VERMINOUS MESENTERIC ARTERITIS (VERMINOUS ANEURYSM AND THROMBOEMBOLIC COLIC)

ETIOLOGY

The etiology is unknown, although it is presumed to result from thromboemboli originating at sites of verminous arteritis in the cranial mesenteric artery.

EPIDEMIOLOGY

The disease is assumed to be more prevalent among horses on poor parasite control programs; however, except in extreme cases that die and have a necropsy examination or exploratory laparotomy, the diagnosis is not confirmed. Therefore accurate measures of its incidence are not available. Cases can occur in foals as young as 3 to 6 months. The incidence of the disease has decreased remarkably with the advent of effective broad-spectrum anthelmintics and almost complete prevention of *Strongylus* spp. infection in horses in developed countries. Postmortem examination of 46 horses in Sardinia that were recorded as having been treated with broad-spectrum anthelmintics identified gross lesions of the cranial mesenteric artery in all horses and *S. vulgaris* larvae in 39% of the horses.[1]

PATHOGENESIS

Migration of the larvae of *Strongylus vulgaris* into the wall of the **cranial mesenteric artery** and its branches occurs in horses. The presence of larvae causes chronic-active inflammatory lesions and thickening of the tunica intima and adventitial tunic of the ileocecal and colic arteries.[1] These lesions can cause thromboemboli that restrict blood supply to the intestines, with subsequent ischemia and dysfunction. The recurrent colic of verminous arteritis is possibly caused by impairment of the vascular and nerve supply to the intestine. The disease is basically an infarction of bowel wall without displacement of the bowel. The small intestine, colon, and cecum can be affected. The disease has also been associated with larval cyathostomiosis.

CLINICAL FINDINGS

Signs vary depending on the severity of the disease. It is assumed that **mild, intermittent colics** that respond to analgesics in the short term and anthelmintics in the long term are caused by verminous arteritis. Affected horses are often depressed and spend long periods recumbent. Weight loss and inappetence are features of the disease in some horses. The disease can have a course of weeks to months.

Acute, severe cases of the disease are caused by infarction of parts or all of the small intestine, cecum, or colon. Affected horses have an acute onset of severe abdominal pain, tachycardia (>100 beats/min), and sweating. Auscultation reveals decreased borborygmi. There is mild distension of small intestine or large colon, depending on the segment of bowel affected, on rectal examination. There are rarely signs of intestinal obstruction. Palpation of the cranial mesenteric artery can reveal thickening and pain but is not a useful diagnostic sign for the acute disease. **Death** is caused by peritonitis secondary to devitalization of the intestine,[2] usually within 24 hours of the onset of signs.

CLINICAL PATHOLOGY

There are no diagnostic changes in the hemogram or serum biochemical profile. Horses with mesenteric artery lesions have higher mean corpuscular volume, mean corpuscular hemoglobin, concentrations of -α-2 globulins, -β-globulins, and -γ-globulins than in healthy horses.[1] Peritoneal fluid in mild cases can have mild elevations in protein concentration and white blood cell count. In severe cases, peritoneal fluid protein concentration is increased (>25 g/L, 2.5 g/dL) as is white blood cell count (9000–100,000 cells/μL, 9–100 × 10^3 cells/L).

NECROPSY FINDINGS

Infarction of the colon and cecum is most common and evident as either gangrene of large sections of the organ or multifocal mottled lesions that are red and edematous. Histologic examination rarely reveals the presence of thrombi. There is often verminous arteritis of the cranial mesenteric artery, evident as thickening of the intima and narrowing of the lumen.[1,3]

DIFFERENTIAL DIAGNOSIS

See Table 7-19.

TREATMENT

Mild, recurrent cases are treated with analgesics such as flunixin meglumine (see Table 7-15), laxatives such as mineral oil (see Table 7-16), and anthelmintics (ivermectin 200 μg/kg orally once; or fenbendazole 50 mg/kg orally every 24 hours for 3 days).

Severe cases are treated with analgesics (see Table 7-15), intravenous administration of fluids (see Chapter 5), and supportive care. Usually the severity of the colic prompts surgical exploration of the abdomen with resection of small lesions. Most severe cases do not survive.

RETROPERITONEAL ABSCESS (INTERNAL ABDOMINAL ABSCESS, CHRONIC PERITONITIS, AND OMENTAL BURSITIS)

A recognized form of recurrent or intermittent colic is associated with an abscess in the abdominal cavity. The abscesses are usually **retroperitoneal**, sometimes involving the omental bursa, and chronic leakage from them into the peritoneal cavity causes chronic or recurrent peritonitis. Complete recovery is difficult to effect, and there is a high failure rate in treatment. These abscesses result from any of the following:

- Infection of a **verminous aneurysm,** especially in young horses
- **Metastatic *S. equi* infection** (metastatic strangles)
- **Minor perforations of intestinal wall** allowing minimal leakage of intestinal contents so that omental containment of the leak occurs
- Erosion through a **gastric granuloma** associated with *Habronema* sp. or a squamous cell carcinoma of stomach wall
- In **mares,** development of an abscess in the pelvic fascia results after **tearing of the rectal wall during pregnancy diagnosis.**
  - Abscesses caused by *R. equi* in foals

Clinical findings suggestive of the disease include persistent or intermittent chronic colic and weight loss. A **fever** is common and **varying degrees of anorexia** are typical. In cases with a concurrent chronic peritonitis or an omental bursitis, the amount of inflammatory exudate may be large enough to cause abdominal distension. When the abscess is perirectal and in the pelvic fascia there may be straining and constipation caused by voluntary retention of feces.

On **rectal examination** it can be possible to feel an abscess or adhesions to one. They are often multiple and quite large and adherent to one another, so that tight bands of mesentery can be felt that will lead the hand to the site of the abscess. Pain is usually elicited by rectal palpation of the infected sites and by firm palpation of the external abdominal wall. Ultrasonography through the abdominal wall has been used to locate large retroperitoneal abscesses in a foal.

The **hemogram**, especially in acute cases, is characterized by a neutrophilia, which may be as high as 30,000/μL with a left shift. **Chronic anemia** caused by bone marrow depression may occur as well as increased **plasma fibrinogen** and **hypoalbuminemia**. Abdominocentesis may yield turbid fluid with a protein content greater than 2.5 g/dL and an increase in leukocytes. If culture is possible the causative bacteria are usually *S. equi, S. zooepidemicus, Corynebacterium*

equi, C. pseudotuberculosis, or mixed infections if there has been intestinal leakage. It is common, even when there is an active infection in a retroperitoneal abscess, to fail to grow bacteria from a peritoneal effusion.

Intraabdominal abscesses must be differentiated from **abdominal neoplasms** in the horse. Anorexia, weight loss, fever, colic, and depression are common to both syndromes. The laboratory findings in both groups are similar, but cytologic examination of the peritoneal fluid may yield an accurate diagnosis in the case of neoplasms.

Compromised or perforated stomach wall can result in adhesions to the spleen and development of splenic abscesses in horses.[1] In these animals a sharp pain response can be elicited on firm palpation of the abdomen in the left flank just behind the last rib. Abscesses in liver are not so easily located. Abscesses in pelvic fascia are usually not very discrete but are instantly noticeable on inserting the hand into the rectum.

TREATMENT

Treatment with broad-spectrum antimicrobials is indicated and the initial response is good but often transitory if the usual course of treatment is only 3 to 5 days' duration. The prognosis is usually tentative because of the difficulty of completely eliminating the infection. Treatment must be continued for at least 2 weeks and in some cases for a period of 2 to even 4 to 5 months. Surgical treatment might be possible, but is usually ineffectual because of the deformity of the area by adhesions, and the usual outcome of tearing the intestine and spillage into the peritoneal cavity while attempting to exteriorize the lesion.

RECTAL TEARS

Iatrogenic tears of the equine rectum are a serious problem in equine practice. They are a leading cause of malpractice suits for the veterinarian, comprising approximately 7% of insurance claims against veterinarians in equine practice in the United States and can be a large economic loss for the owner. The occurrence of rectal tears is often an emotionally charged event because they are unexpected and they usually occur in otherwise healthy horses being subjected to routine rectal examination. Prompt diagnosis and vigorous treatment, along with frank disclosure of the event to the horse's owner or handler, is essential in increasing the likelihood of a good outcome both for the horse and for the veterinarian–client relationship.

Rectal tears also occur in **cattle and sheep** during reproductive procedures including manual pregnancy diagnosis in cattle and during insertion of ultrasound probes per rectum in sheep. The frequencies and risk factors are not recorded.

ETIOLOGY

The etiology of rectal tears is usually readily apparent, with the vast majority of rectal tears in horses being iatrogenic. Iatrogenic rupture occurs during rectal examination by veterinarians or laypersons for reproductive management (broodmare), or examination of other intraabdominal structures, for example, during evaluation of a horse with colic.[1] Spontaneous or noniatrogenic rupture can occur associated with infarctive lesions of the distal small colon or rectum, injuries during parturition or coitus, and malicious trauma caused by insertion of foreign objects by attendants.[2] It is important that rectal tears should not be assumed to be iatrogenic until a thorough evaluation of the animal and the history has been performed.

EPIDEMIOLOGY

Risk factors for rectal tears in horses have not been quantified. Reports of the *frequency* of occurrence do not provide information about the *relative risk* of occurrence in an individual animal. For example, rectal tears occur more frequently in mares, but the risk of a rectal tear occurring in a mare expressed as either the risk per examination or the risk per year might be less than that of a stallion. The less frequent occurrence in stallions (i.e., number of cases) might be because stallions are much less seldom subject to rectal examination. Given this caveat, identified associations with rectal tears include:

- Age: Contrary to earlier speculation, increasing age is likely a risk factor for rectal tears in horses and it is more frequent in animals >9 years of age.[1]
- Gender: The condition is more common in mares,[1] likely because they are more frequently subject to rectal examination as part of routine reproductive management. The relative risk of mares versus stallions and geldings is unknown.
- Breed: Arabian and American Miniature horses appear to be at increased risk of iatrogenic rectal tears.[1]
- Size: Smaller animals can be at increased risk.
- Inadequate restraint: Horses must be adequately restrained for rectal examination (see section Prevention).
- Inadequate preparation of the rectum: The rectum and distal small colon should be emptied of feces before an examination of the reproductive organs or gastrointestinal tract is performed.
- The experience of the examiner is not a factor in the risk of rectal tears in horses.
- The use of ultrasonographic probes per rectum does not appear to increase the risk of rectal tears.

PATHOGENESIS

Rectal tears occur in horses because the rectum of the horse is relatively sensitive and fragile and powerful contractions occur during rectal palpation. In contrast, the bovine rectum is relatively durable and, while often traumatized, is rarely ruptured. Tears occur because of excessive tension on the rectal wall. This usually occurs in horses by peristalsis and contraction of the rectum over the examiner's hand, with splitting of the rectum often occurring over the back (knuckles) of the hand.

Complete rupture of the peritoneal portion of the rectum results in fecal contamination of the abdomen and rapid onset of septic peritonitis and death. Tears in the nonperitoneal portion of the rectum (that is, caudal to the peritoneal reflection) cause perirectal cellulitis and abscessation.

CLINICAL SIGNS

The prominent clinical sign of the occurrence of a rectal tear is the presence of blood on the rectal sleeve of the examiner. Slight bloodstaining of mucus or lubricant is usually not associated with rectal tears (although this should be verified by repeat examination), whereas the presence of frank hemorrhage on the sleeve is usually indicative of a rectal tear. The rectum in an adult, 450-kg horse, is approximately 30 cm long and is partially within the abdomen, where it is covered by peritoneum, and partially in the pelvic canal, where it is not surrounded by peritoneum but is supported by thick connective tissue and muscle. The peritoneal portion of the rectum is supported dorsally by the mesorectum (mesocolon). Most iatrogenic rectal tears in horses occur within 25 to 30 cm of the anus, but can occur up to 60 cm from the anus, in the peritoneal portion of the rectum. The tears are almost always in the dorsal or dorsolateral wall and are longitudinal (parallel to the long axis of the rectum). It is speculated that the dorsal wall of the rectum is weaker than other segments because it is not covered by serosa, and blood vessels perforate the muscularis layers, weakening it.

Rectal tears in the horse have been classified according to the layers of the rectal wall disrupted. The classification is also a useful guide to the clinical signs to be expected and the treatment that is indicated (see the following section Treatment for management of each grade of tear):

- *Grade I:* Disruption of the mucosa only, or the mucosa and submucosa. There are usually no clinical signs other than some blood on the examiner's sleeve. Most of these injuries occur to the mucosa of the ventral aspect of the rectum.
- *Grade II:* Disruption of the muscular layer of the rectal wall with the mucosal and serosal surfaces intact. This is a

rarely recognized form of tear. There are minimal clinical signs.

- *Grade IIIa:* Tear includes mucosa, submucosa, and muscularis, but the serosal surface is intact. This degree of tear usually causes septic peritonitis. If the tear is caudal to the peritoneal reflection the pelvic fascia becomes infected, but the infection may remain contained within it for 7 to 10 days, forming a local cellulitis or abscess. During this period, the horse is likely to be affected by mild chronic peritonitis, with mild abdominal pain, fever, and mild toxemia. At the end of this time, the infection can erode through the peritoneum and cause an acute, severe, diffuse peritonitis or rupture through the perianal tissue causing a fistula.
- *Grade IIIb:* Tear is on the dorsal wall and includes the mucosa, submucosa, and muscularis. Because there is no serosa at this position, the tear extends into the mesocolon. There is usually septic peritonitis.
- *Grade IV:* Complete rupture with leakage of fecal material into the peritoneal space. Clinical signs of septic peritonitis are severe and death is almost inevitable.

Horses with a rectal tear will not display any immediate signs of discomfort. However, if there is a grade III or grade IV tear, the horse will have signs of septic peritonitis, including elevated heart and respiratory rates, sweating, colic, increased capillary refill time, and discolored mucous membranes within 1 to 2 hours.

CLINICAL PATHOLOGY

Hematological and serum biochemical changes in horses with grade III and grade IV tears are consistent with acute septic peritonitis. These changes include leukopenia and neutropenia, increased band cell count, elevated hematocrit, and total protein concentration initially, after which serum total protein concentration can decline as protein leaks into the abdomen. Peritoneal fluid has a high white blood cell count and protein concentration. Cytologic examination reveals the presence of degenerate neutrophils, intracellular and extracellular bacteria, and plant material. Lipid material can be detected in the peritoneal fluid if there has been leakage of mineral oil through the tear.[3]

PROGNOSIS

The **case–fatality rate** varies depending on the type of tear (see later section Clinical Signs). Horses with grade I or II tears almost all survive, whereas the survival rate for horses with grade III tears treated appropriately is 60% to 70%. Almost all horses with grade IV rectal tears die. Survival rates for grades I, II, III, and IV rectal tears are 100, 100, 38, and 2% for horses treated at a referral center.[1]

TREATMENT

If the person doing the rectal examination feels the mucosa tear, if there is blood on the rectal sleeve, or if a horse that has had a rectal examination up to 2 hours previously starts to sweat and manifest abdominal pain, a rectal tear should be suspected. A thorough examination should be conducted immediately but great care is necessary to avoid damaging the rectum further. The principles of care are to verify the presence of a tear, determine its severity, prevent leakage of fecal material into the peritoneum or tissues surrounding the tear, treat for septic peritonitis, prevent extension of the tear, and provide pain relief.

Immediate Care

If a rectal tear is suspected the horse should be appropriately restrained and examined immediately. There should be no delay in conducting this examination. The client should be informed of the concern about a rectal tear. First-aid measures taken at the time of a grade III or IV tear can have a marked influence on the outcome. Horses with grade III or IV rectal tears should receive first-aid treatment and then be referred for further evaluation and treatment.[4]

The existence of a tear should be determined and its severity assessed. This is best achieved by sedating the horse, providing local analgesia of the rectal mucosa and anus, and careful manual and visual examination of the rectal mucosa. Sedation can be achieved by administration of adrenergic agonists (xylazine, romifidine, and detomidine) with or without a narcotic drug (butorphanol, meperidine, pethidine, and morphine). Analgesia of the rectum and anus can be induced by epidural anesthesia (lidocaine or xylazine) or local application of lidocaine gel or lidocaine enema (10–15 mL of 2% lidocaine in 50–60 mL of water infused into the rectum). Peristalsis can be reduced by administration of hyoscine (*N*-butylscopolammonium bromide, 0.3 mg/kg intravenously).

Manual or visual examination of the rectum can then be performed. Manual examination is performed after generous lubrication of the anus and examiner's hand and arm. Some authorities prefer to use bare hands, rather than gloves or a rectal sleeve, for this examination because of the decreased sensitivity when wearing gloves. However, one should be aware of the health risks to the examiner of not using barrier protection (gloves) during a rectal examination. The rectum should be evacuated of feces and a careful and thorough digital examination should be performed. If a tear is detected, the position, distance from the anus, and length and depth of the tear should be determined. Gentle digital examination should be used to determine the number of layers involved and if there is rupture of the rectum and communication with the peritoneal space.

Alternatively, the rectum can be examined visually through a mare vaginal speculum, or using an endoscope. Both of these approaches are likely to minimize the risk of further damage to the rectum. These examinations can be impaired by the presence of fecal material.

If a grade III or IV rectal tear is detected, then the horse should be administered broad-spectrum antibiotics (penicillin, aminoglycoside, and possibly metronidazole) and NSAIDs, and referred for further evaluation. Some, but not all, authorities recommend placement of a rectal pack to prevent further contamination of the rectal tear. This is formed from a 7.5-cm (3-inch) stockinette into which is inserted a roll of cotton (approximately 250 g). The roll is moistened with povidone iodine solution, lubricated, and inserted into the rectum in the region of the tear. Epidural anesthesia will prevent expulsion of the roll in the short term.

Prompt referral and care is essential for maximizing the likelihood of a good outcome in horses with grade III and IV tears.

Grade I and II Tears

Treatment of these tears is medical. Horses should be administered broad-spectrum antibiotics and feces should be softened by the administration of mineral oil. These wounds heal in 7 to 10 days.

Grade III Tears

Both medical and surgical treatments are effective in approximately 60% to 70% of cases of grade III tears. The choice of treatment depends on the expertise and experience of the attending clinician and financial constraints imposed by the horse's owner. Surgical treatment includes direct repair of the tear (for those lesions that can be readily exposed via the anus), placement of a rectal sheath by ventral laparotomy, and placement of a loop colostomy. Various techniques are described.[5,6] Surgical repair is in addition to aggressive treatment of peritonitis.

Medical treatment includes administration of broad-spectrum antibiotics (such as penicillin, aminoglycoside, and metronidazole), antiendotoxin drugs (such as hyperimmune serum or polymyxin sulfate), NSAIDs, crystalloid fluids, colloidal fluids (hetastarch and plasma), and heparin, as well as other care. Peritoneal lavage might be indicated. Manual evacuation of the rectum at frequent intervals (every 1–2 hours for 72 hours and then 4–6 times daily for a further 7 days) was suggested to improve the prognosis, although others caution against manual evacuation of the rectum because of the risk of worsening the tear.

Grade IV Tears

Tears of this severity require immediate surgical intervention to minimize fecal contamination of the peritoneum. However, the grave prognosis and high cost of treatment, and poor success of surgical intervention in these cases, means that most horses are

euthanized. If surgical care is attempted, there should also be aggressive medical treatment of the peritonitis.

PREVENTION

As noted earlier, rectal tears can occur during examination by even the most experienced operators. Ideally, the owner should be informed of the risks of rectal palpation and explicit consent to perform the examination should be obtained. This is especially important for animals that are at increased risk of rectal tears.

The examination should be performed only when there is a clear clinical reason for performing a rectal examination, when the animal is a suitable candidate for rectal examination, and when the animal can be adequately restrained to permit a thorough examination to be performed in relative safety for both the examiner and the animal.

The examiner should proceed cautiously with the examination. The gloved hand and arm of the examiner should be well lubricated with a water-based lubricant. The anus should be gently dilated by using fingers shaped into a cone. Feces should be evacuated from the rectum such that the rectum is empty to the most cranial extent of the region to be examined. If the horse is anxious and straining, or if there is excessive peristalsis, then the animal should be sedated and antiperistaltic drugs (such as hyoscine) should be administered. The examination should be halted if the horse begins to struggle or resist the examination excessively. Application of a nose twitch often facilitates the examination.

During the examination care should be exercised not to resist peristaltic waves; the hand should be withdrawn in front of these advancing waves and reinserted as peristalsis passes. The fingers should not be opened widely during the examination and care should be taken not to put excessive pressure on a small region of rectum, such as might occur when trying to grasp an ovary or loop of distended intestine.

A rectal tear in a horse is a common cause of a malpractice suit and the veterinarian involved with the case is advised to recommend to the owner that a second opinion be solicited from another veterinarian to minimize any misunderstanding.

ACUTE DIARRHEA OF SUCKLING FOALS

ETIOLOGY

The causes of diarrhea in suckling foals are listed in Table 7-22. In a large proportion of foals the cause of diarrhea is not determined, in part because the disease is usually sporadic, mild, and transient. The more common identified infectious causes of diarrhea in foals on breeding farms in Britain include rotavirus, *C. perfringens, Salmonella, Cryptosporidium* sp., and *Strongyloides westeri,* although the relative importance of various pathogens varies from year to year, from farm to farm, and from region to region.[1] Potential pathogens can be isolated from both foals with diarrhea and healthy foals,[2] making etiologic diagnosis of the cause of diarrhea challenging. Of over 1000 foals examined at studs in the UK the most common disease was diarrhea with systemic disease (fever, tachycardia, depression, dehydration, or combinations thereof) affecting 5.9% of foals <30 days of age. Approximately one-half of these foals tested positive for rotavirus.[1]

Etiologic infectious organisms were isolated from 55% of 223 foals hospitalized in the United States for treatment of diarrhea, with 78% of the 122 positive foals having only one organism isolated.[3] Foals were tested for the presence of rotavirus, *Salmonella* spp., *C. perfringens, C. difficile,* coronavirus, helminthes, and cryptosporidium. Rotavirus was the most commonly detected organism and was identified in 20% of the foals.

C. perfringens causes diarrhea in young foals. There are five major types of *C. perfringens* and, while the organism is clearly associated with disease, a definitive role for each of these types in causing disease has not been established, partly because toxin production for strains isolated from foals with diarrhea has not been routinely documented. However, there is clear evidence that *C. perfringens* type C causes diarrhea in foals. *C. perfringens* types A, B, D, and E might be associated with disease in foals, but definitive proof is lacking. β-2 toxigenic *C. perfringens* type A has been described as a cause of colitis in a foal.[4] *C. difficile,* alone or in coinfection with *C. perfringens,* is a cause of diarrhea in foals.[5,6]

E coli, an important cause of disease in neonates of other livestock species, does not appear to be an important cause of diarrhea in foals, although some strains are pathogenic. Similarly, although there are reports of coronavirus causing severe disease in foals, this does not appear to be a common cause of diarrhea in foals. *Candida* spp. can cause diarrhea in critically ill foals and those administered antibiotics, but yeasts are apparently not causally associated with diarrhea in foals.[7] *Yersinia* spp. have been associated with diarrhea in foals but do not appear to be a common cause of disease. *Bacteroides fragilis* is an uncommon cause of diarrheal disease in foals. *C. parvum* or a specific horse-related cryptosporidium causes diarrheal disease in foals and can be isolated from broodmares.[8-10] The role of *Campylobacter* spp. in foal diarrhea, if there is any, is unclear, although it has been isolated from foals with enteritis.[11]

Strongyloides westeri infection, although usually regarded as causing only mild disease, if any, can cause severe disease in a foals and an outbreak of diarrhea.[12]

Group A rotaviruses are an important cause of diarrhea in foals and are discussed separately.[13,14]

Most foals develop transient, clinically unimportant mild diarrhea in the first 2 weeks of life. Colloquially referred to as **foal heat** diarrhea because of its temporal association with postpartum estrus in the dam, the occurrence of diarrhea is not associated with estrus in the dam but rather changes in intestinal flora as the foal ages.[15]

Noninfectious causes of diarrhea in foals include foal heat diarrhea, overfeeding of orphan foals or feeding of incorrect milk replacers, primary or secondary lactose intolerance, and pica (allotriophagia), including eating of sand or dirt. Primary lactose intolerance, the congenital absence of lactase in foals, is reportedly rare.[16] Secondary lactase deficiency occurs in foals recovering from enteritis and responds to feeding of lactose-free milk or administration of exogenous lactase. Acute pancreatitis causes diarrhea in foals, along with signs of abdominal pain and increases in lipase activity in blood and peritoneal fluid.[17]

Diarrhea is common in foals with systemic sepsis (septicemia) in which it can be attributable to the agent causing septicemia also causing colitis/enteritis (for example *Salmonella* spp.) or as a result of systemic organ dysfunction.[18] Approximately 50% of foals with diarrhea treated at a referral institution were bacteremic, although bacteremia was not associated with risk of death.[18]

EPIDEMIOLOGY

Diarrhea is common in suckling foals worldwide although studies of its incidence, risk factors, and outcome are exiguous. Diarrhea affects 21% of foals annually in Texas, being second only to respiratory disease (22%) as a cause of disease. The frequency of disease varies with age: 25% of foals 0 to 7 days of age have diarrhea, compared with 40% and 8% of foals aged 8 to 31 days and 32 to 180 days, respectively. Although a common disease syndrome, diarrhea is not associated with a high death rate (2.6%). Results of the Texas study might not be applicable to foals in other regions as indicated by the finding of 5.9% of foals affected by diarrhea with systemic signs and an additional 2.9% with undiagnosed diarrhea without systemic signs on horse studs in the UK.[1]

Among the common causes of diarrhea the highest death rates are associated with diarrhea associated with *C. perfringens, Salmonella* sp., and *Cryptosporidium* sp.[2]

Risk factors for development of the diarrhea vary depending on its etiology, but generally the disease is less common in foals born on pasture and at low stocking density.[11]

Table 7-22 Epidemiological and clinical features of suckling foals with diarrhea

Etiological agent or disease	Important epidemiological factors	Major clinical findings; *diagnostic criteria*
Idiopathic		
Foal heat diarrhea	Foals <2 weeks of age	No systemic signs of disease; diarrhea is mild and pasty
		No specific diagnostic criteria
Bacterial causes		
Septicemia (coliforms, *Actinobacillus* sp., *Salmonella* sp., *Klebsiella* sp., and others)	Newborn foal to <2 weeks of age; failure of transfer of passive immunity	Signs of systemic sepsis in addition to diarrhea; fever, depression, recumbency, failure to nurse, swollen joints, pneumonia, omphalitis, or omphalophlebitis; *blood culture*
Salmonella sp.	Outbreaks in newborn foals, even those with adequate passive immunity; mare is the likely carrier	Acute onset diarrhea, depression, fever, and toxemia; *culture of blood and feces*
	Hygiene at parturition may prevent disease	
Escherichia coli	Not a well-documented disease in foals (cf. calves and piglets)	Nonfetid diarrhea; *culture of feces yields heavy growth of mucoid E. coli* (*circumstantial evidence only*)
Enterococcus (*Streptococcus*)	Young foals; disease is rarely reported	Diarrhea; *demonstration of S. durans in feces*
Rhodococcus equi	Foals 2–5 months of age, some with history of respiratory disease	Diarrhea associated with *R. equi* pneumonia; *culture respiratory tract*
Clostridium difficile	<2 weeks of age	Colic, fever, ileus, hematochezia, toxemia, and depression; *fecal culture and demonstration of toxin in feces*
C. perfringens type C	Neonatal foals; sporadic disease to annual outbreaks on breeding farms; most foals excrete *C. perfringens* type A, which rarely causes diseases in foals	Colic, fever, ileus, hematochezia, toxemia, depression Culture of *C. perfringens* type C in feces, demonstration of toxin in feces
Lawsonia *intracellularis*	Older suckling foals and weanlings; sporadic or outbreaks on farms	Weight loss, mild to moderate diarrhea, ventral edema, depression, hypoproteinemia; serology and polymerase chain reaction on feces
Yersinia pseudotuberculosis	Suckling foals; outbreaks on breeding farms	Watery diarrhea and suppurative pneumonia; culture of feces and lesions
Aeromonas hydrophila	Reports of disease are uncommon; uncertain importance	Diarrhea; culture of feces
Viral causes		
Rotavirus	<3 months of age; occurs as outbreaks or endemic disease on farm; highly contagious	Profuse watery diarrhea with variable hypovolemia and depression; detection of virus in feces by EM, IFA, ELISA
Adenovirus	Immunodeficient foals (Arabians with severe combined immunodeficiency)	Diarrhea, depression; may be associated with other diseases including pneumonia; detection of virus in feces by EM
Coronavirus	Young foals (age range not well defined)	Diarrhea; detection of virus in feces by EM
	Apparently rare cause of diarrhea in foals	
Parasites		
Cryptosporidium sp.	Foals of any age; may be spread from other species, including calves and crias	Inapparent infection to fulminant disease with diarrhea, hypovolemia, and collapse; chronic diarrhea
		Detection of oocysts in feces, IFA
Strongyloides westeri	Individual foals; uncertain importance as a cause of diarrhea	Acute to chronic diarrhea; patent infections evident by fecal examination for parasite eggs
Other		
Nutritional	Sporadic; orphan foals fed inappropriate or poor-quality milk replacers; nursing foals fed inappropriate supplements	Mild to moderate chronic diarrhea; failure to thrive; *feed diet intended for foals (not plant-, protein-, or bovine-milk–based)*
Lactose intolerance	Nursing foals	Moderate to profuse diarrhea; *historical confirmation of administration of compounds*
Overdosing of cathartics (DSS, $MgSO_4$, $NaSO_4$, castor oil)	Sporadic; secondary to viral diarrhea; occurs only in milk-fed foals	Moderate to severe watery, acidic diarrhea; *oral lactose tolerance test or trial administration of lactase with milk feedings*
Enema	History of administration; diarrhea short lived	Bright alert and responsive foal with mild to moderate diarrhea; no specific diagnostic tests
Antibiotic induced	Administration of antibiotics	Mild to moderate diarrhea; may be associated with *Candida* sp. or *C. difficile*; *culture of feces, examination for C. difficile toxin*

DSS, dioctyl sodium sulfosuccinate; ELISA, enzyme-linked immunosorbent assay; EM, electron microscopy; IFA, indirect fluorescent antibody.

Rotavirus diarrhea is often endemic on farms, and the disease occurs as outbreaks on successive years. Affected foals range in age from less than 7 days to more than 3 months.

Diarrhea caused by ***R. equi*** occurs in foals with *R. equi* pneumonia, and the disease is endemic on some farms. Not all foals with *R. equi* pneumonia develop diarrhea. The disease occurs in foals 2 to 5 months of age.

Salmonellosis also occurs as outbreaks of disease among foals less than 8 days of age on breeding farms and is associated with a carrier status in mares.[12]

Diarrhea associated with ***C. perfringens*** type C occurs in foals less than 10 days of age with most foals being less than 6 days old,[4] and can occur as a farm problem with multiple foals affected on each of several successive years.[13] Farm risk factors include presence of other livestock, stock-horse–type foals, foals born on dirt, and stall or drylot confinement for the first few days of life.[14] *C. perfringens* type A is excreted in feces of most normal foals, whereas *C. perfringens* type C is rarely isolated from feces of normal foals.[15] ***C. difficile*** causes diarrhea in foals not administered antibiotics,[16] in contrast to the situation in adult horses, and usually affects foals less than 14 days of age, although foals up to 120 days of age can be affected.[17] FTPI is not a risk factor for *C. perfringens* or *C. difficile* enteritis in foals.

L. intracellularis causes mild to moderate diarrhea in older suckling or weaned foals. The disease occurs as outbreaks on breeding farms. There are no recognized foal or farm risk factors.

PATHOGENESIS

The pathogenesis of diarrhea varies somewhat depending on the inciting cause (see appropriate sections of this text for discussion of pathogenesis), although if sufficiently severe all cause excessive loss of fluid and electrolytes in feces and subsequent hypovolemia, electrolyte abnormalities, metabolic acidosis, and weakness. Although not demonstrated in foals, diarrhea in calves causes metabolic acidosis through loss of sodium and other cations in feces, which results in a decrease in the strong ion difference in blood, causing acidosis. Bicarbonate loss, per se, is not a cause of the metabolic acidosis, at least in calves. Infectious agents generally cause enteritis, although rotavirus infection is associated with loss of villous cells and subsequent loss of enzyme activity derived from the mature epithelial cell. The loss of enzyme activity, including that of disaccharidases, causes malabsorption of nutrients in milk and other feed. Failure to absorb nutrients in the small intestine causes them to be delivered to the cecum and large intestine where they are fermented. Subsequent reductions in colonic pH and increases in osmotic activity of the colon contents result in excretion of large quantities of fluid and electrolytes. *C. difficile* and *C. perfringens* produce enterotoxins that cause damage to intestinal cells and accumulation of hemorrhagic fluid in the intestine.[16] *L. intracellularis* causes an infiltrative and proliferative enteropathy with subsequent protein loss and malabsorption of nutrients.[19]

CLINICAL SIGNS

Clinical signs vary from mild, pasty diarrhea that adheres to the perineum and causes no detectable systemic signs of disease to profuse watery diarrhea with rapid development of loss of suckling, depressed mentation, tachycardia, increased skin tent, ileus, and recumbency.

Signs of systemic disease include failure to nurse, increased frequency or prolonged duration of recumbency, foals on pasture failing to follow the mare, fatigue, less frequent urination or production of concentrated urine (urine from normal foals is normally dilute), and weakness. Affected foals often have depressed mentation, tachycardia, fever (depending on the cause of the diarrhea), decreased capillary refill time, dry mucous membranes, increased skin tent, and eyes that are retracted into the orbit (consistent with dehydration). Depending on the cause of the diarrhea, foals can have signs of colic, which can range from mild with intermittent flank watching or biting and restlessness, through profound agitation, rolling, and dorsal recumbency. Severely affected foals can have seizures as a result of profound hyponatremia.[18]

Chronic diarrhea and that caused by nutritional imbalance or lactose intolerance causes rapid weight loss, failure to thrive, poor hair coat, and lethargy. Chronic fecal contamination of the perineum and escutcheon causes excoriation and loss of hair.

Diarrhea associated with foal heat is usually mild and transient and not associated with systemic signs of disease. However, diarrhea caused by infectious agents is often severe and accompanied by systemic signs of disease.

Diseases associated with *Clostridium* sp. are often severe with rapid onset of signs of toxemia, colic, hypovolemia, and death. Diarrhea is usually present and is often bloody, although it can be watery and profuse. Severely affected foals usually have signs of colic, toxemia, and ileus and may not develop diarrhea before dying. Salmonellosis can present as septicemia, with subsequent development of diarrhea, although in older foals diarrhea is a common presenting sign.

CLINICAL PATHOLOGY

Diarrhea with systemic signs of disease in foals can cause hyponatremia, hyperkalemia, hypochloremia, metabolic acidosis, hypoproteinemia, and azotemia. The magnitude of abnormalities varies with the cause of disease and its severity. Hyponatremia can be profound (<100 mEq/L). Hypoproteinemia can be a result of loss of protein from the inflamed intestine, a reflection of FTPI, or a combination of both. All young foals with diarrhea should have serum or plasma immunoglobulin concentrations measured or some other test for transfer of passive immunity performed.

Viral causes of diarrhea can be diagnosed by examination of feces by electron microscopy (EM). However, more rapid and sufficiently sensitive and specific tests exist for diagnosis of rotaviral disease (enzyme-linked immunosorbent assay [ELISA] and indirect fluorescent antibody [IFA]). Culture of feces will demonstrate *Salmonella* spp. in most cases if they are the cause of disease. Fecal culture yielding *C. perfringens* or *C. difficile* is insufficient for diagnosis of clostridial enterocolitis because these organisms can be recovered from normal foals. Confirmation of the diagnosis is achieved by demonstration of clostridial toxins in feces, which can be problematic given that the toxins are very labile.[4,6,20]

DIAGNOSTIC CONFIRMATION

For diagnostic criteria for specific diseases, see the appropriate sections in this text.

LESIONS

Lesions associated with diarrhea in foals depend on the inciting cause. Characteristically in severe cases there is enteritis and colitis with ulceration of intestinal mucosa. Foals with rotavirus diarrhea, most of which survive, have flattening of small-intestinal epithelium.

TREATMENT

The principles of treatment are

- Correction and maintenance of hydration, acid-base, and electrolyte status
- Ensuring adequate transfer of passive immunity
- Ensuring adequate nutrition
- Preventing complications of disease, including bacteremia

Correction of hypovolemia and electrolyte abnormalities should follow the general guidelines presented elsewhere in this text. Mildly affected foals, such as those with no systemic signs of disease, might not require administration of fluids orally or parenterally and care involves watchful waiting and intervention as indicated by deterioration in the foal's clinical status. More severely affected foals might require oral supplementation with balanced, isotonic electrolyte rehydration solutions, such as those marketed for use in calves. The amount and frequency will depend on the size of the foal, severity of disease, and response to treatment. Foals that have clear signs of hypovolemia should be administered fluids intravenously. These fluids should ideally be selected based on the foal's serum electrolyte concentrations, but in most instances a balanced, polyionic isotonic fluid such as lactated Ringer's solution is

appropriate. Correction of hyponatremia in some but not all foals requires administration of hypertonic (7%) sodium chloride intravenously. However, rapid correction of hyponatremia, especially if it is long-standing (more than 24 hours) might be associated with an increased risk of cerebral demyelination.[21,22] Correction of hyponatremia will resolve seizure activity.

Correction of acid-base usually occurs with correction of fluid and electrolyte abnormalities. Provision of fluids that are sodium rich and have a high strong ion gap, for instance, lactated Ringer's solution, will usually correct the metabolic acidosis common in foals with diarrhea. However, in some foals the rate of fecal loss of cations including sodium and potassium prevents resolution of metabolic acidosis without administration of sodium bicarbonate. Sodium bicarbonate can be administered intravenously or orally. Oral administration has the advantages that it is convenient and does not require administration of large amounts of fluid or of hypertonic solutions. The dose of sodium bicarbonate can be calculated from the foal's BW and base deficit. As a guideline, a 40-kg foal that is not hypovolemic but has continued profuse watery diarrhea and metabolic acidosis should receive 30 g of sodium bicarbonate orally every 6 hours. Serum sodium and bicarbonate concentrations should be measured at least daily and doses of sodium bicarbonate should be adjusted on the basis of these values. Overdosing, or continued dosing when diarrhea has resolved, results in hypernatremia and metabolic alkalosis.

Foals with diarrhea should have serum immunoglobulin concentrations measured. Hypogammaglobulinemic foals should be administered plasma intravenously (20–40 mL/kg BW).

Ensuring that foals affected by diarrhea continue to ingest sufficient calories is critical to the foal's survival. Foals require up to 150 (kcal/kg)/day for growth but can maintain weight on as little as 50 (kcal/kg)/day, especially if the nutrients are provided intravenously. Foals with mild to moderate diarrhea should be permitted to nurse at will. If there is concern that the foal is not nursing sufficiently, a feeding tube can be placed and the foal's diet supplemented with mare's milk substitute lactose-free milk. Lactase is sometimes added to the milk on the assumption that enteritis causes lactase deficiency (see section Tests of Absorptive Function for details of lactose tolerance testing in foals).

Foals with severe diarrhea can benefit from parenteral administration of nutrition and gastrointestinal rest. Feed withholding results in a marked reduction in fecal volume and the extent of electrolyte and acid-base abnormalities. However, it is critical for foal recovery that complete feed withholding is accompanied by partial parenteral nutrition.

Antibiotics are usually administered to foals with severe diarrhea because approximately 50% of such foals have bacteremia.[18] Although there is no evidence that parenteral administration of antibiotics reduces morbidity or case–fatality rate, the precaution has merit, as it does in calves. Oral administration of antimicrobials to foals with diarrhea is common but is not recommended because of the risk of exacerbating the disease, and unknown efficacy. Foals with suspected clostridial enterocolitis should be administered metronidazole (15–20 mg/kg, intravenously or orally, every 6–12 hours).

Drugs that affect gastrointestinal motility, such as loperamide, parasympatholytics, and narcotics, have no demonstrated efficacy in reducing morbidity or case–fatality rate and their use is not recommended.

CONTROL

Control of foal diarrhea is problematic because it is very common, many cases are mild and transient, a definitive diagnosis is frequently not available in a timely fashion, and it can be associated with a wide variety of infectious and noninfectious agents. Basic principles include ensuring adequate transfer of passive immunity, reducing exposure to pathogens, and minimizing the effect of other risk factors.[23]

Of the important causes of disease, in terms of morbidity and case–fatality rate, control of diarrhea associated with rotavirus and clostridial species is most important. Control of rotaviral diarrhea is discussed elsewhere. Control of clostridial diarrhea on farms with an endemic problems includes vaccinating of mares, administration of metronidazole to at-risk foals, and supplementation of passive immunity with antitoxins to clostridial toxins. Vaccination of mares with toxoids (*C. perfringens* type C and D toxoid) prepared for use in other species has been practiced, but there are no reports of safety or efficacy. Administration of antitoxin raised against *C. perfringens* C, D, and E might provide protection against the α-, β-, and ε-toxins that have the potential to affect foals. The antiserum, which is intended for use in ruminants, is administered orally (50–100 mL per foal) soon after birth. The efficacy of this practice has not been determined. Foals at risk may also be administered metronidazole (10 mg/kg every 12 hours) for the first 4 to 5 days of life. Again, the efficacy of this practice has not been determined. Vaccination of mares with recombinant protein of *C. difficile* toxin resulted in production of specific antibodies, although the efficacy of the vaccine in protecting foals was not tested.[24]

Administration of a probiotic containing *Lactobacillus pentosus* WE7 did not confer any protection against development of diarrhea in foals, and was associated with an increased risk of clinical disease, including diarrhea.

ACUTE DIARRHEA OF ADULT (NONSUCKLING) HORSES

SYNOPSIS

Etiology *Salmonella* spp., *Strongylus* spp., cyathostomes, *Neorickettsia risticii*, *Clostridium difficile*, antibiotic administration, coronavirus, idiopathic

Epidemiology Usually a sporadic disease of young horses, often temporally associated with mild respiratory disease or a stressful event such as transport. Helminthiasis has a seasonal distribution and can occur as a herd problem. *N. risticii* has a defined geographical distribution.

Clinical signs Vary from acute and transient diarrhea with minimal changes in vital signs to acute onset of profuse watery diarrhea with rapid development of severe clinical disease. Depression, fever, dehydration, and anorexia are common. Laminitis occurs as a sequela.

Clinical pathology Leukopenia, hemoconcentration, hyponatremia, hypokalemia, or hyperkalemia, and metabolic acidosis. IFA or PCR for *N. risticii*, fecal culture or PCR of *Salmonella* spp. Fecal culture for *Clostridium* spp. and ELISA to demonstrate toxin in feces

Lesions Colitis with or without enteritis

Diagnostic confirmation Cause is frequently not confirmed.

Treatment Maintenance of hydration and correction of acid-base and electrolyte abnormalities. Severe cases require more intensive care. Oxytetracycline for equine neorickettsiosis (monocytic ehrlichiosis). Metronidazole for *C. difficile*-associated diarrhea. Administration of anthelmintics

Control None

IFA, indirect fluorescent antibody; PCR, polymerase chain reaction.

ETIOLOGY

Causes are as follows:

- **Salmonellosis:** Various *Salmonella* spp.
- **Helminthiasis:** *Strongylus* sp., cyathostomes
- **Equine neorickettsiosis** (Potomac horse fever): *Neorickettsia risticii*
- **Antibiotic administration:** macrolides (lincomycin, tylosin, and erythromycin), tetracyclines, ciprofloxacin, trimethoprim-sulfonamide combination, penicillin, aminoglycosides, ceftiofur, and others[1-3]
- **Intestinal clostridiosis:** *C. perfringens* (types A and C[4]), toxigenic strains of *C. difficile,*[5-8] and possibly *C. cadaveris*
- ***Aeromonas* spp.**: Sometimes isolated from horses with diarrhea but definitive role as a causative agent has not been demonstrated[9]
- **Coronavirus**[10,11]
- **Idiopathic**
  - Intestinal hyperammonemia[12,13]
  - Excessive concentration of sulfate in drinking water[14]
  - Administration of imidocarb for treatment of equine piroplasmosis[15]
  - Intoxication with inorganic arsenic, cantharidin, or purgatives such as castor oil

Unlike other species, *E. coli* does not appear to be an important cause of diarrhea in adult horses.

In most cases (65%) of acute diarrhea in horses the cause is not determined, or if the cause is determined it is frequently at necropsy examination or as a result of serologic or microbiological testing after the horse has recovered.

EPIDEMIOLOGY

Occurrence

The syndrome of acute diarrhea occurs **worldwide** in adult horses of all breeds and both genders. The pattern of occurrence of the syndrome is dependent on the causative factors, with equine neorickettsiosis, associated with *N. risticii,* having a geographic distribution and **acute cyathostomiosis** having a seasonal distribution. Salmonellosis can occur sporadically or as outbreaks in stables, barns, and veterinary hospitals. *C. difficile* enterocolitis is often associated with hospitalization, antibiotic administration, or both to adult horses.

Colitis X refers to an idiopathic peracute to acute enterocolitis with a high case–fatality rate. It is usually a sporadic disease, but multiple cases can occur in a barn or racing stable over a period of weeks and cause considerable economic hardship.

Estimates of incidence, morbidity and mortality, and case–fatality rate are not available for all diseases and are discussed in greater detail in those sections of this text dealing with those diseases.

The **case–fatality rate** for the spontaneous disease can be 25% to 50% even in intensively treated horses, although these estimates are based on horses treated at referral practices. The recovery rate for acute but transient diarrhea in adult horses examined in primary practice is much higher. The case–fatality rate is higher for horses with *C. difficile*-induced diarrhea than for horses with acute diarrhea of other causes and for horses with antibiotic-induced diarrhea. The prognosis is worse in horses with tachycardia, severe dehydration (PCV > 45% [0.45 L/L]), azotemia, metabolic acidosis, low serum albumin concentration, or higher immature neutrophil (band cell) count in peripheral blood.

Risk Factors

The risk factors for salmonellosis, equine neorickettsiosis, and strongylosis/cyathostomiosis are addressed under those topics.

Stress

Stressful episodes, such as shipping or racing, hospitalization, surgery, administration of antibiotics, or mild respiratory disease, frequently precede the onset of diarrhea.

Celiotomy

Celiotomy for colic is associated with an incidence of severe diarrhea of up to 27% in surviving horses. The risk of diarrhea is greatest in horses with large-colon disease or with enterotomy, but is not influenced by the type of antibiotic administered after surgery.

Antibiotic Administration

Antibiotic administration is associated with acute diarrhea in horses, and almost all antimicrobials can cause the disease although some are apparently associated with greater risk or more severe disease. For example, administration of macrolide antibiotics including lincomycin, clindamycin, and erythromycin are consistently associated with higher risk of diarrhea in adult horses. Diarrhea occurs in horses administered antimicrobials, but such horses frequently have other risk factors for development of diarrhea, and the link to antimicrobial administration is unclear.[1] The prevalence of antimicrobial-induced diarrhea in 5300 adult horses in three referral hospitals over 1 year was 0.6% and had an 18% case–fatality rate.[3] However, 6.3% of horses administered antimicrobials developed diarrhea within 7 days of arthroscopic surgery compared with none of 44 horses after arthroscopic surgery and not administered antimicrobials.[16]

The macrolide antibiotic **lincomycin** causes acute, often fatal, disease of horses even when administered at relatively low doses, such as that resulting from horses ingesting medicated pig feed. Erythromcyin is associated with diarrhea in adult horses and in mares of foals administered the combination of erythromycin and rifampin. **Tetracyclines** have been associated with the development of acute diarrhea but, when given intravenously at therapeutic doses (6.6 mg/kg every 12–24 hours) are probably no more likely to cause diarrhea than other broad-spectrum antibiotics. Tetracycline contamination of feed causes outbreaks of diarrhea on horse farms. Enrofloxacin can be a cause of diarrhea in horses.[3] The combination of **trimethoprim and sulfadiazine** given orally caused diarrhea in 7% of hospitalized horses, whereas pivampicillin, a prodrug of ampicillin, caused diarrhea in 3%, although this difference was not statistically significant. The risk of diarrhea was greatest in hospitalized horses administered enrofloxacin or combinations of drugs including gentamicin. However, the number of horses with diarrhea was small and important associations might have not been detected.[3]

PATHOGENESIS

Diarrhea is the result of abnormalities in colonic water and electrolyte metabolism. Approximately 90 L of isotonic fluid enters the colon of an adult (450-kg) horse every 24 hours, and any disruption to the normal absorption of this fluid results in increased fecal water and electrolyte excretion. Horses with colitis have markedly different fecal microbiota compared with healthy horses, with loss of predominance of clostridia normally present in healthy horses and reduced diversity of microrganisms.[17] There appears to be a general dysbiosis of fecal microbiota in horses with colitis.

The pathogenesis of **antimicrobial-associated diarrhea** is unclear but could involve one or more of altered gastrointestinal motility (e.g., erythromycin), disturbed enteric flora allowing overgrowth of pathogens and subsequent enteritis or colitis, or altered microbial digestion of ingesta with abnormalities in water and electrolyte balance.[1] Antimicrobial administration markedly alters the flora of healthy horses.[18] Oral administration of trimethoprim-sulfadiazine or intramuscular administration of ceftiofur to healthy horses for 1 week caused a >99% decrease in the number of viable cellulolytic bacteria in feces for at least 1 week after cessation of administration.[18] Ceftiofur resulted in a marked reduction in the number of viable lactobacilli in feces. Antibiotic-treated horses shed more *Salmonella* in feces and

horses only had *C. difficile* during and after administration of antimicrobials.[18] Potential, or identified, pathogens identified in horses with suspect antimicrobial diarrhea include *C. difficile, C. perfringens, Salmonella* sp., and coliforms. Almost all adult horses with diarrhea from which *C. difficile* or its toxin can be isolated were administered antibiotics before onset of diarrhea.

