovine norovirus	(rarely A)		
Cryptosporidium spp.	*Clostridium difficile*		
Giardia spp.	Rotavirus		
Salmonella spp.	PRRSV		
Eimeria spp. (calves at least 3 weeks old)	*Isospora* spp.		
C. perfringens type C			

PRRSV, porcine reproductive and respiratory syndrome virus.

DIFFERENTIAL DIAGNOSIS

The definitive etiologic diagnosis of septicemic colibacillosis is dependent on the laboratory isolation of the causative agent, which is usually a single species or organism. The septicemias of the newborn cannot be distinguished from one another clinically. The definitive etiologic diagnosis of enteric colibacillosis in newborn calves and piglets may be difficult and often inconclusive because the significance of other organisms in the intestinal tract and feces of diarrheic animals cannot be easily determined.

Table 19-13 lists the possible causative agents of diarrhea and septicemia in newborn farm animals. Using the combined diagnostic approach of detection of enteropathogens in the feces before death and in the intestinal mucosa after death, it is possible to identify where ETEC, rotavirus, coronavirus, *Salmonella* spp., and *Cryptosporidium* spp. appear to be the only or principal causative agents. However, mixed infections are more common than single infections.

Every effort that is economically possible should be made to obtain an etiologic diagnosis. This is especially important when outbreaks of diarrhea occur in a herd or when the disease appears to be endemic. The use of an interdisciplinary approach will increase the success of diagnosis. This includes making a visit to the farm or herd and making a detailed epidemiologic investigation of the problem. The diagnosis depends heavily on the epidemiologic findings, the microbiological and pathologic findings, and sometimes on the results of treatment.

The major difficulty is to determine whether or not the diarrhea is infectious in origin and to differentiate it from dietetic diarrhea, which is most common in hand-fed calves and in all newborn species that are sucking high-producing dams. In dietetic diarrhea the feces are voluminous and pasty to gelatinous in consistency; the animal is bright and alert and is usually still sucking, but some may be inappetent.

TREATMENT

Coliform Septicemia

Intensive critical care is required for the treatment of neonatal coliform septicemia. Early identification of animals suspected of being septicemic and early therapeutic intervention are important determinants of the treatment success. Evidence from human medicine indicates that the survival rate must be expected to decrease by 10% for every hour antimicrobial therapy is delayed in patients in septic shock.[22] A recent consensus statement in human medicine recommends initiation of intravenous antimicrobial therapy within the first hour after having recognized severe septicemia.[23] Thus, in most cases antimicrobial therapy has to be initiated before confirmatory culture results are available.

Although *E. coli* may be cultured from the blood of septicemic foals and calves, a significant percentage of isolates are gram-positive, which justifies the use of antimicrobials that have a broad spectrum. Antimicrobials are given parenterally and may be given continuously intravenously, more than once daily and daily until recovery is apparent. Isolation of the organisms from blood and determination of drug sensitivity constitute the ideal protocol. Intravenous fluid and electrolyte therapy are administered continuously until recovery is apparent (see "Principles of Fluid and Electrolyte Therapy"). Whole blood transfusions are used in calves and foals, especially when immunoglobulin deficiency is suspected from the history or is determined by measurement of serum immunoglobulins of blood. In one series on neonatal septicemia in calves, in which *E. coli* accounted for 50% of the bacterial isolates, the survival rate was only 12%.

Enteric Colibacillosis

The considerations for treatment of enteric colibacillosis include the following:

- Fluid and electrolyte replacement
- Antimicrobial and immunoglobulin therapy
- Antiinflammatory therapy
- Antimotility drugs
- Intestinal protectants
- Alteration of the diet
- Probiotics
- Clinical management of outbreaks

Fluid and Electrolyte Replacement

The dehydration, acidosis, and electrolyte imbalance are corrected by the parenteral and oral use of simple or balanced electrolyte solutions. The provision of fluid therapy in diarrheic dehydrated calves under field conditions in veterinary practice has been described. It is important to obtain an adequate history of the case, including age of the calf, duration of the diarrhea, and all treatments already given by the owner. The physical examination of the calf includes a standard clinical examination with emphasis on evaluating the degree of dehydration and acidosis.

Dehydration is evaluated by two clinical observations:

- **Skin elasticity**. The skin of the middle of the neck is better than the eyelid. A portion of the skin is tented and twisted for 1 second, and then the time to return to the initial position is measured—less than 2 seconds in the normal calf, 6 seconds in moderate (8%) dehydration, and more than 8 seconds in severe (12%) dehydration (Table 19-12).
- **Position of eyeball in the orbit and extent of enophthalmos**. This is determined by measuring the distance between the globe and the orbit. The eyeball is not sunken in healthy calves. Degrees of dehydration of 4%, 8%, and 12% are represented by 2-mm, 4-mm, and 7-mm enophthalmos, respectively (Table 19-12).

The degree of metabolic acidosis can be evaluated by determining the degree of obtundation, muscular tone, ability to stand, intensity of the sucking reflex, temperature of the inside of the oral cavity, and age of the calf that correlate with an estimate of the **base deficit**. The following categories for diarrheic calves are being used under field conditions:

1. Calves with good muscular tone and the ability to stand, strong suck reflex, and warm oral cavity have no base deficit if younger than 8 days of age and up to 5 mEq/L if older than 5 days.
2. Calves that can stand, have a slightly cool oral cavity, and have a weak suck reflex have a base deficit of 5 mEq/L if under 8 days of age and 10 mEq/L if older than 8 days.
3. Calves in sternal recumbency with a cool oral cavity and no suck reflex have a base deficit of 10 mEq/L if under 8 days of age and 15 mEq/L if older than 8 days.
4. Calves in lateral recumbency that lack a suck reflex and have a cold oral cavity have a base deficit of 10 mEq/L if under 8 days of age and 20 mEq/L if older than 8 days.

Categorizing Diarrheic Calves Into Treatment Groups

Based on the history and clinical findings, affected calves can be divided into the following categories according to the type of therapy required and which is most economical:

1. **Oral fluid therapy**—calves with a history of acute diarrhea, less than 7% dehydrated, slightly dry oral mucosa, good suck reflex, good muscle tone, alert, able to stand, and warm mouth. These can be treated with oral fluids and electrolytes.
2. **Oral fluid therapy and hypertonic saline solution**—calves with 7% to 9% dehydration and slight acidosis, weak suck reflex, good muscular tone, and warm mouth. Administer hypertonic saline solution (7.5% NaCl) intravenously at 3 to 4 mL/kg BW in 5 minutes. Assure voluntary intake of oral fluids, or administer oral fluids and electrolytes by stomach tube at 40 to 60 mL/kg BW. Reevaluate in 6 to 8 hours.
3. **Intravenous fluid therapy with alkalinizing agents**—calves that are more than 9% dehydrated, have dry and cool oral mucous membranes, are recumbent, have no suck reflex, and are very depressed. Provide intravenous replacement and maintenance fluid and electrolyte therapy including an alkalinizing agent for a period of 6 to 8 hours and up to 24 to 36 hours if necessary.