Colitis results from physical, chemical, or infectious causes that induce inflammation in the colon. The proximate causes vary with the etiology of the disease. For example, colitis caused by infection from toxigenic strains of *C. perfringens* type C is attributable to binding of β-2 toxin to colonic mucosa, whereas colitis caused by salmonellosis is associated with invasion of the organism and loss of colonic mucosa. Colitis is associated with increased production of inflammatory cytokines, including tumor necrosis factor, in the colon, and with impaired mucosal absorptive function. Additionally, bacterial toxins and inflammation result in an increase in mucosal permeability with loss of plasma proteins into the colonic lumen and systemic absorption of toxins, including endotoxin. Loss of plasma proteins causes a reduction in plasma colloidal oncotic pressure with subsequent extravasation of water and electrolytes and development of edema and decreased effective intravascular volume (hypovolemia). The effect of the decrease in oncotic pressure becomes most apparent in horses that are treated aggressively with fluids. These horses, which often inadvertently receive excessive amounts of sodium as part of their treatment, rapidly develop edema of the ventral body wall and colon, among other tissues. Loss of other plasma proteins, including antithrombin III, and absorption from the gut of activators of coagulation, fibrinolysis, or inflammation, can contribute to the disseminated intravascular coagulation often observed in horses with enterocolitis.

The large volume of diarrhea in horses causes a reduction in body water and electrolyte content. Hypovolemia, hyponatremia, hypochloremia, and hypoproteinemia develop. Derangements in acid-base and electrolyte status impair gastrointestinal motility. Hypovolemia impairs perfusion of peripheral tissues, which, combined with absorption of endotoxin through the damaged colonic mucosa, results in toxemia, lactic acidosis, and death.

CLINICAL SIGNS

The onset of clinical signs is usually abrupt, although in some horses diarrhea can be presaged for up to several days by inappetence, mild depression, and a mild fever. The disease varies in severity from short-lived with mild to moderate diarrhea and minimal systemic signs of disease to a fulminant disease with death in hours. The description here is of the more severe forms of the disease. Once diarrhea occurs there is often **rapid progression**, with some horses dying within 12 hours of initial clinical signs, although most survive at least 24 hours. In a peracute form of the disease horses die, often within 6 hours, before developing diarrhea.

Typically horses are often severely depressed and stand with their heads down. They may play in water, but rarely eat or drink. Horses are usually mildly pyrexic (101.5–103°F [38.6–39.5°C]) but markedly tachycardic (80–100 beats/min), tachypneic (30–40 beats/min), and dehydrated (8%–12%). There is slow capillary refill of mucous membranes, which are usually bright red initially and then become bluish-purple as toxemia and dehydration become severe. The development of a purple line at the gingival margins is a sign of a poor prognosis. Most horses are oliguric.

The diarrhea is profuse and watery. **Abdominal pain** is usually present but mild; the onset of severe abdominal pain is often associated with necrosis of the large colon or cecum and impending death. **Rectal examination** reveals large amounts of fluid feces with minimal distension of the large colon.

Complications of acute, severe enterocolitis include laminitis, thrombophlebitis of the jugular veins, **thrombosis** of vessels including arteries in the limbs, renal failure, pulmonary aspergillosis, and necrotizing enterocolitis. Laminitis develops within 1 to 3 days of onset of diarrhea in approximately 10% of cases and can occur in any horse with enterocolitis, but is most common in horses with Potomac horse fever (equine neorickettsiosis). Thrombophlebitis, which may or may not be septic, usually affects veins, usually the jugular, that have or have had catheters placed or are the site of frequent intravenous injections. Thrombosis of the vein can occur several days to a week after removal of the catheter, although most occur while the catheter is in place. Renal failure occurs as a result of the combined insults of hypovolemia, endotoxemia, and administration of nephrotoxic drugs, including aminoglycosides and NSAIDs. Pulmonary aspergillosis is usually clinically inapparent. Clinically affected horses have rapidly progressive toxemia; respiratory distress; hypoxemia; and blood-tinged, frothy nasal exudates. Fatal necrotizing enterocolitis of horses is characterized by a brief course, with most horses dying within 48 hours of onset of diarrhea, profound dehydration, electrolyte derangements, severe metabolic acidosis and, terminally, severe abdominal pain.

Most horses that survive have resolution of diarrhea in about 7 days, although a small but clinically important proportion develop chronic diarrhea.

CLINICAL PATHOLOGY

Hematological examination reveals an increased hematocrit (45%–60%), variable changes in plasma protein concentration, and neutropenia with a marked left shift. As the disease progresses and horses are treated by intravenous administration of fluids, plasma protein concentrations and plasma oncotic pressure decline. Plasma or serum albumin concentration may be as low as 1.2 g/dL (12 g/L). Changes in **coagulation and fibrinolysis** are evident as increases in one or more of the following occur: one-stage prothrombin time, activated partial thromboplastin time, and concentration of fibrin degradation products, variable changes in plasma fibrinogen concentration, and a reduction in blood platelet concentration. Approximately one-third of horses hospitalized for treatment of severe diarrhea have subclinical evidence of disseminated intravascular coagulation, which carries a reduced likelihood of recovery.

Serum biochemical analysis usually reveals hyponatremia, hypochloremia, variable changes in serum potassium concentration, hypocalcemia (both concentrations of ionized and total calcium), azotemia (increased serum urea nitrogen and creatinine concentrations), hyperphosphatemia, and increased activities of enzymes indicative of muscle (creatine kinase) or intestinal damage (aspartate aminotransferase and alkaline phosphatase).

Blood gas analysis often reveals a severe metabolic acidosis, and the more negative the base excess the worse the prognosis. Interpretation of acid-base status in horses with severe enterocolitis is difficult because of the opposing effects of hypoproteinemia and combination of lactic acidosis and electrolyte loss on blood pH. Hypoproteinemia causes a metabolic alkalosis, whereas increases in plasma lactate concentration and hyponatremia cause metabolic acidosis. The presence of hypoproteinemia therefore tends to diminish the effect of lactic acidosis on blood pH, which underestimates the severity of the acidosis. Acid-base status in horses with severe abnormalities in plasma protein concentration should be ascertained by examination of base excess, strong ion gap, or strong ion difference.

Plasma endothelin concentrations are higher in horses with enterocolitis than in normal horses, although the clinical significance of this finding is unclear.

Abdominal fluid is usually normal initially but becomes bloody and has an increased white blood cell count and protein concentration if intestinal necrosis occurs.

DIAGNOSTIC CONFIRMATION

This depends on the results of fecal culture for *Salmonella* sp., fecal examination for helminth eggs or larvae, and IFA or PCR tests for *N. risticii*. Demonstration of large numbers of salmonellas in feces on multiple fecal samples, or in lymph nodes of horses dying of the disease, is persuasive evidence that the horse had **salmonellosis**. However, demonstration of low numbers of salmonellas in a single fecal culture is not definitive evidence that *Salmonella* sp. infection was the cause of the horse's diarrhea.

Fecal examinations for helminth eggs may be negative in cases of **acute cyathostomiosis**, although large numbers of fourth-stage larvae may be present in the feces. Diagnosis of *N. risticii* infection is based on a positive IFA test. Isolation of *Clostridium* sp. *and* demonstration of **clostridial enterotoxin** in feces of horses with acute diarrhea supports a diagnosis of intestinal clostridiosis, although demonstration of toxin alone is usually considered sufficient evidence for diagnosis. **Latex agglutination tests** are available for the detection of *C. perfringens* type A and *C. difficile* toxins.

NECROPSY

There are extensive lesions at necropsy examination, the most dramatic being in the large intestine, especially the cecum and ventral colon. These include hyperemia, extensive petechiation, and edema of the gut wall in the early stages, and later an intense, greenish-black, hemorrhagic necrosis. The contents are fluid, often foamy and foul smelling, and may be bloodstained.

Histologic examination demonstrates mucosal necrosis with a fibrinohemorrhagic exudate and extensive inflammation of the mucosa and submucosa.

DIFFERENTIAL DIAGNOSIS

Differential diagnosis list:

- Salmonellosis
- Equine neorickettsiasis (Potomac horse fever)
- Cyathostomiosis
- Antibiotic-induced diarrhea
- *Clostridium* sp. infection (*C. difficile*)
- Colitis X
- Intoxication with inorganic arsenic, cantharidin, or purgatives such as castor oil
- The incipient disease in horses before onset of diarrhea can resemble colon torsion or ischemia of the large colon secondary to verminous arteritis.

TREATMENT

Horses with mild disease, those that do not manifest systemic signs of disease, usually recover with symptomatic treatment. However, horses with severe disease require more specific treatment and supportive care, which is often intensive and expensive.

The **principles of treatment** for horses with acute diarrhea are

- Restoration and maintenance of normal hydration
- Correction of electrolyte and acid-base abnormalities
- Provision of analgesia
- Prophylaxis and treatment of the effects of endotoxemia/toxemia including management of systemic inflammatory response syndrome
- Prevention of absorption of toxins
- Correction and prevention of disseminated intravascular coagulation

Restoration of Hydration

Restoration of hydration should be considered an **emergency procedure** in severely affected horses. Fluids should be administered intravenously until hydration is restored, after which hydration can be maintained by either oral (via nasogastric tube) or intravenous administration of fluids. Suitable fluids for restoration of hydration are sodium-rich, isotonic, preferably polyionic, electrolyte solutions such as **lactated Ringer's** or Ringer's solution. **Isotonic sodium chloride** is also suitable. Isotonic dextrose solutions are not suitable because they do not contain any electrolytes. After correction of dehydration, attention should be paid to sodium balance because the administration of excessive quantities of sodium, especially to horses with plasma oncotic pressure that is lower than normal, may cause expansion of the extracellular fluid volume and edema.

Fluid therapy is discussed elsewhere. **Maintenance of hydration** in severely affected horses can be challenging and is best accomplished by intravenous administration of fluids. **Oral administration** of fluids to horses with diarrhea, although not providing ideal rehydration or maintenance of hydration, can be effective and less costly than intravenous administration.

Horses that become **hypoproteinemic** can require transfusions of plasma or administration of synthetic colloids such as hetastarch or pentastarch. Clinical signs indicating the need for transfusion include a persistently elevated heart rate and poor peripheral perfusion in spite of the administration of large quantities of fluids. Ventral edema and edema of the head and legs can develop in hypoproteinemic horses. Sufficient plasma should be administered to restore the plasma protein concentration to at least 40 g/L. Hetastarch or pentastarch provide none of the complex proteins present in plasma and essential for maintenance of normal clot formation and fibrinolysis and do not increase plasma protein concentration. Additionally, synthetic colloids can impair platelet function. Efficacy of administration of synthetic colloids should be assessed by examination of clinical signs or by measurement of plasma oncotic pressure.

Electrolyte and Acid-Base Status

Hyponatremia and hypochloremia will usually be corrected by administration of isotonic, sodium-rich electrolyte solutions such as lactated Ringer's solution. If this does not occur, then sodium chloride or sodium bicarbonate can be added to the intravenous fluids, or given orally. **Hypocalcemia** can be corrected by the addition of calcium gluconate (20 mL of 23% calcium gluconate per liter of fluids) to the fluids, provided that the fluids do not contain sodium bicarbonate. The mixture of sodium bicarbonate and calcium gluconate causes calcium to precipitate out of solution. Affected horses have **total body potassium depletion**, even though serum potassium concentrations may be normal or elevated, and maintenance fluids should contain potassium at up to 25 mEq/L. Fluids with high potassium concentration should be administered slowly. Alternatively, potassium chloride can be given orally (50–100 g per 450 kg every 12 hours).

The **metabolic acidosis** in horses with acute diarrhea often resolves either partially or completely when hydration is restored. However, severe acidosis can be treated with intravenous **sodium bicarbonate**. Oral administration of sodium bicarbonate (100 g per 450 kg every 8–12 hours) is often adequate in restoring and maintaining normal acid-base status. The serum sodium concentration should be monitored if large quantities of sodium bicarbonate are administered.

Antimicrobial Therapy

Approximately one-third of adult horses with acute diarrhea requiring hospitalization have positive blood cultures within the first day.[19] Bacteria detected include *Corynebacterium* spp., *Streptococcus* spp., *Pantoea agglomerans,* gram-negative rod, *Bacillus* spp., and yeast. Horses with positive blood cultures were sicker and 13 times more likely to die,[19] which could be a reflection of the lethality of bacteremia or that horses that were sicker and more likely to die were at greater risk of developing bacteremia. Administration of antimicrobials was not associated with outcome (lived versus died, risk of complications).

Administration of tetracycline to horses with acute diarrhea associated with *N. risticii* is clearly indicated and is often curative. However, the administration of antimicrobial drugs to horses with acute diarrhea other than that associated with *N. risticii* is controversial.

There is no evidence that administration of antimicrobials improves the prognosis of horses with acute diarrhea. The concern with antimicrobial administration is that antimicrobials can exacerbate the diarrhea in some cases. Conversely, withholding antimicrobials from severely ill horses with damaged colonic mucosa, and therefore presumably increased risk of bacteremia, is problematic. Regardless, many clinicians choose to treat horses with acute diarrhea with broad-spectrum antibiotics such as the combination of potassium penicillin (20,000 IU/kg, intravenously every 6 hours) and gentamicin (7 mg/kg intravenously or intramuscularly every 24 hours) or trimethoprim and sulfadiazine (30 mg/kg intravenously or orally every 12 hours). Metronidazole (15–20 mg/kg orally every 6–12 hours) or vancomycin has been recommended for horses with intestinal clostridiosis, although the wisdom of veterinary use of vancomycin, a drug used for the treatment of methicillin-resistant staphylococci in humans, could be questioned. In areas in which equine neorickettsiasis is endemic, all suspected cases should be treated with tetracycline (6.6 mg/kg intravenously every 12

hours for 3 days), or another effective antibiotic, pending confirmation of the disease. Isolates of toxigenic *C. difficile* from horses with diarrhea are almost always susceptible to metronidazole (15–29 mg/kg orally every 6–12 hours).

Prophylaxis and Treatment of Endotoxemia/Toxemia and Systemic Inflammatory Response

Treatment of endotoxemia is covered elsewhere in this text. Administration of plasma from horses **hyperimmunized** with *S. typhimurium* or *E. coli* reduces the severity of clinical signs and shortens the duration of disease in horses with endotoxemia secondary to enterocolitis or colic. **Polymyxin** (5000 IU/kg intravenously every 12 hours) attenuates the effect of endotoxin in experimental disease and is used for the prevention and treatment of endotoxemia in hospitalized horses. Its efficacy in clinical settings has not been determined in appropriate clinical trials. **Aspirin** (10 mg/kg orally every 48 hours) is administered to diminish platelet aggregation around intravenous catheters. **Flunixin meglumine** (1 mg/kg intravenously every 8–12 hours) or **phenylbutazone** (2.2 mg/kg intravenously every 12 hours) is given for analgesia and to prevent endotoxin-induced increases in plasma prostaglandins. **Pentoxifylline** (8 mg/kg orally every 8 hours) is administered for its putative effective in attenuating the effects of endotoxemia. The efficacy of these treatments in a clinical setting and their effect on measures of outcome of disease, such as duration of illness, case–fatality rate, and incidence of complications, has not been determined, with the exception of hyperimmune plasma or serum.

Binding of Toxins

Smectite or activated charcoal is sometimes administered to horses with acute enterocolitis in an attempt to adsorb toxins, such as those produced by *Clostridium* spp., and prevent systemic absorption. There is in vitro evidence that smectite can bind clostridial toxins and endotoxin, but evidence of efficacy in vivo is lacking.

Disseminated Intravascular Coagulation

Prevention and treatment of disseminated intravascular coagulation includes monitoring for changes in variables indicative of coagulation and fibrinolysis including D-dimer concentration; antithrombin III activity; one-stage prothrombin; and activated partial thromboplastin times, platelet count, and fibrinogen concentration. Plasma can be administered to increase blood antithrombin III activity, often in conjunction with heparin or low molecular weight heparin (dalteparin or enoxaparin). Doses of 50 U of dalteparin or 0.5 mg/kg of enoxaparin per kilogram subcutaneously every 24 hours seem to be adequate for prophylactic anticoagulation treatment of horses. For treatment of coagulation disorders or for ill horses that are considered to be at high risk of developing thrombotic disease, dosages may need to be increased to 100 U of dalteparin or 1 mg/kg of enoxaparin per kilogram subcutaneously every 24 hours.

CONTROL

Specific control measures for *Salmonella* spp. infection, equine neorickettsiasis, and cyathostomiosis (strongylosis) are discussed under their respective headings. The incidence of antibiotic-induced colitis can be reduced by minimizing the frequency with which antibiotics are administered to horses. Administration of smectite to horses undergoing colic surgery reduced the proportion of horses with postoperative diarrhea from 41% to 11%.[20] There is no evidence that probiotics reduce the severity of disease or shorten its duration, although most are regarded as safe and easy to administer.[21]

CHRONIC UNDIFFERENTIATED DIARRHEA OF HORSES

SYNOPSIS

Etiology Common sign of many enteric and nonenteric diseases

Epidemiology Sporadic disease of adult horses, except for cyathostomiosis and salmonellosis, which are discussed under those headings

Clinical signs Passage of unformed or liquid feces, either in increased or normal quantities. Weight loss, increased appetite. Otherwise normal physical examination. Rectal examination is usually normal.

Lesions Colitis in most cases

Diagnostic confirmation Examination of feces for cyathostome larvae, rectal biopsy demonstrating lymphoma or granulomatous enteritis, and *Salmonella* spp. in rectal mucosal biopsy or feces. Sand in feces or evident on abdominal radiography

Treatment Supportive: anthelmintics, corticosteroids, antidiarrheal preparations

Control As for cyathostomiosis and salmonellosis

ETIOLOGY

Chronic diarrhea is the **final common sign** of a number of causes of colonic dysfunction in horses. Diseases that cause chronic (more than 2 weeks' duration) diarrhea in horses include: cyathostomiosis, chronic idiopathic colitis, salmonellosis, alimentary lymphosarcoma,[1,2] granulomatous colitis, eosinophilic colitis, ingestion of sand, chronic liver disease, peritonitis, lymphangiectasia, and as a sequela to acute diarrhea. Immune deficiency, including variable adult-onset B-cell deficiency, can predispose a horse to the disease. *Brachyspira* sp. have been implicated as a cause of chronic diarrhea in horses.[3,4] *Campylobacter fetus* subsp. *fetus* has been isolated from feces and rectal biopsy of a 2-year-old Quarter Horse with chronic diarrhea and weight loss. Administration of enrofloxacin was temporally associated with passage of formed feces, although this change did not persist.[5]

There are many causes and their relative importance varies between locations. Even with concerted effort, a definitive antemortem diagnosis is achieved in fewer than 30% of cases.

EPIDEMIOLOGY

The occurrence is sporadic, with only single cases occurring in a group. Other horses in contact are not affected. The case–fatality rate is 35% to 65%. There appears to be no age-related, gender-related, or breed-related variation in incidence. Older horses do not appear to be at increased risk of having chronic diarrhea. The epidemiology of cyathostomiosis (strongyloidosis) and salmonellosis are discussed under their respective headings.

PATHOGENESIS

Diarrhea is attributable to colonic dysfunction, which can result in excessive loss of electrolytes in feces and diminished absorption of nutrients from the large colon. Disease of exclusively the small intestine does not cause diarrhea in horses. Protein-losing enteropathy might be present in addition to the diarrhea. Colonic dysfunction

can be associated with inflammatory or infiltrative lesions of the colon but in many cases an anatomic lesion is not detected. However, the colonic contents of affected horses have a greater fermentative capacity than those of normal horses, suggesting that in some horses the disease is essentially one of abnormal colonic digestion and absorption.

CLINICAL FINDINGS

The characteristic finding is chronic diarrhea. The feces vary in consistency from thick porridge (oatmeal), through undigested fibers in liquid, to liquid without fiber. The consistency of the feces in an individual horse can vary widely from one day to the next. The duration of the diarrhea is variable but might be lifelong. Death or euthanasia usually results from progressive weight loss. The onset of diarrhea is usually abrupt and can be associated with signs of toxemia and dehydration, as described earlier. However, often there is no toxemia or other systemic sign apart from weight loss, and affected horses are bright and alert and have a normal or increased appetite.

Rectal examination usually fails to reveal any abnormalities, although horses with granulomatous enteritis or alimentary lymphosarcoma can have enlarged mesenteric lymph nodes.

Abdominal radiography will reveal the presence of excessive amounts of sand in the large colon in horses with that disease.

CLINICAL PATHOLOGY

- Hematological examination can reveal a mild **neutrophilia** and **anemia**, but these changes are of little use in determining the etiology of the diarrhea.
- Serum biochemical examination typically demonstrates a mild **hypoalbuminemia**, **hypoglobulinemia**, **hyponatremia,** and **hypokalemia**, but again these changes are not specific for any particular disease.
- Hypoalbuminemia is consistent with the presence of protein-losing enteropathies such as chronic colitis, alimentary lymphosarcoma, cyathostomiosis, or granulomatous colitis.
- **Hyperbilirubinemia** and elevated serum concentrations of **serum bile acids** are suggestive of liver disease.
- Increases in **serum alkaline phosphatase** activity, while common, are of no diagnostic utility.
- Horses with cyathostomiosis usually have increased concentrations of β-globulins, although the sensitivity of this test is low.

Peritoneal fluid has a neutrophilic leukocytosis and increased (>25 g/L) protein concentration in horses with peritonitis but is normal in most horses with chronic diarrhea, including those with alimentary lymphosarcoma or granulomatous colitis.

Fecal examination of horses with cyathostomiosis can reveal strongyle-type ova or fourth-stage cyathostome larvae. The presence of **sand** in feces, demonstrated by allowing feces to settle in a transparent rectal glove or similar container, suggests sand accumulation in the colon as a cause of the diarrhea. The presence of **protozoa** in feces has no diagnostic significance. ***Giardia* spp.** are commonly found in feces of normal horses of all ages and, despite earlier reports of their presence in feces of horses with diarrhea, they are not associated with disease. **Coccidiosis** is very uncommon in horses, and *Eimeria leuckarti* is probably not pathogenic.

Demonstration of *Salmonella* spp. in feces or rectal mucosal biopsy, either by culture or PCR, is suggestive but not diagnostic of salmonellosis, given the high proportion of normal horses that shed *Salmonella* spp. in feces. Isolation of *R. equi* from feces of young horses with diarrhea is suggestive of enteric disease associated with that organism.

An abnormal **D-xylose**, **glucose,** or **starch absorption test** indicates small-intestinal disease and is suggestive of granulomatous enteritis, although most horses with this disease do not have diarrhea.

Exploratory laparotomy, either ventral midline under general anesthesia or through the left flank under local anesthesia, and **intestinal biopsy** can demonstrate alimentary lymphosarcoma, granulomatous enteritis, eosinophilic enteritis, chronic colitis, and other abdominal disease. **Rectal biopsy** is less expensive and invasive but has a relatively poor sensitivity, although good specificity for granulomatous enteritis, eosinophilic enteritis, and alimentary lymphosarcoma.

NECROPSY FINDINGS

Necropsy findings are consistent with the underlying disease, although in many cases gross lesions are not evident. The histologic changes in some cases are restricted to a mild inflammatory response and can be difficult to correlate with the severity of clinical disease. In some of these cases the diarrhea probably reflects an imbalance in the microflora of the large bowel, and demonstration of a specific etiologic agent is an unrealistic goal. Conversely, isolation of *Salmonella* spp. from the gastrointestinal tract or mesenteric lymph nodes should be interpreted with caution in the absence of histologic evidence of salmonellosis.

Because of the wide variety of potential causes of chronic diarrhea of horses it is not possible to list all the samples required to a "confirm" a diagnosis. In most instances, formalin-fixed samples from the liver, mesenteric lymph nodes, and numerous levels of the gastrointestinal tract comprise the minimum diagnostic material required. Regardless of what other testing is performed, it is prudent to hold back frozen segments of both large and small bowel (with content) in case other tests are deemed necessary.

DIFFERENTIAL DIAGNOSIS

Differential diagnosis list:

- Chronic idiopathic colitis
- Salmonellosis
- Cyathostomiosis
- Granulomatous colitis
- Sand ingestion
- Lymphosarcoma
- Peritonitis
- Intestinal lymphangiectasia
- Hyperlipemia
- Liver disease
- Basophilic enteritis
- Eosinophilic gastroenteritis

TREATMENT

The **principles of treatment** are to deal with the underlying disease, correct fluid and electrolyte disturbances, give symptomatic treatment of diarrhea, and provide supportive care. Except in cases of cyathostomiosis or sand accumulation, treatment of horses with chronic diarrhea is frequently unrewarding.

Specific Treatments

Cyathostomiosis should be treated with larvicidal doses of anthelmintics such as fenbendazole (50 mg/kg once, or 7.5 mg/kg daily for 3 days), moxidectin (400 µg/kg), or ivermectin (200 µg/kg). Treatment can be unrewarding if there is severe damage to the large colon.

Diarrhea secondary to **sand accumulation** in the gastrointestinal tract should be treated by preventing the horse from ingesting sand and, although the efficacy is debatable, with psyllium mucilloid (1–2 g/kg orally once daily for 4–5 weeks; see section Sand Colic).

Chronic idiopathic colitis can be treated with corticosteroids (dexamethasone 0.2–0.4 mg/kg once daily) or prednisolone (0.5–1.0 mg/kg once daily) for 3 to 4 weeks and the dose reduced as clinical signs permit.

Chronic salmonellosis has been treated with enrofloxacin (2.5–5 mg/kg orally every 12 hours for 3–4 weeks), sometimes in combination with metronidazole (15–20 mg/kg orally every 6–12 hours), but one should be aware of the risk of articular cartilage damage in horses treated with enrofloxacin.

Many diseases commonly associated with chronic diarrhea are not treatable.

Symptomatic and Supportive Treatments

Symptomatic treatments include **metronidazole** (7.5–20 mg/kg orally every 6–12 hours) or **iodochlorhydroxyquin** (10–20 mg/kg orally once daily). Although some horses have resolution of diarrhea while being treated with these compounds, there is no clear demonstration of their efficacy. **Antibiotic** administration, other than as described previously, does not usually alter the course of the disease. **Antidiarrheal** preparations

such as codeine phosphate, **loperamide,** and **bismuth subsalicylate** often provide temporary improvement in fecal consistency. Some horses with chronic diarrhea respond to **transfaunation**, in which 5 to 10 L of colonic fluid collected immediately after death from a horse without enteric disease is administered via nasogastric intubation.

Supportive treatment includes provision of supplemental electrolytes, principally sodium, potassium, and bicarbonate, as a feed additive. Suitable supplements include some commercial products designed for fluid replacement in diarrhetic calves, or a mixture of potassium chloride (300 g), sodium chloride (400 g), and sodium bicarbonate (300 g). This mixture is isotonic when dissolved at the rate of 90 g/12 L, or can be given orally at the rate of 30 to 90 g per 400-kg horse every 24 hours. Unsupplemented water should be supplied without restriction and serum electrolyte concentrations should be monitored. **Severely affected** horses can require intravenous administration of polyionic isotonic electrolyte solutions or plasma.

Nutritional support should include provision of a diet of high-quality roughage and grain. Some trials can be needed to determine the diet that is best for individual horses, but care should be taken that the diet contains adequate energy and is nutritionally balanced. Horses should be fed to attain, and then maintain, an ideal BW.

Spontaneous recovery does occur, particularly in young horses, and this, and the often lengthy duration (6–12 months) of the illness, make it difficult to decide accurately the value of the treatment.

CONTROL

Control of cyathostomiosis and salmonellosis is discussed under their respective headings. Diarrhea caused by sand accumulation in the colon should be prevented by not feeding horses on the ground and by avoiding grazing of short pastures on sandy soil.

IDIOPATHIC CHRONIC INFLAMMATORY BOWEL DISEASES OF HORSES

A syndrome of combinations of weight loss, ill-thrift, diarrhea, recurrent low-grade colic, intestinal malabsorption, and hypoproteinemia attributable to chronic inflammatory disease of the small and/or large intestine of horses is described.

The causes of idiopathic inflammatory bowel disease in horses are not well described, and the syndrome has been subdivided into granulomatous enteritis, eosinophilic enteritis, lymphocytic-plasmacytic enterocolitis, basophilic enterocolitis, and multisystemic eosinophilic epitheliotropic disease. Other causes of chronic inflammatory bowel disease in horses include parasitism, alimentary lymphosarcoma and other gastrointestinal neoplasms,[1] tuberculosis, pythiosis, and histoplasmosis.[2] Intolerance to gluten, a protein found in wheat and similar grains, is a well-recognized cause of inflammatory bowel disease in humans. Although most horses with inflammatory bowel disease do not have evidence of gluten hypersensitivity, a horse with high concentrations of antibodies to gluten and which responded to a gluten-free diet is reported.[3]

Empirical treatment of 20 horses with a presumptive diagnosis of inflammatory bowel disease, based on a combination of hypoproteinemia, hypoalbuminemia, malabsorption, increased intestinal wall thickness on ultrasonographic examination or characteristic changes in rectal mucosal biopsy with a larvicidal anthelmintic, and >3 weeks' administration of corticosteroids resulted in a good response to treatment in 15 of the horses with 13 surviving for at least 3 years.[4] Peak xylose absorption was higher (1.36 ± 0.44 mmol/L) in survivors than in nonsurvivors (0.94 ± 0.36).[4]

GRANULOMATOUS ENTERITIS OF HORSES

Granulomatous enteritis is one of several inflammatory bowel diseases of horses. It is characterized by gradual onset of weight loss and ill-thrift.

The etiology of granulomatous enteritis is unknown. Infection with *Mycobacterium* spp. is suggested as a cause but demonstration of acid-fast bacteria in tissue sections or by culture of gut or mesenteric lymph nodes of affected horses is rare and inconsistent.

The disease occurs with greatest incidence in **Standardbred horses** between 1 and 6 years of age, although it does affect other breeds of horses. The disease is usually sporadic, although it has been recorded in siblings raised on the same farm. Estimates of incidence are not available. The disease has a case–fatality rate of almost 100%, although recovery is documented for a small number of horses.

Accumulation of lymphocytes and multinucleated giant cells in the lamina propria is associated with villous blunting in the small intestine. There is malabsorption of carbohydrates and fats and excessive loss of protein in feces with subsequent hypoalbuminemia, edema, and weight loss.

Weight loss and anorexia are the most common presenting signs. Fever is uncommon. Approximately one-third of horses have diarrhea or a history of abdominal pain. Affected horses can have a diffuse, scaling alopecia and excoriations, especially of the coronary band. Rectal examination can reveal enlarged, soft mesenteric lymph nodes. Colic is an unusual manifestation.

Hematological and serum biochemical examination reveals a mild, macrocytic **anemia** (hemoglobin < 100 g/L, hematocrit < 30%) with a normal leukogram. Hypoalbuminemia is a consistent finding (<25 g/L, <2.5 g/dL) whereas the globulin concentration can be normal, low or, more commonly, high (>50 g/L, >5.0 g/dL). Plasma fibrinogen concentration is usually increased (>4 g/L, 400 mg/dL), and there are no characteristic changes on serum biochemical analysis. Peritoneal fluid is normal.

Absorption tests using D(+)-xylose, glucose, or starch indicate diminished absorption of carbohydrate by the small intestine in many affected horses. The D(+)-xylose absorption test is performed by administering D(+)-xylose at a dose of 0.5 or 1 g/kg as a 10% solution by nasogastric intubation after an overnight fast. The concentration of D(+)-xylose in blood samples collected at 0, 1, 2, 3, 4, and 5 hours after dosing is determined. An abnormal test is one in which there is not an obvious peak in the D(+)-xylose curve and in which the peak concentration is lower than expected for a normal horse on a similar diet. In horses with a normal small intestine, administration of a 10% glucose solution orally at a dose of 1 g/kg BW results in an increase in the plasma glucose concentration of >85% of the baseline values. An increase of <15% over baseline is found in horses with small-intestinal disease that impairs glucose absorption. Intermediate values are found in both normal and diseased horses.

Differential diagnoses include other causes of malabsorption syndrome in horses such as parasitism, chronic inflammatory disease (abdominal abscess), neoplasia,[1] multisystem eosinophilic epitheliotropic disease, and malnutrition.[2] **Diagnostic confirmation** is achieved by histologic examination of a biopsy of the rectum or small intestine. Rectal biopsy has a low sensitivity (less than 50%) but high specificity for diagnosis of granulomatous enteritis. Biopsy of small intestine and mesenteric lymph nodes has a much higher sensitivity than rectal biopsy and is the recommended test. Endoscopic duodenal biopsy might be useful in providing a diagnosis.[3]

Necropsy examination reveals that the intestinal wall is thickened uniformly, especially in the jejunum and ileum. Mesenteric lymph nodes may be enlarged. There is villous atrophy with a diffuse and patchy granulomatous infiltration of the lamina propria of the small intestine. Crypt abscesses are common. Granulomas are also present

in the liver, spleen, kidney, and bone marrow of many cases. The predominant cell types are macrophages and epithelioid cells with occasional giant cells. The disease may be difficult to distinguish from alimentary lymphosarcoma.

Attempts at **treatment** with a variety of antiinflammatory and antimicrobial drugs, including prednisone and sulfasalazine, have been almost university unsuccessful. Resolution of the disease occurred for up to 7 months, whereas a horse was treated with a decreasing dose of dexamethasone, beginning at 40 mg (0.1 mg/kg) intramuscularly every 4 days for 4 weeks, and then slowly decreasing. Surgical resection of defined, solitary lesions is reported, but this is an unusual manifestation of the disease.

There are no effective control measures.

LYMPHOCYTIC-PLASMACYTIC ENTEROCOLITIS

This is an uncommon disease of horses, in contrast to dogs, which affects horses of any age and without discernible breed or gender predilection. The etiology is unknown. Presenting signs include weight loss, diarrhea, and lethargy. Clinicopathologic abnormalities include hypoproteinemia and hypoalbuminemia in approximately one-half and three-quarters of cases, respectively. Results of an oral glucose tolerance test are abnormal in approximately 75% of cases. Histologic examination of a rectal mucosal biopsy reveals abnormal tissue suggestive of the disease in about one-half of cases. The diagnosis is confirmed by biopsy of ileum or necropsy examination. Differential diagnoses are similar to those for granulomatous enteritis. There is marked infiltration of the lamina propria with lymphocytes and plasma cells in the absence of granulomatous changes. Administration of dexamethasone improves clinical signs of disease in a small proportion of horses. Control measures are not available.

Schumaker J, Edwards JF, Cohen ND. Chronic idiopathic inflammatory bowel disease of the horse. *J Vet Intern Med*. 2000;14:258-265.

IDIOPATHIC FOCAL EOSINOPHILIC ENTERITIS

Focal, idiopathic eosinophilic enteritis is an uncommon disease of horses characterized by intestinal obstruction secondary to constrictions of primarily the small intestine caused by an eosinophil-dominated chronic inflammatory reaction.[1,2] The cause of the disease is unknown, although hypersensitivity or immune-mediated mechanisms are likely important in the pathogenesis of the disease. The disease is recognized with increasing frequency in the UK.[3]

Idiopathic focal eosinophilic enteritis occurs without any apparent gender or breed predisposition. Younger horses (<5 years) are at increased risk.[3] The disease is more common during the July to November period in the Northern Hemisphere.[3] The disease is reported in the northern United States, UK, Ireland, and the Netherlands.[4-6]

Clinical signs are usually caused by an acute intestinal obstruction and manifest as colic.[4,5] Affected horses rarely have weight loss or diarrhea. The common form of the disease is one in which the infiltration is segmental and associated with acute colic caused by obstruction of the small intestine or large colon by mural lesions.[4,5] The disease must be differentiated from other causes of colic.

Histologically, the disease is characterized by the presence of eosinophilic infiltrates in a chronic active inflammatory reaction affecting the small or large intestines. The infiltrates are restricted to the intestinal tract. There are activated endothelial cells, eosinophils and neutrophils, and components indicating a duration of inflammation of greater than 3 days.[2] Macrophages and eosinophils are the predominant cell type in the lesions.[2]

Antemortem diagnostic confirmation is achieved by small-intestinal biopsy. *Pythium insidiosum* infection can induce a similar focal enteritis.

The **prognosis** for affected horses is good. The lesion is usually amenable to surgical resection, but this does not appear to be necessary for recovery unless there is acute luminal obstruction of the intestine.[1,4,5] Control measures are not reported.

EQUINE GRASS SICKNESS (EQUINE DYSAUTONOMIA, GRASS DISEASE, AND MAL SECCO)

SYNOPSIS

Etiology Unknown

Epidemiology Horses of all breeds and both sexes in the UK, Europe, and southern South America. Greatest incidence in spring/ early summer

Clinical signs

- **Acute grass sickness** Colic, nasogastric reflux, absent gut sounds, depression, dysphagia, and small intestinal distension of <2 days' duration at time of death
- **Subacute grass sickness** Tachycardia with or without signs of colic, reduced intestinal sounds, impaction of the colon, and clinical course of 2–7 days
- **Chronic grass sickness** Insidious onset weight loss, intermittent colic, decreased appetite, rhinitis sicca, patchy sweating, and mild dysphagia

Clinical pathology None is specific or diagnostic.

Lesions Both forms of the disease have degeneration of neurons of the autonomic nervous system, especially of the myenteric and submucosal plexuses.

Diagnostic confirmation Examination of ileal biopsy. Rectal biopsy is not reliable.

Treatment

- **Acute grass sickness/subacute grass sickness** Supportive. None effective
- **Chronic grass sickness** Nursing care

Control Nonspecific. Vaccination is not currently available.

Equine grass sickness is a noncontagious acute, subacute, or chronic disease with a high case–fatality rate affecting equids in predominantly the UK and northwestern Europe.

ETIOLOGY

There is increasing confidence that equine grass sickness is a toxicoinfectious form of botulism caused by exposure of susceptible equids to *C. botulinum* type C toxin (BoNT/C and/or C2 binary toxin).[1,2] However, the hypothesis of a role for toxicoinfectious botulism in grass sickness of horses does not completely explain the geographic distribution of the disease. The presence of IgG antibodies to BoNT/C in serum of 30.8% (61 of 198) of horses in Israel, where the disease is not recognized, suggests that factors other than simply exposure to BoNT/C are required for induction of the disease.[3] It is speculated that dietary factors (hence "grass sickness") alter gastrointestinal biota of horses and allow proliferation of *C. botulinum* type C or D, or promote increased production or absorption of neurotoxin, and initiate development of the disease.[4] Interestingly, horses with grass sickness have a higher prevalence of *C. perfringens* in feces (7/9 detected by culture and 15/37 by ELISA) and ileal contents than do horses with colic (1/16) of other cause or grazing healthy horses (0/60 by culture and 1/74 by ELISA).[5] This is interpreted as indicative of altered gastrointestinal biota rather than as

indicating a causative role for *C. perfringens* in equine grass sickness.[5]

Evidence supporting a role for *C. botulinum toxins* in the etiology of the disease included the isolation of toxin (BoNT/c) producing strains of *C. botulinum* type C from the ileum of 45% of horses with grass sickness and 4% of clinically normal control horses, the presence of higher concentrations of IgA antibodies to BoNT/C and BoNT/D in the ileum of horses with acute grass sickness than of unaffected controls,[6] and higher risk of the disease in horses with low serum concentrations of anti-BoNT/C IgG antibodies. Vaccination of horses with a botulinum toxoid markedly reduced the mortality rate among vaccinated, compared with unvaccinated, horses providing evidence of a role for immunity to *C. botulinum* toxins in resistance to the disease.[1] Remarkably, this study was conducted in 1922 and 1923. There are plans to conduct further vaccine trials.[7]

EPIDEMIOLOGY

Occurrence

Grass sickness is locally common in its restricted distribution to all parts of Great Britain (including possibly Ireland), the Czech Republic, Sweden, Switzerland, Hungary, Cyprus, and the northern and western coasts of Europe.[2,8-10] A clinically and histologically indistinguishable disease, mal secco, occurs in the Patagonia region of Argentina, southern Chile, and in the Falkland (Malvinas) Islands. Dysautonomia, with clinical signs and histologic changes consistent with equine grass sickness, is reported in a mule from Kansas in the United States.[11]

Horses, ponies, donkeys, zebras, Przewalski's horses, rabbits, and hares are affected. The **incidence** on farms with a history of the disease ranges between 0.4% and 16% per year or 2.1 grass sickness cases per 100 horses per year. Approximately 47% of cases are acute, 20% subacute, and 33% have the chronic form of the disease.[12]

The **case–fatality rate** for acute grass sickness is 100%, whereas that for the chronic form of the disease in horses overall is 49%,[12] and 60% to 70% for those treated at a referral hospital. Horses diagnosed in June are 2.7 times (95% CI 1.4–5.4) more likely to survive than those diagnosed in May.[12]

Horses that survive the initial phases of the chronic form of the disease are often destroyed because of weakness and emaciation, although they can make complete recoveries.

Risk Factors

Animal Risk Factors

The risk and prevalence of disease is greatest in 4- to 5-year-old horses (adjusted OR of 1.9 compared with 0–3 year olds) and then declines such that the risk of disease is lowest in horses >12 years old (OR 0.02 compared with that of 0–3 year olds).[12] Similarly, horses 11 to 20 years of age are at reduced risk compared with horses 2 to 10 years of age (OR 0.32) when only horses in Scotland are considered.[13] The median age at diagnosis is 6 years (mode 5 years) and cases are recorded in horses 2 months to >30 years of age.[12] Foals born of affected mares are clinically normal. There is no apparent breed predilection beyond that attributable to higher numbers of particular breeds of horses in at risk areas,[12] although native Scottish breeds are at increased risk compared with other breeds (OR 3.56) when only horses in Scotland are considered.[13] There is no clear association with gender of the horse when age distribution of genders is considered.[13]

Horses on pasture are at increased risk (hence the colloquial name of the disease), and the disease rarely, if ever, occurs in horses that are denied access to pasture and grazing. A recent (<14 day) change of pasture carries an increased risk (OR 24) of development of the disease. Horses that have been on the farm for less than 2 months are at increased risk of developing the disease. Horses on farms with previous cases of the disease are at increased risk (OR 2.2–45) of the disease, although horses that have been in contact with animals with the disease are at reduced risk (OR 0.1). Horses with lower serum concentrations of antibodies to BoNT/C are at increased risk for the disease.

Environmental Risk Factors

The risk of disease in horses in Scotland increases with increasing latitude (northing) at a rate of OR 1.08 per 10 km.[13] The disease occurs year round with a marked seasonal distribution peaking with 61% of cases occurring in April, May, and June in the UK.[12] Outbreaks of the disease are associated with the occurrence of cooler and drier weather than normal during the 2 weeks preceding the outbreak. There is increased risk associated with more sun hours (OR 1.44–2.48 per additional hour per month, after correction for latitude, as previously mentioned) and more frost days (OR 1.13–1.18 per day per month) and decreased risk with higher average temperature (0.82–0.76/°C).[13]

Pasture and Soil Risk Factors

Access to grazing is an acknowledged risk factor. Examination of pasture and soil reveals that sites that have had horses with grass sickness have significantly higher concentrations of soil nitrogen and herbage iron, lead arsenic, and chromium.[14] *Ranunculus* sp. (buttercup) was common at sites with affected horses.[14] The role, if any, for *Ranunculus* sp. or the heavy metals in pathogenesis of the disease is unclear.

Horses with grass sickness have plasma amino acid profiles expected of those with subacute or chronic cyanide intoxication. This has led to investigation of the cyanide concentration of common pasture plants in areas with affected horses. The concentration of cyanogenic glycosides in white clover (*Trifolium repens*) is higher in pasture associated with cases of equine grass sickness (497 mg cyanide/kg dry matter) than in white clover from control pasture (<300 mg/kg).[4] Although white clover is a common pasture plant in many parts of the world, including areas with cases of equine grass sickness, a role for it in the pathogenesis of grass sickness is speculative. The amount of cyanide ingested by horses on pasture with a high cyanide concentration is predicted to be insufficient to induce toxicosis, but there might be other roles for the plant in predisposing the development of the disease.[4] Alternatively, the changes in pasture cyanogen content could be simply coincidental.

Farm or Premise Risk Factors

Farms with a history of horses with the disease are at increased risk of having further cases.[12] For premises with previous cases of grass sickness there is an increased risk of the disease developing as the number of horses on the farm increases, with the presence of young horses, on stud farms and livery/riding schools, on farms having sandy or loamy soil, and those rearing domestic birds and using mechanical fecal removal. The risk of recurrence of disease on a farm decreased with the presence of chalk soil, cograzing ruminants, grass cutting of pastures, and manual removal of feces. There is no association between the disease and the type of pasture or with provision of supplementary feeds. Feeding hay or haylage is associated with a decreased risk of the disease. Any disturbance of the soil, such as when plowing, increases the risk of disease.

Transmission

The disease is not contagious. Injection of normal horses with serum of affected horses causes lesions, but not clinical signs, consistent with the disease.

PATHOGENESIS

The clinical signs are attributable to widespread damage to the autonomic nervous system, including the sympathetic neurons in prevertebral and paravertebral ganglia,[15] resulting in sympathetic and parasympathetic dysautonomia that is most clinically evident in the gastrointestinal tract. Coincident with damage to the autonomic nervous system are increases in plasma concentrations of dihydroxyphenylalanine, epinephrine, norepinephrine, and dopamine, possibly because of increased secretion of these compounds from affected sympathetic ganglia and neurons. Lesions in the cranial nerves and brainstem are probably responsible for dysphagia and drooling evident in most cases. Rhinitis is associated with diminished noradrenergic, noncholinergic innervation, greatest in neurons positive for substance P

or calcitonin gene-related peptide, of the nasal mucosa in subacute and chronic cases.

Electrocardiographic examination of affected horses reveals evidence of loss of parasympathetic innervation of the heart, which is consistent with lesions in the terminal cardiac ganglia. Splanchnic lesions are most severe in the myenteric and submucosal plexuses of the ileum, with less severe changes in the large colon and celiacomesenteric ganglion. There is also a reduction in interstitial cells of Cajal (cells involved in pacemaker activity and autonomic transmission within the gut). These neuronal changes are associated with a marked impairment of cholinergic activity in ileal tissue of affected horses. Because of the altered autonomic activity, peristalsis decreases (in chronic cases) or ceases (in acute cases) with subsequent accumulation of ingesta in the small intestine, stomach, and large colon. Death is caused by emaciation in chronic cases or rupture of the stomach or intestine in acute cases.

CLINICAL FINDINGS

The clinical signs of grass sickness are varied, and accurate antemortem diagnosis on clinical signs alone is difficult. The diagnosis is usually made based on clinical signs, elimination of disease with similar presentation, and consideration of the horse's provenance.[16] The incubation period of the disease is approximately 10 to 14 days.

Acute, subacute, and chronic forms of the disease are recognized, although some authorities use a designation of acute and chronic. In all cases, there is some dysphagia, resulting in drooling of saliva and trickling of ingesta from the nose. Dried food is impacted between the cheeks and the teeth and the animal plays at drinking. These signs are attributable to lesions in the cranial nerves. Most animals are depressed.

Acute Cases

The onset is sudden and the course of the disease is 1 to 4 days. Abdominal pain may be severe but also may be absent even in the presence of severe tachycardia. There is tachycardia (80–90 beats/min may be >100), decreased to absent gut sounds, lack of defecation, and abdominal distension. On rectal examination, the small intestine is distended with fluid and readily palpable in the caudal abdomen. Nasogastric intubation yields a large (20 L) quantity of fluid. Urination is frequent and may be accompanied by tenesmus. Affected horses may wander about in a restless manner and a fine muscle tremor occurs constantly, especially in the upper forelimb. Periodic attacks of patchy sweating are common. There is noticeable salivation. Esophageal endoscopy reveals linear ulcerations resulting from reflux esophagitis.

Subacute Cases

These cases have signs of mild colic, or may not have any signs of colic, in the presence of tachycardia, depression, reduced gastrointestinal sounds, and impaction of the large colon with characteristic corrugated appearance. The clinical course is 2 to 7 days and death is inevitable. Esophageal endoscopy reveals the presence of linear erosions in many affected horses.

Chronic Cases

The course is usually >7 days and is characterized by weight loss, patchy sweating, and intermittent colic. Horses stand with all four feet close together under them ("elephant on a tub stance") and have a tucked up abdomen. Dysphagia is evident and the gut is empty except for the colon and rectum, which contain dry, hard feces. In the late stages the horse snores, the penis droops, and attempts are made to eat abnormal materials. Most cases of the chronic form have rhinitis, characterized by crusting of mucopurulent material on the turbinates and this is considered, in the presence of appropriate history and other clinical signs, almost pathognomonic for grass sickness. There can be esophageal obstruction with secondary inhalation pneumonia.

Application of phenylephrine (0.5 mL of a 0.5% solution) into one eye causes a dorsal deviation of the eyelashes of the upper eyelid in horses with grass sickness, but not in normal horses.

There is a radiologic discernible defect in esophageal motility in horses with grass sickness.

Horses with acute, subacute, or chronic grass sickness usually (12 of 14 examined) have abnormalities on electromyography including excessive spontaneous activity; fibrillation potentials; doublets, triplets, or quadruplets; neuromyotonic discharges; and complex repetitive discharges.[17]

Recurrence of the disease in a horse is exceedingly rare.