The details for parenteral and oral fluid and electrolyte therapy are described under "Principles of Fluid and Electrolyte Therapy."

Antimicrobial Therapy

Antimicrobials have been used extensively for the specific treatment of colibacillosis in calves and piglets because it was assumed that an infectious enteritis was present. It has been difficult to evaluate the efficacy of antimicrobials for the treatment of enteric colibacillosis because of the complex nature of the interactive factors that affect the outcome in naturally occurring cases. These include the presence of mixed infections, the effects of whether or not milk is withheld from the diarrheic calves, the effects of the immune status of individual calves, the variable times after the onset of diarrhea when the drugs are given, the possible presence of antimicrobial resistance, and the confounding effects of supportive treatment such as electrolyte and fluid therapy.

Change in Small Intestinal Bacterial Flora in Calves With Diarrhea

There has been a paradigm shift in the last 40 years toward categorizing an episode of calf diarrhea as being the result of a specific etiologic agent, such as rotavirus, coronavirus, cryptosporidia, *Salmonella* spp., or ETEC. Although the etiologic approach has correctly focused attention on preventive programs, including vaccination and optimizing transfer of colostral immunity, the approach has diverted attention from the universal finding of all studies, which is that calves with diarrhea of whatever etiology have coliform bacterial overgrowth of the small intestine.

Studies completed more than 70 years ago documented increased numbers of *E. coli* bacteria in the abomasum, duodenum, and jejunum of scouring calves. Moreover, calves severely affected with diarrhea had increased numbers of *E. coli* bacteria in the anterior portion of their intestinal tracts compared with mildly affected animals. More recent studies have consistently documented the fact that calves with naturally acquired diarrhea, regardless of age and the etiologic cause for the diarrhea, have altered small intestinal bacterial flora. Specifically, *E. coli* bacterial numbers were increased 5- to 10,000-fold in the duodenum, jejunum, and ileum of calves with naturally acquired diarrhea, even when the diarrhea was not attributable to ETEC, and where rotavirus and coronavirus were identified in the feces. The largest increase in *E. coli* bacterial numbers occurs in the distal jejunum and ileum, whereas the *E. coli* or coliform bacterial numbers in the colon and feces are similar or higher for calves with diarrhea than calves without diarrhea, with *E. coli* being more numerous in the feces of colostrum-deprived than colostrum-fed calves. Small intestinal overgrowth with coliform bacteria can persist after departure of the initiating enteric pathogen.

In calves with naturally acquired diarrhea, increased small-intestinal colonization with *E. coli* has been associated with impaired glucose, xylose, and fat absorption.

Mixed infections with enteric pathogens are commonly diagnosed in calves with naturally acquired diarrhea, and the clinical signs and pathologic damage associated with rotavirus infection are more severe when *E. coli* is present than when it is absent. Primary viral morphologic damage to the small intestine also facilitates systemic invasion by normal intestinal flora, including *E. coli*.

In calves with experimentally induced ETEC diarrhea, colonization of the small intestine by *E. coli* has been associated with impaired glucose and lactose absorption, decreased serum glucose concentration, and possibly increased susceptibility to cryptosporidial infection.

In summary, calves with diarrhea have increased coliform bacterial numbers in the small intestine, regardless of etiology, and this colonization is associated with altered small-intestinal function, morphologic damage, and increased susceptibility to bacteremia. It therefore follows that administration of antimicrobials that decrease small-intestinal coliform bacterial numbers in calves with diarrhea may prevent the development of bacteremia, decrease mortality, and decrease morphologic damage to the small intestine, thereby facilitating digestion and absorption and increasing growth rate.

Incidence of Bacteremia in Calves With Diarrhea

Calves with diarrhea are more likely to have FTPI, and this group of calves, in turn, is more likely to be bacteremic. Colostrum-deprived calves that subsequently developed diarrhea were frequently bacteremic, whereas bacteremia occurred much less frequently in colostrum-fed calves that developed diarrhea.

Based on field studies of diarrheic calves, it can be assumed that, **on average, 30% of**

severely ill calves with diarrhea are bacteremic, with *E. coli* being the predominantly isolated pathogen. The risk of bacteremia is higher in calves with FTPI than in calves with adequate transfer of passive immunity, and the risk of bacteremia is higher in calves 5 days of age or younger. Veterinarians should also assume that 8% to 18% of diarrheic calves with adequate transfer of passive immunity and systemic illness are bacteremic. The prevalence of bacteremia is sufficiently high in systemically ill calves that effective antimicrobial treatment for potential bacteremia should be routinely instituted, with emphasis on treating potential *E. coli* bacteremia, regardless of transfer of passive immunity status and treatment cost. Withholding an effective treatment for a life-threatening condition, such as bacteremia in calves with diarrhea, cannot be condoned on animal welfare grounds.

Antimicrobial Susceptibility of Fecal *Escherichia coli* Isolates

The most important determinant of antimicrobial efficacy in calf diarrhea is obtaining an effective antimicrobial concentration against bacteria at the sites of infection (small intestine and blood). The results of fecal antimicrobial susceptibility testing have traditionally been used to guide treatment decisions; however, susceptibility testing in calf diarrhea probably has clinical relevance only when applied to fecal isolates of ETEC or pathogenic *Salmonella* spp. and blood culture isolates from calves with bacteremia. Validation of susceptibility testing as being predictive of treatment outcome for calves with diarrhea is currently lacking.

The ability of fecal bacterial culture and antimicrobial susceptibility testing using the Kirby–Bauer technique to guide treatment in calf diarrhea is questionable when applied to fecal *E. coli* isolates that have not been identified as enterotoxigenic. There do not appear to be any data demonstrating that fecal bacterial flora is representative of the bacterial flora of the small intestine, which is the physiologically important site of infection in calf diarrhea. Marked changes in small-intestinal bacterial populations can occur without changes in fecal bacterial populations, and the predominant strain of *E. coli* in the feces of a diarrheic calf can change several times during the diarrhea episode. Furthermore, and most importantly, 45% of calves with diarrhea had different strains of *E. coli* isolated from the upper and lower small intestine, indicating that fecal *E. coli* strains are not always representative of small-intestinal *E. coli* strains. Marked discrepancies in antimicrobial resistance among *E. coli* strains isolated from different segments of the upper and lower intestinal tract of healthy veal calves at slaughter have also been reported in a more recent study.[24]

An additional bias present in most antimicrobial susceptibility studies conducted on fecal *E. coli* isolates is that data are frequently obtained from dead calves, which are likely to be treatment failures. The time since death is also likely to be an important determinant of the value of fecal culture because such a rapid proliferation of bacteria occurs in the alimentary tract after death that the results of examinations made on dead calves received at the laboratory can have little significance. Calves that die of diarrhea are likely to have received multiple antimicrobial treatments, and preferential growth of antimicrobial-resistant *E. coli* strains starts within 3 hours of antimicrobial administration. A further concern with fecal susceptibility testing is that the Kirby–Bauer breakpoints (minimum inhibitory concentration [MIC]) are not based on typical antimicrobial concentrations in the small intestine and blood of calves. Studies documenting the antimicrobial susceptibility of *E. coli* isolates from the small intestine of untreated calves, based on achievable drug concentrations and dosage regimens, are urgently needed. Until these data are available, it appears that antimicrobial efficacy is best evaluated by the clinical response to treatment, rather than the results of in vitro antimicrobial susceptibility testing performed on fecal *E. coli* isolates. Thus, the value of antimicrobial susceptibility testing as a tool to guide the choice of an antibiotic to treat enterotoxigenic colibacillosis must currently be considered as very limited. Nonetheless, antimicrobial susceptibility testing presents an important tool to monitor the development of resistances not only of pathogens, but also of so-called indicator bacteria normally isolated in healthy animals in the field.[25,26] Because antimicrobial resistance can be transferred via plasmids from apathogenic bacteria to pathogens, monitoring trends in resistance patterns in the field is of critical importance.

Surveillance for Antimicrobial Resistance in *Escherichia coli* Isolates

The purpose of monitoring antimicrobial resistance through so-called indicator bacteria is to avoid misjudgment (overestimation) of resistance levels that would be extrapolated from resistance of pathogenic bacteria.[24] As mentioned earlier, pathogens isolated from sick or deceased animals have frequently been exposed to antimicrobial therapy, which is likely to alter resistance patterns. A comparison of antibiotic resistance for *E. coli* populations isolated from groups of diarrheic and control calves in the United Kingdom found a higher incidence of antibiotic-resistant *E. coli* in samples obtained from farms with calf diarrhea than from farms without the disease. Considering all samples, bacterial colonies in 84% were resistant to ampicillin, in 13% to Apramycin, and in 6% to nalidixic acid. Antibiotic resistance among ETEC from piglets and calves with diarrhea in a diagnostic laboratory survey of one geographic area in Canada over a 13-year period found that the least resistance occurred against ceftiofur for all isolates, followed by apramycin and gentamicin for porcine and florfenicol for bovine isolates.

In a UK study over a 5-year period, *E. coli* isolates from calves with diarrhea became more resistant to furazolidone, trimethoprim-potentiated sulfonamide, clavulanic-acid-potentiated amoxicillin, and tetracycline. *E. coli* strains from outbreaks of diarrhea in lambs in Spain became increasingly resistant to nalidixic acid, enoxacin, and enrofloxacin. Some antimicrobial-resistant *E. coli* strains from diarrheic calves in the United States may possess a chromosomal *flo* gene that specifies cross-resistance to both florfenicol and chloramphenicol, and its presence among *E. coli* isolates of diverse genetic backgrounds indicates a distribution much wider than previously thought. In Spain, 5.9% of *E. coli* strains from cattle were resistant to nalidixic acid, and 4.9% were resistant to enrofloxacin and ciprofloxacin. In sheep and goats, only 0.5% and 1.4%, respectively, of the strains were resistant to nalidixic acid, and none was resistant to fluoroquinolones. Most of the quinolone-resistant strains were nonpathogenic strains isolated from cattle. Susceptibility data obtained from 10 European countries for the years 2002 to 2004 revealed that although there was a generally high prevalence of resistance of *E. coli* isolated from diarrheic calves, resistance patterns varied considerably between countries.[25] Generally high resistance of *E. coli* in the range of 50% or higher was reported from most countries for ampicillin, streptomycin, sulfonamides, trimethoprim, combinations of trimethoprim and sulfonamides, and tetracyclines.[25] Although resistance of *E. coli* isolated from diarrheic calves against fluoroquinolones was rare in several countries, resistance rates at or above 20% were reported from Spain, Belgium, and France.[25] In certain regions of Italy the incidence of enrofloxacin-resistant *E coli* strains was reported to have increased from 14.2% in 2002 to over 40% in 2008.[27]

The CTX-M-14-like enzyme has been detected in *E. coli* recovered from the feces of diarrheic dairy calves in Wales. The enzyme is an extended-spectrum beta-lactamase (ESBL), which confers resistance to a wide range of beta-lactam (penicillin and cephalosporin) compounds. Organisms possessing ESBLs are considered to be resistant to second-, third-, and fourth-generation cephalosporins, and in vitro resistance to amoxicillin/clavulanate among producers is variable, reflecting the amount of beta-lactamase produced. In addition to this enzyme, the isolates produced a TEM-35 (IRT-4) beta-lactamase that conferred resistance to the amoxicillin/clavulanate combination. These two enzymes confer resistance to all the beta-lactamase compounds approved for veterinary use in the United

Kingdom. Thus their occurrence in animals may be an important development for both animal and public health. ESBLs in human infections have emerged as a significant and developing problem, occurring in patients in the community and in those with recent hospital contact. Spread of this form of resistance in bacteria affecting the animal population could have serious implications for animal health, rendering many therapeutic options redundant.

Antimicrobial resistance to intestinal bacteria also occurs in dairy calves fed milk from cows treated with antibiotics and has been associated with the prophylactic administration of medicated milk replacer.[28] The resistance increases with higher concentrations of antibiotics in the milk. Susceptibility of fecal and environmental *E. coli*, *Salmonella* spp., and *Campylobacter* spp. to tetracyclines was monitored on farms during use of medicated milk replacer and after discontinuation of this practice. Discontinuing the use of medicated milk replacer resulted in increased susceptibility of these organisms to tetracyclines within 3 months, without causing an increase of disease occurrence.[28]

Antimicrobial Susceptibility of Blood *Escherichia coli* Isolates

The Kirby–Bauer technique for antimicrobial susceptibility testing has more clinical relevance for predicting the clinical response to antimicrobial treatment when applied to blood isolates rather than fecal isolates. This is because the Kirby–Bauer breakpoints (MICs) are based on achievable antimicrobial concentrations in human plasma and MIC_{90} values for human *E. coli* isolates, which provide a reasonable approximation to achievable MIC values in calf plasma and MIC_{90} values for bovine *E. coli* isolates. Unfortunately, susceptibility results are not available for at least 48 hours, and very few studies have documented the antimicrobial susceptibility of blood isolates in calves with diarrhea. In a 1997 study of dairy calves in California, the antimicrobial susceptibility of isolates from the blood of calves with severe diarrhea or illness produced the following results: ceftiofur, 19/25 (76%) sensitive; potentiated sulfonamides, 14/25 (56%) sensitive; gentamicin, 12/25 (48%) sensitive; ampicillin, 11/25 (44%) sensitive; tetracycline, 3/25 (12%) sensitive, although there was a clinically significant year-to-year difference in the results of susceptibility testing that may have reflected different antimicrobial administration protocols on the farm.