Antemortem diagnostic confirmation can only be achieved by examination of biopsy specimens of the ileum, although biopsy of nasal mucosa has been suggested as an alternative. Examination of rectal biopsy is specific (estimated 100% based on detection of at least three chromatolytic neurons), but not sufficiently sensitive (70%), for diagnosis of the disease based on a study of 14 cases and 10 controls.[18] Antemortem rectal biopsy is not reliable for diagnosis of the disease compared with ileal biopsy, which has a high sensitivity.[19,20] Ileal biopsies can be collected via conventional laparotomy or by laparoscopy.[20] The use of formalin-fixed ileum has both sensitivity and specificity of 100%.[21] Immunohistochemical staining for synaptophysin does not aid in the differentiation between autolytic tissue and tissue from horses with grass sickness.[22]

CLINICAL PATHOLOGY

Serum biochemical profiles and hematological examinations do not demonstrate pathognomonic changes. Serum amyloid A and plasma fibrinogen concentrations are significantly higher in horses with grass sickness than in healthy horses or horses with colic not caused by inflammatory disease, but similar to those in horses with enteritis, colitis. or peritonitis.[23] Signs of dehydration, electrolyte imbalances, hyperbilirubinemia, and elevations of serum activity of liver-derived enzymes are all secondary to the disease. Urine from horses with grass sickness has higher specific gravity, protein and creatinine concentrations, and lower pH than that from unaffected horses, consistent with dehydration and electrolyte imbalances that occur with the disease. Peritoneal fluid is often abnormal, with an increased protein concentration and leukocyte count but, because of the considerable overlap with values in horses with lesions of the gastrointestinal tract requiring surgery, is of limited diagnostic value.

NECROPSY FINDINGS

In cases of short duration, the stomach and small intestines are distended with an excess of fluid and gas, and the colon is often impacted with corrugated ingesta coated with black material. In chronic cases, the alimentary tract is empty.

Histologically there is extensive degeneration of neurons of the autonomic nervous system without evidence of inflammation. These neurons include those of the ganglia (cranial cervical, stellate, celiacomesenteric, etc.) and those of the myenteric and submucosal plexuses of the intestines. Degenerative neuronal changes may also be observed in the CNS, including the oculomotor, facial, lateral vestibular, hypoglossal, and vagal nuclei; the ventral horns of the spinal cord; and the dorsal root ganglia. This neuropathy is difficult to confirm unless fresh, well-fixed samples are submitted for histologic examination. Immunohistochemical staining for synaptophysin does not aid in the differentiation between autolytic tissue and tissue from horses with grass sickness.[22]

Samples for Postmortem Confirmation of Diagnosis

Samples for light microscopic examination include formalin-fixed sympathetic ganglia, brainstem, spinal cord with dorsal root ganglia, gastric fundus, duodenum, jejunum, distal ileum, ventral colon, and dorsal colon.

DIFFERENTIAL DIAGNOSIS

Differential diagnosis list:

Acute grass sickness

- Small intestinal strangulation or volvulus
  - Esophageal obstruction
- Large colon displacement or torsion
- Anterior enteritis
- Peritonitis

Continued

- Terminal ileal impaction
- Ileocecal intussusception
  - Hemoperitoneum
  - Hypocalcemia (lactation tetany and exhaustion)

Subacute or chronic grass sickness

- Impaction of the large or small colon
- Helminthiasis
- Mesenteric abscessation or other chronic inflammatory disease
- Gastric squamous cell carcinoma
- Botulism
- Equine motor neuron disease
- Alimentary lymphosarcoma or other neoplasia
- Inadequate diet
- Poor dentition
- Equine motor neuron disease

TREATMENT

Acute cases respond transiently to gastric decompression and intravenous fluid administration, but death is inevitable. Selected chronic cases benefit from careful nursing care with provision of high energy, high-protein diet, and access to grazing. Administration of the promotility, indirect acting cholinergic agent, cisapride (0.5–0.8 mg/kg orally every 8 hours for 7 days) has been recommended but is not rewarding.[16] Administration of brotizolam (a putative appetite stimulant), acetylcysteine (antioxidant and neuroprotectant), and aloe vera gel (antioxidant, antiinflammatory, and laxative) was without beneficial effect in 29 cases.

CONTROL

Successful measures have not been satisfactorily established and no definitive recommendation can be made. However, consideration should be given to the factors identified as increasing the risk of disease, such as pasturing and movement to new properties, especially those on which previous cases of this disease have occurred, and the disturbance of soil. Feeding of hay and haylage is associated with a reduced risk of developing the disease. Although administration of ivermectin is associated with an increased risk of the disease, appropriate parasite control should not be ignored in horses in areas in which grass sickness is endemic.

There is no commercially available vaccine, although trials are planned.[7]

INTESTINAL HYPERAMMONEMIA

Intestinal hyperammonemia is a syndrome recently recognized in horses and characterized by abnormally high concentrations of ammonium ion (NH_4^+) in blood combined with signs of neurologic and gastrointestinal disease but in the absence of clinical or clinicopathologic evidence of liver disease.[1-6] The syndrome is associated with gastrointestinal dysfunction that results in increased production of ammonium (NH_4^+), possibly as a result of altered gut microbiota, or increased absorption of ammonia (NH_3) caused by altered mucosal permeability. The disease is not a hepatic encephalopathy in which increased blood ammonium concentrations are secondary to liver disease and reduced clearance of ammonium.

Ammonium is produced in the hind gut by urease-positive bacteria and in the small intestine by a glutaminase located in the enterocytes. Under normal circumstances ammonia is absorbed and transported as ammonium in the blood to the liver, where it is converted to urea or incorporated into amino acids. A decrease in liver function or absorption from the gut of excessive amounts of ammonium can result in hyperammonemia. Increases in blood ammonium concentration adversely affect neuron and astrocyte function leading to depolarization, activation of *N*-methyl-D-aspartate receptors and cell swelling. There is only a poor correlation between blood ammonium concentrations and signs of neurologic disease, although systemic inflammation combined with hyperammonemia results in more severe signs than hyperammonemia alone.[1]

The epidemiology of the syndrome is not well described. The disease is reported in the UK and the eastern and southeastern United States. Equids of any age can be affected including foals less than 1 day of age.[4] Risk factors include gastrointestinal disease (colitis, enterocolitis, colic, and meconium impaction).[4] Case–fatality rate in equids treated at a referral hospital was 60% (22 of 36 cases). Ingestion of black locust roots (*Robinia pseudoacacia*) caused the disease in two ponies.[7] Infection with *C. sordellii* is a suspected cause in adult horses.[8]

The clinical signs include those of colitis, enterocolitis, or colic and can include diarrhea and depressed mentation. Horses are usually tachycardic and tachypneic but not usually pyrexic. Signs of neurologic dysfunction can be present at the initial examination, with signs of gastrointestinal disease, or can develop over the next 24 to 72 hours. Signs of neurologic disease include profound depression, head pressing, ataxia, central blindness, recumbency, personality changes, aggression, abnormal mentation, compulsive walking, circling, lip smacking, and seizures (petite mal or grand mal).[4]

Hyperammonemia (normal is less than ~55 µmol/L) is present and an essential component of the diagnosis. Blood ammonium concentrations are usually over 100 µmol/L and can exceed 1000 µmol/L, although horses with severe systemic inflammation can have signs of neurologic disease with blood ammonium concentrations as low as 60 µmol/L.[4] Affected horses have hematological signs consistent with inflammation (leukocytosis), hypovolemia (increased hematocrit, and serum total protein concentration), and some have mild increases in serum activity of liver-derived enzymes (GGT).[4]

Treatment is largely supportive, including correction of hypovolemia, protection from self-harm, control of seizures, efforts to reduce blood ammonium concentration, and reduction of systemic inflammation. The underlying disease should be treated as appropriate. Reduction of blood ammonium concentration can involve the administration of oral neomycin, lactulose, or both. The efficacy of these treatments has not been determined. Lactulose (~300 mg/kg orally every 8 hours) is used, but the decrement in blood ammonium concentration in affected horses is undetermined and in healthy horses is modest (3 µmol/L).[4] Lactulose is proposed to act by acidifying the colon contents, favoring conversion of the freely absorbable ammonia (NH_3) to ammonium. Activated charcoal or mineral oil can be given to reduce absorption and increase excretion of ingested toxic materials.[7] Sedatives might need to be administered to control abnormal ambulation or behavior.

Abdominal Diseases of the Pig Including Diarrhea

ACUTE GASTRIC DILATATION IN PIGS

This occurs in pigs as a result of excessive intake of finely ground meal (grain) and water resulting in excessive fermentation and gaseous distension. In the pig, simple gastric distension is usually readily relieved by vomiting.

ACUTE GASTRIC VOLVULUS IN SOWS

This is a much more serious problem. It is most common with once-a-day feeding and is caused by the rapid intake of a large quantity of food followed by physical activity. Volvulus is thought to occur because the sow eats a large, sloppy meal very quickly. The occurrence is specifically related to intense excitement and activity at feeding time. Death occurs 6 to 24 hours after the pig's last meal. At necropsy the stomach is enormous (50–60-cm diameter), with engorgement of vessels and hemorrhagic effusion into the stomach, which contains a large amount of gas, fluid, and usually a great deal of food. Rotation varies in degree from 90° to 360° around the mesenteric axis and can occur in both directions but is usually clockwise. The spleen is markedly displaced, the liver is bloodless, and the diaphragm encroaches deeply into the chest. It is easily prevented by twice daily feeding, especially if automatic feeding is implemented.

GASTRIC ULCERS AND HYPERKERATOSIS OF SWINE

Ulcers can occur in the fundic part of the stomach or in the PE (nonglandular part) of the stomach. The former are uncommon and occur usually as part of other diseases such as salmonellosis, *H. rubidus* infestation in sows, or transmissable gastroenteritis, and their significance in pig medicine is as yet not completely understood. The latter are far more important as a cause of economic loss and clinical importance. They are single or multiple bleeding ulcers often associated with varying degrees of hyperkeratosis. Experimental lesions in the stomach are usually produced in the glandular part of the stomach as a model for the condition in humans.

SYNOPSIS

Etiology Fine particles and pelleted feed. Certain bacterial species and other factors contribute.

Epidemiology Highly variable incidence but is increased with greater intensification of swine industry, emphasis on improving digestibility and feed efficiency and use of fine particle and pelleted feed. Growing and finishing pigs, adult sows, and boars

Signs Sudden death from peracute gastric hemorrhage. Subacute form causes anemia, pallor, unthriftiness, and black tarry feces.

Clinical pathology Hemorrhagic anemia

Lesions Hyperkeratosis, erosions, ulcers of pars esophagea, gastric hemorrhage, and anemia

Diagnostic confirmation Lesions at necropsy

Differential diagnosis list

- Proliferative enteritis of swine
- Enteric salmonellosis
- Swine dysentery

Treatment None that is effective

Control Use of diets prepared through hammer mill screen of at least 6 mm. Incorporate S-methylmethionine-sulfonium chloride in diet and reduce stress.

ETIOLOGY

The etiology of ulceration of the PE is multifactorial. Finely ground and pelleted feed are the important causes of ulceration of the PE. Certain environmental stressors may also be contributing factors.

EPIDEMIOLOGY

Occurrence

There may be a genetic susceptibility which may be related to fastness of growth. Ulceration is not mediated by glucocorticoids.

The disease can occur in all ages but it is most common in pigs of 45 to 90 kg BW but may occur in pigs after weaning and in adults. All breeds are susceptible. Prevalence in groups of pigs may vary anywhere in the world from 1% to 90% depending on husbandry practices and feeding regimes.

Examination of the stomachs of pigs at abattoirs in various countries has revealed a high proportion of pigs with varying degrees of hyperkeratosis, erosions, and ulcers of the PE. Extensive erosions of the PE may be present in up to 63% of sows and 36% of finishing pigs. In pigs at slaughter, a range from 4% to 57% has been seen. The ulcers were mild in 9.5% and severe in 13.4% of cases. The incidence is variable between countries, which may reflect differences in feeding or husbandry methods. The disease has assumed increased economic importance with increased intensification of the swine industry.

The feed manufacturing industry is faced with the dilemma of finely ground pelleted feed providing high digestibility and feed efficiency in growing and finishing pigs but with a high incidence of lesions of the PE, which may affect performance. Pelleting swine feed is also advantageous because it flows more easily and effectively in automated distribution systems in swine farms compared with finely ground meal, which may bridge and clog in distribution systems, decrease dustiness and segregation of ingredients, and increase bulk density. Meal is less damaging than pellets.

The incidence of clinical disease is low, but the case–fatality rate is high when severe hemorrhage occurs. The effects of the lesions on performance may vary considerably. In one study, pigs with extensive lesions gained 50 to 75 g/day less than pigs with no lesions but another showed no effects.

The disease has increased in significance with the occurrence of postweaning multisystemic wasting syndrome and PDNS associated with porcine circovirus type 2 (PCV2). There is also an increased occurrence where there is a problem with porcine respiratory disease complex (PRDC) particularly during summer months.

Risk Factors

Many of the risk factors affect the speed of the passage of the ingesta through the stomach whether or not the stomach contains food. Generally, anything that increases the consistency of the stomach contents reduces ulceration and vice versa. For example, finely ground feed decreases the consistency.[1]

Anything that causes an empty stomach will potentially increase the acidity in the PE region of the stomach is a risk factor. Back in the 1960s all that was needed to produce an esophageal ulcer in a pig was to keep the pig restricted in a feeding or farrowing crate and deprive it of water and food for 24 hours. This would therefore include intermittent feeding and watering, respiratory disease, and hot weather.

Dietary Risk Factors

Generally, ulceration is influenced by grain component, milling procedures, and processing. A hammer mill increases the ulceration risk and in this type of milling wheat shatters more than when it is subjected to a rolling meal. The rolling mill squashes rather than shatters the grains; therefore is not so ulcerogenic. A rolling meal producing a diet based on barley or oats is the least ulcerogenic.

The disease occurs primarily in penned pigs receiving a grain diet and growing rapidly. It has also occurred in pigs fed large quantities of cheese whey or skimmed milk. Too much copper and not enough zinc may also be a factor. The incidence is highest in pigs receiving diets containing a higher proportion of corn (maize) than other grains. The incidence is even greater if the corn is finely ground or is gelatinized or expanded.

Finely Ground Feed

This is the most important risk factor. One of the explanations of this may be the rapid emptying of the stomach when fine particles are used as the food in the stomach becomes more fluid and empties more quickly. There is normally a gradation of ascending pH from the cardia to the esophagus, but with

rapid emptying there is the possibility of the low pH reaching the esophageal region.

Feeding a diet based on finely ground barley to pigs beginning at 10 to 11 weeks results in lesions as early as 1 month later, and the incidence and severity of lesions increased progressively over the next 2 months. Diets high in wheat or corn starch may be worse than diets based on barley or oats.

The particle size and the physical form of the feed are important risk factors. The size of particles in feed is significant whatever feed is used. Finely ground diets (particularly wheat and maize) have detrimental effects on the gastric mucosa of finishing pigs. Grinding through a 4.68-mm screen approximates the screen size used most frequently for grinding barley for pigs in practice and is associated with a low incidence of ulcers. Reducing particle size and pelleting improves growth performance of finishing pigs. For every 100 µm of decrease in size of the article size there is an approximately 1.3% increase in gain efficiency but each time the level of ulcers increases. Fine diets have the effect of increasing pepsin levels as do pelleted diets.

A pelleted diet uses grain that is finely ground before it is compressed into a pellet, but on reaching the stomach it reverts back to the fine particles that were compressed into the pellet. A diet finely ground through a 3-mm screen in a hammer mill and then pelleted will be associated with a 75% incidence of pigs with hyperkeratosis of the PE, and 11% of the pigs may have severe erosions and ulceration of the PE. The incidence of lesions decreases when the diet is ground through a 6-mm screen. Even straw (coarsely ground barley straw at 5%–10% of the ration) gives almost complete protection. In growing pigs, dietary fiber rich in structural polysaccharides has been shown to be important in preventing the development of parakeratotic lesions in the PE. An increase in the crude fiber content of a diet that is finely ground does not affect the occurrence of severe erosions and/or ulcers of the PE.

The processes have additive effects on digestibilities of dry matter, nitrogen, and energy, with maximum nutrient digestibility in pelleted diets with corn milled to a particle diameter size of 400 µm. Reducing the particle size to below 400 µm causes practical problems with milling and an increased incidence of gastric lesions, and it is suggested that a particle size of 600 µm, or slightly less, is optimal for corn in either meal or pelleted diets for finishing pigs.

Using endoscopic examination of the stomachs of pigs fed a fine-particle diet (geometric mean size of 578 µm) it was found that as ulcer severity increases, the growth performance of individually fed pig decreases. Feeding a coarse particle diet (geometric mean size of 937 µm) for 3 weeks resulted in a decrease in the severity of the ulcers.

High levels of unsaturated dietary fat are not helpful, especially if they are accompanied by low levels of vitamin E. Similarly, pigs fed waste food had more severe gastric lesions.

Environmental and Management Risk Factors

It has been suggested that confinement, crowding, transportation, changes in environment, and exposure to other pigs are important in the etiopathogenesis of gastric ulcers of pigs. Method of feeding may also be important. Interruption of feeding may also increase dietary stress. All of these are stresses and many others including anxiety, fear, pain, fatigue, fasting, etc., will be associated with an increase of ulcers. There is an even greater occurrence in summer when water demands are higher. Males are always more affected in prevalence and severity, but they may be more easily stressed. One of the most important factors is time in the lairage. Premortem handling is extremely important. Pigs kept overnight in the lairage have more ulcers than pigs killed on the day of arrival.

Larger herds always show more of the problem, and it is probably a reflection of the different diets that they use (based on wheat and pelleted). The larger farms also have more infection pressure, more selection pressure, and more feed-related factors.

Pigs that receive porcine somatotropin may have an increased level of ulcers possibly caused by the elevated circulating gastrin.

There are a variety of foreign bodies reported from the pigs' stomach including stones, which outside sows chew all the time, and also sand. The majority of the stones are probably passed in the feces, but may accumulate in and stretch the stomach. The stomach capacity is normally about 3 to 6 L. This may lead to reduced appetite and gastritis but is not believed to be a contributor to ulceration. Similarly, hairballs are a common finding, reaching 10 to 15 cm in size in the stomach. The occurrence of rubbish indicates pica or a depraved appetite, which is often an indicator of inadequate feeding. One of the other substances found in outdoor pigs stomachs is the flakes of bitumen that remain from clay pigeon shooting, which are toxic.

Pathogen Risk Factors

Gastric Bacteria

Ulcers in the fundic part of the stomach are often associated with gastritis. *Helicobacter heilmannii* and *Gastrospillium suis* (now called *H. suis,*[2] have been found in gastric ulcers, but not ulcers of the PE of pigs and are unlikely to be the primary cause of the lesion. *Helicobacters* and *Arcobacters* are uncommon before weaning and increase with age; thus over 80% of market hogs may be infected [3] and 90% of adults have them in their stomachs. They are capable of causing ulcers in experimental challenges.[4] They have been found in some studies but not in others. They are normally found in the antrum of the stomach in close proximity to the acid-producing cells in the fundus, and the gastritis they produce may be related to parietal cell stimulation which leads to further hyperacidity and then the damage will extend to the PE. They may extend into the PE if there is gastritis. Experimental inoculation of these *Helicobacter* agents in a carbohydrate-enriched liquid diet has failed to produce ulcers of the PE, but inoculation of *Lactobacilli* spp. and *Bacillus* spp. did produce ulcers when they were given in the same substrate. This may all be related to the degree of fermentation produced, the production of short chain fatty acids, and then the acidity generated.

The spiral-shaped *H. suis* has been found in 84% of the stomach of pigs with frank gastric ulcers of the PE. The organisms were mainly in the mucous layer and in gastric foveolae of the antral and oxyntic mucosa and only occasionally in the cardiac-PE region. The presence of the organism is now thought to be associated with lesions of the pyloric mucosa and gastritis in pigs.[2]

H. heilmannii type 1 has been found more frequently in the stomachs of pigs with ulcers (100%) and in those with preulcer lesions (90%) than in stomachs with macroscopically normal PE (35%).

PATHOGENESIS

In pigs, nearly all naturally occurring gastroduodenal ulcers are localized in the PE of the stomach. Excessive gastric acid production, depletion of the gastric buffering system resulting in prolonged activation of pepsinogens, and changes in mucous composition are suggested as important factors related to gastric ulceration in swine. The physical texture of the feed can influence pepsin and acid secretion, and the fluidity of the stomach contents induced by ulcerogenic diets may alter the normal pH gradient within the stomach. This allows greater pepsin and acid contact to the esophagogastric area.

The concentrations of short chain fatty acids are high in the proximal gastric contents of pigs and associated with intakes high in readily fermentable carbohydrates, like ground corn. These products of bacterial metabolism, principally acetate and lactate, reach high concentrations within 4 hours after feeding because of high pH in the proximal gastric contents, which may allow some types of bacteria to proliferate. These weak acids are lipid soluble in their undissociated form and could penetrate and acidify underlying tissue more readily than free hydrogen ions. In this way, rapid production of short chain fatty acids, followed by their absorption and tissue acidification, may be similar to ruminal acidosis and rumenitis in ruminants following the ingestion of large quantities of readily fermentable carbohydrates.

The rumen epithelium, also a stratified squamous mucosa, is easily injured by short chain fatty acids at pH ≤5.0. The breaking of the barrier by short chain fatty acids could result in underlying inflammation and widespread tissue destruction.

Experimentally, exposing undissociated short chain fatty acids to swine gastric mucosa results in rapid penetration of the outer barrier and acidification of the underlying viable tissue. This results in cell swelling and vesicle formation, followed by sloughing of the outer barrier, erosion into deeper zones, and finally, ulceration.

Weak organic acids, at pH ≤2.5, induce a greater degree of functional and histologic injury in three stomach zones (squamous, cardiac, and oxyntic) than does hydrochloric acid. The predilection for the squamous mucosa in naturally occurring ulcers may be attributed to the lack of defense or repair mechanisms that are present in the cardiac and oxyntic mucosa, which are capable of HCO_3^- and mucous secretion, which may raise the pH adjacent to these epithelial layers. Thus the increased digestibility associated with decreased particle size of the diet may promote rapid fermentation following eating resulting in the production of increased concentrations of short chain fatty acids. Any increase in fluid content will also contribute to the changes in pH gradient that exist in the stomach. Excessive gastrin is then stimulated and more acid secretion follows.

Normally, the PE is white, smooth, and glistening and may be bile stained. The first stage in ulceration is hyperkeratosis. This is followed by erosions, ulcerations, and hemorrhage. The erosions may heal, resulting in a fibrous contraction. Chronic ulceration may occur with the development of several ulcers in combination with fibrous tissue involving all of the squamous mucosa. Advanced hyperkeratosis may cause partial stenosis of the terminal esophagus.

The erosion of a blood vessel within the ulcer will result in acute to subacute gastric hemorrhage. These cases are usually sporadic, causing deaths of individuals within a group, with cases occurring over a period of several weeks. Clinical signs are often not observed, and affected pigs are found dead from acute hemorrhage into the stomach.

The regurgitation of bile into the stomach and the intensity of bile staining of esophagogastric tissue have been linked to the pathogenesis of esophagogastric ulcers in pigs. Almost all stomachs of pigs contain bile and bile staining of the PE; there is no evidence for the hypothesis that the regurgitation of bile into the stomach is associated with esophagogastric lesions in finishing pigs. There is no evidence of an association between gastritis and ulcer.

CLINICAL FINDINGS

The clinical signs reflect the rate of blood loss, but an animal can go from perfectly healthy to ulceration within 24 hours. It is therefore possible to have sudden death (hyperacute) acute, subacute, and chronic stages of the condition. Usually there is no fever. Mortality may be in the range of 1% to 2%, but in some cases where there is a group outbreak it may be higher.

Most cases are subclinical but sows will die of blood loss. Pigs frequently die of ulcers during concurrent disease such as respiratory disease and in this case anorexia may disturb the gastric contents and allow material of high acidity to reach the cardia. Similarly, where there is a reduced consumption of water the integrity of the mucus may be broken into plaques or flakes by desiccation of the mucosal surfaces.

Gastric ulceration is most common in pigs over 6 weeks of age and occurs in adult sows and boars; the clinical findings are dependent on the severity of the ulcers. The effects of ulceration on production may be highly variable. Most pigs with esophagogastric ulcers are clinically normal, and growth rate and feed intake appear unaffected. Some observations suggest that there is no effect of ulceration on growth rate, whereas others indicate that the presence of esophagogastric ulcers results in a marked decrease in growth rate and an increase in the length of time required for the pig to reach market weight. Some affected pigs also eat slowly and regurgitate frequently. Endoscopic monitoring of the stomachs of pigs fed ulcerogenic diets found that as the severity of the ulcer increased growth performance was decreased. The greatest economic losses were associated with sudden deaths caused by hemorrhage and marked decreases in performance associated with fine particle size.

The erosion of a blood vessel within the ulcer will result in acute to subacute gastric hemorrhage. These cases are usually sporadic, causing deaths of individuals within a group, with cases occurring over a period of several weeks. Clinical signs are often not observed, and affected pigs are found dead from acute hemorrhage into the stomach. When pigs are found dead from peracute hemorrhage, inspection of the in-contact pigs may reveal other animals with pallor and black tarry feces (melena), which represent those with subacute hemorrhage.

Cases with subacute gastric hemorrhage may survive for a few days and there is evidence of marked pallor, weakness, anorexia, and black pasty feces changing to mucous-covered pellets in small amounts. The weakness may be sufficient to cause recumbency. Vomiting frothy bile-stained fluid and grinding of the teeth may occur. Abdominal pain may be elicited by deep palpation over the xiphisternum and there may be a reluctance to walk along with a rigid back indicative of pain. Animals that survive are often unthrifty, which is usually caused by anemia from chronic blood loss, and a few cases are affected by chronic peritonitis. When the disease is occurring careful observation may detect early cases. Suggestive signs are a darkening of the feces and the development of pallor. Sows at parturition are also at risk. In cull sow surveys 60% may have stomach lesions and 10% to 15% may have ulcers. It is a common cause of sow mortality or the most common cause. Many sows have scars that indicate previous healed ulcers.

CLINICAL PATHOLOGY

Laboratory testing is not indicated. Animals with gastric ulceration generally have lower than normal hematocrit values, hemoglobin concentrations, and erythrocyte counts. The black tarry feces can be examined for the presence of blood.

NECROPSY FINDINGS

At postmortem animals are usually in very good condition. Ascarids have been found in the stomach, but these are not a factor in the field. If bleeding has been extensive then the carcass may be very pale.

At necropsy, the ulcers are confined to the esophageal region of the stomach, although hyperkeratosis may block the exit from the esophagus and cause increase in the muscular layers of that organ to force through the cardia. In this case pigs often vomit and then start eating again immediately as they have voided the food. Affected stomachs consistently have more fluid contents than unaffected ones. If severe blood loss from the ulcer has been the cause of death, then the carcass is pale and fresh blood is usually present in the stomach (there may be large blood clots) and intestines. The colonic contents may also appear melenic. Early lesions in clinically unaffected animals include hyperkeratinization of the mucosa (usually pale raised areas without bile staining initially), which progresses to epithelial erosion without actual ulceration. Ulcers usually initially occur along the junction of the PE with the glandular stomach but may enlarge to efface the entire squamous portion of the stomach. These more diffuse ulcers are easily missed on cursory examination because of their uniform appearance. Chronic gastric ulcers develop thickened, raised edges caused by ongoing fibrosis, occasionally resulting in a gastroesophageal stricture. The histologic appearance varies with the stage of lesion development, but in fatalities there is typically complete loss of the epithelial layer, with exudation of neutrophils from a bed of mature granulation tissue. In one survey of apparently normal stomachs it was found that 32% had histologic parakeratosis, 38% had mild erosions, and 23% had severe ulcerations. Recent studies have demonstrated *Helicobacter*-like bacteria in porcine stomachs, but further research is required to determine whether this infection plays a significant role in ulcer formation. Small clusters of *H. heilmannii* have been seen in the gastric crypts, but they are not associated with histologic changes. A recent survey suggested no correlation between infection in the cardiac mucosa and the severity of the lesions shown by the esophagogastric region. The macroscopic findings are usually sufficient for the confirmation of a diagnosis

of esophagogastric ulceration. The initial lesion of hyperkeratosis (often stained green by bile) leads to parakeratosis with fissures and the lamina propria is then exposed. The epithelium sloughs off and then ulcers of the epithelium develop with hemorrhage from the vessels. Chronic lesions may be seen as craters floored by smooth muscle. Histologically, the lesions are thickened, with parakeratosis, and there are nucleated cells on the mucosal surface, the papillae are elongated, and there are infiltrations of neutrophils and eosinophils. Usually only the mucosa is ulcerated, but occasionally the submucosa is affected and then the muscularis and very rarely the serosa.

Severity and extent of esophagogastric lesions can be graded according to the following scheme

0 Intact epithelium

1 Small degree of hyperkeratosis (<50% of total surface)

2 Distinct hyperkeratosis (=50% of the total surface)

3 Hyperkeratosis and less than five erosions smaller than 2.5 cm in size

4 Hyperkeratosis and more than five erosions or erosions larger than 2.5 cm in size

5 Hyperkeratosis and more than 10 erosions or erosions larger than 5 cm in size, and/or an ulcer (with or without bleeding) or stenosis of the esophagus toward the stomach

No difference in lesion score was found between Duroc, Landrace, and Iberian pigs.

DIFFERENTIAL DIAGNOSIS

The occurrence of sudden death with a carcass that shows extreme pallor and marble white skin suggests the possibility of peracute hemorrhage from an esophagogastric ulcer. The disease must be differentiated at necropsy from proliferative hemorrhagic enteropathy, swine dysentery, and salmonellosis. Black tarry feces in growing and finishing pigs are characteristically caused by subacute hemorrhage associated with esophagogastric ulceration. There may be anemia and raised plasma pepsinogen levels.

It is possible to detect stomachs with helicobacters by covering the stomach with urea gel containing an indicator sensitive to pH change. If there are large numbers of these urease-positive bacteria then the pH changes.

Severe infestation with whipworms is a differential. The clinical diagnosis can be confirmed by endoscopy, which requires an empty stomach (may cause ulceration in itself) and anesthesia.

TREATMENT

In extremely valuable animals blood transfusions and intravenous fluid injections have been used. Ranitidine syrup at 300 mg per sow per day has been tried. Vitamin K and hematinics have been tried with little success. Bovine serum concentrate given as a 1% solution is supposed to have reduced the extent and severity of signs associated with ulcers in growing pigs, but generally medication does not help. If a diagnosis is made euthanasia is advised.

CONTROL

Attention to social factors such as overcrowding, proper ventilation, slowing growth rate, and reducing stress is important. Administration of melatonin at 5 ppm (5 mg/kg feed) has been used. Methionine has been used but is not really proven as a treatment.

Control of esophagogastric lesions of growing and finishing pigs is dependent on using diets with a particle size and physical form that will provide the most economical performance in terms of digestibility and feed efficiency and minimize the incidence of lesions. A diet based on barley and oats may be more beneficial than one based on wheat or maize. Meal may be better than pellets. Increasing fiber levels is important (oats and sugarbeet pulp). The use of a diet ground through a 6-mm screen instead of 3-mm screen using a roller rather than a hammer mill is recommended. However, screen size is not the only factor affecting particle size. Other factors include the condition of the screen and hammer, the type and variety of grain and its moisture content, the speed of the mill, the 3-week pelleting process, and the flow rate in the distribution of the feed to the pigs. A particle size of 600 µm, or slightly less, is suggested as optimal for corn in either meal or pelleted diets for finishing pigs. Increasing the particle size to 750 µm, using meal instead of pellets for 3 weeks, and using straw as bedding have been shown to produce improvements when an outbreak occurs.

The incorporation of *S*-methylmethionine sulfonium chloride often sold as vitamin U, a nutritional component of many vegetables such as cabbage and carrots, has antigastric ulcer properties. Addition to the diet of this substance, ground through a 3-mm screen, and fed to grower pigs from 45 kg to 107 kg live weight, at 400 parts per million (ppm) decreased the incidence of severe erosions or ulcers by about 50%. The addition of lucerne meal to increase the crude fiber content of one of the experimental diets did not have an effect on the incidence or severity of the lesions. Others have reported the beneficial effects of alfalfa (high in the antioxidants vitamins E and K), but not when somatotropin was used and it produced ulcers. Sunflower hulls in the diet have also been used to reduce the speed of feed transition from the stomach.

Incorporation of zinc in the diet may help. The diet should contain adequate amounts of vitamin E and selenium. The reduction of environmental and managemental stressors with attention to stocking rates may be of value.

Noninfectious Intestinal Disease of Swine

INTESTINAL REFLUX

Acute dilatation also occurs in pigs secondary to acute obstruction of the small intestine. The obstruction may be as far down as the ileocecal valve. The oral segment of intestine dilates and fills with fluid, and refluxes into the stomach, filling it. In the pig, vomiting follows. The outcome depends on whether sufficient gastric motility returns to evacuate the stomach.

DIAGNOSIS

The vomiting in gastric dilatation is more profuse and projectile than that of gastritis or enteritis, but may be simulated by that of obstruction of the upper part of the small intestine.

INTESTINAL OBSTRUCTION IN PIGS

ETIOLOGY

Some causes of intestinal obstruction include the following:

- Torsion of the coiled colon about its mesentery occurs in adult pigs.
- Obstruction of the terminal small colon in young piglets causes very hard fecal balls, or barley chaff used as bedding may be implicated in obstruction. The use of wood shavings or peat as a bedding may cause piglets to become impacted as a result of large consumption of the material.
- Heavy feeding on lactose causes a dilatation and atony of the intestine in the same way as grain feeding does in ruminants.

Sometimes the presence of ascarid worms will block the intestine. Genetic and environmental factors may contribute to the incarceration of the intestine in a patent umbilicus.

CLINICAL FINDINGS

In pigs, distension of the abdomen, absence of feces, and complete anorexia are evident. The distension may be extreme in young pigs when the terminal colon is obstructed. Death usually occurs in 3 to 6 days.

IMPACTION OF THE LARGE INTESTINE OF PIGS

ETIOLOGY

- In pigs, impaction of the colon and rectum occurs sporadically, usually in adult sows that get little exercise and are fed wholly on grain. The disease also occurs in pigs that are overcrowded in sandy or gravelly outdoor yards.
- In young weaned pigs there may be obstruction of the spiral colon.
- A presumed inherited megacolon of fattening pigs is reported as a cause of abdominal distension, constipation, and wasting. There is no anal stricture.

Torsion of the long axis of the mesentery is a common condition in pigs and leads to impaction and rapid death. It can involve the small intestine or the large intestine, or both.

CLINICAL FINDINGS

In impaction of the large intestine the effects appear to be caused largely by autointoxication, although the commonly occurring posterior paresis seems more likely to be caused by pressure from inspissated fecal material.

Retention of the meconium has no specific signs. There is anorexia and dullness and the pig is recumbent much of the time. Feces passed are scanty, very hard, and covered with mucus. Weakness to the point of inability to rise occurs in some cases. Hard balls of feces in the rectum are usually detected when a thermometer is inserted.

In paralysis of the rectum there is inability to defecate and usually some straining. The anus and rectum are ballooned and manual removal of the feces does not result in contraction of the rectum. Spontaneous recovery usually occurs 3 to 4 days after parturition.

INTESTINAL TYMPANY IN PIGS

This is usually an incidental finding at slaughter.

ETIOLOGY

- Primary tympany occurs with ingestion of excess whey. It has been recorded in adult dry sows. Distension of the proximal colon causes rupture with death from endotoxic shock.
- Secondary large bowel tympany is usually secondary to acute intestinal obstruction.

OSSEUS METAPLASIA

The finding of metastatic plates of bone in the mesentery or wall of the small intestine is not an uncommon occurrence and probably results from an attempt to repair local damage by calcification. It does not seem to cause problems and is found at slaughter.

INTESTINAL HEMORRHAGE SYNDROME

This is a sporadic occurrence but occasionally may involve all the finishing pigs in one batch, causing a significant economic loss through sudden death or enforced casualty slaughter. It has had a variety of other names including hemorrhagic bowel syndrome, porcine intestinal distension syndrome, "bloody gut," or "whey bloat." It is similar to intestinal distension. Large pigs are affected usually from 35 kg to adults. They become pale, have a distended abdomen, and die suddenly.

ETIOLOGY

The cause is raised intraabdominal pressure from +3.5 mm Hg or −15 mm to >30 mm Hg.[1] The most pronounced cause is whey bloat, in which where there is excess fermentation of carbohydrate in the large intestine. This causes an anticlockwise torsion of the whole of the intestines so that the cecum is directed cranially. A twist of the mesentery does not usually involve the large intestine. Other possible etiologic factors include allergy because there are large numbers of eosinophils in the gut wall, skim milk not whey and dry meal, and Lawsonia infections.

EPIDEMIOLOGY

On whey-fed units the deaths occur more frequently because the level of whey feeding increases.

CLINICAL SIGNS

The pigs are usually found dead or have abdominal colic. They occasionally appear pallid. There may be a distended abdomen.

PATHOLOGY

The small intestine is almost always autolytic, but there is an underlying loss of epithelium, villous loss, and inflammatory cell infiltration with large numbers of clostridia in the gut. The small intestine is filled with blood-stained fluid and there may be volvulus with gross distension of the colon and blood-stained fluid in the abdomen.

TREATMENT

Usually there is no time for treatment.

CONTROL

The only possible control is to change the diet, particularly to reduce the whey concentrations, but be aware that this may reduce the growth rate and the diet needs to be adjusted to compensate.

DIVERTICULITIS AND ILEITIS OF PIGS

In this disease there is thickening of the wall of the ileum, particularly in the terminal portion, so that the intestine becomes thick and rigid. There is a close clinical similarity to Crohn's disease in humans, and the etiology of both conditions is obscure. Familial predisposition is probable in humans and has been suggested in pigs.

The signs are those of acute peritonitis caused by ulceration and, sometimes, perforation of the affected ileum. Illness occurs suddenly with loss of appetite, excessive thirst, dullness, and disinclination to rise. The temperature is subnormal, the respiration is distressed, and there is a bluish discoloration of the skin. Death occurs in 24 to 36 hours. Acute cases occur in young pigs up to 3 months of age, and chronic cases, caused by ulceration and chronic peritonitis, occur in the 7- to 8-month age group.

At necropsy there may be diffuse peritonitis caused by leakage of alimentary tract contents through perforating ileal ulcers. Gross thickening of the ileal wall with nodular proliferation of the ileal mucosa and enlargement of the mesenteric lymph nodes are common accompaniments. Although the macroscopic findings are similar to those of Crohn's disease in man, the histopathological findings differ markedly. There is an obvious and significant protein loss through the intestinal lesion and a marked hypoproteinemia.

RECTAL PROLAPSE

Prolapse of the rectum is an occasional occurrence in cattle and is rarely seen in other species. Common causes include enteritis with profuse diarrhea, violent straining such as occurs in coccidiosis in young cattle, in rabies sometimes, in spinal cord abscess, and also when the pelvic organs are engorged.

RECTAL PROLAPSE IN PIGS

Rectal prolapse is quite a common condition in pigs. It is a welfare issue often requiring casualty slaughter.

ETIOLOGY

It seems likely that any event producing an increase in intraabdominal pressure to an average of 29 mm Hg may cause prolapse. Such a happening occurs when sows are tethered and strain against the tethers while sitting.

EPIDEMIOLOGY

In a prospective study of rectal prolapse in a commercial swine herd, 1% of the pigs prolapsed between 12 and 28 weeks of age, with a peak incidence occurring at 14 to16 weeks of age. Prolapse rates were highest during the winter and autumn months.

Other risk factors included:

- Male: Relative risk 2.3
- Birth weight less than 1000 g: Relative risk 3.4
- A particular Yorkshire boar: Relative risk 2.8

- Dams of litter number: 1, relative risk 14.9; 2, relative risk 8.2; 3, relative risk 9.8

There was no evidence to support the hypothesis that diarrhea and coughing are factors associated with a risk of prolapse.

It has been suggested that low birth weight pigs may be particularly susceptible in that they have poor pelvic muscle development, which leaves a weakness at the point in the pelvis where perineal hernia is possible, and there is no firm ligamentous attachment of the rectum to the pelvic wall. In the same context excessive anal nuzzling in very young pigs has been suggested as weakening these intrapelvic structures.

Feeding rations with lysine concentrations in excess of the requirements is considered a risk factor for rectal prolapse in swine. Other practitioners have suggested that it occurs when pigs are transported at high stocking densities. It may follow impaction of phosphate crystals in the urethra. Administration of tylosin and lincomycin has also been suggested as a cause, but these effects disappear after 72 hours of treatment.

The use of estrogens as a growth stimulant and access to estrogenic fungal toxins (zearalenone) predispose to rectal prolapse. It has been suggested that mycotoxins in swine rations are a cause of rectal prolapse, but there is insufficient evidence to prove such a claim.

CLINICAL FINDINGS

There is severe abdominal distension, which may be accompanied by coughing and the production of soft feces. Straining may or may not be present. The prolapse may reduce naturally. It may become strangulated, necrotic, drop off, or be bitten off by other pigs.

PATHOLOGY

There may be severe loss of blood and peritonitis.

TREATMENT

Mild cases should be hospitalized individually and severe cases euthanized immediately. Treatment is surgical by reduction under anesthesia.

CONTROL

One possible control is to place weaners in a straw yard for 3 weeks between rearing in a cage system and transferring to slatted floors.

RECTAL STRICTURE

The most common occurrence is as an acquired condition in pigs simply called rectal stricture. Rectal stricture occurs in feeder pigs of 2 to 3 months of age. Rectovaginal constriction occurs as an inherited defect in Jersey cattle.

ETIOLOGY

The cause of rectal structure is unknown, but there a number of associations. A strong genetic component suggests it may be a developmental weakness in the structure of the rectum, which facilitates nonhealing at that particular point just proximal to the anal ring. This may be the inherited component. This point has a poor collateral blood supply as it is the point where the rectum is supplied from the caudal hemorrhoidal artery rostrally (caudal mesenteric originally) and caudally from the perineal arteries from the internal pudendal artery originally from within the pelvis.

EPIDEMIOLOGY

- It may be a sequel to enteric salmonellosis, particularly *S. enterica Typhimurium* or possibly other infections such as *Candida, Selenomonas, Chlamydia, or Lawsonia,* but these may move in after the problem and not be an etiologic factor.
- It may develop from a prolapse.
- It may follow the use of tylosin.
- Quite often it follows 10 days after dietary change.

PATHOGENESIS

The presumed pathogenesis is that a prolonged enterocolitis with ulcerative proctitis results in an annular cicatrization of the rectal wall 2 to 5 cm anterior to the anorectal junction. This results in colonic dilatation and compression atrophy of the abdominal and thoracic viscera. The disease can be reproduced experimentally with *S. Typhimurium* or the surgical manipulation of the rectal arterial blood supply, resulting in ischemic ulcerative proctitis.

CLINICAL SIGNS

In a particular group it may affect up to 10% of the feeder pigs. The pigs are dull, depressed, and fail to grow. There is progressive abdominal distension, inappetence, emaciation, dehydration, and watery to pasty feces. The stricture of the rectum can be palpated on digital examination of the rectum. Some pigs with incomplete strictures are unaffected clinically.

PATHOLOGY

At necropsy there is a low-grade peritonitis and gross dilatation of the colon, and sometimes the terminal ileum also. A stricture is present 2 to 5 cm from the anus, and may be so severe that it exists as a scirrhous cord with or without a narrow luminal remnant in the center. There may be abscessation at the site. Histologically, there is necrotic debris and granulation tissue at the site of the stricture.

TREATMENT

Most affected pigs die or are destroyed on humane grounds. Surgical treatment of the condition is described but it is rarely cost-effective.

Bacterial and Viral Diseases of the Alimentary Tract

SALMONELLOSIS IN SWINE (PARATYPHOID)

Salmonella infections of pigs are important as a cause of salmonellosis in pigs and many serotypes in the pig may act as a potential source of infection for humans.

SYNOPSIS

Etiology *Salmonella* Typhimurium, *Salmonella* Choleraesuis, *S.* Derby, and rarely others.

Epidemiology Worldwide. Important zoonosis and food-borne illness. Prevalence of infection in healthy animals varies according to species and country. Incidence of clinical disease much lower than prevalence; outbreaks occur precipitated by stressors. Spread by direct or indirect means; infected animal is source and this contaminates feed and water supplies.

Disease may become endemic on farm. Carrier animals shed the organism and may introduce infection into herd. Deprivation of feed and water, transportation, drought, intensive grazing and housing, and mixing animals from different sources contribute to the onset of disease. Antimicrobial resistance is a major public health problem with subclinical infection in pigs a potential zoonosis.

Signs Septicemia in pigs up to 4 months of age with high case–fatality rate. Acute diarrhea and dysentery, fibrinous fecal casts, fever, marked dehydration, and toxemia; chronic enteritis; abortion; dry gangrene of extremities; and arthritis and foci of osteomyelitis

Clinical pathology Culture organism from feces. Detect organism with special tests; use hematology for changes in leukocyte picture and clinical chemistry for electrolyte changes.

Lesions Septicemic hemorrhages Mucoenteritis to marked fibrinohemorrhagic necrotic enteritis and enlarged mesenteric lymph nodes. Kidney petechiation, foci of necrosis and thickened intestinal wall in chronic enteritis. Culture organism from blood, spleen, liver, and lymph nodes.

Differential diagnosis list

- Septicemia of neonates
- Coliform septicemia in piglets
- Septicemia in growing pigs
- Hog cholera
- Erysipelas
- Pasteurellosis
- Swine dysentery

Treatment Antimicrobials

Control Prevent introduction of infection into herd. Limit spread of infection within herd by identification of carrier animals,

prophylactic antimicrobials, restricting movement of animals, clean water supply, hygiene, and disinfection of buildings. Dispose of infective materials. Vaccines for immunization are available but not effective.

ETIOLOGY

Serovars of *S. enterica* subsp. I are associated mainly with warm-blooded vertebrates and are responsible for most *Salmonella* infections in humans and domesticated animals. *Salmonella* serovars differ in the range of hosts they can infect and in the nature of disease that may result: this difference is referred to as **serovar–host specificity**. Some *Salmonella* serovars, for example, Typhimurium (STM) and Enteritidis, can infect a wide range of hosts and are termed ubiquitous. They are usually associated with a relatively mild enteric disease, although in some hosts, such as mice, the disease can be systemic and severe.

Other serovars are very restricted in their host range, causing severe systemic disease in only one host, for example, *S.* Choleraesuis (SCS).

A third group of serovars is associated predominantly with disease in one species but may also infect a limited number of other hosts for example, *S.* Dublin (SD). The nature of disease associated with this third group of serovars is variable and usually systemic.

The molecular methods are now available for epidemiologic investigation of *S. enterica* subsp. *enterica* infections. Of recent concern is the emergence of multiple-resistance isolates of SCS and also STM.[1] STM is the most common isolate from pigs in North America[2] and most other parts of the world. Occasionally, other species are found in pigs such as *S.* Heidelberg, which may be associated with PWD, and SD has also been found in pigs.

Localized epidemics of *S.* Typhisuis also occur, and recently it has been shown that it can exist on antibiotics alone.[3] Other serotypes are usually transient and may be associated with special factors. Salmonellas have been recovered from wild boar in Portugal, Spain, and Northern Italy, and STM is one of the serovars recovered.

EPIDEMIOLOGY

Salmonellas are marvelous at surviving because they have the ability to persist in reservoir hosts, have the ability to be shed from carriers, persist within the environment, and use transmission vectors effectively.

Salmonellosis outbreaks are usually in intensively reared weaned pigs, but infection can also be in neonates (protected by colostral antibodies) and adults.

In a survey of *Salmonella* in slurry tanks, in fresh pooled feces from finishers, sows, and weaners it was found that Salmonellas were not so easy to recover in winter and more likely to be recovered from slurry tanks than fresh pooled samples. The four most common types were STM var Copenhagen (31%), SD (12.4%), STM (10.6%), and *S.* Agona (10.6%).[4]

In an interesting study of environmental samples, it was found that certain areas in the indirect environment (compartment aisles, driving boards, central aisle of the barn—areas which are often forgotten) had residual *Salmonella.*[5]

In a study in Germany, it was found that the main risk factors for the spread of salmonellosis were the moving of animals during the finishing period, not having a separate transporter for different age groups of pigs, and pigs having contact with other animals.[6]

In the United States, a study was made of *Salmonella* isolates in 2003 and 2008 from the Iowa State University diagnostic Laboratory.[7] Group C, SCS var. Kunzendorf decreased but Group B strains increased, *S.* Typhimurium var 5 (formerly, Copenhagen), *S.* Agona, *S.* Derby, *S.* Heidelberg, and STM all increased.

Prevalence and Occurrence of Infection

The majority of *Salmonella* infections are subclinical, associated with a large number of serotypes. Factors influencing the prevalence of *Salmonella* spp. in swine farms using a meta-analysis approach have been described in an attempt to explain the variation between various estimates.[8] STM has a worldwide distribution and causes enterocolitis in young pigs.

The incidence has been increasing in some geographic areas. It is usually manifested as a septicemia. On the other hand, there is difficulty in isolating this organism at all in the UK. SCS is frequently isolated from clinically ill pigs but rarely from pig feeds or nonporcine hosts. The major sources are shedding pigs and contaminated environments. Both vertical and horizontal transmissions occur. The presence of other Enterobacteriaceae and the composition of these were not found to be useful indicators of subclinical *Salmonella* infections.[9]

Belgium

In a study in Belgium[10] 7.8% of the pigs were seropositive (12 farms). Open farms (buying in) had twice as many seropositive pigs as closed farms. The results were also twice as high at slaughter age than halfway through finishing. STM was found in 65% of the cases, and 65% of these had a tetra-resistant antimicrobial resistance (AMR) profile.