Evidence-Based Recommendations for Antimicrobial Treatment of Diarrheic Calves

The four critical measures of success of antimicrobial therapy in calf diarrhea are as follows (in decreasing order of importance): (1) mortality rate, (2) growth rate in survivors, (3) severity of diarrhea in survivors, and (4) duration of diarrhea in survivors.

In his review of the literature on the use of antibiotics for the treatment of calf diarrhea, Constable concluded that the statement that oral or parenteral antimicrobials should not be used is not supported by a critical evidence-based review of the literature.[29] The arguments used to support a nonantimicrobial treatment approach have included the following:

- Orally administered antimicrobials alter intestinal flora and function and thereby induce diarrhea, which has been documented on more than one occasion with chloramphenicol, neomycin, and penicillin.
- Antimicrobials harm the "good" bacteria in the small intestine more than the "bad" bacteria (an undocumented claim in the calf).
- Antimicrobials are not effective (a statement that is clearly not supported by the results of some published peer-reviewed studies).
- Antimicrobial administration promotes the selection of antimicrobial resistance in enteric bacteria.

In calves with diarrhea and moderate to severe systemic illness, the positive predictive value (0.65) of clinical tests (sensitivity = 0.39, specificity = 0.91) and the positive predictive value (0.77) of laboratory tests (sensitivity = 0.40, specificity = 0.95) for detecting bacteremia are too low, assuming reasonable estimates for the prevalence of bacteremia (30%). Accordingly, it is recommended that clinicians routinely assume that 30% of ill calves with diarrhea are bacteremic and that bacteremia constitutes a threat to the life of the calf. Antimicrobial treatment of diarrheic calves should therefore be practiced and focused against *E. coli* in the small intestine and blood because these constitute the two sites of infection. In addition, the antimicrobial must reach therapeutic concentrations at the site of infection for a long enough period (the treatment interval) and, ideally, have only a narrow gram-negative spectrum of activity to minimize collateral damage to other enteric bacteria. Fecal bacterial culture and antimicrobial susceptibility testing is not recommended in calves with diarrhea because fecal bacterial populations do not accurately reflect small-intestinal or blood bacterial populations, and the breakpoints for susceptibility test results have not been validated. Antimicrobial efficacy is therefore best evaluated by the clinical response to treatment.

The efficacy of antimicrobial therapy can vary with the route of administration and when given orally, whether the antimicrobial is dissolved in milk, oral electrolyte solutions, or water. Oral antimicrobials administered as a bolus or contained in a gelatin capsule are deposited into the rumen and therefore have a different serum concentration–time profile than antimicrobials dissolved in milk replacer that are suckled by the calf. Antimicrobials that bypass the rumen are not thought to alter rumen microflora, potentially permitting bacterial recolonization of the small intestine from the rumen. Finally, when oral antimicrobials are administered to calves with diarrhea, the antimicrobial concentration in the lumen of the small intestine is lower and the rate of antimicrobial elimination faster than in healthy calves.

In the United States parenterally administered oxytetracycline and sulfachloropyridiazine and orally administered amoxicillin, chlortetracycline, neomycin, oxytetracycline, streptomycin, sulfachloropyridazine, and sulfamethazine are currently labeled for the treatment of calf diarrhea. Unfortunately, there is little published data supporting their efficacy in treating calves with diarrhea. Extralabel antimicrobial use (excluding prohibited antimicrobials) is therefore justified in treating calf diarrhea because of the apparent lack of published studies documenting clinical efficacy of antimicrobials with a label claim and because the health of the animal is threatened; suffering or death may result from failure to treat systemically ill calves.

Administration of Oral Antimicrobials to Treat *Escherichia coli* Overgrowth of the Small Intestine

Based on published evidence for the oral administration of these antimicrobial agents, only amoxicillin can be recommended for the treatment of diarrhea; dosage recommendations are amoxicillin trihydrate (10 mg/kg every 12 h) or amoxicillin trihydrate–clavulanate potassium (10 mg/kg amoxicillin trihydrate and 2.5 mg/kg clavulanate potassium every 12 h) for at least 3 days; the latter constitutes extralabel drug use. Concurrent feeding of milk and amoxicillin does not change the bioavailability of amoxicillin, although amoxicillin is absorbed faster when dissolved in an oral electrolyte solution than in milk replacer, and absorption is slowed during endotoxemia, presumably because of a decrease in abomasal emptying rate. Amoxicillin trihydrate is preferred to ampicillin trihydrate for oral administration in calves because it is labeled for the treatment of calf diarrhea in the United States and is absorbed to a much greater extent. However, a field study comparing oral amoxicillin (400 mg every 12 h) and ampicillin (400 mg every 12 h) treatments for diarrhea reported similar proportions of calves with a good to excellent clinical response (79%, 49/62 for amoxicillin bolus; 80%, 59/74 for amoxicillin powder; 65%, 47/65 for ampicillin bolus; $p > 0.30$ for all comparisons). The addition of clavulanate potassium to amoxicillin trihydrate is recommended because clavulanate potassium, although not having a direct antimicrobial

effect, is a potent irreversible inhibitor of beta-lactamase, increasing the antimicrobial spectrum of activity.

Oral administration of potentiated sulfonamides is not recommended for treating calf diarrhea because of the lack of efficacy studies. Gentamicin (50 mg/calf orally every 12 h) markedly decreased *E. coli* bacterial concentrations in the feces of healthy calves, and treatment with gentamicin has been shown to improve stool consistency in calves with experimentally induced *E. coli* diarrhea. However, oral administration of gentamicin is not recommended because antimicrobials administered to calves with diarrhea should have both local and systemic effects, and orally administered gentamicin is poorly absorbed.

Colistin administered orally is frequently used in calves in piglets to treat enterotoxic colibacillosis. Oral colistin will decrease the number of *E. coli* bacteria in the intestinal lumen and thereby the amount of enterotoxin affecting the intestinal mucosa and can present an effective treatment of uncomplicated cases of enteric colibacillosis. Because colistin is poorly absorbed from the alimentary tract, this treatment is not indicated in cases of suspected septicemia.

Oxytetracycline and chlortetracycline are not recommended for the oral treatment of bacteremia, although tetracyclines may have some efficacy for treating *E. coli* bacterial overgrowth of the small intestine. Tetracyclines are bound to calcium, and oral bioavailability when administered with milk is 46% for oxytetracycline and 24% for chlortetracycline.

Florfenicol achieves high concentrations in the lumen of the small intestine and is 89% absorbed when orally administered to milk-fed calves; however, florfenicol does not provide the most appropriate antimicrobial for treating calf diarrhea, because the MIC_{90} for *E. coli* is very high at 25 µg/mL and florfenicol (11 mg/kg orally) was shown to fail to reach the MIC_{90} value in plasma.

Fluoroquinolones clearly have proven efficacy in treating calf diarrhea, and a label indication exists in Europe for oral and parenteral enrofloxacin and oral marbofloxacin for the treatment of calf diarrhea. Oral fluoroquinolones have a high oral bioavailability. However, it must be emphasized that extralabel use of the fluoroquinolone class of antimicrobials in food-producing animals in the United States is illegal and obviously not recommended. Also, in other countries it may be illegal to use some of the antimicrobials mentioned here because of the regulations regarding their use in food-producing animals.

The indiscriminate use of antibiotics in milk replacers for the treatment of newborn calves and piglets is widespread and must be viewed with concern when the problem of drug-resistance transfer from animal to animal and to humans is considered.

In calves with diarrhea and no systemic illness (normal appetite for milk or milk replacer, no fever), it is recommended that the clinician should monitor the health of the calf and should not administer oral antimicrobials.

Administration of Parenteral Antimicrobials to Treat *Escherichia coli* Bacteremia

A common and widely recommended treatment is ceftiofur (2.2 mg/kg intramuscularly/subcutaneously every 12 h) for at least 3 days. Ceftiofur is a broad-spectrum third-generation cephalosporin and beta-lactam antimicrobial that is resistant to the action of beta-lactamase; the MIC_{90} for *E. coli* is less than 0.25 µg/mL, the recommended dosage schedule maintains free plasma antimicrobial concentrations at the desired value of four times the MIC_{90} value for the duration of treatment in 7-day-old calves, and 30% of the active metabolite of ceftiofur (desfuroylceftiofur) is excreted into the intestinal tract of cattle, providing antimicrobial activity in both the blood and the small intestine. Parenteral (2 mg/kg, intramuscularly once) administration of ceftiofur hydrochloride decreased mortality rate and the severity of diarrhea in pigs with experimentally induced enteric colibacillosis, although these pigs were not suspected to be bacteremic. The beneficial effects of parenteral ceftiofur in these pigs was attributed to decreasing intestinal luminal concentration of pathogenic *E. coli.* Administration of ceftiofur to treat bacteremia and diarrhea in calves constitutes extralabel drug use.

In those countries where the use of fluoroquinolones in food-producing animals is permitted for this indication, parenteral administration to calves with diarrhea has been recommended because of their broad-spectrum bactericidal activity, particularly against gram-negative bacteria. It must be emphasized that extralabel use of the fluoroquinolone class of antimicrobials in food-producing animals in the United States and other countries is illegal and obviously not recommended.

Cephalosporins and fluoroquinolones are among the most commonly used antimicrobials to treat colibacillosis in farm animals because of their proven efficacy and because they have largely maintained their activity against *E. coli.* Recent trends of decreasing susceptibility of *E. coli* and other pathogens mainly to fluoroquinolones and to a lesser degree to third- and fourth-generation cephalosporins have, however, been reported and present a serious public health issue (see following discussion under "Use of Antimicrobials That Are of Critical Importance for Human and Veterinary Medicine").[25-27]

Another recommended treatment is parenteral amoxicillin trihydrate or ampicillin trihydrate (10 mg/kg intramuscularly every 12 h) for at least 3 days. Although parenteral ampicillin has proven efficacy in treating naturally acquired diarrhea, whereas ceftiofur has unproven efficacy, the broad-spectrum beta-lactam antimicrobials amoxicillin and ampicillin are theoretically inferior to ceftiofur because parenterally administered ampicillin and amoxicillin reach lower plasma concentrations and require a higher MIC than ceftiofur, and they are not beta-lactamase-resistant. The intramuscular administration of amoxicillin and ampicillin is preferable over subcutaneous administration because the rate and extent of absorption are superior after intramuscular injection.

Parenteral treatment with potentiated sulfonamides (20 mg/kg sulfadiazine with 5 mg/kg trimethoprim, intravenously or intramuscularly depending on the formulation characteristics, every 24 h for 5 d) is also widely used. The efficacy of potentiated sulfonamides has only been proved when treatment commenced before clinical signs of diarrhea were present. It is therefore unknown whether potentiated sulfonamides are efficacious when administered to calves with diarrhea and depression, although it is likely that potentiated sulfonamides are efficacious in the treatment of salmonellosis.

Parenteral administration of gentamicin and other aminoglycosides (amikacin, kanamycin) cannot currently be recommended as part of the treatment for calf diarrhea because of the lack of published efficacy studies, prolonged slaughter withdrawal times (15 to 18 months), potential for nephrotoxicity in dehydrated animals, and availability of amoxicillin, ampicillin, and ceftiofur.

Chloramphenicol had proven efficacy in treating calf diarrhea resulting from *Salmonella enterica* serotypes Bredeney and Dublin, but it is now illegal for use in food-producing animals in the United States and in many other countries. The related antimicrobial florfenicol (20 mg/kg intramuscularly) failed to reach the MIC_{90} value in plasma and only exceeded the MIC_{90} value for less than 60 minutes when administered intravenously (11 to 20 mg/kg IV).

In calves with diarrhea and no systemic illness (normal appetite for milk or milk replacer, no fever), the clinician should monitor the health of the calf and refrain from administering oral or parenteral antimicrobials.

Use of Antimicrobials That Are of Critical Importance for Human and Veterinary Medicine

Antimicrobials commonly used for the treatment of colibacillosis in food-producing animals include third- and fourth-generation cephalosporins and fluoroquinolones, some of which have a label for the treatment of septicemia caused by *E.coli* in calves in some European and other countries and some of which can be used in an extralabel

manner in certain countries.[30] These classes of antimicrobials are considered to be **critically important for human and animal health,** and thus recent reports of increasing prevalence of resistance of *E. coli*, *Salmonella* spp., and *Enterobacter* spp. against these classes of antimicrobials are very concerning.[25-27] Although there appears to be general consensus that these antimicrobials should be used restrictively in veterinary medicine, there is currently no harmonized approach on prudent use of cephalosporins and fluoroquinolones in animals. Guidance on prudent use of antimicrobials for animals have been published in many countries, but most are on a general level, and cephalosporins and fluoroquinolones are not always specially addressed.[30]

The World Organization for Animal Health (OIE) issued the following recommendations for these classes of antimicrobials:[31]

- They are not to be used as preventive treatment applied by feed or water in the absence of clinical signs.
- They are not to be used as first-line treatment unless justified. When used in a second-line treatment, such use should ideally be based on the results of bacteriologic tests.
- Extralabel/off-label use should be limited and reserved for instances in which no alternatives are available. Such use should be in agreement with the national legislature in force.