Canada

In Canada a study of *Salmonella* serovars found that sows had 43% of the isolates, 29% were in the nursery pigs, and 28% were in grow-finish units. There were 19 different serovars and SD (28.5%) and STM var Copenhagen (19.15) were the most common.[11] In a study of approximately 90 Alberta finishing farms it was found that the sample prevalence was 13.2% (most farms were below 20% seroprevalence) and the on-farm prevalence was 83.3%.[12] In addition, the status changed frequently over the visits. Meal feeding and antibiotics given in water were associated with lower seroprevalence.

Czechoslovakia

In Czechoslovakia, STM dominates in pigs but *S.* Enteritidis (SE) is also quite frequent because it is in several countries in Central Europe.[13] SE colonizes the intestinal tract in higher quantities but was shed in the feces in lower quantities.

Denmark

In Danish pig herds, *Salmonella* infections are usually subclinical. A survey from 1993 to 1994 found that 22% of 1368 larger herds were infected with *Salmonella.* The most prevalent serotypes were STM (62% of infected herds), *S.* Infantis (10%), *Salmonella* 4.12:b (8%), and *S.* Panama (5%). Phage typing of isolates of STM from pigs and humans reveals that pigs are probably a major source of the infection in humans in Denmark. A more recent survey in Denmark showed that STM (mostly DT12 and DT120) was most common in finishers (7.4% + ve in lymph nodes and 3.2% + ve in carcasses) and SD in breeding herds (40.9% were + ve in at least one sample). An AMR to one or more antibiotics was found in 35.2% and to four or more in 19.3%.[14] The prevalence of *Salmonella* in Danish pork decreased from 3.5% in 1993 to 0.7% in 2000 following the introduction of a national program to reduce the prevalence of salmonellas in pork.

In Danish pig abattoirs it was found that by keeping the number of seropositive pigs below 50 it was possible to keep carcass prevalence below 1%, and that improved hygiene practice would reduce the carcass contamination further.[15]

Italy

A similar distribution was found in Italy.[16]

Japan

SCS is also an important pathogen of pigs in Japan.[17]

The Netherlands

In the Netherlands, the infection rate is 25% in healthy pigs at abattoirs, but similar investigations elsewhere record a 10% (New Zealand) and 6% (UK) infection rate.

The serotype and phage-type distribution of *Salmonella* strains isolated from pigs, in the Netherlands from 1984 to 2001, showed that in pig serovars Typhimurium and Dublin were the most common. Monitoring of the population and herd for *Salmonella* seroprevalence in finishing pigs and sows provided a baseline for the success of future intervention and control strategies for *Salmonella* in pork. The seroprevalence of *Salmonella* in sows and finishing pigs in the Netherlands

was determined using indirect ELISAs on blood samples collected at the abattoirs. The population prevalence for finishing pigs in 1996 and 1999 was 23.7% and 24.5%, respectively, and for sows 40.5% and 60.4%, respectively. The prevalence in free-ranging finishing pigs was higher, at 44.6%, than in intensively housed finishing pigs. In 46 multiplying sow herds, the average herd prevalences were 54, 44, and 19%, respectively.

Spain

In Spain, it was found that swine farms are a reservoir of *Salmonella* serovars, particularly STM and also Rissen and Derby.[18] A study in Spain of free-range pigs[19] showed that 33% of the herds had *Salmonella,* and the prevalence was 3.3% and *S.* Anatum and STM were the most commonly isolated.

Sweden

In Sweden the prevalence of salmonellosis in food-producing animals is low because of the *Salmonella* control programs.

Switzerland

In Switzerland, there is a low rate of positivity for *Salmonella* in meat juice ELISA from diaphragm samples (4%).[20]

Thailand

In a study in Thailand[21] it was found that there was fecal prevalence of 63% and a seroprevalence of 72%, and the results were not significantly different. *S.* Rissen was found in 49% and STM in 19% of farms.

United Kingdom

In the UK advisory visits were made to farms with *Salmonella*; 15,790 samples were collected from 296 farms and *Salmonella* was isolated from 28% of the samples. STM accounted for 64% of the samples (phage types U288 and DT193) and SD for 16%.[22]

Salmonella infections (seropositive pigs) on farrow to finish farms decreased from 21 to 65 days and then increased from 65 to 165 days of age.[23] A study in the UK[24] has shown that between 1994 and 2010 the number of *Salmonella* cases has greatly decreased (360–172) and STM has been the most common over the period, although the relative proportions have decreased. Today most cases are DT193 or U288. The numbers of DT104 are much reduced and now are less than 5%. The percentage of monophasic STM has increased over the period and now reaches 25%. The percentage showing AMR to six or more antibiotics has increased from 27.3% in 1994 to 58.3% in 2010. Only 3.3% were fully sensitive to all antibiotics in 2010.

United States

American figures indicate a 10% to 13% infection rate. Salmonellas were isolated from the mesenteric lymph nodes and cecal contents of 84% of slaughtered sows in a Minnesota abattoir. These data are based on abattoir material and should be viewed with caution because of the very rapid increase in infection rate that occurs when animals are held over in yards for several days.

The cecal carriage rate was 23.0%, although carcasses were only moderately contaminated at 5.3%. The meat juice ELISA results indicated that 15.2% of tissue fluid samples were positive at the 40% cutoff level and 35.7% at the 10% experimental cutoff level. This indicates that pigs are exposed to a relatively high level of *Salmonella* during the weeks before slaughter. A national U.S. survey for fecal *Salmonella* shedding by pigs most frequently found *S. enterica* serotypes Derby, Agona, Typhimurium, Brandenburg, Mbendaka, and Heidelberg. STM is most commonly isolated from clinically ill pigs in the United States.[25] In the Midwestern United States, salmonellosis associated with the host-adapted facultative intracellular SCS is an important cause of economic loss in pig herds because of death and reduced productivity. It is the most frequent serotype recovered from pigs and is isolated from more than 95% of porcine salmonellosis outbreaks in Iowa. In a study from the United States, it was found that *Salmonella* increased from the first to the second pull by 9.2% in bacteriologic prevalence and 31.3% in serologic prevalence.[26]

Morbidity and Case–Fatality Rate

The morbidity rate in outbreaks of salmonellosis in pigs is usually high, often reaching 50% or more. The case–fatality rate in septicemia cases can be 100%.

Methods of Transmission and Sources of Infection

Salmonellas are spread by direct or indirect means. Infected animals are the source of the organisms; they excrete them and infect other animals, directly or indirectly, by contamination of the environment, primarily feed, and water supplies. The farm animal may be infected in different ways: by animal-to-animal transmission, especially of host-adapted serovars; by contaminated animal feed; and by a contaminated environment (soil, birds, rodents, insects, and water supplies). In most cases transmission is over short distances, i.e., within the same pen or room, with some transmission between rooms and buildings on the same site but with limited transmission between sites.[27] Usually infection spreads from pen to pen, but it may be over some distances caused by fomites or vectors. Transmission of *Salmonella* between swine farms by the housefly has been shown.[28] Liquid wastes from infected animals may contaminate the environment directly. Bacteria may also be disseminated during the transport of infected animals and during the holding of animals in a lairage before slaughter. In both situations, the excretion of salmonellas is exacerbated by the stress imposed.

When all animals become ill at the same time it is likely that a common source is involved such as water, feed, bedding, or contamination from one source. It is always higher in continuous flow systems in which there is no all-in/all-out systems with cleaning and disinfection. Slatted floors are much better than simple drainage gutters.

Salmonellas can be isolated from piggery wastewater, and the recirculation of contaminated water through the piggery serves as a constant source of the organism. Housing of finishing-age pigs in barns with open-flush gutters may contribute to increased shedding of *Salmonella* compared with pigs housed on partially slotted floors. Methanogenic fermentation in waste ponds does not eliminate *Salmonella* from piggery waste; acidogenic fermentation with the production of free acid can destroy salmonellas and other potential pathogens.

During slaughter, fecal contamination of the carcass commonly occurs and can be carried through all slaughter procedures up to the processing of the raw products. Airborne transmission can be a primary mode of infection of STM. Studies have shown that the organism can survive in air long enough to present a significant hazard of airborne spread.

In a study in Germany of 50 finishing herds with *Campylobacter* spp., *Yersinia enterocolitica* (YE), and *S. enterica,*[29] the sampling of feces, the direct environment, indirect environment, and flies and pests revealed the information shown in Table 7-23.

Respectively, for the three groups, 22 herds (80%), 12 herds (48%), and 7 herds (12%) were positive for both *Campylobacter* and YE, for both *Campylobacter* and *S. enterica,* and for both *Y. enterocolitica* and *S. enterica,* respectively. *Campylobacter* and YE were found more often in the low S risk group.

This study provided evidence that the pigs' environment should be studied when implementing control studies.

Shedding and the Carrier State

In experimental infections with SD it was found that all pigs shed bacteria constantly for 2 weeks and then intermittently for several weeks.[30] Pigs given a high dose of

Table 7-23 Proportion of samples testing positive for one of the listed organisms

	Fecal	Direct environment	Indirect environment	Flies/pests
Campylobacter	38.1%	32.7	5.3	4.6
Yersinia enterocolitica	17.1	8.1	1.2	3.1
Salmonella enterica	11.2	7.1	4.1	1.5

bacteria also seroconverted, whereas those given a low dose did not. Shedding was reduced when pigs were given oral sodium chlorate, topical disinfection, and weaned younger.[31] Sows are more likely to be shedding virus than nursery or grow-finishers.[11] The shedding can be increased by a long list of stressors including mixing of groups, transport, concurrent disease, antibiotic therapy, and food deprivation.

A longitudinal study of *Salmonella* shedding in naturally infected finishing pigs has been studied, and it was discovered that most pigs shed intermittently and there are differences in pigs and within the cohorts.[32] Feeding egg yolk containing anti-*Salmonella* immunoglobulin Y may not be effective in controlling shedding of *Salmonella* in pigs.[33] In many ways shedding is more of a problem for contamination of the food chain for humans than a source of infection for other pigs. Pigs carry low numbers of *Salmonella*, but excretion will occur when there is overcrowding, and isolation for 24 hours will cause excretion. Feed withdrawal increases cortisone production and encourages shedding.

Because salmonellas are facultative intracellular organisms that survive in the phagolysosome of macrophages, they can evade the bactericidal effects of antibody and complement. Thus persistence of infection in animals and in the environment is an important epidemiologic feature of salmonellosis.

For STM the donor can be any domestic animal species, including humans, or any wild animal or bird. Although all infected adults become carriers, it is rarely for any length of time.

The carrier pig is a source of infection in the lairage at the abattoir, especially in the absence of cleaning and disinfection. STM was the most common serotype. At the start of the week following cleaning and disinfection 6% of the swabs were positive, but by the end of the week 44% were positive.[34]

Experimental infection of pigs at 7 to 8 weeks of age with a single oral dose of STM can persist continually, at least until market age. Regardless of the route of infection, SCS can persist in the tonsil and ileocolic lymph nodes, ileocolic junction and colon, and can be excreted in the feces of experimentally infected pigs for at least 12 weeks. The amount of shedding and persistence of infection is dose dependent. Low doses of SCS can be easily cleared, moderate doses can persist for at least 2 months, and high doses result in long-term carrier states. After intranasal inoculation of STM the organism rapidly appears in the intestines, suggesting that the tonsils and lungs may be important sites for invasion and dissemination of *Salmonella* species. Experimental infection with a zoonotic strain of *S.* Newport can also be established in pigs at 7 weeks of age to persist until market age (28 weeks). Long-term persistence of infection is limited generally to the palatine tonsils, the intestinal tract caudal to the midjejunum, and their lymph nodes. The prevalence of the organism in pigs creates a reservoir of infection for animals and humans. The transmission of salmonellosis in pigs can occur in a few days. Exposure to relatively low levels of SCS may result in high morbidity and initiate a severe outbreak in naive pigs within several days of being exposed to infected pigs. Only a small fraction of carrier pigs are responsible for the maintenance of the pathogen in a pig population. SCS may persist for at least 3 months in wet feces and 6 months in dried feces.

Risk Factors Predisposing to Clinical Disease

The clinical characteristics of salmonellosis in large animals vary depending on the various management systems used, the intensity of stocking, whether or not the animals are housed, and the epidemiologic characteristics of the different *Salmonella* species.

Animal Risk Factors

The response to infection varies depending on the challenge dose and the immunologic status of the animal, itself dependent on colostrum intake in neonates, previous exposure to infection, and exposure to stressors, particularly in older animals. It is generally accepted that the intervention of some precipitating factor such as transport, intercurrent disease, dosing with antimicrobials, acute deprivation of food, or other stress is usually necessary to cause the disease Salmonellosis, which is distinct from infection with *Salmonella* spp.

Infection is almost always via the mouth; thus the severity of the disease in an individual, or of an outbreak in a group, depends on the degree of contamination and the environmental conditions of temperature and dryness that determine the survival time of the salmonellas. Just as important is the influence of the host on the outcome of the infection. Many animals become infected naturally and are passive carriers; they shed *Salmonella* in their feces without clinical disease but only for the duration of their cohabitation with other infected animals. It is also possible to reproduce salmonellosis experimentally in most animals using a sufficiently large dose of a virulent strain of the organism. There still remains the common occurrence of the animal that is a subclinical carrier of the infection but develops clinical salmonellosis when exposed to stressors such as long transportation, hospitalization, severe feed deprivation, or parturition. Oropharyngeal secretions may contain salmonellas because the tonsils are rapidly colonized.

Genetic Resistance to Salmonellosis in Domestic Animals

There is evidence of a strong genetic association with resistance to salmonellosis. However, as yet, selective breeding for resistance traits is not used in control of diseases or the carriage of *Salmonella*. The control of *Salmonella* colonization of the gastrointestinal tract of food animals, particularly where intensive rearing occurs such as in pig units, would appear to be a particularly useful objective with enormous potential public health benefits. There may be a role for several inherited immunologic traits, including polymorphonuclear leukocyte function and lecithin-induced mitogenic proliferation.

Salmonella *Choleraesuis*

The epidemiology of SCS infection in pigs is well documented and has changed remarkably since the mid-1960s, when explosive outbreaks occurred that could easily be mistaken for classical swine fever. The morbidity and mortality rates were high and the disease spread rapidly through commercial pig-finishing units. These outbreaks are now rare and small in scope, largely because of the restriction of garbage feeding, much less movement and mixing of pigs through public auction marts, and disease-prevention strategies such as the use of specific pathogen-free (SPF) pigs, an all-in/all-out policy in commercial finishing units, and the vertical integration of pig-producing enterprises. This ensures a constant supply of disease-free growing hogs to finishing units and the assumption of a pyramid-type responsibility at all levels of the enterprise. The marked decline in the prevalence of swine salmonellosis coincided with the decline in and eradication of classical swine fever. However, modern methods of raising pigs in multisite production systems, using all-in/all-out management of finishing pigs, appear to have no benefit in reducing the prevalence of *Salmonella* compared with conventional farrow–finish systems.

Subclinical Infections

S. enterica does not normally cause clinical disease in pigs, but subclinical infections constitute an important food safety problem throughout the world. Comprehensive longitudinal studies of two multisite pig production systems in the United States revealed considerable temporal variability in *Salmonella* prevalence between cohorts of pigs. Cohorts of sows and individually identified growing pigs from their litters were serially sampled to determine the prevalence and serotypes of salmonellas in each stage of production based on fecal culture and feed and environmental samples. A total of 15 different serotypes were isolated from the two systems. Pig prevalence estimates ranged from 0 to 48.1%. Environmental contamination was frequently encountered despite cleaning and disinfection. Feed was only rarely contaminated. The prevalence of infection within and among cohorts of pigs was highly variable, which indicates that point estimates of *Salmonella* prevalence and serotypes are not reliable indicators of the *Salmonella* status on farms, and that uncontrolled studies of interventions to control *Salmonella* on pig farms may yield misleading results.

In the United States, new regulations regarding the safety of meat products have been implemented in response to public concerns about food-borne disease outbreaks. The salient features of the regulations are requirements for approved systems of microbiological monitoring of *S. enterica, E. coli* O157:H7, and generic *E. coli* as an indicator of contamination by gastrointestinal contents. From the perspectives of public health, regulatory compliance, and international competitiveness, *S. enterica* is the most important food-borne pathogen for the U.S. pig industry. This has resulted in longitudinal epidemiologic studies of fecal shedding of *S. enterica* in both breeding and growing pig populations.

The relationship between subclinical infections at the levels of the herd, the individual pig, and at slaughter is complex. The onset and duration of *Salmonella* shedding and the patterns of transmission between individual pigs and between different age groups during the growing period all have influence. Bacteriology and serology can be used to assess this relationship, but repeated sampling in different cohorts of animals is required to correctly assess the infection dynamics.

Longitudinal studies of STM infection in farrow–finish pig herds in Denmark reveal that the *Salmonella* occurrence varies between and within age groups within herds, even in herds with an apparent moderate-to-high infection level. *Salmonella* was predominant in weaners, growers, and finishers, and was only occasionally detected in sows and gilts. This is contrary to the results of studies in the United States, in which *Salmonella* was found to be common in sows. In the Danish study, there was a rapid increase in *Salmonella* prevalence in the nursery, which may be associated with the stressors of weaning such as change in feed, commingling of litters, and piglets being deprived of the antibodies in sow's milk before activation of their own immune response. The observation that no piglets were shedding *Salmonella* just before weaning, but 3 to 4 weeks later in the nursery between 5% and 50% of the piglets were shedding, suggests that horizontal transmission occurred in the nursery. During the finishing period *Salmonella* shedding decreased, but with considerable variation. Some pigs cleared themselves of the infection, whereas others continued shedding. Average shedding time was estimated to be 18 to 26 days. Seroprevalence peaked approximately 60 days after peak prevalence in culture. At slaughter there is a marked increase in the prevalence of *Salmonella* infection. This increase may be caused by rapid cross-contamination during transport and lairage. Rapid infection during transport, and particularly during holding, is a major reason for increased *Salmonella* prevalence in pigs. A high degree of carcass contamination occurs at slaughter from the delivery of *Salmonella*-positive pigs and cross-contamination from the slaughterhouse environment. Contaminated feed trucks also may serve as a potential source of *Salmonella* contamination. The withdrawal of feed from pigs before slaughter does not increase the prevalence of *Salmonella* colonization or the risk of carcass contamination. Over time in a swine production unit it was found that a particular genotype of *Salmonella,* if introduced into a breeding-gestation unit of a farm, would evolve only slowly over short time intervals; its spatial distribution would be limited primarily to adjacent or nearby pens.[35]

Risk factors associated with serologic *Salmonella* prevalence in finishing pig herds in the Netherlands have been examined. Feeding a complete liquid feed containing fermented by-products and the omission of disinfection after pressure washing a compartment as part of an all-in/all-out procedure were both associated with a lower *Salmonella* seroprevalence. A small to moderate herd size (<800 finishing pigs), a previous diagnosis of clinical *Salmonella* infection in the herd, the use of tylosin as an antimicrobial growth promoter in finishing feed, and herds that have more than 16% of their pigs' livers condemned at slaughter because of white spots were associated with a higher *Salmonella* seroprevalence. There was no effect on experimental *Salmonella* infection of the use of tylosin as an antimicrobial growth promoter.

In those herds in which the disease does occur, introduction is usually associated with the importation of infected carrier pigs. However, it is possible for the infection to be spread by flies and the movement of inanimate objects such as cleaning equipment and utensils. Feedstuffs do not provide a favorable environment for SCS, so food-borne infection is not common. Survival in soil and water is approximately 6 months and in slurry up to 5 weeks. Persistence in streams fouled by piggery effluent is unlikely. Susceptibility to salmonellosis in pigs is thought to be increased by intercurrent disease, especially hog cholera, nutritional deficiency of nicotinic acid, and other nutritional stress such as a sudden change in diet.

Immune Mechanisms

Early immune responses have been described,[36] and there is a higher expression of proinflammatory cytokines and T-helper type 1 cells.

In an experimental STM study, along the intestinal tract (jejunum, ileum, and colon) it was shown that there were different changes in gene expression along the tract.[37] All chemoattractant cytokines were upregulated in the ileum and jejunum and IL-8 was overexpressed in the colon.

Most information on the mechanisms of immunity to *Salmonella*, including the safety and immunogenicity of most *Salmonella* vaccines, has been done experimentally in mice. In primary infections in mice, early bacterial growth in the reticuloendothelial system is controlled by the contribution of both macrophages and polymorphonuclear cells and is affected by the virulence of the strain. In lethal infections, the early growth of the bacterins the tissues results in high bacterial numbers that lead to death of the animal. Following natural infection with *Salmonella* antibody, responses to lipopolysaccharides (LPS) and protein determinants can be detected. Anti-*Salmonella* IgM appears in serum early after infection followed by IgG. T-cells have a critical role in the later stages of primary infection. The presence of STM in mesenteric lymph nodes was examined, and it was found that there was an immune response marked by a substantial infiltration of phagocytes and an upregulation of proinflammatory genes. This resulted in a reduction of STM but not the total elimination. It might be that STM interferes with dendritic cell–T-cell interactions.[38,39]

Environmental and Management Risk Factors

Farming Practice in General

There are a wide variety of contributing factors to *Salmonella* infections. These include other livestock on the farm, herd size, previous clinical cases, bowl-type drinkers, dry feeding, pelleted feed, *Salmonella*-positive breeding herds, solid or partially slatted floors, reduced floor space allowance, persistent floor contamination, reduced floor space allowance, coinfections, porcine reproductive and respiratory syndrome (PRRS) infections, lack of hygiene and biosecurity practices, contact between pigs in adjacent pens, continuous flow systems, multiple pig suppliers, environmental temperature fluctuations, and *Salmonella*-contaminated feed. In a study of split marketing it was found that a significant increase in *Salmonella* prevalence occurs between the first and last groups to leave the finishing lots with the close-out groups posing a higher risk for *Salmonella* contaminations.

Longitudinal Dutch studies have shown that 25% of herds are never infected, 24% are constantly infected, and 50% are infected most of the time. There appear to be infection cycles when infection reaches a peak over the 2 to 4 weeks following the arrival of an infection, and between 5% and 30% may still be excreting by the end of the finishing period.

Intensification of husbandry in all species is recognized as a factor contributing significantly to an increase in the new infection rate. A typical example is the carrier rate of 54% observed in intensive piggeries in New Guinea compared with the 9% in village pigs. Any significant change in management of the herd or a group of animals can precipitate the onset of clinical salmonellosis if the infection preexists in those animals. Pelleted feed is associated with increased *Salmonella* prevalence.[40]

The association between biosecurity and *Salmonella* species prevalence on English pig farms was suggested.[41] Farms practicing biosecurity had a lower muscle tissue ELISA score than those that did not. Effective implementation of biosecurity in large herds may be the reason they have a shorter high serology period compared with smaller herds.[15]

Temperature and wetness are most important, because salmonellas are susceptible to drying and sunlight. STM can remain viable on pasture and in soil, still water, and feces for up to 7 months. Survival times of the bacteria in soil are influenced by too many variables to make any overall statement meaningful.

The survival time of *Salmonella* spp. in cold liquid manure depends on several factors, including pH of the slurry and the serotype of the organism, and can be as long as 28 weeks. Drinking water can remain infected for long periods (up to 9 months). Thus infection can be introduced by infected domestic animal carriers.

Housed Animals

In housed animals the premixing of food into a liquid form for pumping to feeding stations in piggeries is an effective way of spreading salmonellosis if infection is present in the feedstuffs and the mix is allowed to stand before feeding. Nose-to-nose contact through pens is also associated with a raised prevalence.[40]

In a longitudinal study of nucleus breeder and multiplier units in England there was an association between the *Salmonella* serovar and the immediate environment of the pens.[42] Pens holding breeding stock designed for production units were frequently positive, and herds under common ownership frequently had the same serovar combinations. Serovars from the wildlife were similar to those found on the associated premises.

Contaminated Feedstuffs

Housed animals are generally more susceptible to infection from purchased feeds. Organic feedstuffs, including bonemeal, are being increasingly incriminated in the spread of salmonellosis and although the usual figure, for example, in the UK, is 23% of consignments being infected, the figure may be as high as 70%. Most of the contamination of meat and bonemeal occurs after heat sterilization, especially if the material is left in digester tanks. Fishmeal is one of the most frequently and badly contaminated feedstuffs. For example, most of a recent increase in reported isolations of salmonellas in the United States was from *S.* Agona introduced in Peruvian fishmeal. These feed meals need to be heated at 82°C (180°F) for an hour to be sterilized. The infection of these materials may derive from antemortem infections in the animals used to make the by-product, but soiling of the material at the preparation plant or abattoir or during storage may also occur. Stored feed not of animal origin, especially grain, is also commonly contaminated by the droppings of rodents or birds that infest it, and this can lead to sharp outbreaks of salmonellosis caused by STM. All feed stores should be protected from birds and rodents. Dried milk products appear to be relatively safe. Vegetable material can also be a source of infection.

Some serotypes such as STM have been isolated from 2.8% of pig feed and feed ingredient samples and from 46% of farm feed samples tested. SCS was not isolated from pig feed.

The risk of culturing *Salmonella* with or without AMR was higher if pelleted feed was used compared with mash or liquid feed. Fecal samples from farrow to finish farms had a lower chance of testing positive than grow-finisher farms.[43]

Commercial feed is potentially a vehicle for *Salmonella* transmission.[44] In a study in the UK it was found that cereals could become contaminated, particularly with STM, and the most likely reason was the storage of grains on cattle farms with access for birds and wildlife.[45] The effect of carbohydrate composition in barley and oat cultivars was studied in vitro, and it was shown that the population of salmonellas decreased with hull-less barley cultivars and increased with oat cell cultivars.[46]

Introduction of the Infection to a Farm

Contaminated feedstuffs, carrier animals, and infected clothing of visitors and casual workers are the most common methods of introducing infection. Less common methods include free-flying birds, such as the herring gull, and nematode larvae that are already infected with salmonellas. Salmonellas have been isolated from a wide variety of wild animals, which could act as reservoirs for infection of domestic animals under certain conditions.

Pathogen Risk Factors

Salmonellas are facultative intracellular organisms that survive in the phagolysosome of macrophages and can therefore evade the bactericidal effect of an antibody. Compared with other organisms of the same family, salmonellas are relatively resistant to various environmental factors. They multiply at temperatures between 8°C and 45°C, at water activities above 0.94, and in a pH range of 4 to 8. They are also able to multiply in an environment with a low level of or no oxygen. The bacterium is sensitive to heat and will not survive temperatures above 70°C. It is sensitive to pasteurization. Salmonellas have been shown to be resistant to drying, even for years, especially in dried feces, dust, and other dry materials such as feeds and certain foods. Prolonged survival in water and soil has also been described. They are quite sensitive to beta and gamma irradiation. The O-antigen LPS of salmonellas is toxic and an important virulence factor, and immunity directed against the LPS is thought to be of major importance in the host defense against salmonellosis.

Fimbrial antigens of some *Salmonella* species have been described and characterized. The fimbriae mediate a variety of virulence factors important for the maintenance and survival of the organisms in the host and environment, including initiation and stabilization of the organism to epithelial cells, colonization of the organism to receptor sites, maintenance of persistent infection in the host by mediating selective bacterial trapping by phagocytic cells, and evasion of the host's specific immunologic defense mechanisms. The fimbriae are also useful in diagnostic tests.

Naturally occurring strains with varying virulence factors and antimicrobial susceptibility patterns can be identified in herds with endemic infection.

Antimicrobial Resistance of Salmonella

Strains of *Salmonella* spp. with resistance to antimicrobials are now widespread. Since 1990 there have been dramatic increases in the occurrence of multiresistant strains of *Salmonella* spp. in many developed countries. Of particular note has been the epidemic spread of STM DT104, which now has a worldwide distribution. AMR in zoonotically transmitted salmonellas is an undesirable but almost inevitable consequence of the use of antimicrobials in food animals. Generally, such use is legitimate. Recommendations have been made that new antimicrobials with cross-resistance to those used in human medicine should not be used for prophylaxis in food-animal production. For example, it is argued that the use of antimicrobials in food animals has been a major factor in the development of decreased susceptibility to antibiotics such as ciprofloxacin in zoonotically transmitted salmonellas. Multidrug resistant strains that also carry specific virulence factors are more likely to be of clinical significance.[47]

AMR of *Salmonella* has been a major controversial concern in veterinary medicine and human public health. Antimicrobials are used in food-producing animals for the treatment of infectious diseases and for growth-promoting effects. Their continued use has long been incriminated as a major cause of selective pressure that leads to the appearance and persistence of resistant strains. The resistance is usually to multiple antimicrobials and its existence is considered as a potential risk factor. The significance of AMR is most obvious in its impact on the treatment of human infections. If the frequency of drug resistance increases, the choice of antimicrobials for the treatment of systemic salmonellosis in humans becomes more limited. There

is also an association between drug-resistant salmonellas and the routine clinical use of antimicrobials for infections other than salmonellosis. The AMR *Salmonella* infections can complicate antimicrobial therapy of other infections; prior antimicrobial therapy allows fewer numbers of AMR *Salmonella* to cause symptomatic infections, and an increase in the proportion of *Salmonella* species that are AMR will increase the overall frequency of salmonellosis.

Infections in humans associated with AMR *Salmonella* are increasing and have become a cause for public health concern. Prospective studies in the United States claim to show that human infections with AMR *Salmonella* are increasing, and that these resistant strains can be traced to foods of animal origin. There are wide variations from country to country in the percentage of *Salmonella* isolates that are AMR. Generally, AMR among *Salmonella* is much higher in the United States than in other countries. In the UK, over a period of about 20 years, little change has occurred in the AMR patterns of salmonellas isolated from animals. Most of the resistance in STM is associated with phage-type DT204C. Serotypes other than SD and STM show low levels of resistance to most antimicrobials, with the exception of sulfonamides and tetracyclines, to which resistance is increasing.

AMR in *Salmonella* in the UK has been monitored since 1970 using disk diffusion tests. A total of 76% of all *Salmonella* isolates are still sensitive to all 16 antimicrobials used for testing.

In the Netherlands, from 1984 to 2001, monitored resistance was most common in STM. Among the strains from humans, pigs, and chickens, the level of resistance to tetracycline, ampicillin, chloramphenicol, and trimethoprim-sulfamethoxazole increased over the 17 years.

Since their introduction into veterinary medicine in Europe in the late 1980s and early 1990s, the susceptibility of several bacterial species to fluoroquinolones has increasingly been reported to be decreasing and their resistance to quinolones has been reported to be increasing. The incidence of quinolone resistance in strains of *Salmonella*-isolated pigs in Germany between 1998 and 2001 has increased.

In Canada, resistance in STM isolated from animals, animal food products, and the environment of animals to each of seven antibiotics (ampicillin, chloramphenicol, kanamycin, neomycin, streptomycin, sulfisoxazole, and tetracycline) increased persistently during each of the years from 1994 to 1997, and none of the isolates showed decreased sensitivity to ciprofloxacin.

The prevalence of STM and SCS isolates from pigs and humans that are fluoroquinolone and multidrug resistant has increased in Taiwan, and the isolates have become widespread across the country. The SCS isolates from humans and pigs were closely related genotypically, suggesting the nationwide dissemination of the organism from pigs to humans.

In Japan, Taiwan, and Thailand there is SCS resistance to many antibiotics and many are multiresistant, including fluoroquinolone and cephalosporins.[17]

AMR to an antibiotic was more common in fecal samples (98%) than environmental samples (65%),[48] and multidrug resistance followed a similar pattern (35.7% from the barns versus 56.4% in the feces).

In the UK AMR was seen in 92% of isolates tested.[22] The highest frequencies were seen with tetracyclines (T), sulfonamide compounds (SU), ampicillin (AM), sulfamethoxazole/trimethoprim (SXT), streptomycin (S), and chloramphenicol (C). Fifty-nine AMR patterns were observed with the one listed previously in 33% of cases.

In a study in the United States between 2003 and 2008, it was shown that SD had increased resistance to spectinomycin and sulfadimethoxine, as did *S.* Heidelberg (and also with florfenicol). Other species had increased resistance to spectinomycin,[7] but only two or three isolates were resistant to enrofloxacin.

In Korea, there was also a catalog of increased resistance in STM. All the isolates were resistant to 4+ antibiotics, particularly streptomycin (94.1%), tetracycline 90.1%, and ampicillin (64.7%).[49]

In a study in Belgium,[10] 7.8% of the pigs were seropositive (12 farms). STM was found in 65% and of these 65% had a tetra-resistant AMR profile.

A study in Spain of free-range pigs[19] showed that multidrug resistance (four or more) was found in 36% of the pigs. Streptomycin (46%) and tetracyclines (30%) were commonly resistant.

In a study of AMR in the United States, comparing the years 2000 and 2006, it was found that 6.2% and 7.2% of the samples (2000) and 34.2% and 52.6% (2006) of the farms were positive. STM, SD, and *S.* Agona were the most common serotypes. The most common AMR pattern was streptomycin, sulfisoxazole, and streptomycin. The proportion susceptible to all antibiotics was 38.1% in 2000 and 20.4% in 2006. The proportion resistant to three or more antibiotics was similar in both years (52.8% and 52.7%).[50] A later study at Purdue University in the United States showed similar results in AMR but they also noted that STM and others possessed multiple AMR to amoxicillin/clavulanic acid, ampicillin, ceftiofur, and cephalothin.[51]

In a study of AMR in Korea,[52] it was found that STM, *S.* Rissen, and *S.* Schwarzengrund were most commonly isolated in normal pigs, but STM was the most commonly isolated in diarrheic pigs (89.7%). The most common were PT194 and PT203. Only 3% were DT104. The most common resistance in *Salmonella* was to streptomycin, sulfamethoxazole, and tetracycline. Nearly all STMs were resistant to more than four antibiotics.

The genetic diversity and AMR profiles of *S.* Derby in pigs in France have been described.[53] The patterns were very similar among pigs, pork, and humans. Only 15.5% *S.* Derby had no AMR. The majority (over 70%) had AMR to more than three antimicrobials. Only a few isolates had resistance to β-lactams. The pig reservoir is the second largest contributor to human salmonellosis in the EU.

A longitudinal study of salmonellas in a unit that did not use antibiotics and a conventional production unit showed a 4% AMR in the conventional unit pigs and 11.7% in their environment and 0.2% in the pigs in the antibiotic-free unit and 0.6% in their environment. There were 42 serotypes (particularly Anatum, SD, STM, and Infantis) and they were resistant to tetracycline, streptomycin, and sulfisoxazole. Multidrug resistance was found in 27% of the pigs on the conventional unit.[54]

Zoonotic Implications From Pigs

The disease has assumed increasing importance in recent years because of the much more frequent occurrence of human salmonellosis, with animal salmonellosis as the principal reservoir.[2,25] *Salmonella* is the second most important zoonosis to *Campylobacter.*

Human infection is usually through food and four are commonly isolated from swine (Typhimurium, Heidelberg, Agona, and Infantis), but there is also the possibility of direct contact as a source of human salmonellosis.[55] The important pathway today is pigs and poultry, and in Denmark this was an important source of human salmonellosis until control measures were instituted. In most instances the increase in human infections is with *exotic* serotypes other than STM that come by animal feedstuffs to pigs and chickens and then to humans through pork and chicken products. The most serious risk is that the transmitted bacteria will have acquired resistance to specific antibiotics because the animals from which they originate have been treated with the particular antibiotics repeatedly or over a long period. It is usually enteritis in humans with the exception of SCS, which often produces a septicemia.

Infected pigs leaving the farm are the major source of infection for the abattoir in which the spreading of salmonellas occurs. The longer the length of time in the lairage the greater is the chance of spread of infection.

The *Salmonella* status in lairages in Ireland in relation to the slaughter process has been assessed and it was found that the lairage, evisceration operatives, conveyor belts, and equipment in the boning hall were significant sources of contamination.[56] Cross-contamination within the plant

accounted for up to 69% of the *Salmonella* carcass contamination.

A study of the small abattoirs in Wisconsin suggested that contamination could be reduced by chilling carcasses 2 days before fabrication and by improving carcass-handling hygiene.[57]

Salmonella Serovar Typhimurium DT104

The increasingly common isolation of STM DT104 (definitive phage type) is of major concern for public health officials. STM DT104 was first reported in the UK in 1984 and emerged in the 1990s as an increasing cause of *Salmonella* infections in humans and animals in the UK and other European countries such as Germany, France, Austria, and Denmark, as well as Canada. A wide range of potential reservoirs is associated with this infectious strain, from humans to the traditional food animals such as poultry, cattle, sheep, and pigs. Over a 1-year period in Scotland it was the predominant *Salmonella* isolated from nine species of animal (cattle, pigs, sheep, chickens, pigeons, horses, cats, dogs, and rabbits). All isolates were resistant to at least one antimicrobial and 98% were resistant to multiple antimicrobials.

The organism has been found in a variety of human foods, including salami and sausages. Human infections may result from contact with farm animals and from consumption of contaminated foods such as pork, sausages, and meat pastes.

Clinical signs in humans infected with DT104 include diarrhea, fever, headache, nausea, and vomiting. Septicemia may develop in a small percentage of cases with potential complications of meningitis and foci of infection in bones and joints.

The AMR factor of DT104 is a major concern. Resistance to ampicillin, chloramphenicol, streptomycin, tetracyclines, and sulfisoxazole is characteristic of the organism. There is now evidence that DT104 is developing resistance to trimethoprim and fluoroquinolones such as ciprofloxacin, the drug of choice for treating human adult *Salmonella* infections.

Control and prevention of infection with DT104 will depend on increasing surveillance activities, investigating outbreaks, and identifying vehicles and risks of infections.

Various clinical forms of salmonellosis (gastroenteritis, bacteremia, and other systemic abnormalities) can occur in veterinarians working with *Salmonella*-infected animals.

Economic Importance

Salmonellosis is a significant cause of economic loss in farm animals because of the costs of clinical disease, which include deaths, diagnosis and treatment of clinical cases, diagnostic laboratory costs, the costs of cleaning and disinfection, and the costs of control and prevention. In addition, when the disease is diagnosed in a herd it can create considerable apprehension in the producer because of the difficulty in identifying infected animals. The veterinarian is also often in a difficult position because the diagnosis, treatment, and control of the disease are less than reliable and it is difficult to provide advice with confidence. The losses incurred by livestock producers include reduced feed efficiency and reduced weight gains or deaths because of salmonellosis.

PATHOGENESIS

Infection is much more common than clinical disease. The development of disease is very variable. Severity is influenced by serotype, virulence, host resistance, route, and quantity of the infective dose. Over 200 virulence factors have been identified. The establishment of experimental infections requires large numbers of organisms (10^8–10^{11}). The initial infective dose in the field is probably much less than that required experimentally.

The ability to invade is a requirement for pathogenesis and is encoded by a serotype-specific plasmid. STM resides as an extracellular pathogen in the tonsils independently of biofilm mechanisms.[58]

There are many virulence factors but two of the most important are genes encoding for two different type III secretion systems (T3SS) localized on the two major pathogenetic islands 1 and 2.[59] Island 1 gets into the cell and it encourages the cell to take up *Salmonella*. It is found in the tonsil (SPI-1) and SPI-2 is important for intracellular survival. The T3SS of SCS is important for the invasion of the intestine and causes enteropathy,[60] and one of its effector proteins, SipB, induces capsase-1–dependent apoptosis in macrophages and plays an essential role in *Salmonella* pathogenesis. STM SPI-1 genes promote intestinal but not tonsillar colonization in pigs[61] and start the initial influx of neutrophils.

The replication of SCS and STM is associated with their differential virulence.[62] Enteric virulence of STM is associated with rapid replication in the intestinal wall and with rapid induction of proinflammatory cytokines (tumor necrosis factor [TNF]-α, IL-8, and IL-18), whereas the systemic virulence of SCS is associated with enhanced persistence in mesenteric lymph nodes which may help it to evade host innate immunity. The induction of seroconversion and persistence of STM in pigs is strain dependent.[63]

The suppression of cytokine signaling in the palatine tonsils may facilitate the initial colonization of the palatine tonsils.[13] Septicemic isolates may have a particular pattern of invasion.[64]

The pathogenesis of salmonellosis is a complex and multifactorial phenomenon. The nature of the disease that occurs following infection is dependent on the specific combination of serovar and host known as serovar–host specificity. A range of infections is included in the term *salmonellosis*. The most common type of infection is known as "the carrier state," in which carriage of the organism is not accompanied by clinical abnormalities or clinical disease. In production animals, these carriers are of importance because they may serve as reservoirs for further spread of infection through shedding and may be present as contaminated food products.

The infected oral secretions may lead to the possibility of aerosolized secretions, feces, or contaminated dust particles.

The evolution of host-specific *Salmonella* serovars is considered to be associated with an increase in pathogenicity for the specific host. The hypothesis is based on the fact that broad-range serovars (Typhimurium and Enteritidis) are generally associated with severe disease only in young animals, whereas host-restricted serovars cause high mortality in both young and adult hosts.

The mycotoxin deoxynivalenol promotes uptake of STM in porcine macrophages coinciding with cytoskeleton reorganization.[65]

Infection

Salmonella infects animals and humans by the oral route. Following ingestion, a proportion of the organisms resists the low pH of the stomach, reach the distal ileum and the cecum, invade the mucosa, and replicate in the submucosa and Peyer's patches.

In young animals, and in adults whose resistance has been lowered, spread beyond the mesenteric lymph nodes occurs and the infection is established in the reticuloendothelial cells of the liver; from there it invades the bloodstream. These steps in the infection process can occur very rapidly. Once systemic infection has been established, salmonellosis as a disease can develop. Its principal manifestations are as septicemia, enteritis, abortion, and a group of localizations in various tissues as a result of bacteremia. It is likely that stress increases the effects of the salmonellas, as the catecholamines released will result in decreased gastric acid production and increased intestinal motility, aiding the passage of the salmonellas through the stomach and into the intestine and colon.

During the invasion process there is induction of synthesis of new proteins that enhance intracellular survival. Many epithelial types may be infected, but the Peyer's patches may be a major site of invasion.

SCS localizes in the colon on the luminal surface of the ileal M-cells of Peyer's patches. Attachment of epithelial receptors triggers microfilament-controlled uptake, vacuole formation, vacuole transport through the cell, and entry into the lamina propria via exostosis through the basement membrane. They cause mild and transient enterocyte damage. Salmonellas can synthesize over 30 proteins, which in practice can make the bacteria virtually intracellular parasites. Spread

to local lymph nodes can take place rapidly because of transport by CD18+ phagocytes to the spleen and the liver and then the macrophages and dendritic cells. At the same time there is an acute macrophagic inflammatory reaction and microvascular damage. Neither STM or SCS in a refeeding experiment produced changes in systemic TNF-α or Il-1β, although SCS reduced the growth rate by 25%.[66] Part of the first line of defense against invading pathogens is the innate immune system, and part of this is the release of antimicrobial peptides into the lumen of the intestinal tract, and a group of these are the defensins. Thus far in the pig 12 peptides have been identified, and the expressions of pBD-1 and pBD-2 have been described in the small intestine of the pig.[67,68] The porcine ileal cell line expressed increased levels of both when exposed to viable STM but not to SCS.[69]

STM does not spread effectively beyond the intestinal tract and draining lymph nodes in weaned pigs.[70] The lower cytokine signaling but higher toxicity of STM for macrophages correlates with the higher virulence for pigs of this serotype compared with SD or *S.* Infantis.[71]

Septicemia, Bacteremia, and the Carrier State

After invasion of the bloodstream a febrile reaction follows in 24 to 48 hours, and the acute phase of the disease, similar to that seen in natural cases, is present 3 to 9 days later. The early septicemia may rapidly be fatal. If the systemic invasion is sufficient to cause only a bacteremia, acute enteritis may develop, and abortion is a common final sequel in sheep and cattle. Many animals survive this stage of the disease, but localization of the salmonellas occurs in mesenteric lymph nodes, liver, spleen, and particularly the gallbladder. In experimental STM infection in pigs, the organism can persist from 6 to 8 weeks of age until market age with long-term persistence in the palatine tonsils, gastrointestinal tract, and adjacent lymph nodes. In healthy adults there may be no clinical illness when infection first occurs, but there may be localization in abdominal viscera. In either instance the animals become chronic carriers and discharge salmonellas intermittently from the gallbladder and foci of infection in the intestinal wall into the feces and occasionally into the milk. For this reason they are important sources of infection for other animals and for humans. Carrier animals may also develop an acute septicemia or enteritis if their resistance is lowered by environmental stresses or intercurrent infection. Salmonellas can reside intracellularly where they are able to escape antibody-mediated killing, and the numbers of organisms are controlled by cellular defense mechanisms involving the macrophages in which they reside.

Septicemia in pigs associated with SCS can cause pneumonia in pigs similar to the pneumonia in pasteurellosis and infection with *Actinobacillus pleuropneumoniae,* hepatitis, enterocolitis, and encephalitis.

Enteritis

Enteritis may develop at the time of first infection or at some other time in carrier animals. The best information available on the pathogenesis of enteritis is derived from the experimentally produced disease. In most instances the disease is produced by the administration of massive doses of bacteria, and this may result in the production of a different syndrome from that which occurs naturally. The pathogenesis of enteric salmonellosis is much more complex than cholera, involving an increase in mucosal cell cyclic AMP content and prostaglandin concentration, as well as an inflammatory response to the invading bacteria. Intestinal invasion is a characteristic feature of *Salmonella* pathogenesis. The organism must invade the intestinal mucosal epithelium to cause disease. Neutrophil recruitment and transmigration across the epithelium is important in the enteritis. Host-derived caspase-1 can act as a proinflammatory agent by cleaving IL-1-β and IL-18 into active molecules. SipA is a protein that *Salmonella* injects into the host cells, which has also been shown to contribute to the inflammatory response by activation of phosphokinase C. This activates the transepithelial migration of neutrophils into the intestinal lumen. Diarrhea is a result of decreased sodium absorption and increased chloride secretion caused by cholera-like and Shiga-like enterotoxins. Certain *Salmonella* outer membrane proteins also mediate cell damage. Survival within the phagocyte (O side chains, smooth LPS, and an LPS core are important) is also an important attribute of virulent salmonellas.

STM requires a functional type III secretion system encoded by SPI-1 to cause diarrhea. The SPI-1 secretion system mediates the translocation of secreted effector proteins into target epithelial cells. These effector proteins are key virulence factors required for *Salmonella* intestinal invasion and the induction of fluid secretion and inflammatory responses.

Although there is sufficient obvious enteritis to account for the diarrhea that characterizes the disease, there appear to be other factors involved. For example, it has been shown experimentally that in *Salmonella* enteritis there is stimulation of active chloride secretion combined with inhibition of sodium absorption, but invasion of the mucosa is not essential for these changes to occur. These observations are of interest in light of the known hyponatremia that characterizes the disease. In pigs, ulcerative lesions may develop in the intestinal mucosa and may be of sufficient size to cause chronic intermittent diarrhea. In pigs it has also been observed that villous atrophy is a sequel to infection with SCS.

In pigs, most clinical cases of salmonellosis are associated with SCS or STM. SCS is host-adapted to pigs, causing a systemic, typhoid-like disease. STM is not host-adapted to pigs, and infection results in a localized enterocolitis.

In the **pig** the development of enteritis associated with SCS begins 36 hours after infection with the appearance of erosions and edema of the cecal mucosa. At 64 hours the wall is thickened and there is diffuse caseation overlying the erosions. Microvascular thrombosis and endothelial necrosis in the submucosa and lamina propria, probably caused by endotoxins, are important early lesions in porcine salmonellosis. This then facilitates the ischemia that results in the mucosa mediated via IL-1. They have direct effects on the tissues or have effects on a variety of cytokine mediators. The necrotic membrane sloughs at 96 hours, and at 128 hours all function is lost, and the entire intestinal wall is involved in the inflammatory process with the muscular coat obliterated by 176 hours. The colon is usually the major organ affected in STM infections in pigs, causing either focal or diffuse necrotizing colitis. The organisms proliferate in the intestine, invade the intestinal epithelium, stimulate fluid secretion, and disseminate from the intestine to mesenteric lymph nodes and other organs. SCS invades enterocytes by penetration of the brush border, resulting in focal loss of microvilli, and the bacteria are endocytosed into membrane-bound vacuoles. Experimental infection of ileal–gut loops of pigs with *S. enterica* results in preferential bacterial adherence to M-cells within 5 minutes, and by 10 minutes, bacterial invasion of the apical membrane occurs in M-cells, goblet cells, and enterocytes. Experimental perfusion of porcine livers with polysaccharide or live SCS results in the release of mediators that mediate biological activities that have an important role in reducing the severity of bacterial infections.

CLINICAL FINDINGS

The disease is most satisfactorily described as three syndromes, classified arbitrarily according to severity as **septicemia, acute enteritis, and chronic enteritis.** These are described first, but the differences between the animal species are sufficiently significant to justify describing the disease separately in each of them. There are no significant differences between infections associated with the different *Salmonella* species.

Porcine Salmonellosis

In pigs, the disease varies widely and, although all forms occur in this species, there is often a tendency for one form to be more common in any particular outbreak. In the septicemic form in pigs affected by SCS a dark red to purple discoloration of the skin is evident, especially on the abdomen and ears, and subcutaneous petechial hemorrhages may also be visible. Nervous

signs, including tremor, weakness, paralysis, and convulsions, may be prominent and occur in a large proportion of affected pigs. The case–fatality rate in this form is usually 100%.

A semispecific entity occurring in pigs up to 4 weeks old is manifested by meningitis and clinical signs of prostration and clonic convulsions.