Immunoglobulin Therapy

One of the important factors determining whether or not an animal will survive enteric colibacillosis is the serum immunoglobulin status of the animal before it develops the disease. The prognosis is unfavorable if the level of immunoglobulin is low at the onset of diarrhea, regardless of intensive fluid and antimicrobial therapy. Most of the literature on therapy omits this information and is therefore difficult to assess. There is ample evidence that the mortality rate will be high in diarrheic calves that are deficient in serum immunoglobulin, particularly IgG, in spite of exhaustive antimicrobial and fluid therapy. This has stimulated interest in the possible use of purified solutions of bovine gammaglobulin in diarrheic calves that are hypogammaglobulinemic. However, they must be given by the intravenous route and in large amounts, the cost of which would be prohibitive. In addition, they are unlikely to be of value once the calf is affected with diarrhea; they are protective and probably not curative. Whole blood transfusion to severely affected calves may be used as a source of gammaglobulin, but unless given in large quantities will not significantly elevate serum immunoglobulin concentrations in deficient calves. Limited controlled trials indicate that there is no significant difference in the survival rate of diarrheic calves treated with either a blood transfusion daily for 3 days; fluid therapy given orally, subcutaneously, or intravenously, depending on the severity of the dehydration; or fluid therapy with antibiotics. Those calves that survived, regardless of the type of therapy, had high immunoglobulin concentrations before they developed diarrhea. This emphasizes the importance of the calf ingesting liberal quantities of colostrum within the first few hours after birth.

Analgesic and Antiinflammatory Therapy

Pain in sick farm animals has become an important issue for veterinarians and producers and is perceived as important animal welfare issue by the public. Adequate pain management should be part of any state-of-the-art treatment approach.

Diarrhea can be accompanied by abdominal pain as a result of intestinal inflammation and cramping. In addition to controlling pain, the main objectives of antiinflammatory therapy in animals with colibacillosis are to control the inflammatory process in the intestinal tract and to ameliorate the effects of endotoxemia and septicemia.[32] Several field studies reported that diarrheic calves receiving nonsteroidal antiinflammatory drugs (NSAIDs) in conjunction with fluid therapy showed less signs of pain, made a faster recovery, and had better weight gains in the reconvalescent period.[33] Although the underlying mechanisms do not appear to have been studied in detail, the proven beneficial effects of several NSAIDs have been attributed to their analgesic, antiinflammatory, antipyretic, and antisecretory properties.

Two broad categories of antiinflammatory agents that are available are the corticosteroids and the NSAIDs. Little evidence documenting the efficacy of corticosteroids for the treatment of calf diarrhea is available, but the use of this class of antiinflammatory drugs has been discouraged on the theoretical grounds that diarrheic calves already tend to have higher concentrations of plasma cortisol of endogenous origin and because of the immunosuppressive effect of these compounds.[32]

The efficacy of different NSAIDs such as meloxicam, ketoprofen, or flunixin meglumine in diarrheic calves that were systemically ill has been investigated in several studies.[32] A single treatment with meloxicam (0.5 mg/kg intravenously [IV]) and treatment with ketoprofen (6 mg/kg IV) twice, 4 hours apart, were both found to improve general attitude, the fecal score, and the feed intake of systemically affected calves with diarrhea.[32] Flunixin meglumine (2.2 mg/kg IV) hastened clinical recovery, but only for animals that had visible amounts of blood in feces.[34]

Because treatment with NSAIDs in diarrheic animals bears the risk of causing renal damage by further decreasing renal perfusion in already dehydrated animals, adequate oral and/or parenteral fluid therapy must be assured. An empirical guideline posits that treatment with NSAIDs should be limited to a single treatment whenever possible but should not exceed three treatments, a recommendation that has been justified by the risk of abomasal ulceration that is associated with prolonged use of these antiinflammatory agents.[32]

Antimotility Drugs

Administration of substances reducing intestinal motility to treat diarrhea in farm animals is advocated by some veterinarians. Compounds such as hyoscine-N-butylbromide and atropine have a proven inhibitory effect on intestinal motility, which undisputedly results in a rapid decrease of the fecal output in diarrheic patients. Although reducing fecal production may be interpreted as positive treatment outcome, it can also be seen as sequestration of gut fluid in the intestinal tract. Delaying the excretion of intestinal contents in patients suffering from malabsorptive diarrhea bears the risk of enhanced fermentation of unabsorbed carbohydrates and other nutrients. This could not only exacerbate enteral dysbiosis, but also the accumulation of D-lactic acid, which was found to markedly contribute to the clinical symptoms observed in diarrheic calves.[12] There does not appear to be any hard evidence in favor or against the use of antimotility drugs in diarrheic animals. Their use is nonetheless discouraged based on the possible negative effects that certainly outweigh the subjective perception of clinical improvement that is based on the apparent reduction of feces production.[32,35]

Intestinal Protectants

Intestinal protectants such as kaolin and pectin are in general use for diarrheic animals; however, as with antimotility drugs, their value is uncertain. When they are used, the feces become bulky, but intestinal protectants do not have any known effect on the pathogenesis of the disease.

Alteration of the Diet

Whether or not diarrheic newborn animals should be deprived of milk during the period of diarrhea is under controversial debate. Diarrheic piglets are usually treated with an antimicrobial orally and left to nurse on the sow. Diarrheic beef calves are commonly treated with oral fluids and electrolytes and left with the cow. However, in dairy calves it is a common practice to reduce the milk intake of diarrheic animals for up to 24 hours or until there is clinical evidence of improvement. The withholding of milk from diarrheic calves has been advocated based on the consideration that lactose digestion is impaired and that "resting" the intestine for a few days will consequently minimize

additional osmotic diarrhea caused by fermentation of undigested lactose in the large intestine. In contrast, the argument in favor of continuous feeding of milk is that the intestinal tract requires a constant source of nutrition, which it receives from the ingesta in the lumen of the intestine. To date, there is no scientific evidence available confirming that transiently starving diarrheic animals has any beneficial effects on the clinical outcome. Studies exploring the effect of continuous milk feeding in diarrheic calves failed to confirm any deleterious effect, such as prolonged morbidity time, higher mortality rate, or higher treatment frequency. To the contrary, calves kept on milk had higher weight gains during the period of reconvalescence.[32,36] Although diarrheic animals clearly should be supplemented with oral electrolyte solutions to assist the compensation of excessive fluid and electrolyte loss, the currently available evidence is clearly in favor of maintaining the animal on milk or milk replacer. Calves should be offered reduced quantities of whole milk per feeding with higher feeding frequency. Milk should not be diluted with water because this may interfere with the clotting mechanism in the abomasum. In contrast to oral electrolyte solutions, milk should not be force-fed with an esophageal tube feeder because this will prevent closure of the reticular groove and thus foster accumulation of milk in the rumen, where it would be subject to bacterial fermentation.