In the acute form there is also a tendency for pulmonary involvement to occur, but the main feature of the disease is enteritis, with pneumonia and occasionally encephalitis present as only secondary signs. In some situations, pigs dying of septicemia more commonly yield SCS, whereas those with acute enteritis are usually infected with STM. Acute pneumonia is a common accompaniment of this form of the disease in pigs, and nervous signs and cutaneous discoloration as described in the septicemic form may also be present. Meningitis caused by STM DT104 in 1-week-old piglets has been reported. Incoordination, paralysis, opisthotonus, paddling, and polyarthritis resulting in runts and deaths were common. Bronchopneumonia resembling pasteurellosis, and pleuropneumonia resembling *A. pleuropneumoniae* infection can be associated with SCS.

A syndrome of rectal stricture occurs in feeder pigs as a sequel to enteric salmonellosis associated with STM and is described under that heading.

Septicemia

This is the characteristic form of the disease in young pigs up to 4 months old. Commonly, there is profound depression, dullness, prostration, high fever (40.5–42°C; 105–107°F), and death within 24 to 48 hours. There is often a soft, moist cough with dyspnea. There may be cyanosis of the extremities. Diarrhea is not a feature until 3 to 4 days. Rarely nervous signs may be seen. Pregnant sows may abort. Morbidity is usually low (<10%), but case mortality rates may be high.

Acute Enteritis

This is the common form in adult animals of all species. It is most commonly associated with STM. There is a high fever (40–41°C; 104–106°F) with severe, fluid diarrhea; sometimes dysentery; and occasionally tenesmus. The fever often subsides precipitously with the onset of diarrhea. The feces are often a watery yellow without mucus or blood initially; have a putrid smell and contain mucus, and sometimes blood; have fibrinous casts, which may appear as complete tubular casts of intestine; and have intestinal mucosa in sheets or casts. There is complete anorexia and in some cases increased thirst. The heart rate is rapid, the respirations are rapid and shallow, and the mucosae are congested. Pregnant animals commonly abort. The case–fatality rate without early treatment may reach 75%. In all species, severe dehydration and toxemia occur and the animal loses weight, becomes weak and recumbent, and dies in 2 to 5 days. Newborn animals that survive the septicemic state usually develop severe enteritis, with diarrhea becoming evident at 12 to 24 hours after the illness commences. If they survive this stage of the illness, residual polyarthritis or pneumonia may complicate the recovery phase.

Chronic Enteritis

This is a common form in pigs following a severe outbreak. Although chronic enteritis may occur initially, it usually succeeds an acute episode. Episodes may occur at regular intervals. Affected pigs may have pyrexia, decreased feed intake, and are dehydrated.

CLINICAL PATHOLOGY

There is heterogeneity in diagnostic accuracy revealed by using a review/metaregression approach.[72]

A definitive etiologic diagnosis of salmonellosis depends on culture of the organism from feces, blood, and other body fluids or tissues. Feed and water samples may also be cultured to determine the source of the organism. Numerous serologic tests are available but lack sensitivity and specificity.

Clinicopathologic support helps:

- Diagnosis in the individual animal, when its treatment and prognosis depend on a definitive diagnosis
- Diagnosis of a herd problem to ensure that expensive herdwide control measures are not implemented unnecessarily

The diagnostic techniques available are as discussed in the following sections.

Bacterial Culture and Detection

This is the only way of making a definitive etiologic diagnosis of salmonellosis and of exactly determining the serotype. However, culturing the organism may be unreliable for various reasons, including the method used to collect samples, the amount of sample submitted, variation in the shedding of the organism, and the bacteriologic method used. A major complicating factor is the occurrence of apparently healthy carriers, which shed the organism intermittently in the feces, and silent carriers, which do not shed but harbor the organism in mesenteric lymph nodes or in the mucosa of the cecum and colon. The difficulty varies according to genotype. The conventional drag swab method probably gives a better recovery than the Swiffer wipe method.[48]

A discussion of enrichment media suggests that the modified semisolid Rappaport–Vassiliadis medium (MRSV) is beneficial in isolating *Salmonella*.[73] In a study in Japan it was shown that this method of culture was as good as flow-through immunocapture PCR.[74]

Fecal Culture

The culturing of salmonellas from feces is common but can be unreliable. This difficulty is noticeable with SCS infections in pigs. The difficulties relate to dilution by diarrhea and the heavily contaminated nature of the sample; a sample of fluid feces collected in a container is superior to a fecal swab. Clinical laboratories generally require at least 48 hours for presumptive diagnosis of *Salmonella* spp. in feces. Biochemical and serologic confirmation of the genotype and the antibiogram may require an additional 24 to 48 hours. The use of extended enrichment of fecal samples with tetrathionate broth is superior to primary enrichment for detection of salmonellas from cattle.

Multiple Fecal Cultures

An antigen-capture ELISA with enrichment culture for detection of salmonellas from fecal samples is more rapid than routine culture techniques, with a test sensitivity of 69% and specificity of 97%.

DNA Probes

The use of the DNA probe encoding a well-conserved VG of the *Salmonella* virulence plasmid is a sensitive method for screening large numbers of samples to detect potentially virulent *Salmonella* spp.

A reverse transcriptase-polymerase chain reaction (RT-PCR) may be a useful alternative to culture for screening large numbers of samples particularly when *Salmonella* prevalence is low.[75]

Serology

In a study of pulsed-field gel electrophoresis (PFGE) subtypes there was a correlation of serotype to PFGE subtype. PFGE using XbaI restriction provided a possible method for screening and identifying swine *Salmonella* serotypes.[76]

Serum Enzyme-Linked Immunosorbent Assay

The Danish mix-ELISA (DME) is a combination of LPS extractions of SCS (O antigens 6 and 7) and STM (O antigens 1, 4, 5, and 12), used to assay serum samples collected from live animals on the farm or from meat juice (collected when a meat sample from the carcass is frozen and thawed). The DME was designed for surveillance and is recommended for monitoring herds and detecting high levels of *Salmonella* infection. The test has been the basis for national *Salmonella* control programs in Denmark (SALINPORK), Germany, and the UK and is being considered in the Netherlands and Belgium. In a series of studies using pigs experimentally infected with either STM or *S. infantis,* the sensitivity of the DME was more than 95% and the specificity 100% compared with culture used to determine the positive or negative status of the pigs. There is a strong association between herd serology and the prevalence of *Salmonella* measured at three sampling sites: cecal content, pharynx, and carcass surface. A comparison of three commercial ELISAs showed that the results from the three different tests were very different.[77]

The meat juice ELISA results are always lower than the serum ELISA results.[78]

Indirect Tests

These include a total and differential white cell count. A leukopenia, neutropenia, and severe degenerative left shift are highly suggestive. There is also a marked hyponatremia and a mild hypokalemia.

A positive diagnosis depends on culture of the organism, usually from feces but possibly from blood in the septicemic stage. If serologic diagnosis is available a serum sample should also be submitted. Indirect tests are very valuable and, if laboratory availability is good, a total white cell count and estimation of serum sodium levels should be undertaken urgently. A presumptive diagnosis is often all that can be stated, and this may be supported by a herd diagnosis—a diagnosis that the disease or infection is present in the herd and that it is presumed that the subject case is one of the group.

Herd Diagnosis

A serologic examination of a sample of animals is a first step. A completely negative serologic test would indicate that the infection is not present. Positive results indicate a need for further examination, and periodic fecal cultures at 15-day intervals using enriching media should be undertaken. When STM is the causative bacteria, the feces of other species of animals on the farm should be examined, because ducks, dogs, horses, pigs, sheep, and cattle may be sources of infection for each other. It is always advisable to examine the drinking water and feed for evidence of infection.

Detection of Clinically Normal Carrier Animals

The most difficult diagnostic problem in salmonellosis is the detection of the clinically normal carrier animal.

The reliability of diagnosis based solely on culture of fecal swabs is not high and represents the major difficulty in detecting carriers. A combination of fecal culture and serologic tests offers some improvement in accuracy, but even with the agglutination or complement fixation (CF) tests, accuracy is insufficient.

Determination of Prevalence of Infection in Population of Animals

It is particularly important to determine the prevalence of *Salmonella* infection in a population of pigs. Pork and pork products are important sources of nontyphoidal *Salmonella* for humans consuming these products if they are not handled with care. Pigs entering the abattoir that are carriers of *Salmonella* are the most important source of carcass and product contamination. To be able to estimate the number of infected animals entering the abattoir and estimate the size of the *Salmonella* problem in pig herds, the population and herd level prevalence of *Salmonella* have to be investigated. An estimation of the prevalence of *S. enterica* infection in finishing pigs in Iowa was done using on-farm fecal cultures, culture of on-farm necropsy and abattoir-collected samples, and serum ELISA using serum exudate (meat juice). Fecal samples collected on the farm detected only 13.3% of all positive pigs necropsied on the farm. Abattoir and on-farm results combined, the fecal sample detected 57.4% of positive pigs. Abattoir-collected samples provided prevalence estimates much higher than on-farm collected samples (39.9% versus 5.3%). Thus fecal samples have a low sensitivity for detecting infected pigs, and abattoir-collected samples overestimate the on-farm *S. enterica* prevalence. A study of subiliac lymph nodes at slaughter showed that they had a low rate of detection compared with the on-farm incidence.[79] Pigs can become infected during routine testing or holding periods during marketing when exposed to relatively low numbers of *Salmonella* in the preslaughter environment. Intervention at this step on the production process may have a major impact on the safety of pork products.

The probability of detecting *Salmonella* in seropositive pig herds with a correlation between serologic and fecal culture results was examined in pig herds as part of an international research program sponsored by the European Commission, Salmonella on Pork. Samples were examined from herds in Denmark, the Netherlands, Greece, and Germany. The serologic herd status was determined by blood sampling 50 finishing pigs. There was an increased probability of recovering *Salmonella* with increasing within-herd seroprevalence, but the correlation was only moderate.

NECROPSY FINDINGS

Septicemia

There may be no gross lesions in animals that have died peracutely, but extensive submucosal and subserosal petechial hemorrhages are usually evident. The petechiae are very prominent and may give the kidney the "turkey-egg" appearance usually associated with hog cholera. A rhomboidal area of gastric mucosal infarction is usually present in pigs sometimes with frank hemorrhage. Congestion and hepatization of lung tissue may also be present with bronchopneumonia. Skin discoloration is marked and, depending on the severity of the case, this varies from extreme erythema with hemorrhage, to plaques and circumscribed scabby lesions similar to those of swine pox. There may be infarction of the tips of the ears, which may slough completely. The lymph nodes are often enlarged, moist, congested, and hemorrhagic. The liver may have focal areas of necrosis and the wall of the gallbladder may be thickened and edematous. In some cases the necropsy findings may include splenomegaly and pinpoint white foci in the liver (paratyphoid nodules). The histologic lesions are extensive, but none specific with the exception of the somewhat granulomatous character of the older paratyphoid nodules. There are areas of coagulative necrosis, with neutrophils and histiocytes. There may be fibrinoid thrombi in the venules of the gastric mucosa, in cyanotic skin, glomerular capillaries, and pulmonary vessels. The spleen and lymph nodes show reticular cell hypoplasia and histiocytosis.

Acute Enteritis

The most common lesion is an enterotyphlocolitis usually involving the ileum, cecum. and spiral colon. In the past, in the UK, infection with SCS has been associated with significant "button ulcers" in the affected segments, particularly near the ileocecalcolic junction. The mesenteric lymph nodes are consistently markedly enlarged and moist. The stomach contents are usually scant and bile-stained. Often cecal or colonic contents are black or are sand-like and gritty.

Some of the changes associated with the septicemic form are often present, but the most consistent damage is found in the large and small intestines. The character of the inflammation here varies from a mucoenteritis with submucosal petechiation to diffuse hemorrhagic enteritis. Congestion and infarction of the gastric mucosa is often seen. Infections with STM are characterized by severe necrotic enteritis in the ileum and large intestine. The intestinal contents are watery, have a putrid odor, and may contain mucus or whole blood. In cases that have survived for longer periods, superficial necrosis and fibrin exudation may proceed to the development of an extensive diphtheritic pseudomembrane and fibrin casts. The mesenteric lymph nodes are enlarged, edematous, and hemorrhagic. The wall of the gallbladder may be thickened and inflamed.

Histologic lesions are most common in the cecum and spinal colon but may be found elsewhere. The *lamina propria* and the submucosa are typically infiltrated by neutrophils and then macrophages and a few lymphocytes. Fibrin thrombi are frequently observed in the capillaries. There may be a fibrinonecrotic crust on the surface of the mucosa often containing other bacteria and *Balantidium coli.*

Survivors of the septicemic and acute enteric forms of salmonellosis may develop rectal strictures. Lesions in pigs with *S.* Heidelberg are mild or nonexistent.

Chronic Enteritis

In pigs the lesions in chronic enteritis are diffuse. Less commonly the lesions are discrete in the form of button ulcers, occurring most frequently in the cecum around the ileocecal valve. The mesenteric lymph nodes and the spleen are swollen. In all species,

chronic pneumonia and a variety of other localized inflammatory processes such as polyarthritis and osteomyelitis may be found.

DIAGNOSIS

Clinical signs and lesions may lead to a presumptive diagnosis of salmonellosis, but all porcine septicemias are superficially similar.

Salmonellas are present in the heart, blood, spleen, liver, bile, mesenteric lymph nodes, and intestinal contents in both septicemic and acute enteric forms. In the chronic form, the bacteria may be isolated from the intestinal lesions and less commonly from other viscera. Culture is more successful if enrichment media such as tetrathionate broth are used. In pigs experimentally infected with STM and SCS the organisms can be detected with peroxidase–antiperoxidase immunoenzymetric labeling and Immunogold techniques. Surveys that set out to determine the percentage of carriers in animal populations by examining abattoir material show that by far the largest number of isolations are made from the lymph nodes draining the cecum and lower small intestine.

Samples for Confirmation of Diagnosis

- ***Bacteriology:*** Ileocecal lymph node, ileum, colon, spleen, lung, liver, culture swab from gallbladder (CULT). It requires brilliant green bismuth sulfite, blood agar, or MacConkey agar. Enrichment is not required unless there is fecal contamination or mishandling. In these cases, tetrathionate broth at 42°C to 43°C is the enrichment medium of choice. Selenite broth is inhibitory for SCS. Ileum is not good for septicemia confirmation.
- ***Histology:*** Formalin-fixed samples from these tissues plus kidney, stomach, brain

Other tests are not used routinely. PCR has a high cost and lacks sensitivity without preenrichment.

Serology (ELISAs) is used for herd diagnosis. Mixed ELISA meat juice is most important for assessing infection at slaughter.

Note the zoonotic potential of these organisms when handling carcasses and submitting specimens.

DIFFERENTIAL DIAGNOSIS

The clinical diagnosis of salmonellosis is difficult because of the number of diseases that resemble each form of the disease. Salmonellosis is characterized by septicemia in young animals and acute and chronic enteritis in adults, although acute enteritis can occur in neonates. Thus the septicemic form of the disease must be differentiated from all other causes of septicemia and the enteric forms from all other causes of diarrhea in both young and adult animals. At necropsy the isolation of salmonellas from tissues and intestinal contents, although suggestive of the presence of salmonellosis, does not of itself confirm the diagnosis, and care must be taken to ascertain whether other disease is present.

Pigs

Septicemic salmonellosis occurs in pigs 1–4 months of age and is characterized by fever, depression, skin color changes, diarrhea, and rapid death.

- **Hog cholera**, **African swine fever, coliform gastroenteritis of recently weaned pigs**, and **pasteurellosis** may resemble septicemic salmonellosis very closely and laboratory examination is usually necessary for identification.
- **Acute erysipelas** is characterized by typical skin lesions, fever, swollen joints, and typical lesions at necropsy.
- **Swine dysentery** is characterized by mucoid feces with dysentery and typical lesions of the large intestine.

Acute enteritis

The differential diagnosis of diarrhea includes:

Swine dysentery

Proliferative enteropathy

Coronaviruses

Circovirus

Colibacillosis

Coccidiosis

Trichuriasis

TREATMENT

Primary Treatment: Antimicrobial Therapy

The choice of antibiotic should depend on the use of an antibiogram and the practitioner's previous knowledge and experience. In most salmonellas AMR is plasmid mediated.

The DT104 is especially worrying because it has a chromosomally integrated multiple AMR.

The use of antimicrobials for the treatment of clinical salmonellosis is controversial and different approaches to the problem exist among veterinarians. The controversy centers on two parts of the response to treatment and which view is taken depends to a large extent on the experience one has with respect to them.

The first issue is that of the success of treatment in saving the lives of clinically affected animals. It is the author's experience that early treatment with broad-spectrum antimicrobials is highly effective in reducing mortality and returning animals to normal function. It is generally agreed that treatment must be early, because delay means loss of the integrity of intestinal mucosa. A common pattern of response to treatment in a herd is that the first one or two cases are regarded lightly by the owner and they are treated 24 to 48 hours after diarrhea begins. When these cases die, a more prompt regimen is instituted in which the farmer has the approved drug on hand and begins treatment as soon as diarrhea with fever is observed. The cure rate is then likely to be around 100%.

The second issue in the controversy about antimicrobial therapy for salmonellosis is the risk of inducing "carrier" animals. In humans and in animals there is some evidence that antimicrobials can prolong the duration of the period after clinical recovery during which the causative bacteria can be isolated from the intestine. It is accepted that this can occur and that the use of antimicrobials can theoretically contribute to the spread of disease. However, because of the way in which animals are kept, and because they constantly ingest contaminated pasture or other feed, there is an almost universal carrier segment in animal populations, and to regard another survivor from salmonellosis as a significant contributor to the carrier frequency seems an exaggeration. In many situations this appears to be the correct view, but in other situations an animal can become infected, for example, in a veterinary hospital or at an exhibition or show, recover clinically with treatment and, after returning to its parent herd, initiate an outbreak of fatal and debilitating salmonellosis. Both epidemiologic patterns occur, and they seem to occur in different places, so that the most appropriate attitude to take seems to be the one that fits local circumstances. In an area in which only sporadic cases of the disease occur in herds, it would be professionally negligent not to treat infected animals with appropriate antimicrobials. In endemic areas, recovered animals should not be sent into herds until they are known not to be carriers.

Other related issues are the creation of drug-resistant strains of the bacteria and the effect on the normal intestinal flora that results from oral medication. The problem with resistant strains would not have become significant if only individual animals had been treated, but mass medication of in-contact animals and prophylactic treatments have generally resulted in a large population of resistant strains.

Oral treatment in pigs is recognized as a satisfactory treatment. In summary, antimicrobials are recommended for all clinically affected animals (see later). The choice of antimicrobials depends on a test of drug sensitivity in each case or outbreak, but failing this the following generalizations can be applied.

For pigs with septicemic salmonellosis, trimethoprim-sulfadoxine is recommended, along with a combination of mass medication of the water supply with chlortetracycline and sulfamethazine (75 mg of each per liter of water). Where large numbers of pigs are affected, mass medication via the feed or drinking water is usually practiced. Because sick pigs do not eat, water treatment is necessary, and if drugs are unpalatable individual treatment is the last recourse. Drugs that dissolve readily and are palatable are therefore

in demand. Experimental disease of pigs with *S. typhisuis* can be controlled by the inclusion of low concentrations of chlortetracycline, penicillin, and sulfamethazine in the feed.

CONTROL

It has become clear that successful interventions must be based on a range of preventive approaches.[80] Although in theory increased hygiene and establishing all-in/all-out production should reduce the level of *Salmonella* in practice, it is not easy to do so.[81]

Control of *Salmonella* in pigs can be divided into three main areas. Herd interventions are not sufficient to reduce *Salmonella* to <1% the desired target of the Danish schemes.[82] The cost-effectiveness of abattoir interventions varies with the size of the plant, and the most likely to succeed are steam vacuum and steam ultrasound. As yet these have not been tested for effectiveness.

Preventing Infection From Entering the Herd (Biosecurity)

In a simulation study in France, it was found that if the movement of animals was based on the level of prevalence, and movement was not allowed from herds with high herd prevalence to those of low herd prevalence, then *Salmonella* could be significantly reduced.[83]

Avoidance of infection is the major objective but is not easily achieved. The principal sources of infection are carrier animals and contaminated feeds containing foodstuffs of animal origin.

Breeding stock should only be bought from herds that are certified free if the receiving herd is free from salmonellas. Buying in gilts or sows is a much greater risk than buying in boars.

For the pig finishers the following rules apply:

- Introduce the animals directly from the farm of origin. Avoid auction marts, saleyards, and public transport, all of which are likely to be sources of infection. Ensure that the farm of origin is free of salmonellosis. Finishers receiving growers that were positive had a much higher level of seroprevalence in the finishers than those that did not.
- If possible, purchase animals when they are older to provide an opportunity for specific and nonspecific immunity to develop. Animals from vaccinated herds are desirable but not always available.
- The premises of dealers, saleyards, and transport vehicles must be under close surveillance, and the need for frequent vigorous disinfection must be stressed. With decreasing levels of infection it is important that the infections in transport systems and the lairage are managed.[84] Introduce only those animals likely not to be carriers. Unfortunately the detection of carriers is inaccurate and expensive. To have any confidence in the results, fecal samples for culture must be submitted on at least three occasions. Even then, occasional carriers with lesions in the gallbladder or tonsils will escape the net and be capable of reviving the disease on the farm or transferring it to another one.

Rodent and bird control is essential. Control of access to potential human fomites is also important, and they should be provided with clean protective clothing and boots before entering the herd. The significance of various environmental sources is often neglected and should be studied more intensely, such as lairages and truck-washing facilities.[85]

Increased Hygiene to Prevent Intraherd Spread

Possibly the most effective method for the control of *Salmonella* infection in weaners appears to be segregated early weaning (no extra benefit before 3 weeks) into clean accommodations.[86]

When an outbreak occurs, procedures for limiting spread, as set out next, need to be strictly enforced, and medication of affected groups, and of susceptible groups at high risk, must be performed. The drugs to be used are those listed under treatment as well as the choice of the individual drug depending on its efficiency and cost.

- **Identify carrier animals and either cull them or isolate and treat them vigorously.** Treated animals should be resampled subsequently to determine whether a "clean" status has been achieved.
- **The prophylactic use of antimicrobials** such as oxytetracycline in the feed at the rate of 10 g/tonne, or chlortetracycline in the drinking water at the rate of 55 mg/L, is used but not recommended, because results are poor and there is a risk of developing resistant strains.
- **Restrict the movement of animals around the farm** and limit the infection to the smallest group. Pasture and permanent buildings are both important, although the major source of infection in most cases is the drinking water.
- **The water supply should be provided in troughs that are not susceptible to fecal contamination.** Static drinking water or pasture may remain infected for as long as 7 months.
- **Rigorous disinfection of buildings is important.** An all-in/all-out policy should be adopted and steam cleaning and chemical sterilization performed after each batch of animals. Piglets can be reared free of *Salmonella* infections up to 6 weeks of age by removing the piglets from infected herds to isolation facilities when they are weaned at 10 to 21 days of age. The movement of pigs either at weaning, from the nursery, or from the grower unit to newly built or rigorously cleaned and disinfected finishing units with a known history of *Salmonella* infection is highly successful. If economics permit, individual pens for calves are beneficial. Where calves are reared indoors these pens are common and economical. Pig houses need especially careful treatment. Dirt yards present a problem, especially those used for sheep and calves, but, provided they can be kept dry and empty, two sprayings, 1 month apart, with 5% formalin are recommended. Disinfection greatly reduces the numbers but does not eliminate the organism,[48] irrespective of which disinfectant is used.
- **Suitable construction of housing is important.** Impervious walls to stop spread from pen to pen, pen design to permit feeding without entering the pen, avoidance of any communal activity, and slatted floors to provide escape routes for manure all assist in limiting the spread of enteric diseases. Deep litter systems are satisfactory provided they are kept dry and plenty of bedding is available. With pigs the opportunity for oral–fecal cycling of the organism and buildup and spread of infection within and between groups must be kept to a minimum. Pen design and the environment should encourage proper eliminative behavior and good pen hygiene. Drinkers should be sited at one end of the pen, preferably on a narrow end with oblong pens, to encourage defecation in this area. Wet or damp areas of the floor in other parts of the pen will encourage defecation and urination there and should be eliminated. Drinkers of the nipple type rather than bowls are preferable for hygienic reasons. Communal dunging alleys increase the possibility of spread, especially during the cleaning procedure, and the trend is toward slatted or meshed areas over a channel. A totally slatted or mesh floor for pigs from weaning until 10 to 12 weeks of age will markedly reduce the opportunity of oral–fecal cycling of organisms in this age group, which is especially susceptible to enteric disease. Feeders should allow the ingress of the pig's head and should be constructed to avoid fecal and other contamination of feed. Pigs need to be grouped according to size, and overcrowding, which may result in improper pen hygiene, must be avoided. Space requirements vary according to pen and housing design but generally fall in the region of 0.3 m^2 for recently weaned piglets to 0.6 to 1 m^2 for market-size pigs. In conventionally floored or partially slatted floored pens, approximately $\frac{2}{7}$ of the area should be available for the dunging area. The construction of the pen should allow for easy and efficient cleaning. In problem herds an especial vigilance for the

occurrence of enteric disease is needed following the breakdown of pen hygiene on very hot days.

- **Disposal of infective material should be done with care.** Carcasses should be burned or, better still, sent to an institution for diagnosis, rather than to a rendering plant to be converted into still more contaminated bonemeal. Slurry decreasing the storage time and manure for disposal should be placed on crops rather than on pasture. Slurry does not constitute a danger via hay, and salmonellas do not survive silage making. When slurry is used on pasture it should be stored for at least a month beforehand and even longer if silo effluent is included. Slurried pasture should not be grazed for 1 month, and for young animals a 6-month delay is recommended. Pig slurry is most dangerous and should always be avoided. Urea and to a lesser extent ammonia may be used to disinfect *Salmonella*-contaminated slurry, decreasing the storage time required while increasing its fertilizer value.[87]
- **All persons working on infected premises should be warned of the hazards to their own health.** Other peripatetic species, especially dogs, should be kept under close restraint. Restrictions on staff movements within the unit may also prevent cross-infection.
- No moving back of animals from pen to pen is essential.

Reducing Exposure to Pathogens

- Promoting appropriate personal hygiene
- Using effective methods for cleaning and disinfection
- Controlling the flow of human and animal traffic
- Implementing protocols for prompt identification of patients with signs of contagious disease
- Controlling birds, rodents, and flies

Avoiding Increasing Susceptibility to Pathogens

- Controlling ambient temperature
- Using antimicrobials appropriately
- Aiding in establishing normal intestinal or rumen flora
- Controlling endotoxemia

Monitoring Effectiveness of the Infectious Disease Control Program

- Bacterial culture of fecal samples of animals admitted to the hospital
- Regular culture of environmental samples

Feed Interventions to Aid the Pigs' Defenses

Physical Form of the Feed

Herds that use pelleted feed have on average three times the seroprevalence of herds that mix their own feed. This is surprising because most pelleted feed follows stringent rules for production and home-mixed diets use nonheat-treated soya. Home-mixed feed and coarse ground feed protect pigs against *Salmonella*, although there is a loss of productivity.

The addition of 25% of nonheat-treated, nonpelleted wheat or barley does have a beneficial effect in those herds with a high seroprevalence. Meal feeding increased the viscosity of the stomach contents compared with pelleted feed and a higher content of organic acid producing lactobacilli were found in the stomach. Increasing the amount of barley also has a protective effect.

The use of organic acids in dry pelleted feed could reduce the seroprevalence in finishers, and 0.8% of formic acid or lactic acid could also reduce *Salmonella* prevalence.[88] The same can be achieved by placing organic acids in drinking water. They seem to be more beneficial in weaner diets than in finisher diets. These effects are probably much reduced in sows. In a study of direct-fed microbials or organic acids, there was no effect on the treatments except for the in-feed antibiotic.[89]

The effect of organic acids on *Salmonella* colonization and shedding in weaner pigs in a seeder model has shown that the organic acids could reduce fecal shedding and numbers of coliforms and salmonellas in cecal digesta. Colonization of tonsils and ileocecal colic lymph nodes by salmonellas was not affected.[90]

Liquid feed for finishers seems to reduce the level of seroprevalence by two-thirds compared with herds using dry feed. The key seems to be to keep the pH of the feed below 5.5 so that the piped feed is also acidic by encouraging fermentation or by the addition of formic acid.

Oxygenated drinking water enhances the immune activity and response of pigs exposed to STM.[91]

Organic Acids

In a study of the effects of a mixture of formic acid and lactic acid (both 0.4% w/v) or 1.0% lactulose influenced the numbers of *Salmonella* in the ileum and cecum of experimentally challenged pigs.[92]

The administration of organic acids to drinking water during the last 2 weeks before slaughter on *Salmonella* shedding by slaughter pigs and the contamination of carcasses was shown to be ineffective in reducing the levels of bacteria.[93] The effect of the addition of organic acids in drinking water or feed during part of the finishing period on the prevalence of *Salmonella* in finishing pigs has been described.[94] Pigs received a mixture of acids (lactic, formic, and propionic) or potassium diformate. At the end of the trial the proportion of seropositive pigs was less with either treatment than in the controls. The frequency of fecal shedding was also lower.

Heat treatment of feed is an effective procedure for pigs. Heating during pelleting greatly reduces the bacterial content of feed, and the special treatment is worthwhile because of the very high proportion of animal-derived feeds that are infected. The availability of such feeds guaranteed to be *Salmonella*-free would be an advantage.

Feed Withdrawal

As feed withdrawal times increased before slaughter, so the numbers of salmonellas increased as the numbers of lactobacilli decreased.[95]

Other Options

In the future there is the potential use of bacteriophages to reduce the populations of salmonellas,[96] but this study showed that they were at very low levels in the commercial swine population. Experimental phage cocktail therapy of slaughter pigs significantly reduced the cecal STM concentrations and reduced numerically the ileal *Salmonella*.[97]

It may be possible to use 2-nitro-1-propanol and 2-nitroethanol with added chlorine as feed additives to control *Salmonella*.[98]

Immunization

Salmonella Vaccinology

A successful vaccine should prevent colonization of the host, shedding of the organism to the environment, the development of the carrier state, and the development of the clinical state.[80] At present no vaccine fulfills all these criteria, but vaccines can reduce the on-farm pressure.[99-103] An attenuated vaccine reduced STM numbers in a model simulating preslaughter stress.[104]

A live attenuated STM expressing swine interferon (IFN)-α has antiviral activity and alleviates clinical signs of TGE. The result indicates the value of attenuated *Salmonella* vaccines as delivery systems of cytokines.[105]

An inactivated STM bacterin was shown to reduce the shedding and horizontal transmission of STM as well as the proportion of shedders or carriers at slaughter.[94]

Immunization of pregnant sows with a novel virulence gene (VG) deleted live *Salmonella* vaccine, and protection of their suckling piglets against salmonellosis has been successful. The systemic and mucosal immune responses were highly induced by the vaccine candidate, especially when this was administered by both routes of intramuscular prime and oral booster and oral prime and booster.[106]

The literature on *Salmonella* vaccines has been reviewed. Host resistance to *Salmonella* relies initially on the production of inflammatory cytokines leading to the infiltration of activated inflammatory cells in the tissues. Thereafter, T-cell– and B-cell–dependent specific immunity develops, allowing the clearance of *Salmonella* from the tissues and

the establishment of long-lasting acquired immunity to reinfection. The increased resistance that develops after primary infection or vaccination requires T-cell cytokines such as IFN-γ, TNF-α, and IL-2, in addition to opsonizing antibody. Seroconversion and/or the presence of detectable T-cell memory do not always correlate with the development of acquired resistance to infection.

Immunization with live salmonellas induces early resistance rechallenge with virulent organisms that appear 1 day after infection or vaccination with live but not killed organisms. Early protection is nonspecific and effective against different *Salmonella* serotypes. Long-term immunity using live attenuated vaccines is serotype specific and involves the recall of immunologic immunity. Killed vaccines induce strong antibody responses but trigger insufficient T-helper-1 (Th1)-cell responses.

Vaccines have been developed and tested in pigs. If vaccination is combined with the hygienic precautions described, the vaccines are an aid to management. Killed bacterins and live attenuated vaccines are available. Either can be used as a prenatal vaccine to provide passive immunization of the newborn. It is now generally accepted that live *Salmonella* vaccines are more effective immunogens in calves than are killed vaccines. Experimentally, a live STM vaccine delivering recombinant *E. coli*, K88ab, K88c, Fed A, and Fed F has been shown to be highly immunogenic.[106]

A commercial vaccine containing living, attenuated SCS has also been shown to protect neonatal pigs after vaccination of sows and weaned pigs. Because of the early age at which pigs need to be immune, it is recommended that sows be vaccinated three times at 7- to 14-day intervals. The young pigs are vaccinated at 3 weeks of age. A live avirulent SCS vaccine has been developed and evaluated for protection against experimental challenge. Vaccinated pigs were able to maintain normal BW gains during a 4-week observation period following challenge inoculation with a high dose of a virulent strain. It has consistently been safe and efficacious in pigs as young as 3 weeks and provides protection for at least 20 weeks. An STM live negative-marker (OmpD) vaccine has been constructed and given to pigs that will not interfere with meat juice ELISA diagnosis[107] and this holds hope for the future. A sophisticated plasmid-cured and CRP gene-deleted SCS live vaccine has been described, and the mutant may form the basis for a new vaccine.[108]

Most cases of salmonellosis in pigs are subclinical and caused by *S.* Typhimurium. The ideal vaccine against STM would prevent colonization, shedding of the organism in the environment, development of carriers and clinical salmonellosis, and promote elimination of the organism from infected animals. Live vaccine strains are considered to provide superior protection compared with inactivated vaccines.

Monitoring

Statistical methods to categorize pig herds based on serologic data have been described[109,110] as well as descriptive spatial epidemiology.[111]

Herds can be classified quite differently according to the test used[112] when three ELISAs were compared and their results examined.

Nationwide Surveillance and Control Programs

In 1993, the Ministry of Food, Agriculture, and Fisheries of Denmark and the Danish Bacon and Meat Council initiated an ambitious program to eliminate pork as an important source of human salmonellosis. In the early 1990s pork had become recognized as an increasingly important source of human salmonellosis in Denmark. In Denmark, the proportion of human salmonellosis attributable to pork was estimated to be 10% to 15% in 1997 and 1998. In the Netherlands, it was estimated that approximately 15% of human cases of salmonellosis were associated with the consumption of contaminated pork.

The Danish Salmonella Surveillance and Control Program for pigs operates at all stages of the production chain and has been applied nationally since 1995. As a result of the program the level of *Salmonella* in Danish pork declined from 3.5% in 1993 to 0.7% in 2000. Simultaneously, the number of human cases of salmonellosis caused by pork declined from approximately 1444 in 1993 to 166 in 2000. Quality control has been described.[113]

The control program is integrated from "feed to food." It is based on routine testing and classification of slaughter pig herds and the subsequent slaughter of pigs according to the inherent risk, as measured by the continual test program. In a study of culture and ELISA testing, it was found that results cannot be compared easily, because some seronegative pigs were + ve on culture and some culture – ve pigs were + ve on serology, so the test has to be selected to answer a specific question.[114] Methodological problems related to the optical density data obtained from meat juice ELISAs have been shown to require recalculation; otherwise there would be an underestimation of actual seroprevalence.[115]

The Danish Control system and a description of an extended preharvest surveillance and control program has been described.[116] Only hot-water decontamination was socioeconomically profitable in a comparison with the control plan as it operated in 2006.[117]

Basically, the level of *Salmonella* is controlled at various stages. The UK plan has been described.[118] The barriers to the adoption of measures to control *Salmonella* in pigs in the UK has been reviewed[119] and one of the most important measures was the failure of farmers to recognize the importance of *Salmonella* control. Other factors are the low awareness of pork as a risk for *Salmonella,* the low incidence of *Salmonella* associated with pork, and the food chain members do not want to raise the problems. It is important to recognize that pooled sampling is highly efficient compared with individual sampling and that clustering at pen level influences the results; thus it is important to take this into account in the estimation of appropriate sample sizes and the estimation of prevalence from pooled sample data.[120] These data can be used to study spatial disease epidemiology.[121]

Feedstuffs

Compounded feeds are heat treated at 81°C to eliminate *Salmonella.* The national program requires mandatory *Salmonella* testing in all plants producing animal feeds. In 2000 the level of *Salmonella* spp. in final products was only 0.3%.

Low-level nitrate or nitroethane preconditioning enhances the bactericidal effect of chlorate treatments, and this may offer opportunities to control *Salmonella* in the future.[122] The supplementation of meal diets with potassium dichromate significantly reduced the duration of survival and increased the rates of decline in *Salmonella.*[123]

The direct feeding of microencapsulated bacteriophages has been shown experimentally to reduce colonization and shedding.[124]

A probiotic strain of *E. faecium* fed to pigs resulted in an enhanced infection but also an increased level of specific antibodies to STM DT104.[125] High-dosage dietary zinc oxide had no protective effects on weaned pigs with DT104.[126] Caprylate in the form of encapsulated beads or as an oil might be a *Salmonella*-reducing additive in pig feed.[127]

Breeder and Multiplier Herds

Each month all herds are blood sampled and examined for *Salmonella* antibodies. Based on the level of antibodies, a *Salmonella* index is calculated. If the index exceeds 5, pen fecal samples must be taken and examined for the presence of *Salmonella* spp. When the index exceeds 15, a sales ban on breeding pigs is imposed until the index has declined below 15 again.

Weaner Producers

If a sow herd sells weaners to a *Salmonella* level 2 or 3 finishing herd, pen fecal samples must be taken and examined for *Salmonella.*

Slaughter Pigs

In a study of slaughter pigs, ileal contents were 18.7% + ve, the lymph nodes 17.8%, 7.2% in the rectal contents, and 3.6% in the carcass swabs.[93]

Slaughter herd pigs are monitored continuously by serologic testing of meat juice.

Meat samples are frozen, and meat juice (harvested after thawing) is examined for specific antibodies against *S. enterica* using an ELISA. The ELISA combines several *S. enterica* O antigens and allows detection of antibody response after a variety of serovar infections. The meat samples for testing are collected at the slaughter line, and the number of samples and frequency of sampling are determined by the size of the herd. Herds sending fewer than 200 pigs to slaughter per year are not examined, which amounts to about 1.6% of slaughter pigs. The herds are categorized in four levels based on the proportion of seropositive meat juice samples during the previous 3 months. Based on the optical density percent of the ELISA test, the herds are classified into the following levels:

Level 0: Herds having only seronegative over 3 months or more
Level 1: Herds with acceptable low *Salmonella* prevalence
Level 2: Herds with moderate *Salmonella* prevalence
Level 3: Herds with unacceptable high *Salmonella* prevalence

The herd information as to status can be used to direct the risk-based approaches to surveillance.[128-130]

A herd categorized as level 2 or 3 must receive an advisory visit by a practicing veterinarian and a local extension specialist, and certain management precautions must be adopted. In a level 3 herd, the finishing pigs must be slaughtered under special hygiene conditions. In a study in the UK, an increased risk of carriage at slaughter was associated with >12 hours in the lairage, pigs transported from northeast UK, and not feeding when there was no bedding available.[131]

The proportion of serologically positive meat juice samples collected during 1995 ranged from a mean of 2.9% in small herds to 6.1% in large herds.

Segregated transport to the abattoir has additional costs but may reduce contamination.[132] Costs were governed by the percentage of changed shipments and the additional distance of a changed shipment.

In a study of hog carcasses in Canada it was shown that the cleanliness of the hogs and the status of the scald water were the two most important factors involved in the *Salmonella* carriage at the end of the slaughter process.[133] Decontamination of pork carcasses can be achieved using hot water and acidified sodium chlorite.[134]

The use of lactic acid sprays as a decontamination measure when used with good manufacturing processes during processing will significantly reduce *Salmonella* contamination of pork variety meats (liver, heart, intestines, and stomachs).[135]

Cleaning and disinfection in the slaughterhouse, particularly the lairage area, is an area that can influence the presence of *Salmonella* on the carcass.[34]

Enumeration of *Salmonella* in feces of naturally infected pigs has been described.[136] Most exposures to *Salmonella* of swine are at doses below the infectious dose. Doses >10^3 CFU increase the probability of infection in swine.[137] Only a few high concentrations of *Salmonella* in feces were clustered within the pig and the pen. Identification and removal of high shedders may be very effective to reduce carcass condemnation. The robustness and rapidity of the direct q-PCR assay can be a very useful screening tool for removal of the high shedder at the lairage. In an experimental evaluation of on-farm interventions, five activities were ranked feeding meal > inclusion of acids in ration > feeder pen disinfection or > *Salmonella* spp. vaccination > in-feed tetracyclines.[138]

Slurry

The addition of urea to pig slurry will add additional antimicrobial ammonia and carbonate anions. It could greatly reduce the time needed to eliminate *Salmonella in slurry* and reduces the pathogen recycling risks associated with using porcine waste as a fertilizer.[139]

At Abattoir

Lesion profiling at processing can be used to predict *Salmonella* contamination of swine carcasses.[140]

The roles of slaughtering in *Salmonella* spreading and control in pork production has been reviewed,[141] and they have indicated that there is a continuous source of infection from the farm. At the slaughterhouse there are some dressing activities that can reduce the carcass contamination but others may jeopardize carcass hygiene.

INTESTINAL CLOSTRIDIOSIS IN THE PIG

There are three Clostridia involved in intestinal clostridiosis in the pig.

- ***C. perfringens*** type C (CPC) affects pigs of 1 to 14 days, usually less than 7 (rarely older) and produces hemorrhagic, watery diarrhea and sudden death.
- ***C. perfringens*** type A (CPA) affects pigs of 2 to 10 days (rarely older) and produces creamy, watery mild diarrhea and decreased growth rate.
- ***C. difficile*** (CD) affects pigs of 1 to 5 days of age (rarely older) and produces creamy diarrhea, dehydration, and death.

CD is an important cause of diarrhea in humans associated with antibiotic usage. It may also present as a colitis, or fulminant colitis followed by ileus, toxic megacolon, and bowel perforation. It may also cause diarrhea in antibiotic treated foals, hamsters, and guinea pigs. Some authors highlight the high level of relatedness of CD ribotypes found in human and porcine isolates.[1,2] It was originally associated with hospital infections but now approximately 40% may be community-associated CD infections.[3,4] The ribotype O78 is an emerging strain in humans and pigs.[5] There is still confusion as to whether this is a potential zoonotic or food-borne disease.[6] It is likely that there is little food-borne risk because the level of infection in slaughter pigs is greatly reduced.[7] It has been suggested that humans and pigs may be exposed to the same environmental sources of CD. The comparative pathology of CD-associated disease has been described.[8] It may be the most important uncontrolled cause of neonatal diarrhea in the pig.[9]

ETIOLOGY

CPC is a primary pathogen but can colonize other lesions. It is a large, gram-positive rod that only occasionally forms spores and produces the α- and β-toxins (CPA and CPB toxins). The β-toxin is more important and is sensitive to protease/trypsin. A second toxin, the β-2 toxin, has been found in necrotic enteritis, and the function of this is not yet clear. Variable amounts of α-, β- and δ-toxin are produced. *C. perfringens* type B is found occasionally.

CPA is a normal inhabitant of the intestinal microflora of the newborn piglet but can also cause severe disease via the α-toxin, which it produces. Immediately after birth, there are large numbers in the stomach of piglets and later large numbers in the colon. Quite often, there are greater numbers in the healthy piglets than diarrheic piglets. The *cpb2* gene and its expressed protein a 27.6-kD toxin (CPB2) was first described in an isolate from necrotic enteritis. It was subsequently demonstrated by PCR in a variety of animals with diarrhea and necrotic enteritis.[10] The CPB2 toxin is encoded by either a "consensus gene" or by an "atypical gene" with 80.4% similarity between the two proteins.[11] In a study of cpb2 encoding CPA and diarrhea it was shown that the consensus cpb2 was present in 93% of the isolates in healthy and diarrheic piglets and the atypical gene was shown in only 56% healthy and 32% diarrheic piglets.[12] The presence of CPB2 toxin in the intestinal contents of normal and diarrheic piglets did not differ significantly. There is a role for β-2 toxin, and nearly all of the strains of type A also produce this toxin. There are also some strains that produce enterotoxin.

CD can be asymptomatic or can cause diarrhea in piglets. Spores germinate in the ileum, cecum, and colon. It has emerged as a cause of enteritis in pigs. It is classified by ribotype (O) and toxin types, e.g., O76 toxin type V. It produces two major toxins, A (lyses epithelial cells) and B (damages underlying tissues), both of which are involved in the pathogenicity, as well as a third binary toxin. Ribotype O78 was found in 83% of pig isolates from North America.[13]

EPIDEMIOLOGY

The prevalence and diversity of toxigenic CPC and CD among the swine herds of the Midwest United States was studied.[14] CPC was isolated from 89.8% of the pigs and CD from 57.7% of the pigs. Most of the CD isolates were toxinotype V, but there was considerable diversity in the CD isolates.

In a study from Poland, CPC was found in 92% of feces samples and all the isolates belonged to type A and 48.7% of them contained the *cpb2* gene. Type A subtype β-2 isolates showed expression of *cpa* genes in 100% of strains and *cpb2* gene in 71% of the analyzed strains. The isolate from 1-day-old piglets demonstrated both *cpa* and *cpb2*.[15]

CPC occurs in most pig-producing countries; necrotic enteritis has even been seen in isolated communities in Switzerland.[16] In Switzerland it occurs on breeding farms that do not vaccinate for CPC.[17,18]

It may be transmitted from piglet to piglet but the source is usually sows' feces. It often follows the introduction of new stock to a farm and then may occur for a few months. If regular imports are made it may last for 15 months. They are usually present in small numbers in the feces of sows but are capable of outgrowing the other flora in the neonatal pig gut and eventually multiply in huge numbers.

The organism persists in the environment as spores that are resistant to heat, disinfectants, and ultraviolet light.

The epidemiology of CPA has been studied on Ontario farms with special reference to cpb2-positive isolates.[19] The conclusion was that if type A strains were involved in neonatal enteritis then there might be strains that were not identified by the existing genotyping system. In this study the

cpb2-positive and expressing CPB2 population was clonal, and this lineage appeared to be adapted to the young piglet. This was the first time this was established at the farm level.

CPA infections usually occur in the first week of life and sows are the source of infection. It is ubiquitous in the gut and the soil, and there are some strains that cause disease and others that do not, but at the moment it is not possible to tell them apart unless CBP2 positivity is shown on PCR. There are likely to be spores formed and the organism can be found in feed.

CD has appeared worldwide but particularly in Canada, the United States, France, and recently the Netherlands. Nearly two-thirds of piglets in major swine-producing areas in the United States have CD with some herds having 100% infection. It may reflect the routine use of antibiotics and also bad husbandry and hygiene. In a study in Spain,[20] the bacteria were recovered from newborn piglets (25.9%) and were not recovered from 1- to 2-month-old pigs. Genes for the production of both toxins were found in most of the isolates, and only a few had neither of the toxin genes. In this study there was no clear link between bacterial isolation and neonatal porcine diarrhea. A longitudinal study comparing CD in conventional and antimicrobial-free pigs at farm and slaughter[21] showed that CD was at its highest in both systems in the farrowing house and decreased with age. At slaughter it was very low in both carcasses and equipment. Toxinotype V was the most common type isolated at about 90% and the others were type XIII. The authors found antibiotic resistance regardless of antibiotic use on the farm.

In a study of acquisition of CD by piglets in the Netherlands a group of six sows, their crates, and their litters were studied.[22] Within 48 hours of birth all 71 piglets were positive for CD. One was positive within 1 hour. All six sows were positive within 113 hours, and the crates were intermittently positive. CD was found in the air and on the sow's teats. All were O78 and as in most of the Netherlands the same clonal spread except one isolate. This study showed that O78 spreads easily through the sows, piglets, and the environment. Vertical transmission was not found and is not likely to be a factor.

Piglets may be infected within 1 hour of birth, but there is no vertical transmission. The high prevalence of CD ribotype O78 in Iberian wild pigs has been demonstrated[23] as well as its occurrence in feral pigs.[24]

In a study in Switzerland,[25] no CD was found in pigs or ground meat.

In a study of slaughter pigs in the Netherlands, a higher incidence of CD was found than was expected.[26] The prevalence was 8.6%, and 16 different ribotypes were identified with O78 the most common. No specific farm factors were identified associated with the prevalence of CD.

A similar study in 2011 showed a high prevalence of CD ribotypes in pigs arriving at the slaughterhouse.[27] The results showed that pigs had CD ribotypes after they were stunned and bled in a slaughterhouse. Pigs from 9/10 different farms were positive with seven different PCR ribotypes, and O15 was the predominant ribotype.

In a recent study in the United States,[28] 88% of the pigs had a single strain of CD (196/223 pigs) but 12% carried multiple strains. This was the first report of multiple strains in one pig. Overall this study showed that a significant percentage of strains were toxigenic and often are associated with AMR genes, although they are not resistant to drugs that are used to treat CD infections.

C. difficile genotypes in piglet populations in Germany have been described.[29] The organism was isolated from 73% of rectal swabs from piglets. The rate of isolation was at 68% postpartum, 94% in animals from 2 to 14 days of age, and declined to 0% after 49 days of age. There was no link between isolation and antibiotic treatment. This study demonstrated that the human pathogenic PCR ribotypes 078 and 126 are dominant in piglets in Germany. The presence of CD in pigs is correlated with animal age but not with antibiotic treatment or clinical disease.

PATHOGENESIS

The type C organisms colonize the neonatal bowel within 24 hours of birth. They can multiply very rapidly in the absence of colostral immunity and attach to the jejunal epithelial cells at the tips of the villi. These then slough off and the organisms proliferate along the basement membrane. Necrosis is extensive and hemorrhage follows. The necrosis may extend through the gut wall to the muscular layers. Then there may be perforation and peritonitis. The lethal and necrotizing β-toxin is the key factor.[30] The β-toxin binds to the endothelial lining of vessels showing early signs of thrombosis. Initially, it binds to small-intestinal mucosal endothelial cells in the early stages of experimentally induced CPC.[31] It disrupts the actin cytoskeleton of the cell and causes cell border retraction and cell shrinkage followed by cell death.[32]

Trypsin secretion deficiencies and colostral protease inhibitors probably account for the susceptibility of piglets less than 4 days old.