Probiotics

The use of so-called probiotics for treatment and prevention of diarrhea has become increasingly popular over the past decades. Probiotics are defined as live microorganisms that, when administered in adequate amounts, confer a beneficial effect on the health of the host.[37] Most probiotics intended for veterinary use belong to the broad class of lactic acid bacteria, which include *Lactobacillus*, *Bifidobacterium*, *Enterococcus*, and *Streptococcus* spp. Probiotics have been claimed to promote gastrointestinal health and immunity, to reduce the shedding of potential pathogens in feces, and to reduce the need for therapeutic intervention.[38] Most importantly, probiotics are widely considered not to be present any health risk for the patient. Unfortunately, to date there are no published clinical data obtained in animals supporting any of these claims. Of particular concern is that the use of probiotics in humans has been associated with *Lactobacillus* bacteremia in several immunocompromised patients, and deleterious effects with some commercial products have been observed in neonatal foals.[39] In veterinary medicine concerns have been voiced about the uncritical use of probiotics, particularly in neonates with systemic disease or with a compromised intestinal mucosa.[40,41] With the current knowledge, the use of probiotics cannot be recommended for treatment or prevention of neonatal diarrhea.

Clinical Management of Outbreaks

Veterinarians should consider the following principles when outbreaks of colibacillosis in neonatal farm animals are encountered:

- Visit the farm and conduct an epidemiologic investigation to identify risk factors.
- Examine each risk factor and how it can be minimized.
- Examine affected animals.
- Identify and isolate all affected animals if possible.
- Treat all affected animals as necessary.
- Take laboratory samples from affected and normal animals.
- Make recommendations for the control of diarrhea in animals to be born in the near future.
- Prepare and submit a report to the owner describing the clinical and laboratory results and how the disease can be prevented in the future.

TREATMENT

Calf enterotoxic colibacillosis

Fluid therapy (highest priority)

Parenteral fluid therapy to correct acid–base and water and electrolyte imbalances* (R-1)

Oral rehydration solution* (R-1)

Antimicrobial therapy

Amoxicillin (10 mg/kg IM/PO every 12h for at least 3 days) (R-2)

Amoxicillin-clavulanate (12 mg combined/kg PO/IM every 12h for at least 3 days) (R-2)

Ampicillin (10 mg/kg PO/IM every 12h for at least 3 days) (R-2)

Colistin (100,000 IU/kg PO every 24h for at least 3 days) (R-2)

Enrofloxacin (2.5 to 5 mg/kg IV/IM/SC/PO every 24h for at least 3 days) (R-2)

Neomycin (10 mg/kg PO q12h) (R-2)

Trimethoprim-sulfonamide (25 mg combined/kg IV/IM/PO every 12h for at least 3 days (R-2)

Antiphlogistic therapy

Flunixin meglumine (2.2 mg/kg IV once) (R-2)

Ketoprofen (6 mg/kg IM once) (R-2)

Meloxicam (0.5 mg/kg IV/SC once) (R-2)

Antimotility drugs (R-3)

Probiotics (R-3)

Calf septicemic colibacillosis

Antimicrobial therapy

Amoxicillin-clavulanate (25 mg/kg IV/IM every 6–8h) (R-2)

Ampicillin-sodium (10 mg/kg IV/IM every 8h) (R-2)

Cefquinome (2 mg/kg IM every 24h) (R-2)

Ceftiofur (2.2 mg/kg IM/SC every 12 h) (R-2)

Enrofloxacin (5 mg/kg IV/IM every 24 h) (R-2)

Florfenicol (20 mg/kg IM every 24h) (R-2)

Trimethoprim-sulfonamide (25 mg combined/kg IV every 8–12h) (R-2)

Piglet enterotoxic colibacillosis

Fluid therapy (highest priority)

Oral rehydration solution* (R-1)

Amoxicillin (10 mg/kg PO/IM every 12h for at least 3 days) (R-2)

Amoxicillin-clavulanate (12 mg combined/kg PO/IM every 12h for at least 3 days) (R-2)

Ampicillin (10 mg/kg PO/IM every 12h for at least 3 days) (R-2)

Ceftiofur (1.1 to 2.2 mg/kg IM every 24h for at least 3 days) (R-2)

Chlortetracycline (20 mg/kg PO every 24h for at least 3 days) (R-2)

Enrofloxacin (2.5 to 5 mg/kg IV/IM/SC/PO every 24h for at least 3 days) (R-2)

Colistin (100,000 IU/kg PO every 24h for at least 3 days) (R-2)

Oxytetracycline (10 mg/kg IM every 24h for at least 3 days) (R-2)

Neomycin (10 mg/kg PO every 12h for at least 3 days) (R-2)

Trimethoprim-sulfonamide (25 mg combined/kg IV/IM/PO every 12h for at least 3 days (R-2)

**See "Principles of Fluid and Electrolyte Therapy."*

CONTROL

Because of the complex nature of the disease, it is unrealistic to expect total prevention, and control at an economical level should be the major goal. Effective control of colibacillosis can be accomplished by the application of three principles:

- Reduce the degree of exposure of the newborn to the infectious agents.
- Provide maximum nonspecific resistance with adequate colostrum and optimum animal management.
- Increase the specific resistance of the newborn by vaccination of the dam or the newborn.

Reduction of the Degree of Exposure of the Newborn to the Infectious Agents

The emphasis is on ensuring that newborns are born into a clean environment. Barns, confinement pens, and paddocks used as parturition areas must be clean and should preferably have been left vacant for several days before the pregnant dams are placed in them.

Dairy Calves

The following comments are directed particularly at calves born indoors, where contamination is higher than outdoors:

- Greatest attention must be paid to maternity pen hygiene. Calves should be born in well-bedded clean and dry box stalls.
- Obstetric intervention and assistance to calving should be provided by adequately trained personnel in a calm and hygienic manner.

- Immediately after birth the umbilicus of the calf should be swabbed or dipped 2% iodine tincture or chlorhexidine solution.
- In herds with high disease incidence the residence time of calves in the maternity pen should be kept as short as possible and calves moved to clean, dry, and well-bedded individual calf pens or hutches as soon as possible after birth.
- Calves affected with diarrhea should be removed from the main calf barn if possible and treated in isolation.

Beef Calves

Beef calves are usually born on pasture or on confined calving grounds, and the following guidelines apply:

- Calving grounds should have been free of animals previous to the calving period; the grounds should be well drained, dry, and scraped free of snow if possible. Each cow–calf pair should be provided with at least 2000 sq ft of space. Calving on pasture with adequate protection from wind is ideal. Covering the calving grounds with straw or wood shavings provides a comfortable calving environment.
- In large beef herds, in a few days following birth when the calf is nursing successfully, the cow–calf pair should be moved to a nursery pasture to avoid overcrowding in the calving grounds.