The toxin has been found in the intestinal contents and the peritoneal fluid. This suggests that death may be caused by the effects of intestinal damage and toxemia.

Type A pathogenesis is not understood but it is likely to be similar to type C without the attachment of organisms to the epithelium. Attachment and invasion do not occur in experimental infections, but epithelial necrosis does occur in these, although less obviously than in natural cases. There is a minimum of lesions, which suggests this is a secretory diarrhea. CPB2 is likely to be a marker of virulence because it occurs in >90% of natural enteritis cases but is rarely found in normal pigs. The role of the toxins is still uncertain, and the association of neonatal diarrhea requires the isolation of large numbers of cpb2-positive bacteria and the exclusion of other causes. In swine the CPB2 is nearly always the consensus type and is almost invariably expressed. The CPA nearly always belongs to a clonal type. Diarrhea disease isolates nearly all carry the CPB2 compared with a smaller proportion of CPB2-positive isolates from healthy pigs.

CD is likely to possess pili, capsule, and degradative enzymes but toxins are essential to produce the clinical picture. The two toxins produced by CD are the largest known bacterial toxins. A type of enterotoxemia is associated with the presence of monomeric CD toxin A (TcdA; 308 kDa). It causes fluid production in the intestine. Toxin B ((TcdB; 270kDa) does not appear to bind to any tissue nor does it produce lesions in explants,[34] but it appears to be a cytotoxin that is extremely toxic to cultured cells. Both toxins are internalized by target cells and disrupt the cytoskeleton. There is cessation of enzyme production and cell division. Degranulation of mucosal mast cells and release of inflammatory mediators follows with resultant tissue damage. The key event appears to be the receptor-mediated endocytosis in intestinal epithelial cells.[35]

A pore-forming toxin has been identified in necrotic enteritis strains of *C. perfringens*.[36]

A large survey of AMR and toxin genes in commercial swine was undertaken.[37] In young pigs, sampled at farrowing time, 73% had CD, and it was isolated from 47% of sows. Only one pig was positive in the nursery and no finishing pigs were positive. Resistance to ciprofloxacin was found in 91.3% in young pigs and in 94% of sows. The profile ciprofloxacin–erythromycin–tetracycline was detected in 21.4% of the piglets and 11.75 of the sows. Most had TcdA (65%), TcdB was found in 84%, and the binary toxin CdtB was found in 77%. The presence of CD spores in the feces of food-producing animals represents a risk for contamination of meat products.[38] In colon explants, toxin A produces cell swelling, swelling of mitochondria and other organelles, distension of cytoplasmic vesicles, expansion of paracellular spaces, apoptosis, and necrosis.[35]

C. perfringens type E rarely causes damage in the pig gut but it can in weaned pigs and does so when maternal antibodies have disappeared.

CLINICAL SIGNS

In all three forms of intestinal clostridiosis it is likely that the picture varies with immune status and age of the pig.

In CPC the pigs are normal at birth, and in peracute cases there is often sudden death

without other clinical signs. There may also be hemorrhagic diarrhea with perineal staining. Affected pigs are weak, reluctant to move, and become rapidly moribund. They may then be crushed or starve to death. Many pigs are found dead within 12 to 36 hours.

In acute cases, the piglets may survive 1 to 2 days after the onset of clinical signs. The feces may be reddish brown (bloodstained) with tissue debris and perineal staining, and they rapidly become dehydrated, weak, and die.

In subacute cases there is yellow diarrhea without blood, but they become progressively emaciated, may pass tissue flakes, and become very thin, dehydrated, and then die usually at about 5 to 7 days of age.

Chronic cases may have intermittent diarrhea for more than 1 week. The feces are yellowish gray and mucoid, and the tail and perineum may be fecal stained. Lesions are not visible through the serosa.

In CPA cases the condition may occur over 10 to 21 days, but there is often a creamy diarrhea within 2 days of birth, the piglets have a rough hair coat, and there is perineal fecal staining. Diarrhea may last up to 5 days and may become mucoid and pink. Most piglets recover but some may be growth retarded.

In CD cases the piglets are affected between 1 and 7 days of age and quite often they are born to gilts. The prevalence decreases with age and is uncommon after 60 days of age. They present with a history of early onset scours, and occasionally with respiratory distress. The piglets develop dyspnea, emaciation, abdominal distension, and scrotal edema. Diarrhea occurs and animals rapidly dehydrate with sunken eyes and perineal staining. It can cause preweaning losses up to 90% but 50% is the norm. There is a suggestion that piglets born to sows that have been treated with fluoroquinolones are more susceptible to CD.

PATHOLOGY

The pathology of hyperacute CPC is characterized by severely hemorrhagic small intestines full of bloodstained pasty feces and bloodstained fluid in the peritoneal cavity. Lesions are usually in the jejunum (may be only a part) and ileum but can almost reach forward to the pylorus. Mesenteric lymph nodes may be congested.

Histologically, there may be necrotic villi with a surface pack of gram-positive organisms on the epithelial surface. The crypts may be necrotic and there may be significant hemorrhage.

The pathology of acute CPC is less severe. The lesions are usually localized and there may be emphysema. Often these lesions are segmental. There may be a fibrinous peritonitis, and the intestinal wall may be thickened with blood and necrotic debris. In the subacute cases, there may be a thickened intestinal wall. The chronic cases may have a diphtheritic membrane over the jejunum, and the contents are more watery.

Histologically, there is severe villous necrosis with an overlying carpet of necrotic debris, blood, and fibrin with large numbers of gram-positive bacteria.

The pathology of CPA is much less severe. The intestine is usually thin-walled, gas-filled with watery contents, and without blood. The small intestine is often congested. The necrotic areas may be seen on the intestinal surface. The inflammation is mild occasionally with adherent debris. The large intestine does not usually have lesions but may be full of pasty contents. Usually there is nothing to see outside of these gut lesions.

Microscopically, there may be villous tip necrosis. There may be large numbers of organisms on the surface or in the lumen. There is no hemorrhage. The stomach usually has no lesions.

Enterotoxigenic strains may produce superficial mucosal necrosis and villous atrophy. Experimentally, these cases have creamy diarrhea and emaciation with low mortality to profuse bloodstained diarrhea, enteritis, and death.

In CD infections, there is sometimes mesocolonic edema, and the intestines are filled with pasty to watery yellow feces. Many piglets are toxin positive in an infected barn and piglets without signs may be toxin positive.[39-41] Focal suppuration in the colonic lamina propria is the key lesion, and colonic and serosal edema is common. There is frequently an inflammatory infiltrate. There is frequently segmental erosion of colonic mucosal epithelium, and exudation of neutrophils and fibrin into the lumen also occurs. The association of CD toxins and gross and microscopic lesions was evaluated.[42] There was no significant correlation between CD toxins and mesocolonic edema. There was a significant correlation between toxins and colitis and typhlitis. The toxins were isolated in a significant proportion of the healthy pigs, which may represent a significant subclinical reservoir in swine.

DIFFERENTIAL DIAGNOSIS

A presumed diagnosis of type C is formed when the clinical signs, pattern of mortality, and gross and microscopic lesions are evaluated.

A more chronic form may require detection of type C organisms in the lesions. Although it may be confused with coccidiosis, rotavirus, TGE, porcine epidemic diarrhea (PED), it is most likely to be confused with CPA, especially in the less severe forms. This requires bacteriologic culture, toxin detection, or genotyping.

Diagnosis of type A is more difficult because the clinical signs and epidemiology are more equivocal. You can find large numbers of gram-positive organisms particularly in the stomach but also the small intestine and from feces. Genotyping reveals type A organisms with CBP2 toxin (β-toxin). In a summary of a recent study,[12] it was said that it was impossible to separate healthy and diarrheic piglets on the basis of bacterial numbers in the intestine, the presence of consensus CPB2 in CPA isolates, the expression of CPB in the intestine of pigs, and between diarrheic piglets with known or unknown causes of diarrhea. There was also no association between histologic findings and the presence of CPB2. The exclusion of other agents is not an adequate diagnostic criterion,[12] and the large numbers of cpb2-positive type A CP should be regarded as normal.

A very interesting document was sent to swine practitioners and veterinary pathologists to see how they diagnosed CPA infections.[43] Most practitioners diagnosed it based on the age of the pig affected (1–7 days), and 41% of pathologists were not certain of the diagnosis even based on the isolation of the organism, genotyping, or detection of the toxins and ruling out other pathogens through histopathology.

Diagnosis of CD is by finding the lesions in the colon and by finding TcdA and TcdB in the feces or colonic contents using commercially available enzyme immunoassays.

LABORATORY DIAGNOSIS

Bacteriology

It is possible to smear the intestinal contents and the mucosal lesions. Large gram-positive rods are visible. In culture the organisms are 3 to 5 mm in diameter, gray, and circular after 24 hours on horse or bovine blood agar. The CPC produces an inner zone of hemolysis associated with theta toxin (perfringolysin O) and an outer less complete area caused by the β-toxin. A large gram-positive rod that grows anaerobically and has a double layer of hemolysis is *C. perfringens*.

Toxin testing is then essential. The β-toxin is demonstrated in the intestinal contents or peritoneal fluid. Clonal relationships can be detected by multilocus sequence typing (MLST).[33]

Enzyme immunoassays are now in use to detect the genes for the toxins. An RT-PCR can be used for the detection of CP toxin genes in animal isolates.[43]

The presence of enterotoxin in fecal infiltrates can be confirmed using commercial reversed passive latex agglutination tests, counter electrophoresis, ELISA, and Vero cells. An antigen-capture ELISA for CP β-2-toxin has been developed.[45] PCRs for the genes are also in use. The detection of toxigenic CD in pig feces has been described.[46] The authors developed three different sequences: the triose phosphate isomerase gene *tpi*, specific for CD, and the *TcdA* and *TcdB* genes, which code for the A and B toxins of CD, respectively.

Four different diagnostic tests were used to detect CD in piglets.[47] It was concluded

that all four tests had a low performance as a test for CD in pigs. The RT-PCR was the most appropriate test to screen for negativity in a herd as a first step, followed by toxigenic culture as the second part of the two-step algorithm.

HISTOLOGY

Large gram-positive rods can be seen in sections. The hemorrhagic lesions can be almost diagnostic.

In many instances the clostridia are found in association with other agents causing diarrhea in the neonate (e.g., rotavirus, TGE, PED, coccidia, cryptosporidiosis).

TREATMENT

Treatment is of little use in type C cases and prophylaxis is the most important. Protection against type C can be achieved by the use of equine antitoxin in nonimmune sows, or given to the piglets parenterally immediately after birth, when it will usually protect for about 3 weeks.

Treatment is of more use in type A infections and antimicrobials will work.

Treatment of CD may be successful using tylosin. A North American study showed 99% resistance to ciprofloxacin, while 1% showed resistance to tetracycline and 6% to erythromycin.[21]

CONTROL

For type C infections oral antibiotics such as ampicillin or amoxicillin should be given immediately after birth and continued daily for 3 days. There may be resistance and tetracycline-resistant plasmids have been identified.

Sows should be vaccinated with type C toxoid at breeding or midgestation and 2 to 3 weeks before farrowing. The disease is usually eradicated after one farrowing cycle. Booster injections should be given 3 weeks before the next farrowing. Even after repeated vaccinations and the absence of clinical necrotic enteritis on the farm, CPC can still be detected.[18]

To prevent type A infections autogenous vaccines can be made and toxoids for α-toxin and β-2-toxin have been used in sows for protecting piglets or some other products used off license. In addition, avoparcin and salinomycin have been used in feed.

For CD there is a limited approach with Bacitracin methylene disalicylate, which can be used in the sows to protect the piglets. It is given at 250 g/tonne for 2 weeks in the feed prefarrowing and in the lactation ration at the same level for 3 weeks.

In a recent study the use of recombinant *C. perfringens* toxoids α and β produced in *E. coli* elevated antepartum and passive humoral immunity and could possibly be used for the development of a commercial vaccine.[48]

There has also been a suggestion that competitive exclusion with nontoxigenic organisms can also inhibit CD toxigenic strains.[49] Spores were given to the dams or sprayed on the teats or given orally to the piglets.

ESCHERICHIA COLI INFECTIONS IN WEANED PIGS

Diarrhea is most frequent when pigs are exposed to pathogenic *E. coli* strains. The effect of weaning is to produce a marked decrease in the diversity of coliforms in the individual piglet. Different strains of *E. coli* were predominant in different animals, which may in turn facilitate the spread of pathogenic strains.

Many strains are nonpathogenic. Nonpathogenic *E. coli* supports the physiologic intestinal balance of the host. Pathogenic *E. coli* with VG profiles can cause outbreaks of diarrhea. It was concluded that VG carrying *E. coli* are a normal part of the intestinal bacterial population.[1] Pathogenic *E. coli* can be divided into a variety of pathotypes, but there are three major types. These are ETEC, verotoxin-producing *E. coli* (VPEC), and attaching and effacing *E. coli* (AEEC).

There are two major complicating factors in pigs: one of these is that the intestine has different distributions of receptors with changing age. The other is that nearly all isolates (94.8%) that carry the enterotoxin genes also carry genes for one of the fimbrial adhesins. The two most prominent genotypes are K88, LT1, STb and F18, STa, STb, and SLT.

Enterotoxigenic *Escherichia coli*

ETEC have two major virulence factors: (1) adhesins or fimbriae and (2) enterotoxins. The adhesins promote or control the adherence to small-intestinal epithelial cells and include K88, K99, F41, 987P, and F18. Only F18 and K88 are frequently associated with disease in weaned pigs. Only young pigs are susceptible to K99 or 987P. Age-related susceptibility is related to the presence or absence of the appropriate receptors in the small intestine. The enterotoxins belong to two groups; heat-labile enterotoxin (LT) and the heat-stable enterotoxins STa or STb. Only weaned pigs are susceptible to F18, and resistance develops by 8 weeks of age, because the binding appears to be blocked. The receptor for F18 has not yet been identified, but it is a glycoconjugate in which the attached carbohydrate acts as a target for the fimbriae. The F18 adhesin occurs in two forms: ab found in VTEC and ac found in ETEC.

There is also an F4 fimbrial antigen that is on a different chromosome from F18. F4 ETEC cause problems in the first week after weaning, but F18 VTEC cause problems 1 to 2 weeks after weaning.

Verotoxin-Producing *Escherichia coli*

These strains produce Shiga toxin or Shiga-like toxins (verocytotoxins) and cause edema disease (ED). Swine VTEC colonize the intestine via the F18 pilus, as do some swine ETEC. It is not uncommon to find F18-positive strains that produce enterotoxins and verotoxins and can cause both diarrhea and ED.

Attaching and Effacing *Escherichia coli*

These bacteria possess the *eae* gene, which encodes for intimin. This is an adhesin factor that facilitates the attachment of bacteria to intestinal epithelial cells. It is on a plasmid that is distinct from the K88-encoding plasmid in ETEC and ETEC strains that produce attaching and effacing lesions.

The following strains are found:

- K88 ab, ac, and ad
- F18ab (more associated with ED) and F18ac
- F41, usually associated with K99 fimbriae
- Strains containing LT, STa, STb, Shiga-like toxin 2e (Stx2e), and possibly enteroaggregative *E. coli*

Twenty years ago most of the pig strains were 987 or K99 positive. The genes for Stx2e and F18 were rare then, but are much more common now.

O157 in Pigs

In a recent survey in Sweden only two O157:H7-positive and four O157:H7-negative strains were found. Pathogenicity is indicated by genes encoding for one or more of the Shiga toxins, but several other factors may also be necessary. Most strains do not possess Shiga toxins but do carry the F4 or F18 fimbrial adhesins. A third of the strains examined produced STa or STb, but less than a third produced STx and half the *eae* gene.

Postweaning diarrhea (PWD) and **ED** are two common *E. coli* infections of weaned pigs. In PWD, there is diarrhea, dehydration, and often death. In ED or enterotoxemia there is subcutaneous edema of the forehead and eyelids, and neurologic clinical signs such as ataxia, convulsions, recumbency, and death. ETEC strains isolated from cases of PWD mainly belong to O Groups O8, O141, O147, O149, and O157. Strains associated with ED predominantly have O Groups O138, O139, or O141. PWD is a significant cause of mortality between weaning and slaughter in some herds. Although the clinical signs in these two diseases are different, they occur in similar age groups, and the same type of management change may precede their occurrence. Weaning and weaning age are both associated with significant effects on the microbial populations. In PWD the bacteria disappear more quickly, usually by about 7 days postinfection (DPI), but in ED they may still be there 9 DPI but with a slower buildup to a peak within 3 to 5 DPI. A typical scenario would be 4 to 5 days PWD followed by clinical ED with mortality reaching as high as 50%. Both are associated with the proliferation of predominantly hemolytic serotypes of *E. coli* within the small intestine. However, it is rare to encounter both diseases concurrently on the same farm. In PWD the serotypes are ETEC and the major manifestation is diarrhea resulting from enterotoxin activity at the time of proliferation. In ED nonenterotoxigenic strains produce a verotoxin that, after a period of time, indirectly produces the neurologic syndrome characteristic of this disease.

One of the features of virulence in *E. coli* is the presence of mobile genetic elements such as plasmids, bacteriophages, and pathogenicity islands. A pathogenicity island coding for F18-positive fimbriae has been found. Cytolethal distending toxins have also been described. In many countries the prevalence of ED has decreased, whereas coliform gastroenteritis has increased. It is possible that this change reflects the trend toward earlier weaning of pigs, although the emergence and spread of new ETEC strains may also be a factor. More recently a third disease, cerebrospinal angiopathy, has been attributed to the effects of infection with *E. coli*. Although there are some similarities in the etiology and epidemiology of these diseases, they are sufficiently different to warrant a separate description.

One of the major features in common is the process of weaning, which is probably the most serious disturbance a young piglet may face. This change of diet from liquid to solid is also accompanied by a multitude of other changes such as moving, mixing, environmental, and managemental. It also alters immune functions and produces stress and profoundly alters the intestinal microflora, particularly the coliform flora. Some strains may increase but others may decrease.

It is also important to realize that some *E. coli* may also cause fatal shock. They are usually F4 (K88-positive) ETEC (O149, O157, or O8) or ED causing *E. coli* (Stxe). Death occurs before either the diarrhea or the edema is produced. It is probably caused by the rapid release of large amounts of LPS by colonizing ETEC, which then produce a cytochrome storm (TNF-α, IL-1, and IL-6). There are usually no clinical signs and minimal lesions including congestion and blood-tinged enteritis.

Systemic *E. coli* infections also occur in pigs of any age but often in the very young when there is little colostral protection. Usually, the infections are ETEC. The clinical signs are quite variable and develop within 12 hours, with as little as distended abdomens on or piglets are found dead within 48 hours on the other.

EDEMA DISEASE (GUT EDEMA, *ESCHERICHIA COLI* ENTEROTOXEMIA)

ED occurs in weaner and grower pigs and is characterized by subcutaneous and subserosal edema, progressive ataxia, recumbency, and death. Although isolated strains from pigs are unlikely to be associated with severe human disease, healthy pigs cannot be excluded as a potential source of human infection with Stx2e-producing STEC (Shiga toxin producers).[2]

SYNOPSIS

Etiology *Escherichia coli* strains producing verocytotoxin and Shiga-like toxin

Epidemiology In rapidly growing weaner pigs between 4 and 12 weeks of age following change in diet or feeding practices and waning of maternal antibody

Sign Sudden death. Incoordination, falling, edema of eyelids and face; piglets die in 6–36 h.

Clinical pathology Culture *E. coli* from feces.

Lesions Facial edema, full stomach, and mesenteric edema

Diagnostic confirmation Culture specific organism

Differential diagnosis list

- Pseudorabies
- Viral encephalomyelitis of pigs
- Encephalomyocarditis
- Streptococcal meningitis
- Salt poisoning
- Organic arsenic poisoning
- Mulberry heart disease

Treatment None

Control Avoid drastic changes in diet.

ETIOLOGY

ED is associated with *E. coli* strains producing a Stx,Stx2e toxin, which enters the bloodstream and damages vessel walls. Three serogroups cause ED: O138, O139, and O141 and sometimes O147. They are called EDEC and are nearly all α-hemolytic. The strains have adhesins that enable the bacteria to colonize the intestine and elaborate protein exotoxins. The biochemical phenotypes were studied in Sweden and O138, O139, and O141 are dominated by one phenotypic type, even though others do occur within the serotype. The entire pathogenicity island known as ETT2 is necessary for the ED virulence factors in O138, O139, or O141. Isolates of *E. coli* have been found in which the toxin or F18 fimbrial types were not related to selected electrophoretic types. This suggests that toxin and F18 genes in the isolates from pigs with PWD or ED occur in a variety of chromosomal backgrounds. The bacteria colonize the small intestine without causing significant changes by means of the adherence factor F18 (F107), usually F18ab or occasionally F18ac, as the fimbrial adhesin. The *E. coli* strains with the highest mucin-binding capacity belonged to potential ST toxin producers, whereas strains without genes encoding for toxin production displayed a much weaker binding to mucin capacity. In a recent outbreak in Denmark, in which ED had not previously been observed, most isolates were O139, but a few were untypeable. All the isolates from the Danish pigs with ED were in one cluster in contrast to isolates from other countries, which did not form any clusters. In the Denmark study, 563 isolates were serotyped and O149 was found in 49.9% of the isolates, O138 in 14.9%, O139 in 6.9%, O141 in 4.1%, and O8 in 3.7%. The VGs were examined and they fell into six pathotypes that covered 65.7% of all isolates. The F107 fimbriae are a major colonization factor in *E. coli* that causes ED.

Inheritance of Susceptibility to ED

Inheritance of resistance to intestinal colonization with *E. coli* causing ED is thought to be under the control of one locus consisting of two alleles with susceptibility (S)-dominating resistance(s). Genetic susceptibility to ED is caused by the ability of F107-expressing *E. coli* to adhere to and colonize intestinal brush border cells and not toxin susceptibility. There is a high correlation between intestinal F18 receptor genotype and susceptibility to disease, but pigs with resistant F18 receptor genotypes were not entirely protected against colonization by *E. coli*.

EPIDEMIOLOGY

Possibly the most significant factor in the development of ED is the loss of milk antibodies at weaning. The environment of the weaner unit is the most likely source of the *E. coli*, either from other weaned pigs or from a dirty environment. Not all infected pigs develop the disease.

The specific serotypes of *E. coli* that may cause disease are introduced into a piggery and become part of the normal intestinal flora. They may not cause disease until a particular set of environmental conditions arises, such as when they proliferate excessively within the intestine to produce toxin. The disease occurs predominantly in pigs between 4 and 12 weeks of age. It may occur sporadically but more commonly occurs as an outbreak affecting up to 50% of the pigs within the group. Characteristically, the larger and faster growing pigs within the group are affected. The disease is not common in runt or poorly thriving pigs. Age at weaning, diet, overcrowding, chilling, transportation, and other factors influence the susceptibility of pigs to *E. coli* -producing SLTIIe, and could determine whether subclinical or clinical ED occurs following infection. Piglets fed high-protein diets are more susceptible to experimental clinical ED than piglets fed low-protein diets. The disease frequently occurs within 1 week following a change in diet or ad libitum feeding but may also follow such factors as weaning, vaccination, pen change, and regrouping. A study even found VPEC O139 in water storage tanks and drinking water.

F18 fimbriae have increased greatly since 1997 from 10% to 70%, and this may be tied into the genetic selection of the stress gene.

The outbreak is sudden in onset but short-lived, averaging 8 days and seldom exceeding 15 days. The epidemiology of the disease in affected herds is not characteristic of a highly contagious disease, and it does not usually spread to involve other pens of pigs on the same farm.

The disease follows proliferation of the relevant serotypes within the intestine. Serotypes of *E. coli* associated with gut edema may be isolated from the feces of healthy pigs. The factors initiating proliferation are unknown, but changes in the composition or amount of diet commonly precipitate the onset. Management factors that potentiate oral–fecal cycling of these organisms are likely to be important to spread within the group.

PATHOGENESIS

A number of F18ab or F18ac strains produce both enterotoxins and Stx2e, and in these cases PWD is usually more common than ED. There may also be mixed infections of both ETEC and EDEC strains in which diarrhea usually predominates.

The F18 receptors important in ED are not fully expressed in pigs under 20 days of age. The F18-positive strains cause ED about 5 to 14 days after weaning. The fimbrial receptors can be moderated by lectins in the diet, and this may be the reason that the F18 colonization is reduced after weaning. Toxemia resulting in severe edema in specific sites that have absorbed Stx2. Colonization by EDEC develops on the tips and sides of the villi in the distal jejunum and ileum. The Stxe is absorbed into the circulation and causes vascular damage to the target organs. It is not normally absorbed, but is under the influence of unknown factors that may include bile. Absorption causes a degenerative angiopathy of small arteries and arterioles. In the brain the changes may be exacerbated by the anoxia that results from the slow blood flow.

It is a simple progression. The intestine of a susceptible pig, which is usually fast-growing and without maternal antibody, has receptors for F18 pili. This appears to be the major factor, and then colonization by *E. coli* occurs with toxin production, absorption of toxin, and damage to vascular epithelium. The endothelium appears to have a specific toxin receptor for Stx2e, and finally edema develops in target tissues. Epithelial receptors for pathogenic ED are not found in all pigs. The receptors for both F14 are on one chromosome (13) and for F18 on another.[3,4] The numbers of *E. coli* rapidly proliferate when infected to levels of 10^9/g feces.

Nutritional factors and gastrointestinal stasis result in proliferation of the *E. coli* strains in the small intestine and toxin production. There is generally a delay between the initial period of maximal intestinal proliferation and the onset of clinical signs. In the experimental disease, clinical signs occur 5 to 7 days following initial oral challenge with bacteria and up to 36 hours following intravenous inoculation with toxin. The delay appears to be related to the development of vascular lesions, with increased vascular permeability leading to edema formation and encephalomalacia. The experimental oral inoculation of the ED-producing *E. coli* results in colonization of the small intestine, and lesions of the vessels of the intestinal mucosa are detectable as early as 2 days after infection. An experimental model for subclinical ED in weaned pigs has been described. Microscopic vascular lesions were found in pigs 14 days after oral inoculation with a SLT2-positive strain of *E. coli* . Once PWD occurs there is an increased intestinal permeability that predisposes to ED, and once developed the influx of SLT toxin into the bloodstream is facilitated further, precipitating the disease. ED is associated with metabolic acidosis, which might be explained by endogenous acid production and small-intestinal acidosis. Intestinal acidosis is known to cause mucosal hyperexcitability.

CLINICAL FINDINGS

PWD and ED can occur simultaneously. The case mortality rate varies from 50% to 90%. It may appear suddenly and disappear suddenly. Recurrence on premises is not unusual. It usually occurs after weaning but can occur at any time.

The diseases occur sporadically and unexpectedly in a group, often affecting a number of pigs within a few hours, and show no tendency to spread from group to group. The thriftiest pigs are most likely to be affected and, once the diagnosis is made, all pigs in the pen should be examined in an attempt to detect other animals in the early stages of the disease. The incidence in a litter will vary up to 50% or more.

Quite often pigs may become inappetent, with swelling of the eyelids and forehead. The earliest and most obvious sign is incoordination of the hindlimbs, although this may be preceded by an attack of diarrhea. The pig has difficulty in standing and sways and sags in the hindquarters. There is difficulty in getting up and in getting the legs past each other when walking because of a stiff, stringhalt-like action affecting either the forelegs or hindlegs. In some cases there are obvious signs of nervous irritation manifested by muscle tremor, aimless wandering, and clonic convulsions. Complete flaccid paralysis follows. A peculiar squeal may also be heard. There is usually no diarrhea or fever. There may be pruritus. In the terminal stages there may be a watery diarrhea.

Subclinical disease may occur when pigs are clinically normal and may then develop vascular lesions and have a slow growth rate.

On close examination, edema of the eyelids and conjunctiva may be visible. This may also involve the front of the face and ears but cannot usually be seen until necropsy. The voice is often hoarse and may become almost inaudible. Blindness may be apparent. The feces are usually firm, and rectal temperatures are almost always below normal. The course of the disease may be very short, with some pigs being found dead without signs having been observed. In most cases, illness is observed for 6 to 36 hours, with a few cases being more prolonged. Recovery does sometimes occur,

but some degree of incoordination may persist.

CLINICAL PATHOLOGY

As an aid to diagnosis, while affected animals are still alive, fecal samples should be cultured to determine the presence of hemolytic *E. coli*. Knowledge of the drug sensitivity of the organism may be important in prescribing control measures. The ED principle is cytotoxic to Vero cells and may be useful in an assay system for diagnosis. The toxin Stx2e has been detected in the peripheral blood of pigs with clinical disease, which not only shows that toxin is transported but may eventually lead to a technique for the detection of early cases.

NECROPSY FINDINGS

The pig is well grown for its age, the stomach is full of feed, and the feces are usually normal. Edema is variable. Edema of the eyelids, forehead, belly, elbow and hock joints, throat, and ears is accompanied by edema of the stomach wall and mesocolon in classical cases. The gelatinous edema may be very thick around the stomach and mesentery. The mesocolon is also edematous and edema of the gallbladder is sometimes observed. The lymph nodes may be swollen and edematous. Quite often the stomach is full of dry food. Colonic contents may be reduced. There may be pulmonary edema and petechial hemorrhages in the epicardium and pericardium. Excess pleural, peritoneal, and pericardial fluid is also characteristic, and the skeletal muscles are pale. The edema may often be slight and quite localized, so examination of suspected areas should be performed carefully, using multiple incisions, especially along the greater curvature of the stomach near the cardia. Hemolytic *E. coli* can be recovered in almost pure culture from the intestine, particularly the colon and the rectum, and in some cases from the mesenteric lymph nodes. Polyclonal antisera directed against serotypes of *E. coli* associated with ED are used to confirm the diagnosis via an agglutination test.

In some cases, an atypical hemorrhagic gastroenteritis has been described with marked edema, but the mucosae of the small and large intestine show extensive hemorrhage and there is a watery diarrhea, followed by death.

There may be multifocal encephalomalacia in the brainstem together with typical lesions in small arteries and arterioles.

Histologically, the important lesions are mural edema, hyaline degeneration, and fibrinoid necrosis in arteries and arterioles. Sometimes the lesions are minimal and difficult to recognize. In subacute to chronic cases this angiopathy may result in focal brain hemorrhages and encephalomalacia. Patchy layers of bacteria are adherent to distal jejunal and ileal mucosa but have often disappeared by the time the pig dies.

Samples for Confirmation of Diagnosis

- *Bacteriology:* Ileum and colon (CULT); culture of the types of *E. coli* and confirmation of serotype and virulence factors is essential. In ED a large number of the *E. coli* may have disappeared. The presence of hemolytic *E. coli* is not diagnostic for ED because there are some strains of EPEC that can cause ED but are nonhemolytic. There are more cases of mixed infections with *E. coli* now than before. The differentiation of pathogenic and nonpathogenic *E. coli* can be achieved through PCR. A multiplex PCR has been developed for STa, STb, K99, 987P, and F41.[5] A multiplex PCR assay for nine different virulence factors associated with *E. coli* that cause ED in swine is available.[6] The tests tell you that the gene is present but not whether it is actually encoding for the proteins.
- *Histology:* Formalin-fixed colon, ileum, jejunum, gastric fundus, brain, and mesenteric lymph node (LM).

DIFFERENTIAL DIAGNOSIS

The appearance 2 weeks postweaning is suggestive, as are visible edema and nervous signs. Although there are a number of diseases of pigs in the susceptible age group in which nervous signs predominate, gut edema is usually easy to diagnose because of the rapidity with which the disease strikes, the number of pigs affected at one time, the short duration of the outbreak, and the obvious edema of tissues. Affected pigs are usually in prime condition. The ataxia and recumbency must be differentiated from diseases of the nervous system of pigs that cause ataxia and recumbency. These include pseudorabies, viral encephalomyelitis (Teschen disease), encephalomyocarditis, streptococcal meningitis, salt poisoning, and organic arsenic poisoning. Mulberry heart disease and encephalomyocarditis can produce similar signs, and differentiation on necropsy findings and histopathology is necessary. In poisoning by *Amaranthus* spp. and *Chenopodium album* the signs may be roughly similar, but the edema is limited to the perirenal tissues.

TREATMENT

Sick pigs should be treated initially with antimicrobials and electrolytes parenterally because they do not eat or drink. Administration in water may then follow. Treatment is ineffective. Elimination of the toxin-producing bacteria may be attempted by use of antimicrobials in the feed or water supplies. The choice of antimicrobial will vary depending on area variations of the drug sensitivities of *E. coli*. The drug should be highly active in the lumen of the gut (possibly fluoroquinolones, cephalosporins, apramycin, ceftiofur, neomycin, or trimethoprim), depending on the prescribing rules in each country. The feed consumption of the unaffected pigs in the group should be reduced immediately and then gradually returned to previous levels over a period of a few days. Recovered pigs have protective antibodies to Stx2e.

CONTROL

Nurseries should be managed as all-in/all-out facilities and properly cleaned, disinfected and dried, and rested before the next arrivals. Correct temperatures for weaning and the avoidance of cooling drafts are especially significant.

The strains of PWD and ED of all the *E. coli* are the ones that are likely to show the most antibiotic resistance.

Pigs should be kept on the same creep feed for at least 2 weeks after weaning, and the change in feed should be made gradually over a 3- to 5-day period. Feed restriction through the critical period is frequently practiced and may reduce the occurrence of ED. Similarly, an increase in crude fiber and decrease in nutrient quality of the diet through this period may reduce the incidence. However, it is evident that a severe restriction and marked decrease in nutrient quality is required to fully achieve this effect, and this is not compatible with the purpose of growing pigs. It is essential that pigs on restricted intakes be provided with adequate trough space to allow an even intake of food among the group. For similar reasons, litters of pigs that are batched at or after weaning should be divided into groups of approximately equal BW.

The strategic incorporation of an antimicrobial into the feed during the risk period may be necessary on some farms. A reduction in the potential for oral–fecal cycling of organisms in the group may reduce the incidence of ED. A reduction in the age of weaning may also reduce the incidence. Both organic acids and medication with 50 ppm of enrofloxacin are useful in controlling and/or preventing PWD or ED.

Treatment with anti-VT2E serum can provide protective immunity against ED in pigs.

Spray dried porcine plasma has helped because it contains specific anti-ETEC antibodies. The use of eggs from previously vaccinated hens has also been used.

No successful vaccine is available to produce the increased levels of IgA required to neutralize the attached *E. coli*. A new recombinant vaccine has been developed for a Stx22e subunit vaccine.[7] Only vaccines with the preformed fimbriae induce protection, and this is limited to the homologous variant but, experimentally, vaccination of piglets with a genetically modified Shiga-like toxin 2e prevents ED following challenge with the Shiga-like toxin after weaning. The concentration of protein in the diet also influenced susceptibility to ED. Pigs fed a

low-protein diet and not vaccinated developed subclinical ED. Pigs fed a high-protein diet and not vaccinated developed clinical ED. Pigs fed a high-protein diet and vaccinated had a reduction in the incidence of subclinical edema and did not develop clinical ED.

POSTWEANING DIARRHEA OF PIGS (COLIFORM GASTROENTERITIS)

PWD is common within several days after weaning and is characterized by a reduced growth rate associated with alterations in the mucosa of the small intestine and, in some pigs, by acute coliform gastroenteritis characterized by sudden death, or severe diarrhea, dehydration, and toxemia. It is a major cause of economic loss from both mortality and inferior growth rates for several days to 2 weeks following weaning. The etiology, epidemiology, and pathogenesis are multifactorial and complex because of the several weaning-associated factors that may interact. In some instances the PWD may be followed by ED.

SYNOPSIS

Etiology Specific serotype of enterotoxigenic *Escherichia coli*

Epidemiology Three to 10 days postweaning; high morbidity and case–fatality rates. Stressors of weaning are risk factors (change of feed, loss of maternal contact and maternal antibody, mixing litters, and environmental changes)

Sign Some pigs found dead. Outbreaks of severe diarrhea a few days postweaning. Fever, dehydration, anorexia, loss of weight, and death in a few days

Clinical pathology Culture organism from feces and intestinal contents.

Lesions Dehydration, serofibrinous peritonitis, fluid-filled intestines, and mesenteric edema

Diagnostic confirmation Isolate specific serotypes of *E. coli.*

Differential diagnosis list
- Gut edema
- Swine dysentery
- Salmonellosis
- Erysipelas
- Pasteurellosis

Treatment Antimicrobials in water supply

Control Minimize stress at weaning. Antimicrobials in feed and water postweaning. Intestinal acidification. Zinc oxide in diet postweaning

ETIOLOGY

Some strains of *E. coli* can cause both ED and PWD. The key feature is the disappearance after weaning of antibodies to *E. coli* previously provided by milk. The disease is associated with ETEC that produce adhesion factors that allow colonization of the intestine and mediated by enterotoxins that induce the intact intestinal mucosa to secrete fluid. It can also be caused by EPEC that do not possess any of the virulence factors of PWD or ED. A summary would be that PWD is associated with fimbrial types F4 (K88) and F18 variants (F18ac or F18ab as fimbrial adhesins)[1,2] and carrying the genes for the Shiga-like toxin 2(SLT-2E), LT, and/or Shiga toxin A and B (STa or STb). Toxin and F18 fimbrial genes in *E. coli* isolated from pigs with PWD or ED occur in a variety of chromosomal backgrounds. The three F4 receptors (F4ab, F4ac, and F4ad) are encoded on distinct loci.[3] Nearly all are α-hemolytic and belong to a limited number of serotypes.

The presence of the F4 receptor was associated strongly with pigs being high shedders of *E. coli.*[4] Most commonly, F4 is serotype O149, and F18 is serotype O 139, O138, O141, O149, and O157, which are associated with the disease. Most serotypes appear to be O149:STaSTbLT:F4 (K88). The strains of O149 isolated in recent years from weaned pigs with diarrhea possess the gene for an additional enterotoxin STa, which older strains lack. Of the new strains that correspond to O149 H10, 92% code for this gene. This enteroaggregative *E. coli* heat-stable enterotoxin 1 (*EAST 1*) gene is found in isolates from weaned pigs that have diarrhea or ED. The F107 fimbriae can be found in association with PWD isolates, and other adhesive fimbriae such as Av24 and 2134P have been described. Many ETEC isolates colonize the small intestine of weaned pigs but lack known colonization factors. The serogroups of *E. coli* isolated from pigs with PWD in piggeries in Spain include strains that produce the ETEC and VTEC *E. coli* and cytotoxic necrotizing factor toxins. The disease can be reproduced consistently in weaned pigs, provided the pig's epithelial cell brush borders are susceptible to the adhesin of strains of *E. coli* with fimbrial antigen F4 (K88). The DNA sequences coding for the F18 fimbrial antigens and AIDA adhesin are on the same plasmid in *E. coli* isolated from the cecum. Usually they were LTSTb or STb (13%) and 12% were hemolytic and F18-positive. The remainder were nonhemolytic, belonging to the K48 serogroup.

Although there is an etiologic similarity between PWD and neonatal enteric colibacillosis in suckling piglets, the relationship is not exact. Strains associated with neonatal enteric colibacillosis may not have the ability to produce PWD, and many strains isolated from coliform gastroenteritis lack $K88^+$ antigen.

Cytotoxic necrotizing factor strains of *E. coli* have been isolated from weaner pigs with necrotic enteritis in South Africa.

Some nonenterotoxigenic O45 isolates of *E. coli* associated with PWD produce AEEC, and their proliferation may be associated with diet. Dual infection with AEEC may also be associated with PWD.

Infection with rotavirus may be an etiologic factor. The rotavirus may infect and destroy villous epithelial cells of the small intestine, which may allow colonization of the *E. coli*. Experimentally, a high nutrient intake fed three times daily to piglets weaned at 3 weeks of age produced the most prolonged diarrhea, colonization of the intestine by hemolytic ETEC, and persistent shedding of rotavirus. However, other observations cast doubt on the importance of rotaviruses as a cause of the diarrhea, because rotaviruses may be found in the feces of pigs without diarrhea a few days after weaning. The acute disease can be reproduced using K88 *E. coli* strains without concomitant infection with rotavirus.

A number of F18ab-positive or F18ac-positive strains produce enterotoxins and Stxe, and in these strains it is more likely that PWD will occur rather than ED.

EPIDEMIOLOGY

It is found worldwide and in a single geographic area a serotype may predominate.[4,6] Occasionally different serogroups may be involved in an outbreak.

PWD occurs predominantly in pigs 3 to 10 days after they are weaned. There is considerable variation in the morbidity and mortality between groups, rooms of pigs, and buildings. The age group clinically affected varies with pig age and diet. F4 receptors are expressed in pigs of all ages, but F18 is not fully expressed until pigs are 2 to 3 weeks of age. The diet may push back the time of PWD to as far as 6 to 8 weeks after weaning if substances such as zinc or acidifying agents are added to the diet.

Most outbreaks are in early weaned pigs. Infections are usually picked up from the environment. Most commonly, pigs are first observed sick or dead on the fourth or fifth day. The spread within affected groups is rapid and a morbidity rate of 80% to 90% of the group within 2 to 3 days is not uncommon. Frequently, other pens of susceptible pigs within the same area will also develop the disease within a short period of the initial outbreak. The problem may persist within a herd, affecting successive groups of weaned pigs over a period of weeks or months. The

onset of the problem may be associated with the introduction of a different batch or formulation of the creep feed. The case–fatality rate may be as high as 30%, and survivors may subsequently show a reduced growth rate. The weaning of piglets at 3 weeks of age is commonly followed in a few days by a postweaning reduction in growth rate, variations in total dietary intake, and the development of diarrhea. Piglets weaned at 3 to 4 weeks of age into an uncomfortable dirty environment appear especially susceptible.

The proliferation of *E. coli* in the intestine following weaning appears secondary to some underlying gastrointestinal disturbance. After weaning there is a progressive increase in viscosity of the intestinal contents, which alters the intestinal structure and growth and stimulates the proliferation of ETEC in newly weaned pigs. In all groups of pigs examined the number of serotypes or diversity of intestinal flora was reduced in the first week after weaning. The disease is associated with an earlier, more prolonged and greater proliferation of ETEC in the small intestines than occurs in healthy pigs after weaning. Some studies have shown that susceptibility to adhesion with $K88^+$ ETEC is a requirement for the production of the disease. Experimentally, pigs that did not have the adhesin receptor did not develop diarrhea when challenged with $K88^+$ *E. coli* and when in the same environment as the adhesin-positive pigs.

It is believed that several factors commonly associated with weaning predispose pigs to PWD associated with ETEC. Some of these risk factors include:

- Stress from loss of maternal contact
- Introduction to strange pens and penmates
- Inadequate ventilation in the weaning pens
- Reduction in ambient temperature
- Change in diet
- Cessation of lactation immunoglobulins
- Decreased gastric bactericidal activity attributable to a temporary increase in gastric pH
- Preweaning exposure (creep feeding) to the dietary antigens fed after weaning

Hand-washing and donning clean outerwear did not prevent the transmission of *E. coli*, but showering and donning clean outerwear did.

Experimentally, there is some evidence that the stress of cold ambient temperature (15°C) can result in a greater incidence of diarrhea in weaned pigs than in those housed at 30°C.

The nature and the amount of the diet that the piglet consumes before and after weaning may be a predisposing factor. One hypothesis suggests that a transient hypersensitivity of the intestine may occur if piglets are primed by small amounts of dietary antigen before weaning (creep feeding), followed by ingestion of greater quantities of the diet after weaning. Pigs that develop diarrhea tend to be those that consume more food after weaning than their contemporaries.

Generally, weaning at 3 weeks of age is associated with alterations in the villous epithelium of the small intestine that result in varying degrees of malabsorption and a reduction in daily growth rate that may last for 2 weeks. There are large rapid reductions in intestinal lactase activity that coincide with reductions in growth rate and a reduced ability to absorb xylose. There is a reduction in villous height and an increase in crypt depth in the small intestine, but these alterations are not necessarily associated with the consumption of creep feed before weaning, which does not support the hypothesis that hypersensitivity to a dietary antigen caused by priming before weaning is a factor. There is now considerable doubt about the validity of the intestinal hypersensitivity hypothesis. Recent experimental work indicates that creep feeding is not required for the production of the diarrhea and does not induce morphologic changes characteristic of an allergic reaction in the small intestine. The presence of nondigested food in the gut lumen favors proliferation of ETEC. Proteins of animal origin may provide some protection.

Dietary manipulation can modify several changes that normally occur in the small intestine of the piglet after weaning. Feeding a sow milk replacer or a diet based on hydrolyzed casein reduces the increases in crypt depth and the reductions in brush border enzymes. The use of an antibiotic to suppress the microbial activity does not alter the changes in the mucosa after weaning.

The ecology of *E. coli* and rotavirus in the stomach and intestines of healthy unweaned pigs and pigs after weaning has been examined. Gastric pH is higher in weaned pigs and may not reach a level sufficient to prevent significant numbers gaining access to the small intestine. This factor can be of importance in pigs weaned in pens where oral–fecal cycling of *E. coli* may provide a massive challenge. After weaning, the hemolytic ETEC serotype O149:K91, K88ac (Abbotstown strain), commonly colonizes the rostral small intestine from lower down the intestinal tract. This serotype has never been found in the gastric contents of weaned pigs. When this serotype is present it tends to dominate the *E. coli* flora at all levels of the intestine. Although rotaviruses are common in the intestinal contents of weaned pigs, the presence of the virus is not necessary for production of PWD.

The loss of lactogenic immunity at weaning may be a risk factor. Milk from sows whose progeny develop PWD contain antibodies capable of neutralizing the enterotoxigenic effect of the homologous *E. coli*. This suggests that the presence of antibody-mediated activity against ETEC may be important in preventing the disease during the nursing period. At weaning this protection is removed and the piglet is unable to produce its own antibodies rapidly enough to prevent the disease. The stress of weaning does not appear to affect the immune mechanisms of the pig.

The weaning of piglets at birth or at 1 day old is associated with a high mortality rate caused by diarrhea and septicemia. The high mortality rate is associated with a lack of colostral antibodies and the strict hygienic conditions required for the artificial rearing of pigs weaned at birth.

PATHOGENESIS

Different parts of the porcine intestinal tract may harbor different strains of *E. coli*, and it may be that these strains have different characteristics.[5]

The colonization and proliferation of *E. coli* in the small intestine originates from organisms in the lower part of the intestinal tract. There is a rapid increase in numbers of the organisms in the small intestine epithelium or the mucus covering from the midjejunum to the ileum serotypes of *E. coli* associated with PWD, which may be found in the feces of healthy pigs. The virulence factors for PWD are associated with the F4 and F18 fimbrial antigens that carry the genes for the production of toxins (STa, STb, LT, SLT2a, and SLX2e). The receptor for the F4 adhesin is not found in all pigs. There are five phenotypes based on the susceptibility of brush borders of different pigs to adherence of isolates producing variants F14ab (K88ab), F4ac (K88ac), and F4ad (K88ad). Pigs with at least one copy of the dominant allele for the receptor are susceptible to epithelial cell adherence and therefore colonization. The F18ab variant is expressed by the *E. coli* O139 strain producing Shiga-like toxin and causing ED. The F18ac fimbrial *E. coli* strains often relating to O141 or O157 cause diarrhea by expressing enterotoxins (STa or STb) either together or with or without Shiga-like toxins. STb binds to a particular receptor.[6] The PWD strains also produce LT, which lead to hypersecretion of electrolytes and water.[7,8] Following weaning, their numbers in feces normally increase markedly, even in pigs that remain healthy. The *E. coli* proliferate in the small intestine and produce an enterotoxin that appears to attach to the receptors. This triggers the uptake of calcium into the cell, which results in the excretion of water and electrolytes into the lumen. This causes a net loss of fluid and electrolytes to the lumen and subsequent diarrhea. After weaning, the net absorption of fluid and electrolytes in the small intestine of pigs is temporarily decreased.

In porcine EPEC the intimin binds to its receptor on the apical surface of the cells of the small and large intestine[9,10] with most in the colon and the duodenum. How they produce diarrhea is not really understood.

Heat-labile enterotoxins type IIa and type IIb are involved in the pathogenesis of ETEC for neonatal pigs.[48]

The number of hemolytic *E. coli* present in the proximal portion of the jejunum may be 10^3 to 10^5 times higher in affected pigs than healthy weaned pigs of the same age. The susceptibility of the small intestine to the enterotoxin varies according to area; the upper small intestine is highly susceptible, and susceptibility decreases down through the more distal portions. Unlike many other species, the weanling pig depends largely on its large intestine for absorption of fluid and electrolytes with only small changes in net fluid movement occurring along the jejunal and ileal segments. In fatal cases, death results from the combined effects of dehydration and acidosis resulting from fluid and electrolyte losses. In the peracute and acute forms of the disease, there is a shock-like syndrome with marked gastric and enteric congestion, hemorrhagic enteritis, and death.

The experimental model of the disease is characterized by the three syndromes:

- Peracute fatal diarrhea
- Moderate diarrhea of 3 to 4 days' duration, accompanied by fecal shedding of the inoculated organism and reduced BW gain
- Fecal shedding of the organism with reduced weight gain but without diarrhea

The role of the rotavirus in the pathogenesis of PWD is uncertain. It can be found in the feces of healthy unweaned and weaned pigs. The virus is capable of infecting and destroying villous epithelial cells that could contribute to the partial villous atrophy, loss of digestive enzyme activity, malabsorption, and reduced growth rate. Experimental inoculation of an ETEC and the rotavirus causes a more severe disease than either agent does alone.

Changes in the mucosa of the small intestine of recently weaned pigs have been observed and are the subject of much controversy. There is a reduction in the length of the villi, a marked reduction in intestinal disaccharidase activity, and an increase in the depth and activity of the intestinal crypts. These changes are maximal at 3 to 7 days following weaning, persisting until the second week and coinciding with the reduced growth rate.

CLINICAL FINDINGS

PWD and ED can occur simultaneously. Usually in PWD mortality is 1.5% to 2.0% but in prolonged outbreaks may reach 25%. The mortality is similar to the neonatal disease but is less severe, and there is a lower mortality. Morbidity may reach 100%. The postweaning reduction in growth rate may affect 50% to 100% of the pigs within a few days after weaning and persist for up to 2 weeks. In some situations diarrhea may not develop in any of the pigs in the group or may be delayed for 6 to 8 weeks. A reduction in feed intake, gaunt abdomens, and lusterless hair coats are characteristic findings of piglets with postweaning "check." They may appear unthrifty for 10 days to 2 weeks, by which time they will improve remarkably.

It is common for one or two pigs, in good nutritional condition, to be found dead with little seen in the way of premonitory signs. At this time the others within the group may appear normal, but closer examination will reveal several pigs showing mild depression and moderate pyrexia. A postmortem examination of dead pigs should be conducted early in the examination. A proportion of the group will develop diarrhea within 6 to 24 hours, and by 3 days after the initial onset the morbidity may approach 100%. Feed consumption falls precipitously at the early stages of the outbreak, but affected pigs will still drink. Affected pigs may show a pink discoloration of the skin of the ears, ventral neck, and belly in the terminal stages. Diarrhea is the cardinal sign—the feces are very watery and yellow in color but may be passed without staining of the buttocks and tail. Pyrexia is not a feature in individual pigs once diarrhea is evident. Affected pigs show a dramatic loss of condition and luster and become progressively dehydrated. Voice changes and staggering, incoordinated movements may be observed in the terminal stage in some pigs. The course of an outbreak within a group is generally 7 to 10 days, and the majority of pigs that die do so within the initial 5 days. Surviving pigs show poor growth rate for a further 2 to 3 weeks, and some individuals show permanent retardation in growth. In outbreaks in early weaned pigs diarrhea is usually evident before death occurs. There is some evidence to show that PWD may be activated by PRRS.

CLINICAL PATHOLOGY

Culture of the feces and intestinal contents for ETEC strains of *E. coli* is indicated.

NECROPSY FINDINGS

Pigs dying early in the course of the outbreak are in good nutritional condition, but those dying later show weight loss and dehydration and occasionally cyanosis. Mild skin discoloration of the ears and ventral areas of the head, neck, and abdomen is usually present. In acute cases there is a moderate increase in peritoneal fluid, and barely perceptible fibrinous tags between loops of the small intestine may be present. The vessels of the mesentery are congested and occasionally petechial hemorrhages and edema are present. The stomach may be distended with dry food, and the small intestine may be dilated with slight edema and hyperemia. The gastric mucosa is congested, and an infarct (ulceration) may be present along the greater curvature. The small intestines are dilated and contain yellow mucoid liquid or occasionally bloodstained material. The mucosa of the small intestine is congested and sometimes there are hemorrhagic areas. The content of the large intestine is fluid to porridge like in consistency, and the mucosa may be congested. Pigs dying later may be emaciated and smell of ammonia. In some cases mild mesocolonic edema is visible. Hemolytic *E. coli* can be isolated in large numbers from the small intestine and mesenteric lymph nodes. Polyclonal antisera directed against known pathogenic serotypes are usually used to test the isolate, but a negative result does not preclude the strain from being an enteropathogenic organism.

Microscopically, there may be no lesions, but there is usually bacterial adherence to intestinal villi. This is at its worst in the duodenum and the colon. There may be bacteria in the cells in enterocytes, and sometimes these cells disintegrate and lead to sloughing. Other changes are those commonly associated with endotoxemia, especially microvascular thrombosis in a variety of organs.

Samples for Confirmation of Diagnosis

- *Bacteriology:* Mesenteric lymph node, segment of ileum, colon (CULT); in PWD cases the culture usually yields of hemolytic (ETEC) and nonhemolytic (EPEC) *E. coli*. An RT-PCR assay for the detection of *E. coli* F14 in pig fecal samples by targeting part of the *rfb* sequence specific for this group has been used.[11] A multiplex PCR for nine different virulence factors associated with *E. coli* that cause diarrhea and ED in swine has been described.[12] An RT-PCR for the differentiation of F4 (K88) variants (F4ab, F4ac, and F4ad) of ETEC from diarrheic piglets has been described.[47]
- *Histology*: Formalin-fixed stomach, several segments of small intestine, colon, liver, lung, spleen (LM); colonization of the epithelium can be seen by light microscopy, and confirmed using immunohistochemistry (IHC) or in situ hybridization (ISH).

DIFFERENTIAL DIAGNOSIS

Postweaning diarrhea is the prime consideration in pigs that are scouring or dying within a 3- to 10-day period after a feed or management change with marked dehydration and low to moderate mortality. The gross lesions and the associated smell are helpful.

Swine dysentery and salmonellosis are manifested by diarrhea and death but they are not necessarily related to weaning or feed change, and both are more common in older growing pigs. Salmonellosis poses the greatest difficulty in initial diagnosis from coliform gastroenteritis. In salmonellosis, the feces are generally more fetid with more mucus, mucosal shreds, and occasionally blood, and the skin discoloration is more dramatic. On necropsy examination enlarged hemorrhagic

Continued

peripheral and abdominal lymph nodes and an enlarged pulpy spleen are more suggestive of salmonellosis; however, cultural differentiation is frequently required. If there is doubt, the pigs should be treated to cover both conditions until a final decision is obtained. The onset of swine dysentery is comparatively more insidious than that of postweaning diarrhea; the characteristic feces, clinical and epidemiological pattern, and postmortem lesions differentiate these two conditions.

Swine fever should always be a consideration in outbreaks in pigs manifested by diarrhea and death. However, the epidemiological and postmortem features are different.

Other common causes of acute death in growing pigs such as erysipelas, pasteurellosis, and *Actinobacillus pleuropneumoniae* infection are easily differentiated on necropsy examination.

Edema disease occurs under similar circumstances to coliform gastroenteritis, but the clinical manifestation and postmortem findings are entirely different.

TREATMENT

Antimicrobial Resistance and *E. Coli*

In a study in Spain,[13] it was shown that *E. coli* in the pig fecal microbiome were highly dynamic and show a high level of diversity. The finishing pigs showed the lowest levels of AMR. On-farm AMR did not select for the VGs in *E. coli* carried by a population of healthy pigs.[14]

In a study of pigs fed antibiotics it was shown that bacterial biotypes shifted after 14 days of treatment, with the medicated pigs showing an increase in Proteobacteria (1%–11%) compared with the nonmedicated pigs. Antibiotic resistance genes increased in diarrhea and diversity. Some of the new genes conferred resistance to antibiotics that had not been given.[15]

The *E. coli* stored in a storage tank was more diverse than that in fresh feces. The detection of resistance to specific antibiotics was not significantly different.[16]

There may a horizontal exchange of AMR genes. Almost half (47%) of *E. coli* and *Salmonella* isolated from the same fecal samples showed the AMR genes at the same level.[17,18]

Significant space-time clusters of resistant *E. coli* were found in parts of Denmark.[19] In a study of *E. coli* isolated from pigs in China it was found that most isolates were genetically unrelated. AMR was found in 89% of *E. coli* strains. Most prevalent VG was *East 1*, followed by Stx2e and *eae*. The authors stressed that there was a great need to monitor changes as a result of the high incidence of VG and AMR.[20] The pharmacodynamics of antimicrobials at different levels of the intestinal tract of pigs and their relationship to *E. coli* resistance patterns in the pig have been described.[21] A study of AMR and virulence profile genes in multidrug-resistant ETEC isolated from pigs with PWD in Australia[22] has shown that nine serogroups were identified, particularly O149. None showed resistance to ceftiofur or enrofloxacin, and 9.4% were resistant to florfenicol. O141 had a higher AMR index than other serogroups. There were few associations between AMR and VGs. The multidrug-resistant ETEC ARG/VG profiles suggested that there was a considerable strain and plasmid diversity reflecting various selection pressures at the individual farm level rather than emergence and lateral spread of multidrug-resistant clones.

A Swedish study showed that, except for resistance to tetracyclines, sulfamethoxazole, and streptomycin, antibiotic resistance is not equally spread across *E. coli* isolates. Tetracyclines should not be the first choice of treatment because of the rapid acquisition of resistance. Nearly all isolates are highly susceptible to enrofloxacin, gentamicin, and neomycin.

It is imperative that treatment of all pigs within the group is instigated at the initial signs of the onset of PWD, even though at that time the majority of pigs may appear clinically normal. Delay will result in high mortality rates. Any pig within the group that shows fever, depression, or diarrhea should be initially hospitalized, treated individually, both parenterally and orally, and the whole group should then be placed on oral antibacterial medication. Water medication is preferable to medication, although the feed is easier to institute, but affected pigs will generally drink (less than usual if sick) even if they do not eat. Neomycin, tetracyclines, sulfonamides, or trimethoprim-potentiated sulfonamides and ampicillin are the usual drugs of choice. Danofloxacin is safe and highly effective. Experimental infection with K88-positive *E. coli* was controlled by ceftiofur sodium given intramuscularly daily for three consecutive days. When pulse dosing is used there appears to be less resistance. In herds with PWD problems, prior sensitivity testing will guide the choice of the antibacterial to be used. Antibiotic medication should be continued for a further 2 days after diarrhea is no longer evident and is generally required for a period of 5 to 7 days.

Consideration should be given to the medication of at-risk equivalent groups of pigs within the same environment. Intraperitoneal fluid and electrolyte replacement for severely dehydrated pigs and electrolytes in the drinking water should also be considered.

CONTROL

Recommendations for effective and economical control of postweaning reduced growth rate and PWD in pigs weaned at 3 weeks of age are difficult because the etiology and pathogenesis of this complex disease are not well understood. Epidemiologically, the disease is associated with weaning and the effects of the diet consumed before and after weaning. In all cases the piglet should be 4.5 kg (10 lb) and preferably 5.5 kg (12 lb) at weaning. Protective antibodies are produced in recovered animals.

A whole variety of techniques, including intestinal acidification; antimicrobial medication in water or feed; environmental modifications; competitive exclusion; feeding probiotics; binding agents such as eggs, milk, or bacterial by-products (most of these studies show they do not work); zinc oxide; or vaccination of sows and piglets with toxoids have been tried. The use of dietary egg yolk antibodies may or may not be effective.

Spray dried plasma powder obtained from pigs immunized with a vaccine containing ETEC fimbrial subunit F4 and LT can reduce diarrhea because of spontaneous antibodies against ETEC.[23] This study showed that the combination of anti-LT and anti-F4 antibodies is most effective.

Intestinal acidification reduces the binding of the *E. coli* to the epithelial surface, and a pH of 3.5 to 4.0 at the trough or nipple drinker is best. Citric acid, formic acid, propionic acid, or a citric acid/copper sulfate mixture can be used.

Zinc oxide in particular stabilizes the intestinal flora. It impacts both host cell and pathogen metabolism and may provide insight into the mechanisms for diarrhea reduction.[24] Piglets given lactose and fiber were least affected, and the next least affected were animals that received zinc oxide. Pigs fed dietary antibiotic growth promoters and zinc oxide had lower counts of anaerobic bacteria in their feces than control piglets. The removal of these ingredients from the diet will increase days to slaughter. In a study of the effect of feeding kaolin on ETEC infections in weaned pigs,[25] it was found that there was a protective effect on the course of ETEC. Colonization and shedding of ETEC by piglets fed the kaolin were milder and of shorter duration.

It has been traditionally accepted, without reliable evidence, that the sudden transition in diet at weaning is the major predisposing factor, but the experimental observations are conflicting. One set of observations indicates that, if pigs eat a small quantity of creep feed before weaning, they are then "primed" and develop an intestinal hypersensitivity that, following the ingestion of the same diet after weaning, results in PWD. On the other hand, it has been suggested that piglets should consume at least 600 g of creep feed before weaning to develop a mature digestive system. Another set of observations indicates that those pigs that consumed an excessive quantity of feed after weaning developed the disease.

The complete withholding of creep feed followed by abrupt weaning at 3 weeks of age seemed to have a protective effect, possibly

associated with a low dietary intake. Farms with lower rates of PWD used their first piglet ration (phase 1 feeding) for much longer and also changed over to the second ration over a much longer period. Competitive exclusion has been shown to be beneficial.

The recommendations set out here are based on the hypothesis that the consumption of adequate quantities of creep feed before weaning is the most effective and economical practice. Every effort should be made to minimize the stress associated with weaning. Stressors influence the fecal shedding of ETEC by young piglets by a mechanism that may not involve modulation of the immune response. To avoid a sudden transition in diet at weaning, creep feed should be introduced to the suckling piglets by at least 10 days of age. It is important that the creep feed and feeder area be kept fresh to maintain palatability. The same feed should be fed for at least 2 weeks following weaning, and all subsequent feed changes should be made gradually over a 3- to 5-day period. Feed restriction in the immediate 2-week period following weaning may reduce the incidence but generally is not successful. It is a common field observation that the incidence of diarrhea varies with different sources of feed, but experimental studies to confirm this relationship are not available.

The addition of fiber to the diet may be beneficial but leads to a reduced growth rate. In a study[26] of the role of fiber in the control of PWD it was found that there were two major means of reducing enteric disorders: (1) by minimizing the use of nonstarch polysaccharides (NSPs) such as pearl barley and guar gum, which lead to increased digesta viscosity and (2) by including moderate levels of NSPs that do not increase digesta viscosity, such as oats and inulin, especially where there are levels of high crude protein. NSP fractions affect the taxonomic composition and metabolic features of the fecal microbiota.[27]

The use of low-protein diets may reduce the toxic products and reduce PWD. A diet with decreased protein content reduces protein fermentation and the incidence of PWD challenged with ETEC.[28] The development of greater digestibility or stimulation of higher feed intake may also be responsible for reduction of PWD.[29] Zinc oxide in the diets at 300 to 4000 ppm may stop PWD by preventing colonization of the epithelial lining of the intestine. A variety of feedstuffs reduced the adhesion of ETEC to a porcine intestinal cell line and reduced the inflammatory response.[30]

A symbiotic preparation of starch and anti-ETEC K88 probiotic in the presence of raw potato starch is an effective method for reducing the negative effects of ETEC in the piglet model.[31]

Organic acid administration in drinking water to reduce the pH to 4.0 has shown that there was a reduction in the excretion of fecal *E. coli*, but there was also a significantly decreased water intake.[32]

β-Glucans also reduce susceptibility to ETEC,[33] and in this study there was a reduced excretion of F4 + *E. coli* and a reduced F4-specific serum antibody response.

Colicin also reduced PWD[34], as did prebiotics.[35] One study of a probiotic has shown promise.[36]

A tryptophan-enriched diet improved feed intake and growth performance of ETEC-challenged (K88 +) pigs[37] and *E. coli* F4.[38]

Where possible, at weaning, the sow should be removed and the pigs should be kept as single litters in the same pen for the immediate postweaning period. If grouping of litters is practiced at this time, or later, the pigs should be grouped in equivalent sizes. Multiple suckling in the preweaning period may reduce stress associated with groupings of part-weaned pigs. With all pigs, but especially those weaned earlier than 6 weeks, the pen construction should encourage proper eliminative patterns by the pigs and good pen hygiene to minimize oral–fecal cycling of hemolytic *E. coli*. The environment also appears especially important in this group, and draft-free pen construction should encourage proper ventilation. It is preferable to wean pigs on weight rather than age, and in many piggeries a weaning weight of less than 6 kg is associated with a high incidence of PWD.

There is a development of bacterial resistance against a wide range of antibiotics. This means that the susceptibility of microorganisms should be tested before their use.

The inclusion of an antimicrobial in the feed or water to cover the critical period of susceptibility (generally for 7–10 days after weaning) can be used as a preventive measure. Apramycin at the rate of 150 g/tonne of feed for 2 weeks after weaning may be associated with improved growth rates and a reduction in mortality. The high incidence of drug resistance in isolates of *E. coli* makes prior sensitivity testing mandatory, and the antibiotic may need to be changed if new strains gain access to the herd. The routine use of prophylactic antibiotics for this purpose needs to be considered in relation to the problem of genetically transmitted drug resistance; however, it is currently often necessary for short-term control of a problem.

Vaccination may offer an alternative method of control. Injectable vaccines for sows are designed to produce an improved colostral provision of antibodies but do not increase suitable IgA antibodies in the weaned pig intestine.

However, currently there are no vaccines available for the control of colibacillosis in weaned pigs. Oral inoculation with 5×10^8 to 10^9 of nontoxigenic strains can be followed with K88 at day 1 of move, K88/F18ab at day 7, and F18 at days 13 to 15. Only the oral vaccines with the preformed fimbriae appear to produce any protection from the homologous fimbrial variant. The results vary, and some authors think that the prolonged transit time in the stomach after weaning may deactivate the F4 fimbriae when this has been used as a fimbrial vaccine. Microencapsulated ETEC and detached fimbriae have been used for peroral vaccination in pigs. Parenteral vaccination for the control of coliform gastroenteritis has proved of variable value, probably because parenterally administered antigens do not usually stimulate the production of IgA antibodies and intestinal immunity. Oral immunization by the incorporation of *E. coli* antigens into creep feed has been shown to reduce the incidence and severity of PWD. A live avirulent experimental *E. coli* vaccine with $K88^+$, LT^+ ETEC in weaned pigs provided protection. Rearing early-weaned piglets artificially for the purpose of increasing the efficiency of the sow is an attractive management concept. However, high death losses from diarrhea have slowed progress in this new development. The incorporation of antibodies in the diet of such piglets as a prophylactic measure should be possible and is being explored.

Bacteriophages can be used to prevent and treat diarrhea caused by experimental ETEC O149 infection.[39]

A vaccine candidate expressing ETEC adhesins (*K88ab, K88ac, K99, FasA,* and *F41fimbrial* genes) inserted into a plasmid and transferred to *Salmonella* produced a significantly increased antibody response.[40] The study showed that the candidate vaccine can effectively protect their young pigs against colibacillosis.

A commercial vaccine of F4 fimbrial origin has shown to be useful in preventing a virulent F4 ETEC challenge.[41,42] An F18 fimbrial vaccine did not induce protective immunity.[43]

Chitosan-alginate microcapsules for oral delivery of egg yolk immunoglobulin (IgY) has been evaluated in a pig model of enteric colibacillosis,[44] and it has been shown that it is useful and may be a future method for preventing *E. coli* disease.

The ultimate control of PWD is to remove the receptor gene in the population. Although this has been done experimentally, these animals are not yet available in large numbers commercially. The MUC13 gene may provide potential markers for the selection of ETEC F14ab/ac (K88ab/ac)-resistant animals.[45]

Oral antimicrobials increase AMR in porcine *E. coli.*[46]

CAMPYLOBACTERIOSIS IN PIGS

Several species of the genus *Campylobacter* are known to cause disease in farm animals; some are potentially zoonotic and the role of some is uncertain. The organisms are a cause of diarrhea, often with mucus, in 3-day-old to 3-week-old pigs and in nonimmune pigs in older age groups. They are often not diagnosed because they are not suspected.

ETIOLOGY

There are two main species in the pig, *C. coli* (CC) and *C. jejuni* (CJ). Both are gram-negative, microaerophilic rods that are catalase positive and cause disease naturally and in experimental infections.[1] Other species have been given experimentally to pigs and have caused disease (*C. hyointestinalis, C. sputorum*) and some have been found naturally, often in high numbers, in the pig and have been sometimes associated with disease (*C. hyointestinalis* subsp. *hyointestinalis, C. hyointestinalis* subsp. *lawsonii, C. mucosalis, C. hyoilei, C. lari*, and *C. lanienae*). They also have been found in wild boar and feral pigs. Virulence factors include motility, secreted toxins,[2] flagella, virulence proteins,[3] inflammation, and invasion.[4,5] Six species of *Campylobacter* were isolated from feral swine in California.[6]

EPIDEMIOLOGY

Prevalence of Infection

The prevalence of *Campylobacter* infections in both diarrheic and nondiarrheic piglets may average around 50%, but there is no correlation between the occurrence of the organism in the feces and the presence of diarrhea. However, the presence of these organisms constitutes a potential zoonosis among animal handlers.

CJ, CC, and *C. lari* can be isolated from pigs in commercial swine herds. The organisms are present worldwide. CC is isolated from the intestinal contents of 99% of pigs at slaughter. Approximately 60% of the specimens of healthy slaughter pigs may yield *C. jejuni* (CJ).

The prevalence of CC may be 100% in young pigs and others such CJ may be under 10% in young pigs. Both can be isolated from the intestines of healthy pigs. Carriage of the organism is in the gallbladder, ileal mucosa, and large-intestinal mucosa.

Risk Factors

Possible risk factors for CJ were application of manure with broadcast spreaders, feeding of whole cottonseed or hulls, and accessibility of feed to birds.

Transmission

The organisms are spread by the fecal/oral route from the dam, infected feces, or water. Piglets have the same genotypes of CC as their dams[7] at the start of their lives, but these are then partially replaced by strains from elsewhere so that by 66 days of age 33% of piglet isolates were from other sources. Infected animals may secrete organisms at a high level (10^3–10^4/g feces) for months. It will survive at 4°C for 24 hours and at 22°C for 6 days. Parturition enhances fecal shedding by the sow and accounts for the piglet infection.[8] Piglets are infected when young and the infection then spreads. Management factors are correlated with herd size with the smaller farms having a higher prevalence of campylobacters.[9]

Pathogen Risk Factors

Wild birds probably constitute the main natural reservoir of infection but possibly also other farm livestock and rodents.

The distribution and diversity of *Campylobacter* in a large-scale farming environment in the UK was determined by systematic sampling of feces, soil, and water. Warmer months, large farms, and individual housing were identified as risk factors for shedding by sows.[10] The annual increase in *Campylobacter* infections in England and Wales begins in early May and reaches a peak in early June, and this seasonal incidence may be associated with transmission of the organism by flies.

There is an unprecedented level of heterogeneity in the CC in the United States.[11]

CJ is adapted to the intestinal tract of warm-blooded animals and does not normally replicate outside this environmental niche. The single polar flagellum and corkscrew shape facilitates motility in the viscous intestinal mucus. The bacterium gradually dies outside the host's intestinal tract. CJ strains could not be isolated from water after 3 weeks but may survive for up to 60 days in unstirred water.[12]

CC was widespread, with low levels of antibiotic resistance, high genetic diversity, and a strain of CC*i*, which may have become adapted to survival or persistence in water. The pig farm may become a reservoir for CC for transmission to poultry.

Antimicrobial Resistance

Increasing AMR in *Campylobacter* is being recognized worldwide, and resistance to the quinolones is most common in isolates of both CJ and CC from food-producing animals, especially poultry. In Switzerland, there were many novel sequence types in pigs with macrolide resistance,[13] and the use of tylosin selects for resistance.[14] In Canada, a study showed a high level of resistance to macrolides, lincomycin, and tetracyclines but not to fluoroquinolones.[15] In a study in eight states in the Midwest United States where there was no antibiotic usage on a pig farm there were fewer resistant organisms.[16] A high prevalence of CC in the stomach of pigs at slaughter in France was recorded, and a high proportion of the strains were resistant to tetracyclines and erythromycin.

In Japan, AMR was associated with the resistance in CC both within and between classes of antimicrobials.[17] Tetracyclines are most often used to treat pig diseases, followed by β-lactams and macrolides.[18] Most CC were resistant to one or more antibiotics in some form.[19] In Australia, pigs are more resistant to oxytetracycline than poultry. A dose–response relationship between macrolide use and macrolide resistance has been shown.[20] The use of fluoroquinolones was the most important factor associated with the emergence of fluoroquinolone-resistant CC.[21] The resistant strains are persisting environmental isolates that have been acquired by the different livestock species.

Zoonotic Implications

Campylobacter is the leading bacterial cause of diarrhea in humans in many industrialized countries. The most important cause of indigenous food-borne disease is contaminated chicken. Red meats (beef, lamb, and pork) also contribute to illness despite the lower risk.

There is a strong association of *Campylobacter* infection in humans living on farms, and contact with diarrheic animals is a major risk for *Campylobacter* enteritis in humans. Fecal contamination is the main cause in retail raw meats (chicken, turkey, pork, and beef) sampled in supermarket chain stores at levels of 1% to 10%.[22] Both of the main organisms have been identified in pig meat[23] and in livers at abattoirs,[24] but the pig is not a significant contributor to human disease,[25] although it can pose a threat to human health through the food chain.[26,27] In addition, antibiotic treatment of farm animals may have increased resistance in CC isolated from food.[28]

There is good evidence that isolates of CJ from human disease and farm animals are very similar. The use of MLST is being used to compare the genotypes of CJ from farm animals and the environment with those from retail food and human disease. The risk of a meat product being contaminated is associated with pigs that shed higher concentrations of *Campylobacter* before slaughter.[29]

PATHOGENESIS

The role of CJ as primary pathogens in farm animals is uncertain. The organism is not normally pathogenic in farm animals. In humans, the infectious dose is considered to be <1000 *Campylobacter* organisms.

The flagellated motile organisms are more invasive than the nonflagellated nonmotile ones. They can survive for long periods of time inside both phagocytes and epithelial cells. The attachment, invasion, and translocation of CJ in pig small-intestinal cells have been described.[30]

Following infection the organism rapidly multiplies, particularly in the ileum in close contact with the mucosa, but it does not appear to invade the mucosa in large numbers. They may then spread to the gut-associated lymphoid tissues, tonsils, spleen, and gallbladder.[1] It may, however, produce a cytotoxin. The organism then spreads to the large intestine.

It has been shown recently that the secretion of IL-4 damages the paracellular junctions and allows the increased invasion of CJ into cells.[31]

CLINICAL FINDINGS

The disease may be so mild as to be unapparent, without fever, and may be manifested only by mild depression and soft feces with occasional strands of mucus. The incubation period may be 1 to 3 days.

Maternal immunity usually protects against clinical disease but not infection, and most piglets have antibody by 5 to 7 weeks of age.

The clinical signs include a mild fever for 2 to 3 days and a watery or creamy diarrhea with mucus and occasional flecks of blood for a few days. In older pigs with CC there may be a chronic mucoid diarrhea with weight loss.

CLINICAL PATHOLOGY

The information on the various methods used for the detection and identification of *Campylobacter* in laboratory samples has been reviewed. Because of the unique growth characteristics of *Campylobacter,* isolation of these organisms from field samples requires the use of special media and culture conditions and is generally laborious and time-consuming. However, isolation of *Campylobacter* from feces is possible with high success rates. Recovery of *Campylobacter* from environmental samples can be difficult because the organism does not propagate in the environment. The use of molecular detection methods has greatly facilitated the specific and rapid detection and identification of *Campylobacter,* but has not replaced the gold standard of traditional culture methods. Detection and quantification of CJ in the feces of naturally infected cattle is possible using real-time quantitative PCR.

NECROPSY FINDINGS

At necropsy, lesions are restricted to the small intestine; there may be diffuse catarrhal to severe hemorrhagic enteritis of the jejunum and particularly the terminal ileum. The lymph nodes may be enlarged, and the terminal ileum may be thickened. There may be ileal villi loss, and the mucosa may be slightly inflamed. Histologically, the most important finding is proliferation of the lymphoid tissue in the terminal ileum. Large numbers of *Campylobacters* may be seen on smears from the mucosa and isolated in culture.

DIAGNOSIS

If there is a mucoid diarrhea with some mucus and perhaps a little blood in young piglets with no great morbidity and no mortality, then campylobacteriosis should be suspected.

Culture is sufficient but can be supplemented by DNA probes and PCR and improved by using RT-PCR.[32] Discrimination of the major capsular types of CJ is possible using multiplex PCR.[33] It is possible in some laboratories to use ELISA for serum antibody, but this has limited commercial availability.

TREATMENT

Treatment is rarely performed, which is good as a high proportion of CC are resistant to erythromycin (5%–62%) and streptomycin (70% in Canada).[34] Potential macrolide resistance is associated with farms that use tylosin for the treatment of diarrhea in young pigs.[26] A high resistance was also reported for pig CC for ciprofloxacin.[25]

CONTROL

Control depends on sanitation and hygiene in livestock barns to reduce the bacterial populations in the environment of the animals. A high dosage of zinc oxide dietary supplement has an inhibitory effect on CC excretion in weaned piglets.[35]

PORCINE PROLIFERATIVE ENTEROPATHY

SYNOPSIS

Etiology Lawsonia *intracellularis* (ileal symbiont intracellularis)

Epidemiology Four to 8 weeks after weaning; feeder pigs, and young gilts, sows, and boars. Risk factors not known

Signs Diarrhea, weight loss, inappetence, and may recover. Outbreaks of bloody diarrhea and rapid death may occur in feeder pigs, young gilts, and boars.

Clinical pathology Demonstrate organism.

Lesions Proliferative ileitis. Proliferative hemorrhagic enteropathy, fibrinous casts, and blood clots

Diagnostic confirmation Demonstrate organism in tissues.

Differential diagnosis list
- Esophagogastric ulceration
- Intestinal hemorrhage syndrome
- *Clostridium perfringens* type C hemorrhagic enteritis

Treatment Antimicrobials in feed

Control No reliable strategies. Medication of feed

Porcine proliferative enteropathy (PPE) has been called a variety of names in the past, including **ileitis regional ileitis, porcine proliferative enteritis complex, porcine intestinal adenomatosis (PIA), PPE, necrotic enteritis, regional enteritis, and proliferative hemorrhagic enteropathy (PHE) of pigs**. All of these terms are a reflection of the lesions caused by LI.

PPE causes considerable economic loss. There is a close relationship to the *Desulfovibrio* species, and it is closely related to *Bilophila wadsworthii*, which is a known inhabitant of the human colon and associated with appendicitis. It is widely found in pigs in Australia. There are no known associations with human disease.[1] It does cause disease in young horses and can be isolated from laboratory animals.[2] There may be two biovars, one for pigs and one for the other species.[3] The pig LI are >99% similar worldwide in 16S rDNA and outer membrane proteins. Most work has been performed using a mucosal homogenate challenge model.[4]

ETIOLOGY

The causative agent, first described in Iowa in the 1930s, is LI, which was isolated and Koch's postulates fulfilled in 1993. It is a gram-negative, curved rod (vibrioid shaped) obligate intracellular bacterium in the cytoplasm of intestinal epithelial cells. Molecular typing of the organism and sequencing of the genome and the three small plasmids have been described. The isolates worldwide are similar.

Both pure cultures and mucosal homogenates of LI will produce clinical signs, lesions, and shedding. It is best cultivated in cell-free media and also in a rat enterocyte cell line.[5]

The disease is complex, often just called ileitis, and occurs in two forms. There is an acute form called porcine hemorrhagic enteropathy or regional ileitis that occurs from 4 to 12 weeks and a chronic form usually referred to as PIA or necrotic enteritis, which occurs from 6 to 20 weeks.

EPIDEMIOLOGY

Occurrence

There is a worldwide occurrence. The PPE complex affects pigs from weaning age to feeder pigs and also young gilts, sows, and boars. It is characterized clinically by diarrhea, loss of BW and inappetence in recently weaned pigs, and sudden death in feeder pigs, young gilts, and boars. The essential lesions are proliferative, and there seems to be an etiologic and pathologic relationship between PIA, necrotic enteritis, regional enteritis, and hemorrhagic enteropathy. Nonhemorrhagic proliferative enteritis occurred most often in pigs 6 to 24 weeks of age.

PHE usually affects pigs over 16 weeks of age but occurs in pigs as young as 6 weeks and as old as 4 years of age. PHE is one form and appears to occur in most countries. It probably has a worldwide distribution with 30% to 60% of herds affected depending on the country. In Germany, 82.7% of finishing herds had seroconversion. It is especially common in hysterectomy-derived or SPF herds and has a higher prevalence in the hot summer period. In some countries its prevalence is increasing, and it is emerging as a major syndrome in SPF herds.

The disease in all ages is frequently associated with the concurrent occurrence of PIA, but it is unknown whether the hemorrhagic syndrome results from some insult to the intestine that also predisposes to a proliferative enteropathy or whether it is simply an acute manifestation of this disease. The related syndromes of necrotic enteritis and regional ileitis can be found in apparently healthy pigs examined at slaughter. Because the disease is common in pigs, suboptimal growth of pigs in nutritional studies may be caused by the disease complex.

It has been suggested that it can live extracellularly within the environment for 2 weeks at 5 to 15°C. It appears highly resistant to a lot of cleaning agents such as povidone iodine or potassium permanganate, but may be susceptible to 3% cetrimide. In one study transmission occurred despite cleaning, use of footbaths, dedicated boots, etc.

It has been suggested that it normally lives in organic matter in weaner units awaiting the arrival of batches of susceptible pigs, with the resultant sudden increase in shedding 4 to 12 weeks after weaning. The recent finding of LI in the tonsil may be a coincidental finding, as they may have just been trapped in the crypts after licking infected material, because they were only found in this site in 2/32 pigs. Mixed infections are found in 10% of growers, and there is a strong association between diarrhea and prevalence of *Brachyspira hyodysenteriae* and *B. pilosicoli*.

Prevalence of Infection

A study in Belgium suggested that 24% of slaughtered pigs had a thickened ileum with a range in farm batches from 10% to 49%. In Denmark 94% of herds were infected with a mean within herd prevalence of 30%. In Canada, there is a widespread distribution between 50% and 100% of herds in the provinces with 5% to 89% of pigs affected. In the United States it was found using the immunoperoxidase monolayer (IPMA) test to study antibodies that 75% of growing herds had antibodies, and within the herd the prevalence was 11% to 91%. Of the breeding herds 78% had antibodies with two peaks at the time of infection and 9 to 18 weeks later and with an overall prevalence of 5% to 61%.

In Canada, studying 96 cases of PPE, it was found that 15% were in weaners (8–10 weeks), 36% in growers from 10 to 18 weeks, and 14% among finishers of 18 to 26 weeks. A further 16% were in mature pigs of >26 weeks.

Estimation of the incidence of disease is complicated by the difficulties in making an accurate clinical and pathologic diagnosis. Surveys of pig farms in Australia indicated that 56% had either observed the disease or the veterinarian had made the diagnosis.

Surveys of fecal samples from swine herds in Taiwan revealed an overall prevalence of infection of LI in 30% of herds and 5.5% of pigs.

Morbidity and Case Fatality

The disease can occur in all ages of postweaned pigs, but it has a high incidence in young replacement gilts and boars at 6 to 9 months of age and in pigs approximately 4 to 8 weeks after weaning. The high incidence in replacement gilts may be caused by suppression of the disease by low-level feeding of antibacterial agents during the growing period, but frequently the syndrome appears first in gilts and some time later in the growing pigs. In gilts, outbreaks may be explosive, but generally are short lived with

morbidity rates of up to 50% of the group occurring within a 2- to 3-week period. The case–fatality rate does not usually exceed 10%. In large herds with continual addition to the replacement gilt herd and in herds where the disease occurs in grower pigs, outbreaks may be more prolonged. The disease in growers generally has equivalent morbidity and case–fatality rates. It is more severe in that runting of surviving and contemporary pigs may occur, necessitating further economic loss through culling.

When given experimentally at a high level of 10^9 to 10^{10} LI per pig, mortality in the untreated groups varied from 10% to 50%, which is considered much higher than in the natural outbreak.

Risk Factors

There may be two patterns of infection. One is an early infection and the second is a delayed infection, which is seen in farms that separate pigs at weaning and have all-in/all-out methods of production.

Very little is known about the risk factors of PPE. A gene has been discovered that encodes for a surface antigen (LsaA) that is believed to be associated with attachment to and entry into cells and that is synthesized during infections. A study of recorded outbreaks of PHE indicated the disease often occurred within 12 months after repopulation of the herd and following withdrawal of antimicrobials from the feed. It has been proposed that the introduction of breeding stock from herds in which the disease is endemic may be a risk factor, but this is not documented. In a study in the UK showed there seemed to be a higher risk when there were more than 500 sows. An older parity structure in the sow population seemed to reduce infection. There seemed to be a higher risk if buying in boars. Fully slatted or fully meshed floors also carried a higher risk of infection compared with solid floors or straw. A higher risk was seen in those herds in which large numbers of pigs entered the finishing units simultaneously. Pigs on concrete slats may also be predisposed. Intensive systems were more severely affected than outdoor systems. There was a reduced risk if there was thorough cleaning and disinfection (all-in/all-out) before the next group of pigs arrived. Seroconversion usually occurred as the pigs entered the finishing site suggesting that the exposure takes place in the nursery. There may be five major types of risk factor: comingling, temperature fluctuations (overheating/ chilling), transportation, depopulation, and new buildings. Sows may have low levels of antibody and are capable of passing on colostral protection to the piglets. Maternal antibodies have usually declined by 3 to 5 weeks of age but may be extended to 42 days by repeated sow vaccination, by which time exposure may have occurred and there may be both active and passive antibodies.

Methods of Transmission

The organism is found in hamsters, ferrets, foxes, hares, deer, emus, ostriches, and primates. Colonization of rodents and wild rodents has been described.[6] The significance of these alternative hosts has not yet been ascertained. The role of vectors is not clear, but the main source of infection is the incoming pig (both growing pigs and adults). Gilts can be shedders and carriers, and the organism can probably survive in the extracellular world for 1 to 2 weeks at 5°C to 15°C. It may be transmitted on boots, other fomites, and by insects and flies.[7] The method of transmission between pigs is assumed to be the fecal–oral route.[8]

PATHOGENESIS

Contact-dependent excretion systems, such as the type III secretion system (T3SS), play an important role in the pathogenicity of many gram-negative organisms.[9,10] This system transfers bacterial proteins (effectors) into the cell where they disrupt the various cellular processes[11] and promote bacterial pathogenicity. They have shown that the system is operative in LI.[9]

The infection is by oral means and enters the epithelial cells of the crypts of the small intestine. The process appears to go ileum first then colon, to cecum, and finally rectum.[4] The infection process appears to take about 3 weeks to peak with the organisms appearing in the feces about 1 week after experimental infection. The histologic lesions may have cleared from the ileum by day 29 following inoculation. Considerable progress has been made using porcine ileal models.[12]

Proliferative enteropathy is characterized by the hyperplasia of the epithelial cells of the intestinal crypts, particularly in the ileum and colon. The presence of nonmembrane bound, curved bacteria free in the cytoplasm of the affected enterocytes is a consistent feature of the disease. The bacteria associate with the enterocyte and enter through an entry vacuole, which then breaks down and the LI live freely in the cell. The organisms infect the immature cells of the mucosal glands and stop them from maturing.[13] The goblet cells decrease and then disappear. The cells lose protein and fail to absorb nutrients, which then contributes to the weight loss that occurs.[14] This causes them to multiply without leaving the gland, and the cells then degenerate probably by apoptosis and the glands continue to proliferate.[15]

Gross and microscopic lesions typical of acute proliferative enteritis can be reproduced by inoculation of cell-cultured LI into pigs 3 or 7 weeks of age. The incubation period is about 7 to 14 days with the early lesions appearing in the terminal ileum. Fecal shedding usually occurs about 7 days postchallenge and the animals seroconvert about 14 days postchallenge. The disease peak is about 21 days postinfection. The clinical signs decrease, and the lesions begin to resolve after 28 days. The disease process results in a 2-week delay in marketing. Inoculation of gnotobiotic pigs does not cause the disease. It now seems certain that LI is the causative agent of the disease complex. Infection of intestinal epithelial cells is causally linked to marked hyperplastic proliferation of affected tissue.

The organism internalizes and multiplies within the cells, and it is proposed that the organism is capable of affecting, directly or indirectly, the cell cycle within the intestinal epithelium. This may or may not be concerned with the role of cyclin kinase p27, which regulates differentiation of immature crypt cells into the differentiated form. The changes in the experimental disease are similar to those in the natural disease. Following experimental infection there is almost complete replacement of normal ileal mucosa by adenomatous mucosa. Affected crypts are enlarged and branched, with loss of goblet cells and marked proliferation of crypt epithelial cells. Hyperplastic lesions may develop 2 to 3 weeks after challenge and persist for several weeks. In older animals, the lesions may be complicated by acute mucosal hemorrhage or necrosis. In the progressive stage of the disease, 3 weeks after infection, numerous organisms are consistently present within affected intestinal epithelial cells but not elsewhere. In the developed and recovering stage of the disease, 7 to 9 weeks after infection, ultrastructural features in affected intestinal tissues consist of pale, swollen, protruding epithelial cells and shrunken epithelial cells. This is followed by the appearance of apoptotic bodies in both epithelial cells and macrophages, the reappearance of normal goblet cells, and reduced numbers of organisms within the lesions. Bacteria are released from cells via cytoplasmic and cellular protrusions into the intestinal lumen and can be found in fecal samples.

In the experimental disease in pigs, seroconversion to the organism does not occur, confirming the weak response characteristic of the natural disease.

The proliferative lesion may result in suboptimal performance in otherwise normal pigs or unthriftiness, or be manifested as acute intestinal hemorrhage during the recovery stages of intestinal adenomatosis. The hemorrhagic lesions are more difficult to explain, but there may be direct or indirect toxic damage to the endothelium of the blood vessels.

It has been suggested that there is a close association between the presence of LI and reduced T-cell and B-cell numbers. This provides evidence of an immunosuppressive effect operating in this disease. It seems also that macrophages have an important function with activated macrophages accumulating in the infected hyperplastic glands. At day 14 postinfection there were a few

pinpoint lesions, and the percentage of infected crypts was minimal. At the same time the number of CD3+ cells was reduced and the number of intraepithelial CD3+ cells was also reduced, while the CD8 and CD4 cells showed no changes. Apparently there is an induction of an immunosuppressive phenotype with downregulation of an adaptive immune response through the reduction in the CD8+ T- and B-cells.

CLINICAL FINDINGS

The disease can occur in pigs from a few weeks of age to adults and lasts about 6 weeks on average. It is most common in the newly weaned. Morbidity may reach 12% and the mortality rarely exceeds 6%, even when the hemorrhagic form is very severe.

This disease is one of the common causes of failure to grow, weight variation in batches of pigs, and delay to market. In many cases, the clinical signs are not obvious as they are growth effects. Pigs may appear gaunt and may pass watery stools.

Between 6 and 20 weeks the endemic form is called porcine intestinal adenomatous with wasting and ill-thrift. In vaccination studies the improvement has been of the order of 5% for average daily gain or feed conversion ratio.[16] A 56 g/day reduction in average daily gain for each log 10 unit increase in LI excretion has been found. In a German study, LI PCR positivity had a significant negative effect on average daily gain.[17]

Regional ileitis is the most common differential diagnosis of the granulomatous enteritis that is seen in PCV2-associated enteric disease. In many cases both PCV2 and LI have been seen in the same case as both target the ileum.

PPE or ileitis occurs in pigs 6 to 16 weeks of age. In the chronic form, a reduction in growth rate and failure to thrive are common. Affected pigs are afebrile and diarrhea occurs but is unremarkable. Most cases recover spontaneously within 6 weeks of the onset of signs. When inflammation and necrosis have resulted in necrotic enteritis and regional ileitis, diarrhea and severe weight loss occur followed by death, often by ileal perforation in the case of regional ileitis.

PHE occurs in older pigs, such as young gilts and boars, and is manifested primarily by bloody diarrhea and sudden death. Others within the group may show skin pallor and hemorrhagic feces with fibrin casts but otherwise appear clinically normal. In some pigs there is continual blood loss, and death occurs within 48 hours of the onset of hemorrhage, but in the majority of pigs the hemorrhage is transient. In outbreaks, up to 70% of pigs affected with dysentery may die within 24 hours after the onset of signs. Fever is not a feature and the majority of pigs suffer only a minor setback for a 2-week period. A small percentage will develop chronic ill-thrift.

In grower pigs the disease is economically more severe. As in gilts, acute death with marked skin pallor and without premonitory signs can occur, but survivors show ill-thrift, and as the outbreak progresses contemporary pigs may show a chronic syndrome of ill-thrift with the periodic passage of bloody feces.

When sows are affected in early pregnancy they may abort. Usually about 6 days after the onset of clinical signs and in late pregnancy they can infect their newborn litter.[18]

Pigs that have been experimentally infected are resistant to later reinfection.[19]

CLINICAL PATHOLOGY

Many affected pigs are pale and anemic and the packed cell blood volume may be only 20% of normal. In these instances there may be black feces (melena) from the digested blood.

The organism can be detected in the feces of healthy 10- to 25-week-old growing/finishing pigs, which is probably the age group of pigs serving as the main source of infection for younger nursery pigs.

A PCR assay is highly reliable for the detection of the organism in feces and intestinal tissues. It may detect as few as 2×10^2 bacterial cells per gram of feces, but it is more likely that the PCR detects shedding of 10^3 or greater per gram of feces.

Positive results with the PCR are only present in animals with active lesions of proliferative enteropathy. Shedding as detected by PCR may start as early as 6 to 8 weeks and continue to 28 weeks. From seroconversion to first shedding was 2 to 8 weeks.

A fluorescent ISH technique targeting 16S ribosomal RNA using an oligonucleotide probe successfully identified LI. The indirect IF test works as soon as 2 weeks postshedding of LI.

Seroconversion may commence between 12 and 27 weeks. The range for positivity from first detection was 7 to 23 weeks. Maternal antibody appears not to prevent infection of piglets. ELISAs detect antibodies 21 to 28 days postinfection.

NECROPSY FINDINGS

The immediate impact of PPE is a thickened ileum and cecum and less frequently a spiral colon. Not all cases have lesions. Some may be so mild they are overlooked. Obvious gross lesions occur in severe cases, but in the less severe cases histology is needed. The pathology is related to the dose. As long as you remember these facts you can monitor LI in the abattoir.

A complex gross, histologic, and immunohistochemical study of LI has been made in which the pigs showed complete recovery and were IHC –ve by 35 days postinfection. The antigen was detected in the intestine, lymph node (macrophages), and tonsils (free living in the crypts). They were found in the rectum and in several portions of the large intestine. The first site of colonization was the jejunum and ileum and then the lower intestinal segments. On day 29 there was nothing in the small intestine, but the LI were still observed in the cecum, proximal colon, and rectum. Mucosal IgA was first detected on day 15 and was still detectable on day 29, but in all cases the titers varied from only 1:4 to 1:16.

The macroscopic lesions of proliferative enteropathy were first detected at 11 days postinfection, which is the same time as histologic identification with enterocyte hyperplasia and reduced goblet cells. Immunohistochemical identification can be seen at 5 days postinfection and continues until day 29.

In PIA, the prominent lesions are in the terminal ileum and proximal portion of the large intestine. There is gross thickening of the mucosa and submucosa of the terminal ileum, and the colonic mucosa may also appear congested and slightly thickened.

In both forms of the disease the mucosal surface may be eroded and may look granular with abundant adherent material in the form of fibrinonecrotic debris. There may also be a fibrinonecrotic core filling the lumen. In PHE the only difference may be that the surface of the mucosa may be covered by large undigested blood clots.

Histologically, the mucosal change consists of marked proliferation of immature epithelial cells and a suppurative cryptitis. In many cases the affected crypts are 5 to 10 or more cells thick with numerous mitotic figures.

In **necrotic enteritis** the lining of the intestine may be covered in yellow or gray masses of necrotic material.

In regional ileitis (called hosepipe gut) the distal ileum is rigid from thickening of the intestinal wall caused by muscular hypertrophy and granulation tissue formation. The initiating mucosal damage is often somewhat masked because of colonization of the ulcerated mucosa by secondary bacterial invaders.

In PHE, the carcass is usually very pale, and massive amounts of blood are often present within the intestinal tract. The mucosa and submucosa of the ileum are thickened and may be coated in fibrin. Fibrin casts are also sometimes present. Although the intestinal wall is dark red and hemorrhagic, there may be no obvious points of hemorrhage. Histologically, there is evidence of vascular congestion, fibrin thrombi, increased permeability of blood vessels, and necrosis of the intestinal mucosa. The character of the vascular lesion resembles an acute bacterial infection and type I hypersensitivity reaction. Again, the key microscopic feature is the presence of proliferating immature epithelial cells with basophilic nuclei,

which line the greatly elongated crypts. There are no goblet cells in this site. In an analysis of histologic lesions crypt abscesses were seen in 20% of pigs, decreased goblet cells in 90%, hypertrophy and hyperplasia in 3%, hypertrophy of both muscle coats in 78%, increased eosinophils in 34%, and lymphoid hyperplasia in 90%.

In chronic cases the lesions described previously are nearly all replaced by fibrous connective tissue, and the diagnosis may rely on seeing just isolated pieces of mucosa.

Lawsonia are also a common cause of colitis. In 70% of cases of colitis LI are also found in the colonic mucosa. In three cases, LI were found only in the colon, and in these infected large bowels there was an excess of mucus on the surface.

Staining of smears of ileal mucosa with modified acid-fast stains may reveal typical curved bacterial rods in the apical cytoplasm of the infected proliferating enterocytes, permitting a presumptive diagnosis. It is not always specific for *Lawsonia.* They are not always present in necrotic debris or autolyzed tissue. IHC or silver stains (Warthin–Starry) of formalin-fixed gut are usually sufficient to detect the intracellular organisms in all forms of proliferative enteritis. LI can also be identified using a PCR assay. It is possible to find bacterial antigen in the lamina propria and draining lymph nodes of the ileum. This is a result of the natural process of infection clearance.