In beef herds, breeding plans should ensure that heifers calve at least 2 weeks before the mature cows. Limiting the breeding and therefore the calving season to 45 days or less for heifers also offers several advantages. A short calving season allows the producer to more effectively and economically concentrate personnel resources on calving management compared with a longer calving season. Calving heifers earlier allows them additional time required before the next breeding season to be on an increasing plane of nutrition necessary to maintain a high conception rate. The earlier calving of heifers also provides less exposure of their calves to infection pressure from the mature animals in the herd.

The incidence and severity of neonatal disease will typically increase, and the age at disease onset will decrease, as the calving season progresses. This phenomenon is common in beef herds because of the effect of the calf as a biological amplifier. The more the calving season is shortened, the more the biological amplification effect is negated.

For beef herds, it is necessary to have a plan for cattle movement throughout the calving season. This requires a minimum of four or five separate pastures: a gestation pasture, a calving pasture, and a series of nursery pastures. To ensure that beef calves are born in a sanitary environment, the herd should be moved from the gestation pasture to the calving pasture 1 to 2 weeks before calving. One day after birth, the cow or heifer and her calf should be moved to a nursery pasture. Cow–calf pairs should be added to a single nursery pasture until the appropriate number of pairs has been reached. Thereafter, cow–calf pairs can be added to a second nursery pasture. The difference in age between the oldest and youngest calf in a nursery pasture should never exceed 30 days, and smaller differences are preferable. This negates the biological amplification effect. The longer the calving season, the greater the need for a large number of nursery pastures. Calves that develop diarrhea should be removed immediately to an area away from healthy calves, treated, and not returned until all calves in the group are at low risk for developing diarrhea (>30 days of age).

The nutrition of the pregnant cows, and particularly the first-calf heifers, must be monitored throughout gestation to ensure an adequate body condition and sufficient resources to provide an adequate supply of good-quality colostrum.

Veal Calves

Veal calves are usually obtained from several different sources, and 25% to 30% or higher may be deficient in serum immunoglobulin. The following guidelines apply to veal calves:

- On arrival, calves should be placed in their individual calf pens, which were previously cleaned, disinfected, and left vacant to dry.
- Feeding utensils are a frequent source of pathogenic *E. coli* and should be cleaned and air-dried daily.
- Calves affected with diarrhea should be removed and isolated immediately.

Lambs and Kids

The principles described earlier for calves apply to lambs and kids. Lambing sheds can be a source of heavy contamination and must be managed accordingly to reduce infection pressure on newborn lambs.

Piglets

Piglets born in a total-confinement system may be exposed to a high infection rate. The following guidelines apply to piglets:

- The all-in/all-out system of batch farrowing, in which groups of sows farrow within a week, is recommended. This system will allow the herdsman to wean the piglets from a group of sows in a day or two and clean, disinfect, and leave vacant a battery of farrowing crates for the next group of sows. This system will reduce the total occupation time and the infection rate. The continuous farrowing system without regular breaks is not recommended.
- Before being placed in the farrowing crate, sows should be washed with a suitable disinfectant to reduce the bacterial population of the skin.

Provision of Maximum Nonspecific Resistance With Adequate Colostrum and Optimum Animal Management

The first step of fostering maximum nonspecific resistance is the provision of optimal nutrition to the pregnant dam, which will result in a vigorous newborn animal and adequate quantities of colostrum. At the time of parturition, surveillance of the dams and the provision of any obstetric assistance required will ensure that newborns are born with as much vigor as possible. Parturition injuries and intrapartum hypoxemia must be minimized as much as possible.

Colostrum Management

The next most important control measure is to ensure that liberal quantities of good-quality colostrum are available and ingested within minutes and no later than a few hours after birth. Although the optimum amount of colostrum that should be ingested by a certain time after birth is well known, the major difficulty with all species under practical conditions is to know how much colostrum a particular neonate has ingested. Because modern livestock production has become so intensive, it is imperative that the animal attendants make every effort to ensure that sufficient colostrum is ingested by that particular species. In a recent national survey in the United States, the estimated prevalence of failure of passive immunity transfer in female dairy calves was 19.2%.[41]

Failure of transfer of passive immunity (FTPI), as determined by calf serum immunoglobulin IgG_1 concentration below 1000 mg/dL at 48 hours of age, occurred in 61.4% of calves from a dairy in which calves were nursed by their dams, 19.3% of calves from a dairy using nipple bottle feeding, and 10.8% of calves from a dairy using tube feeding. A higher prevalence of FTPI in dairy calves can occur because an insufficient volume of colostrum is ingested by the calf. When artificial feeding is used, inadequate immunoglobulin concentration in the colostrum fed is the most important factor resulting in FTPI. The prevalence of FTPI in dairy herds can be minimized by artificially feeding all newborn calves large volumes (3 to 4 L) of fresh or refrigerated first-milking colostrum from cows that had nonlactating intervals of normal duration. This volume is considerably greater than the intake that Holstein calves usually achieve by sucking and also exceeds the voluntary intake of most calves fed colostrum by nipple bottle.

Calves need to ingest at least 100 g of IgG_1 in the first colostrum feeding to ensure adequate transfer of passive immunity. Thus the routine force-feeding of a sufficient amount of pooled colostrum immediately after birth results in high serum levels of colostrum immunoglobulin in dairy calves and is becoming a common practice in dairy herds.

Encouraging and assisting the calf to suck within 1 hour after birth is also effective. The

provision of early assisted sucking of colostrum to satiation within 1 hour after birth will result in high concentrations of absorbed immunoglobulin in the majority of calves. The ingestion of 100 g or more of colostral immunoglobulin within a few hours after birth is more effective in achieving high levels of colostral immunoglobulin in calves than either leaving the calf with the cow for the next 12 to 24 hours or encouraging the calf to suck again at 12 hours, which will not result in a significant increase in absorbed immunoglobulin.

Despite early assisted sucking, a small proportion of calves will remain hypogammaglobulinemic because of low concentrations of immunoglobulin in their dams' colostrum, usually associated with leakage of colostrum from the udder before calving.

In large herds where economics permit, a laboratory surveillance system may be used on batches of calves to determine the serum levels of immunoglobulin acquired. An accurate analysis may be done by electrophoresis or an estimation using the zinc sulfate turbidity test. Blood should be collected from calves at 24 hours of age. Samples taken a few days later may not be a true reflection of the original serum immunoglobulin concentrations. The information obtained from determination of serum immunoglobulin in calves at 24 hours of age can be used to improve management practices, particularly the early ingestion of colostrum.

Quality of Colostrum

Specific Gravity