There has been a considerable interest in the relationship between PCV2 and LI and the difficulties in separating the two.[20,21]

Samples for Confirmation of Diagnosis

- **Bacteriology:** Distal ileum, proximal colon (direct smear and PCR); the organism needs to grow on tissue cell lines at oxygen and CO_2 concentrations that mimic the small intestine. It is not really an option because these techniques are difficult and the organism is an obligate intracellular organism. A simple staining with Ziehl–Neelsen or a modified Gimenez stain will show up the organisms.

There has been a considerable development in PCR techniques for feces as an antemortem technique. This is a variable sensitivity that is affected by sample quality and the presence of inhibitory factors in feces, but the specificity is around 97%. It appears to be very useful in the clinically ill but not so reliable in the subclinically affected. The PCR is more specific when applied to the ileal mucosa rather than to feces. It has been reported that fecal samples are more likely to be PCR-positive in herds with PHE rather than in PIA herds. It is more sensitive than either WS staining or immunofluorescence antibody test (IFAT). Shedding commences around 7 weeks and is observed most between 13 and 16 weeks. A one tube–nested PCR has been developed that is very sensitive and less prone to false positives compared with a standard nested PCR. A 5′ nuclease assay has been developed with a detection limit of one LI cell per PCR tube. A real-time PCR has been designed as a high-throughput test for use on feces. It is as specific as a conventional PCR but is more sensitive. It can be quantified and performed with pure cultures, tissue homogenate, or bacteria shed in feces.

A multiplex PCR has also been described for *B. hyodysenteriae, B. pilosicoli,* and LI.[22] It has a 100% specificity for the three species and does not generate false positives. The PCR can detect 10^2 to 10^5 LI per gram feces. A TaqMan quantitative PCR for use on feces and tissue samples[23] was shown to be more sensitive and more specific than conventional PCR on tissues.

There is also an indirect fluorescent technique, but this requires expertise and a reliable *Lawsoniana*-specific antibody, and again is not 100% for subclinically affected animals. The percentage of agreement between IFAT and IPMA was 98.6%. It has been suggested that IFAT is more sensitive than PCR in antemortem testing.

- **Histology:** Distal ileum, proximal colon (LM, IHC); IHC was described.[24]
- **Serology:** Serum antibody response in pigs to LI is specific and involves both IgM and IgG.

Methods utilize LI grown in enterocytes or LI prepared on slides as the antigen. These assays are specific because cell cultures or slides are examined microscopically, and specifically stained bacteria can be distinguished from any background. Staining of bacteria is either by fluorescent (IFA), which detects antibodies 28 days after infection, or peroxidase-labeled IPMA. The IPMA test is highly specific (100%) and fairly sensitive (90%) in experimentally infected animals. It is an appropriate diagnostic test for herd screening but not for diagnosing PPE on an individual animal basis. The IgG antibodies may be only short lived and found only between 18 to 24 weeks. These have proved useful for routine PPE diagnosis, although the humoral response is often weak and short lived. Titers of 1:30 to LI appear about 2 weeks after infection, and 90% become positive by about 3 weeks after challenge with 5% having titers of 1:480 or above. They are, however, already decaying by about 4 weeks after challenge. Antibody was not detected until 16 weeks of age and often not until 19 to 22 weeks. Today there are ELISAs for herd diagnosis.

A cell-mediated response can be detected in the research laboratory using an enzyme-linked immunospot assay (Elispot-T-cell assay) that measures the LI-specific secretion of IFN-γ by lymphocytes. It appears to follow the same pattern as the humoral response, and it also starts to decay from about 3 weeks although more slowly.

Both humoral and cell-mediated responses can still be detected 13 weeks after challenge or vaccination.

DIAGNOSIS

In a comparative review of diagnostic methods in 2009, it was suggested in that gross and histopathological examinations including the use of Warthin-Starry staining (34% sensitive but 100% specific) of tissue sections were of limited value.[24] The authors suggested that PCR examination of feces was the most useful in terms of sensitivity but less specific (95%) than either IHC (99%) or ISH (100%).

DIFFERENTIAL DIAGNOSIS

Porcine intestinal adenomatosis
Characteristic clinical findings are inappetence, loss of weight, and mild diarrhea in recently weaned pigs. Must be differentiated from postweaning coliform gastroenteritis, which is clinically much more severe, and death rapidly occurs. The postweaning drop in average daily gain (postweaning check) occurs within several days after weaning, and recovery occurs within several days following consumption of a normal daily intake of feed.

Proliferative hemorrhagic enteropathy
Occurs in feeder pigs, young gilts, and boars and is characterized by sudden death and extreme pallor of the skin. Must be differentiated from fatal hemorrhagic esophagogastric ulceration, acute swine dysentery, and intestinal hemorrhage syndrome

Esophagogastric ulceration
Occurs in all ages of pigs but especially in growers. The necropsy finding of ulceration in the nonglandular portion of the stomach at the esophageal entrance along with hemorrhage into the stomach with passage into the intestines provides easy differentiation. Acute death with intestinal hemorrhage occurs occasionally in swine dysentery. More common in adults affected with the disease and at the onset of an outbreak. Skin pallor is not as marked, and hemorrhage is restricted to the large intestine and associated with the characteristic lesions of swine dysentery in this area. Contemporary pigs show clinical and necropsy findings typical for this disease, and the diagnosis can be confirmed with laboratory studies.

Intestinal hemorrhage syndrome
More difficult to differentiate from the proliferative hemorrhagic enteropathy. Occurs most commonly in 3- to 6-month-old pigs that are well nourished, and many but not all outbreaks have been associated with whey feeding. Typically associated with abdominal distension and evidence of abdominal pain preceding death and the presence of marked intestinal tympany on postmortem examination. In many cases, hemorrhage in

Continued

the intestine appears to result from torsion, which occludes the mesenteric veins. It occurs in all areas of the intestine except the proximal duodenum and stomach, which have separate drainage. Because of intestinal distension the torsion may be easily missed, but it is best determined by the abnormal cranial direction of the blind end of the cecum and palpation of the mesentery. This distribution of hemorrhage may occur without the occurrence of torsion, and the etiology in these cases is unknown.

Other diseases

Infectious necrotic enteritis associated with *Clostridium perfringens* type C may cause hemorrhage into the intestine but it is easily differentiated on clinical, epidemiologic, and laboratory findings. **Mild *brachyspiral* enteritis, salmonellosis, porcine circovirus type 2, and nutritional diarrheas are alternative diagnoses.**

TREATMENT AND CONTROL

Treatment is via antimicrobials, and control relies on biosecurity, antimicrobial therapy, and biosecurity and resolute hygiene, particularly between buildings, is also important. Strict rodent control and fly control is advisable.

Biosecurity to prevent the entry of infection is the key to control. Quarternary ammonium compounds are very effective disinfectants,[25] and iodine and Virkon S also are effective. Beware of carrier pigs; isolate for 30 to 60 days, use preventive antibiotics as outlined later, use laboratory diagnostics, and vaccinate using the new water vaccine.

A program for the monitoring of LI in breeding herd gilts has been described[18] in which gilts were tested at regular intervals before sale in an infected herd and on arrival at the recipient herd. In addition, the growing pigs in the recipient herd were also tested. It was found that it was possible to establish herd profiles and to prevent transmission from herd to herd.

Eradication using early weaning is not a possibility, but using medication and vaccination is a possibility. It has been said that pigs between 30 to 50 kg shed fewer LI in the feces when they are fed nonpelleted and nonheated (home-mixed) feed. An eradication scheme for LI used in Denmark following the use of antimicrobials (tiamulin, lincomycin, and tylosin) failed. A control program was tried in the UK using PCR to identify affected animals and medication with chlortetracycline and tiamulin for control. The number of PCR-positive animals declined from 50% to 70% to 0%. In pigs over 14 weeks there were some PCR positives derived from treated groups. Another farm used tylosin phosphate and these remained clean.

Antimicrobials

It is likely that administration of antibiotics is necessary in the early stages in water or in feed. This is usually around 8 to 11 weeks of age. A preferred treatment would be tiamulin 120 ppm or tylosin 100 ppm for 14 days.

In acute disease, water medication and particularly individual medications are more effective than treatment through in-feed medication.

Continuous medication for LI can prevent infection but is frowned upon because it can prevent the development of immunity and extend susceptibility to infection. In fact, the timing of any medication can affect the immune response, subsequent fecal shedding, and the development of lesions.

There is no published information available on the treatment of individually affected pigs. The disease is usually treated on a herd basis by medication of the feed.

There appears to have been no changes in the in vitro minimum inhibitory concentrations (MICs) since the 1980s and 1990s. There are probably four reasons why medication does not work: (1) underdosing; (2) concurrent infections; (3) some other disease or nutrition problem, i.e., misdiagnosis; and (4) antibiotics given too late to be effective.

If antimicrobials are going to be used, it is a good idea to start at least 3 weeks before the anticipated acquisition of the infection.

In a study of 10 North American and European LI isolates it was found that for extracellular activity valnemulin was the most active with intermediate activity from chlortetracycline, tylosin, and tiamulin, but lincomycin showed the least activity.[26] For intracellular activity carbadox, tiamulin, and valnemulin were the most effective. Tylosin and chlortetracycline showed intermediate activity, and lincomycin was the least effective.

The antimicrobial susceptibility of the organism isolated from pigs with proliferative enteropathy was determined in a tissue culture system. Penicillin, erythromycin, difloxacin, virginiamycin, and chlortetracycline were the most active compounds tested. Tiamulin and tilmicosin were the next most active, and the aminoglycosides had the highest minimum inhibitory concentrations. Both lincomycin and tylosin were relatively inactive against the strains of the organism tested.

In the field Bacitracin, virginiamycin, and salinomycin are useless as are penicillins and fluoroquinolones.

Oral chlortetracycline, one of the oldest drugs, is still used; at 300 ppm or 600 ppm it can prevent challenged pigs from developing clinical disease. Chlortetracycline at 300 ppm and tylosin at 600 ppm have prevented the clinical signs of PPE.

Tylosin is ideal for treatment by injection, in feed, or through water and was successfully used for treating PPE at 100 ppm. For effectiveness, the antimicrobial would have to accumulate in the cytoplasm of the intestinal cell and block bacterial protein synthesis. The macrolides, tetracyclines, and virginiamycin act by selectively blocking protein synthesis in ribosomes. The oral administration of tylosin phosphate at a dose of 100 ppm or 40 ppm in the feed to pigs for 4 days before experimental challenge and continued for 16 days when the dose was reduced to 40 and 20 ppm was effective in preventing the clinical signs and lesions of proliferative enteropathy. It does not appear to block the pattern of seroconversion to LI. Tylosin at 110 ppm significantly reduced fecal shedding of LI and histologic lesions consistent with PPE. Injection of tylosin produced an improved diarrhea score and clinical impression score, which improved weight gain. Tylosin tartrate in drinking water for the treatment of ileitis was effective in reducing clinical signs, lesions, and reduction in growth rate.

Lincomycin is ideal for injection, water treatment, and in-feed treatment. Linco-Spectin at 80 ppm used consecutively was shown to be useful for treatment of PPE. Lincomycin at 44 and 110 ppm for 21 consecutive days was effective in controlling the clinical signs of PPE and at 110 ppm also reduced the mortality associated with PPE. Lincomycin water-soluble powder at 250 mL/gal is also effective.

Aivlosin was found to be useful at concentrations 25% less than those used for tylosin.[27] Valnemulin was also shown to be effective at 75 ppm in the feed. Tiamulin is useful for in-feed medication and water administration. Tiamulin given 50 ppm, 2 days before experimental challenge and kept for 3 weeks prevented clinical disease. In addition, pigs given 150-ppm tiamulin 7 days after challenge remained clinically normal and had no specific lesions of proliferative enteropathy at necropsy. Tiamulin in water is very useful, but a study showed that in water it interfered with seroconversion, whereas administration in feed did not.

The use of Bacitracin Zinc in the feed of growing/finishing pigs at 300 ppm or 200 ppm from weaning up to 100 days of age, or 200 ppm or 100 ppm from 100 to 125 days of age, and 100 ppm or 50 ppm from 125 to 156 days of age was effective in controlling the effects of proliferative enteropathy in pigs on a farm with a previous history of the disease.[7]

Carbadox and zinc oxide might have some effect against LI. It has been shown to be useful if fed in the final 2 weeks in the nursery. It reduces fecal shedding, clinical signs, and no IHC + ve or PCR + ve animals were found in one study.

Hyperimmune chicken eggs fed to the swine have been suggested for controlling LI infection in growing swine.

Vaccines

The main difference between respiratory and alimentary diseases in the last few years has been the development of vaccines for the former but not the latter. The recent development of an ileitis vaccine is the first of these for the enteric diseases.[28,29] This vaccination[30] may increase daily gain by as much as 46 g/day,

increase the carcass weight, and shorten the finishing period. It is given orally from 3 weeks of age or in clean drinking water. Be careful with the use of antimicrobials before vaccination because this may reduce the response to the vaccine. In a recent study in Denmark,[29] the use of oxytetracycline for treatment of LI was reduced by 79% with a significantly lower number of pigs being treated.

Vaccinating pigs through the administration of drinking water using the water proportioner is a safe, labor-saving, efficient, and easy method of vaccination. In the presence of feed medication, vaccinated pigs performed better than the nonvaccinated pigs when exposed to an LI challenge. The percentage morbidity was reduced, the feed conversion better, and the average daily gain increased by about 6%. There was also a 23% reduction in culls. It is best given in a 7-day antibiotic-free period. The present vaccine is given in water to 70- to 90-lb (30–40 kg) gilts. It can be dispensed with antimicrobials and produce protective immunity. There is a reduction in gross and microscopic lesions in the complete absence of antimicrobials when the gilts are vaccinated as finishers and the animals receive a booster vaccination every 6 months.

BRACHYSPIRAL COLITIS (SWINE DYSENTERY, PORCINE SPIROCHETAL COLITIS) AND NONSPECIFIC COLITIS

The postweaned pig is susceptible to several severe enteric bacterial diseases causing considerable economic loss. *Brachyspira hyodysenteriae* (BH) (swine dysentery), *Lawsoniana* and *Campylobacter* infections, postweaning *E. coli* infections including bowel edema and *B. pilosicoli* (BP; porcine spirochetal colitis [PCS]) are the main contenders. In addition ulcers, torsion, rectal stricture, and rectal prolapse add to the gamut of gut disorders of the older pig.

SWINE DYSENTERY

Swine dysentery is a highly fatal disease characterized by mucohemorrhagic diarrhea and death if untreated for a few days. It causes economic loss (circa $10–$15 per pig) from mortality, morbidity, slow growth and poor feed utilization, and high costs of medication and biosecurity. It is of no public health significance. Human intestinal spirochetes are distinct.

SYNOPSIS

Etiology *Brachyspira hyodysenteriae*

Epidemiology Probably the most economically important enteric disease in growing pigs, 8–16 weeks of age. Transmitted by fecal–oral route. Crowding and high stocking density are risk factors. High morbidity and moderate mortality if not treated

Signs Mucohemorrhagic diarrhea, and weight loss that are commonly persistent if not treated

Lesions Colitis and typhlitis

Diagnostic confirmation Detection of organism, in intestine. Serological diagnosis in herd

Treatment Tiamulin, valnemulin, tylosin, and lincomycin by injection and in water and in feed. Organic arsenicals in feed and water supplies and carbadox and monensin in feed and water in some countries

Control Eliminate infection with treatment in the feed and water supplies. Prevent reinfection and avoidance of introduction of carrier animals into herd. Eradicate by depopulation and repopulation, medication, and biosecurity measures.

ETIOLOGY

The genus *Brachyspira* contains seven species including others not yet officially named. They are gram-negative, filamentous, snake-like organisms. The seven species that are known to occur in swine are listed in Table 7-24. The species characterization has recently been described.[1]

These species can be distinguished by their zones of β-hemolysis, ability to produce indole, and enzymic profiles. They all have subtypes with unusual phenotypes and genotypes. All are distinct from B. hyodysenteriae on ultrastructure, gene sequences, biochemical tests, and antigenic grounds. B. hyodysenteriae has two specific antigens, the 36-kDa protein and the 46-kDa periplasmic flagellar protein. There is much antigenic heterogeneity among isolates of B. hyodysenteriae. There are 11 serogroups with subdivisions into serovars. Serotyping of isolates of the organism is important in terms of diagnosis and epidemiologic evaluation. The range of serologically distinct strains of the organism is much wider than previously realized. B. hyodysenteriae has heterogeneous antigens in the LPS portion of the outer membrane, and several serotypes of B. hyodysenteriae have been described on the basis of agar gel double immunodiffusion precipitation. Some serotypes predominate in certain geographic areas.

Table 7-24 Biochemical characteristics of species of Brachyspira isolated from pigs

Species	Main features
Brachyspira hyodysenteriae (swine dysentery)	Strongly hemolytic, indole +ve, some –ve
B. pilosicoli (porcine spirochetal colitis)	Weakly hemolytic, some +ve
B. suanatina (pigs and mallard)[2]	Strongly hemolytic, indole weakly +ve
B. murdochii (rarely, mild colitis in pigs)	Weakly hemolytic, indole –ve
B. intermedia (rarely diarrhea and colitis)[3,4]	Weakly hemolytic, indole –ve
B. innocens (rarely diarrhea, commensal?)	Weakly hemolytic, indole –ve
B. hampsonii (new species, colitis)	Strongly β-hemolytic

B. hyodysenteriae (formerly *Serpulina* and before that *Treponema*), a large strongly β-hemolytic spirochete, is the principal causative agent. It is supposedly indole positive, but in a study in Belgium half were indole negative. It will cause typhlocolitis in captive rheas. Rats and mice may act as reservoirs. They are all anaerobic organisms, but they are oxygen tolerant and will grow in the presence of 1% oxygen. The genomes have been studied.[5-8] The diversity of isolates has been shown by MLST[2,9] and multilocus variable number tandem-report analysis.[10] B. hyodysenteriae can be confirmed using random amplified polymorphic DNA analysis.[11] It seems that they have the ability to acquire genes from each other and other enteric bacteria. They can be differentiated by pulsed field electrophoresis and multilocus electrophoresis, and the former is particularly good at differentiating strains that are genetically 53% to 100% similar. Strains of B. hyodysenteriae possess several antigens, some of which are shared by both B. hyodysenteriae and BP species. Organisms have been described that are phenotypically characteristic of B. hyodysenteriae, but their 23s RNA genetic

signature and sequence are consistent with *B. innocens*. Within the genus of B. hyodysenteriae there are some strains that are apparently nonvirulent or of reduced virulence potential. In some cases there may be clonal groups of B. hyodysenteriae.[12] The comparative virulence of *Brachyspira* isolates has recently been compared[13] and it was suggested that the phenotypic cultural characteristics results may be a more sensitive indicator of potential to induce dysentery-like disease than molecular identification alone based on current PCR assays. The virulence factors of B. hyodysenteriae have also been examined,[14] and although several factors were isolated only the *nox* gene was found in all the isolates and *tly*A and *hly*A/ACP were restricted to some B. hyodysenteriae isolates only. In this study a high degree of heterogeneity was seen.

EPIDEMIOLOGY

Occurrence

A Swedish study showed that brachyspirae species were isolated from 58.5% of all samples. Of these 25.4% were B. hyodysenteriae, 16.4% were BP, and 58.2% were *B. intermedia, B. innocens,* or *B. murdochii*.

Swine dysentery occurs worldwide and is an important disease of pigs in South America, South East Asia, and Europe. The disease had until recently declined in North America, probably because of strict biosecurity and the use of carbadox. It is most common in the 7- to 16-week-old age group but may affect older pigs to 6 months. Adult pigs and suckling pigs are seldom affected. The overall occurrence is probably around 10% with control through drugs, particularly growth-promoting antibiotics. Once a farm is affected the organism will remain, evolve, or acquire new antibiotic resistance unless there is depopulation, disinfection, and restocking or whole herd medication.

Risk Factors

In a recent study of an outbreak in East Anglia, UK, that began on one farm following the movement of 400 pigs to an outdoor unit in mid-2006, it was found that by early 2009 it had spread to 29 units by a variety of methods (Table 7-25).

Table 7-25 Importance of fomites and animals in spread of Brachyspira sp. on one farm

Method of spread	Out of 29 (%)
Pig movement	13 (44.8)
Local spread	3 (10.4)
Management	4 (13.9)
Contractor	1 (3.4)
Pig transport	3 (10.4)
Birds	2 (6.9)
Feed truck	1 (3.4)
Unknown	1 (3.4)

Animal Risk Factors

Pigs from 8 to 16 weeks of age are most susceptible to swine dysentery. Most outbreaks occur after purchasing infected animals from herds known to have the disease or where the disease is not acknowledged (sold as weaners) and trading continues. Infection is spread within and between swine herds by carrier pigs. It has been found in feral pigs and wild boar and occasionally affects birds, mice, rats, and dogs on infected farms. Mice are capable of carrying the organism for up to 180 days after inoculation.

Pathogen Factors

There are many latent infections without clinical signs. There is some evidence that the organism destabilizes the microbial community in the large intestine. Experimentally, the oral inoculation of gnotobiotic pigs with a combination of B. hyodysenteriae and *B. vulgatus* or *F. necrophorum* will result in the development of the characteristic clinical signs and lesions of swine dysentery. The disease has been reproduced with pure cultures of B. hyodysenteriae in conventional and SPF pigs. Challenge of gnotobiotic pigs with pure cultures results in colonization, but disease does not occur until other intestinal organisms are given, which suggests that the disease is the result of a mixed synergistic infection of the spirochete and other intestinal anaerobic organisms. These results and others are consistent with the concept that B. hyodysenteriae is the primary causative agent of swine dysentery and that the presence of one or more other anaerobes is a prerequisite for expression of pathogenicity of B. hyodysenteriae. This prerequisite can be met by a variety of anaerobes. There is considerable variation in virulence among strains of different serotypes of B. hyodysenteriae when given orally to SPF piglets or mice. A virulent B. hyodysenteriae has been isolated from a herd free of clinical swine dysentery, which indicates that the organism can still be present in herds considered to be free of the disease.

The major polypeptides of B. hyodysenteriae are strong immunogens and present in the various serotypes, but there is considerable diversity in the antigenicity of LPS between those same serotypes. A PCR-based DNA fingerprinting technique can analyze genetic profiles of isolates of the organism from cases of swine dysentery in different herds, which could be important epidemiologically.

Potentially pathogenic weakly β-hemolytic intestinal spirochetes may be present in swine herds with a high incidence of diarrhea and can be distinguished from nonpathogenic strains by the hippurate hydrolysis test. The prevalence of these strains is reduced in herds medicated with olaquindox.

Environmental and Management Risk Factors

The usual source of infection is through the import of pigs. It is, however, difficult to control these because of asymptomatic carriers. Investigation has shown that it may be the dirty truck that is important. In other words, biosecurity has failed.

Overcrowding and the buildup of fecal wastes in pens contribute to an increased incidence of swine dysentery. The failure to clean solid floor pens on a regular basis results in an accumulation of fecal wastes, which increases the infection pressure. The contamination of pens with fecal effluent from adjacent pens or by open flush gutter systems allows pigs access to the flush water and can provide sources of infection and reinfection. The continuous introduction of young pigs into pens that have not been previously cleaned out and washed provides sources of infection. The mixing of weaner pigs from different sources is often a source of infection for susceptible pigs.

Several factors affect the survival of the organism from the feces of infected pigs. It can survive 10 days in soil at 10°C and up to 78 days if there is 10% pig feces in the soil. The organism can survive for up to 48 days in dysenteric feces at 0 to 10°C (32–50°F); survival is reduced to 7 days at 25°C (77°F) and to less than 24 hours at 37°C (98.6°F). Dilution of dysenteric feces with tap water (1:10) enhances survival to 61 days at 5°C (41°F). It has been found in feces after 112 days. Drying and disinfection rapidly eliminates the organism from the environment. Phenolic and sodium hypochlorite disinfectants are most effective. The organism can survive in lagoons for up to 60 days. In swine herd facilities with an open gutter-flush system that has housed dysentery-infected swine, the lagoon water is used to expel feces from the building, allowing the pigs to drink the effluent as it flows through the gutter. Under these conditions the organism may survive for 5 to 6 days after the removal of infected shedders. The organism has been isolated from the lagoon of a waste-handling system of a swine farm, which could be partially responsible for maintenance of swine dysentery within a herd.

The effects of dietary constituents on the commensal bacterial flora of the large intestine are not well understood. It was thought that nonstarch polysaccharide was drawn into the distal parts of the colon and was then available for fermentation. The inclusion of wheat and soybean and/or the addition of exogenous enzymes to pig diets might influence the large intestine microflora, but did not prevent swine dysentery. The colonization of the gut by spirochetes was highly related to soluble nonstarch polysaccharide, and the development of swine dysentery was influenced by the resistant starch content of the diet. Feed containing large amounts of soya bean meal and group housing of pigs were considered to be the major contributing factors in the experimental production of swine dysentery. Feed containing high levels of soluble nonstarch polysaccharides results in an increase in viscosity of gut contents, an

increased amount of gut fluid, a low pH, and an increased number of coliforms in the intestines. A recent experiment with feeding and swine dysentery showed no effect of feeding rice in the diet. The feeding of rice was not able to prevent swine dysentery, and the increase of nonstarch polysaccharide or resistant starch was not able to reduce the incidence or prevalence of swine dysentery; in fact the clinical signs were worse.

Methods of Transmission

B. hyodysenteriae is present in the feces of affected pigs. Infection is by ingestion, and transmission is enhanced by conditions leading to fecal–oral cycling. Spread of infection within a group is slow, taking up to 7 to 14 days, and it may spread to other pens of pigs over a 2- to 3-week period. Pigs that have recovered from clinical disease with or without treatment may become carriers and still have the ability to shed the organism and infect in-contact animals for 50 to 90 days. Clinical disease may initially be precipitated by stress, but infection subsequently spreads by direct contract. The frequency of shedding varies with time, and only a small proportion of a convalescent population may be expected to be carriers. Every method of fecal transmission is a likely source (trucks, people, clothing, boots, etc.).

PATHOGENESIS

B. hyodysenteriae survives gastric acid and reaches the large intestine. In viscous environments B. hyodysenteriae has an improved movement. The agent possesses several outer membrane proteins including a 29.7-kDa lipoprotein (B. hyodysenteriaelp29.7) and a 39-kDa variable surface protein.[15] It also has an LPS in the outer envelope that may help it to disrupt the colonic epithelial barrier. In addition, NADH oxidase activity protects it from oxygen toxicity. Hemolytic activity is an essential virulence factor possibly controlled by four genes, *tly* A, B, and C and *Lly*A.

A hemolysin with cytotoxic activity extracted from a virulent strain of the organism causes severe epithelial damage when injected into ligated loops of the ileum and colon of germ-free pigs and is a virulence factor in swine dysentery. The organism can adhere to a culture of intestinal cells in vitro, which may be one of its virulence factors. The organism is also highly motile, which provides it with the ability to move through mucus and facilitates penetration into the mucosa. This may be a very important virulence factor. A wide variety of other virulence factors may be important. The organism probably does not attach to the epithelial surface of cells; instead it colonizes the overlying mucous layer. Chemotactic attraction of the organism to sites containing mucus is also a potentially important factor. It penetrates the mucus and moves down into the crypts and disrupts the colonic epithelium, causing mucohemorrhagic colitis while resisting oxygen toxicity. The organism colonizes the intestinal mucosa by association with intestinal mucus in both the mucous gel covering the epithelium and the mucous-filled crypts (on the other hand, the weakly β-hemolytic *B. pilosicoli* [BP] attaches by one cell end to the luminal surface of the colonic epithelium to form a dense carpet of adherent spirochetes).

It is still not known if invasion is a necessary feature of infection for swine dysentery. Where it lives normally is unknown, but in the intestine it can obviously breed more quickly than it is evacuated. The pattern of colonization appears to be random. The hemolysin lyses the intestinal mucosal cells, which then supply the brachyspirae with the vital sterols from the membranes. Several genes may be involved in virulence including *tly*A and *LlyA*. For infection to become established, it seems that a gene for the production of NADH oxidase is required because it protects against the effects of oxygen toxicity. Similarly, there may be a *Brachyspira* iron transport system, and the presence of this may correlate with the pathogenicity of B. hyodysenteriae. Another gene of interest is the *mgl*B gene, which may eventually be shown to be of great importance. Lipooligosaccharide production may also be a virulence factor.

Chemotactic- or motility-regulated mucous association appears to be the predominant mechanism of mucosal association. There is progressive erosion of superficial epithelium, excess mucous production, edema, and hemorrhage of the lamina propria and pseudomembrane production. When the numbers of organisms reach 10^6/cm^2 of mucosa then lesions begin to appear. The spirochetes appear in the feces about 1 to 4 days before the diarrhea starts. The erosive colitis is the cause of the diarrhea, dysentery, and excessive quantities of mucus in the feces. Some CD8+ cells may be associated with susceptibility to experimentally induced swine dysentery, whereas monocytes and CD4+CD8+ T-cells appear to be the major responding leukocytes during the disease. Death results from chronic dehydration and bacterial toxemia. In some animals, an acute shock syndrome results in rapid and sudden death. Early in the disease it activates IL-1 and IL-6 and stimulates macrophages. In the later stages T-cells play an important part in defense.

The diet has a major effect on the outcome of B. hyodysenteriae infections. Colonization can be controlled by feeding diets high in digestibility, which alter the colonic microbiota and encourage species that inhibit spirochetes to flourish.[16,17] Diets rich in inulin will do the same.[18,19]

CLINICAL FINDINGS

The disease usually affects growers and finishers a few weeks after moving from the nursery, and rarely weaners. Occasionally it affects sows at farrowing or in midlactation. It usually affects 6- to 12-week-old pigs, but can be of any age. The incubation period in the field may be 7 to 60 days but experimentally is usually 4 to 14 days.

Morbidity within a group of pigs can range from 10% to 75%, mortality from 5% to 25%, and if untreated the case–fatality rate can be as high as 50%. Most often, initially, only a few pigs are affected within a group, but spread occurs over a period of a few days to 2 weeks to involve the majority. Affected pigs are slightly depressed, have a reduced appetite, and a moderate fever (40.0–40.5°C). The feces are only partially formed, usually of a porridge-like consistency, and are passed without apparent conscious effort and splatter on contact with the pen floor. Affected pigs commonly defecate almost anywhere and on anything in the pen. The feces are light gray to black and on close inspection a great deal of mucus is present and flecks of blood and epithelial casts may be seen. In some pigs, the presence of larger amounts of blood will discolor the feces accordingly. The occurrence of blood in the feces generally occurs 2 to 3 days after the initial onset of diarrhea. Affected pigs become progressively dehydrated and their abdomens appear gaunt and sunken. Death usually occurs some days to weeks after the initial onset of signs and results primarily from dehydration and toxemia. Pigs with a severe hemorrhagic diarrhea die more quickly. Skin discoloration is not a feature except in the terminal stages.

In untreated pigs the disease may persist for 3 to 4 weeks before clinical recovery. Less commonly an outbreak may start with the sudden death of one or two pigs with no evidence of premonitory signs or a terminal hemorrhagic diarrhea. This occurs more often in market-age pigs and adults in herds in which swine dysentery has been introduced for the first time. It also is a rare cause of sporadic death of gilts and sows in conventional herds.

The disease responds well to treatment, but following withdrawal of treatment the disease may recur within the same group of pigs. It can also recycle on farms at 3- to 4-week intervals and reappear after the cessation of antibiotic therapy. A chronic form of the disease with persistent diarrhea and failure to grow occurs in some pigs with irreversible lesions of the colonic mucosa.

Immunity

Maternal antibody must be present to protect the young pigs. Clinical disease is associated with development of specific IgG, IgA, and IgM antibodies in serum and local production of IgA in gut mucosal tissues. The IgG levels correlate with detection of clinical signs. IgA in the large intestine indicates recent infection. Treated and untreated convalescent pigs develop elevated titers that are maintained as long as 150 days after infection. The relationship between the magnitude of the agglutinin titers and protective immunity is not clear. Carrier pigs shed B.

hyodysenteriae while elevated agglutination titers against the organism are present.

Untreated pigs that recover from swine dysentery are resistant to experimental challenge for up to 16 to 17 weeks postinfection, and these are partially species specific. In herds affected with swine dysentery, the disease may reappear at 3- to 4-week intervals following treatment, and the more efficacious drugs may inhibit the development of immunity.

CLINICAL PATHOLOGY

Hematology may well show an elevation of the leukocytes with a shift to the left. The acute phase proteins may increase. There is an early increase in the erythrocyte sedimentation rate and fibrinogen levels. Total plasma proteins may be elevated. The blood levels of sodium, chloride, and bicarbonate decrease. A marked metabolic acidosis and terminal hyperkalemia may follow. In experimental swine dysentery, neither blood glucose nor lactate showed any changes, but the serum concentrations of glucogenic nonessential amino acids such as serine, alanine, glutamine, and tyrosine decreased.[20] Lysine increased during the swine dysentery and leucine increased during the recovery.

Detection and Culture of Organism

The organism may be detected in the feces of affected pigs by dark-field microscopy as highly motile organisms with a characteristic serpentine motility or in dried smears with Giemsa or Victoria blue 4R staining. The best diagnosis is achieved by taking samples from the upper colon. Fecal samples submitted for laboratory examination should be diluted (1:10) in phosphate-buffered saline or rectal swabs placed in Amies medium to avoid death of the organisms, which will occur when the samples are stored at room temperature or sent in the mail. Microagglutination tests (MATs), slide agglutination tests, and indirect and direct FATs are also used to detect the organisms.

The organism can be cultured on Trypticase soy agar containing 5% defibrinated bovine blood under specific atmospheric conditions.

Florescent antibody staining aids considerably in its demonstration, but may not distinguish nonpathogenic strains and false-positive and false-negative results are common. The presumptive diagnosis from the fluorescent antibody test (FAT) can be supplemented with a variety of laboratory tests that serve to identify the spirochetes as pathogenic. The **slide agglutination test** is a useful and specific means of identifying an organism but requires an appreciable amount of growth of spirochetes on the surface of the agar to perform the test. The **microscopic agglutination test** is a rapid test for the definitive laboratory identification of B. hyodysenteriae, but it cannot distinguish the avirulent strains of the organism.

A major diagnostic problem has been the identification of carrier pigs that are infected with the organism and are a potential source of infection to other pigs. Indirect and direct FATs used to examine feces and colonic material from pigs for B. hyodysenteriae have not been sensitive or specific enough to identify individual infected pigs.

Any diagnostic test must be able to distinguish between the different *Brachyspira* spp. Some are harmless commensals, whereas others are potentially pathogenic. *B. innocens,* a nonpathogenic inhabitant of the porcine large intestine, is very similar to B. hyodysenteriae in both morphology and growth characteristics and shares many of the same surface antigens. Numerous serologic tests with sera from pigs that have recovered from B. hyodysenteriae infection have demonstrated the presence of cross-reactive antibodies between B. hyodysenteriae and *B. innocens,* which makes differentiation difficult.

Antigen detection methods based on the use of DNA probes or PCR have recently been developed and show considerable promise. They use portions of the 16sRNA and 23sRNA gene or the *nox* gene or *tyl*A gene. The PCR is usually performed on the primary isolation plate (3–5 days), which can also be used for antimicrobial sensitivity.

A PCR was developed that could detect 10^3 to 10^4 organisms, and this was more rapid and detected more positive samples than did fecal culture and isolation.

The duplex PCR developed was also more sensitive than the culture and biochemical tests, which were shown to detect 10^2 bacteria per gram of tissue and would be used to differentiate B. hyodysenteriae from BP.

A multiplex PCR has been developed that will differentiate B. hyodysenteriae, BP, and *L. intracellularis.*[21,22] RT-PCR enables detection of the numbers of the bacteria. ISH will also work for B. hyodysenteriae.

The most definitive method for differentiating B. hyodysenteriae, *B. innocens,* and BP is the DNA–DNA relative reassociation method.

Serologic Tests

Monoclonal antibodies against the serotype-specific LPS antigens of B. hyodysenteriae can be used in ELISA,[23] indirect immunofluorescence, and immunoblot assays to differentiate between B. hyodysenteriae and *B. innocens.*

Serologic tests such as microtiter agglutination tests and ELISAs can be used on a herd basis to identify infected herds. It is 100% sensitive and specific but cannot confirm individual infected animals. The ELISAs will detect 10^2 organisms per milliliter of feces.

A variety of serologic tests have been used, and typically these tests have used whole cultures or LPS as the antigen.[9] The former tends to increase false positives, and the latter increases false negatives but gives fewer false positives. Generally, these techniques are useful for detecting infected herds but are unable to detect individual infected pigs that may be acting as carrier animals. Recently a 30-kDa outer membrane lipoprotein (BMPB), which is specific to B. hyodysenteriae and is recognized in both experimentally and naturally infected pigs, was identified, the gene cloned and sequenced, and specific epitopes on BMPB are being identified.

Serologic tests can assist in the identification of carrier pigs. An evaluation of several serologic tests for detection of antibodies against B. hyodysenteriae concluded that only the MAT detected antibodies to the organism. The ELISA has been used to detect antibodies in individual pigs, but cross-reactions between B. hyodysenteriae and *B. innocens* are common. An ELISA using serotype 2 B. hyodysenteriae as antigen could not differentiate between stages of infection but could indicate if the pig had been infected.

NECROPSY FINDINGS

Lesions are restricted to the cecum and colon and occasionally the rectum,[24] and these can be found in healthy pigs. Sometimes the lesions extend over the whole large intestine or are localized. There may be hyperemia and edema of the large-intestinal walls and mesentery. The mesenteric lymph nodes may be swollen with edema fluid. The mucosal lesions vary from catarrhal to fibrinonecrotic to hemorrhagic typhlocolitis. They are often covered by mucus and fibrin and flecks of blood. Colonic contents are soft to watery. With progression the edema and mucosal lesions become more severe with increased fibrin exudation and the formation of a thick mucinous pseudomembrane containing blood. Goblet cell hyperplasia is very prevalent. The cells at the base of the crypts may be elongated and hyperchromic. There may be spirochetes in the goblet cells and in disrupted epithelial cells. Some spirochetes may be found around blood vessels.

The carcasses of pigs that have died from swine dysentery usually show weight loss, dehydration, and a microscopically visible typhlitis and colitis. The colitis is initially present in the apex of the spiral colon but subsequently spreads to involve the whole colon and the cecum. In the early stages, there is inflammation and necrosis with varying degrees of hemorrhage into the lumen. The submucosal glands are enlarged and frequently visible through the serosa of the colon as opaque spots. In advanced cases a fibrinonecrotic exudate is adherent to a reddened and granular mucosal surface. Intestinal contents may also adhere to the mucosa. The crypts are often thickened with edema. The draining lymph nodes are enlarged and congested. The small intestine is spared except for involvement of the terminal ileum in advanced cases. Spirochetes may be demonstrated in large numbers using Warthin/Starry stains in smears from the mucosal

surface of these lesions, especially in early cases, but there is no systemic invasion.

Electron microscopic examination of the colon of pigs with swine dysentery reveals changes indicative of stasis in the microcirculatory vessels of the lamina propria. The earliest colonic lesion consists of superficial vascular congestion and dilatation, edema of the lamina propria, and intercellular separation of the epithelial cells at the crypt shoulders. This lesion progresses to epithelial cell necrosis and extrusion with extravasation of red blood cells into the lumen. Degeneration, necrosis, and extrusion of superficial colonic enterocytes follows progressively. Large spirochetes are present in the crypts, in the cytoplasm of damaged epithelial cells, and in cavities around vessels of the lamina propria. The characteristic lesion of swine dysentery is necrosis of the superficial colonic epithelium. This feature may be difficult to appreciate in partially autolyzed tissues, or if the animals sampled are recovering from the infection or being treated with antibiotics. In subacute lesions the crypt hyperplasia and goblet cell hyperplasia is more pronounced, and the extensive mucous production distends all the crypts.

B. hyodysenteriae is difficult to culture, requiring anaerobic conditions and selective media. This has promoted the development of alternative diagnostic techniques such as PCR and immunohistochemical stains. Wet mount preparations from the colonic mucosa are often used to make a presumptive diagnosis and an FAT is available to confirm.

A consecutive study was made of the pathology of lesions by repeated endoscopy and biopsy samplings was made.[24] On the third day, endoscopy showed a hyperemic reactive mucosa and excessive amounts of mucus. Histologically, there was crypt hyperplasia, depletion of goblet cell mucus, and epithelial erosions. At the same time there were elevations of acute phase proteins, circulating monocytes, and decreased numbers of CD3+ cells. After 5 days the pigs returned to normal.

DIAGNOSIS

The history and clinical signs indicate either B. hyodysenteriae or *B. hampsonii* and are more severe than those of BP. Confirmation can be started by smears of feces or mucosal smears and finding typical spirochetes. The rest of the confirmation requires laboratory testing using the methods described earlier, particularly culture on selective media. Spirochetes can be confirmed by growth inhibition tests and by specific antisera, and enzyme analysis using the API ZYM system is useful because B. hyodysenteriae lacks α-galactosidase.

Samples for Confirmation of Diagnosis

- **Bacteriology:** Colon culture (culture has special requirements such as an agar gel plate with added spectinomycin, colistin, and vancomycin media or BJ medium). Direct smear (modified acid-fast stains), FAT, PCR
- **Histology:** Formalin-fixed colon, several sites (LM, IHC). ISH and an IFA can be used on fixed tissue.

DIFFERENTIAL DIAGNOSIS

Swine dysentery must be differentiated from other diseases in which there is diarrhea in growing pigs. Pigs with swine dysentery are usually emaciated, dehydrated, have a rough hair coat and fecal staining of the perineum, and have mucohemorrhagic colitis.
Identification of the new species *Brachyspira hampsonii* also requires laboratory identification.

Porcine colonic spirochetosis: This is the most difficult differential diagnosis of swine dysentery and is associated with a mild diarrhea in weanlings and growing pigs. It requires laboratory confirmation.

Coliform gastroenteritis, salmonellosis, and **hog cholera:** Characterized by more rapid onset and spread within a group than with swine dysentery and death occurs earlier. In coliform gastroenteritis and salmonellosis, the initial sign may be sudden death or severely depressed and weak pigs with fever, skin discoloration, anorexia, and a profuse watery diarrhea. Coliform gastroenteritis occurs within a few days after weaning, whereas hog cholera occurs in all ages of pig with a high mortality. Swine dysentery is more insidious at onset, the appetite is rarely completely lost, and the feces are soft and mucohemorrhagic. At necropsy the lesions of swine dysentery are confined to the large intestine, whereas in coliform gastroenteritis, salmonellosis, and hog cholera lesions are also present in the small intestine. Salmonellosis has deep hemorrhagic, necrotic lesions with coagulative necrosis. Other diseases may result in the passage of bloody feces. *Trichuris suis* is usually grossly visible in large numbers.

Intestinal hemorrhage syndrome: Generally persists as a severe hemorrhagic diarrhea with rapid death rather than as a chronic syndrome, but pathological differentiation may be necessary. It is usually associated with whey feeding. Swine dysentery does not affect the small intestine. Chronic hemorrhage caused by **esophagogastric ulcer** results in melena; the epidemiological findings are different, and the necropsy findings are characteristic in the intestine and other organs.

TREATMENT

Affected pigs may need supportive therapy.

Antimicrobial Therapy

Some authorities have suggested that the recurrence of B. hyodysenteriae in the United States may be caused by increasing antibiotic resistance as has happened in Europe and Asia. In a recent study, the MICs against lincomycin and gentamicin were high, as were the patterns shown by *B. murdochii* and *Brachyspira* species rather than B. hyodysenteriae. The other antibiotics had MICs at the low end of the range.

Antimicrobials are usually administered by mass medication to all pigs within the affected group. Treatment by water medication rather than feed medication is preferable, because it is generally easier and quicker to put into place, and affected pigs usually continue to drink (but perhaps not in the same quantities as when unaffected) while they are anorexic. Pigs with severe hemorrhagic diarrhea and toxemia may not drink sufficient medicated water and must be treated initially by parenteral injection.

Medication of feed is most suitable for subsequent prophylaxis. When outbreaks occur, all severely affected pigs should be treated individually, and the drinking water medicated for several days at therapeutic levels, followed by possible medication of the feed for up to 3 weeks or longer at prophylactic levels.

Choice of Antimicrobials

Several antimicrobials are suitable for the treatment and control of swine dysentery, and the choice is largely dependent on availability, cost, efficacy, and the regional withdrawal regulations. The antimicrobials and their dosages given here are used in treatment and control.

Currently, tiamulin, lincomycin, and the nitroimidazoles (dimetridazole, ronidazole, and ipronidazole) are the most effective antimicrobials for treatment by water medication. In some countries, certain antimicrobials may not be approved for use in pigs. The most efficacious antimicrobials for use in the feed are carbadox, the nitroimidazoles, tiamulin, and lincomycin.

A macrobroth dilution in vitro technique determined the antimicrobial sensitivity of a group of isolates of B. hyodysenteriae from Australia, the United States, and Canada. Dimetridazole and tiamulin were effective against most of the isolates. Lincomycin inhibited the growth of some isolates, and tylosin failed to inhibit most of the isolates tested. A group of isolates of B. hyodysenteriae from the UK were all sensitive to tiamulin, and there was no evidence that the organism was developing resistance to the drug. A large number of strains of B. hyodysenteriae isolated in Hungary between 1978 and 1992 were tested against seven chemotherapeutic agents commonly used for the treatment of swine dysentery, and the changes in patterns of resistance were also monitored. All strains remained sensitive to carbadox. The sensitivity to dimetridazole gradually decreased with about 50% of strains still sensitive. Most strains were

resistant to tylosin. Resistance to lincomycin gradually increased but about 50% remained sensitive. Tiamulin was most effective but some resistant strains have emerged. Monensin was effective for prevention but resistance may evolve quickly. Sedecamycin, a macrolide antimicrobial, was effective but the MICs were much higher than expected. Isolates of B. hyodysenteriae in Denmark were sensitive in vitro to virginiamycin, but medication of the feed at 20 ppm was ineffective for control. A combination of tiamulin and salinomycin, and salinomycin alone in the feed for 105 days in diminishing doses is effective in controlling naturally occurring disease and in the first 30 days (60 ppm salinomycin and 30 ppm tiamulin), in the next 60 days (30 ppm each), and the next 15 days (30 ppm salinomycin). For salinomycin alone the diminishing dose is the first 30 days (60 ppm), the next 60 days (30 ppm), and the next 15 days (30 ppm; Table 7-26).

Organic arsenicals are the least expensive and are recommended as the first drug of choice when available in the country. When given in either the feed or water, there is a risk of toxicity. The general recommendation is to administer the medication for a 7-day period and then withdraw it for a 7-day period before reintroduction. However, this is frequently impractical, and continuous medication at 250 ppm in the feed is often used as follow-up therapy. Toxicity does not usually occur below levels of 500 ppm, but it has occurred at levels as low as 200 ppm where continuous medication is practiced, and constant surveillance for signs of toxicity is necessary. Although resistance to organic arsenicals has been suspected, it has not been documented. There has been a marked decline in the use of arsenicals for the clinical management of swine dysentery.

It is essential to use agar or broth dilution methods to reach MICs for the various antibacterials, because there is a need to standardize at this time of decreasing sensitivity[26] and increasing transfer of resistance genes.[27]

Failure to Respond to Therapy

For elimination of B. hyodysenteriae the selection of an effective drug is necessary. The major problems with the treatment of swine dysentery are the failure of some outbreaks of the disease to respond favorably to treatment, and relapses or new cases that may occur following withdrawal of medication of the feed or water. Several drug-related problems have been postulated to explain these problems.

Drug-delayed swine dysentery occurs several days after withdrawal of medicated feed. It may be caused by either an ineffective drug or inadequate dosage of an effective drug and failure to eliminate the causative organism from the colon. However, reinfection from other swine must also be considered. The nitroimidazoles at high levels will apparently prevent the delay or recurrence of dysentery.

Table 7-26 Antibiotic therapy in use for swine dysentery

Antibiotic	Dosages
Tiamulin	10 mg/kg BW IM for 3 days
	8 mg/kg for 5–7 days in water
	(60 mg/L for 5 days in water)
	106–120 ppm (30–40 g/tonne) for 7 days in feed
	Followed by 30–40 mg/tonne for 2–4 weeks
	Recovery often occurs in 24 h
Valnemulin	3–4 mg/kg BW/day for 3–4 weeks in feed
	For prevention 25 ppm (1.0–1.5 mg/kg) for 7–28 days
	Both valnemulin and tiamulin cross-react with ionophores (salinomycin, narasin, and monensin) and they should not be given together.
Carbadox	50 mg/kg of feed for 30 days to 35 kg only or combined with sulfamethazine at 100 mg/kg of feed
Lincomycin	11 mg/kg BW IM daily for 3 days, <10 days
	In water at 44 ppm (8 mg/kg BW) in water for <10 days
	In feed at 100 g/tonne for 3 weeks or until signs disappear
	Followed by 40 g/tonne
	Not suitable for animals over 110 kg
	Resistance occurs at an MIC of 30 mg/L.
Lincomycin/spectinomycin	66 ppm of both in the feed for 8 days
	Followed by 44 ppm for 20 days
Tylosin	10 mg/kg BW IM twice daily for 3–5 days
	5–10 mg/kg BW in water for 5–7 days
	Then next 100 g/tonne for 3 weeks in feed
	Followed by 40 g/tonne in feed
	Widespread resistance, but where sensitive it works
Aivlosin	Can be used when there is tylosin resistance[25]
Imidazoles	
Nitroimidazole	(Not in the United States or Europe) 260 ppm in water for 7–14 days
Dimetridazole	200 g/tonne in feed
Ronidazole	60 ppm in water for 3–5 days, 120 ppm (60 mg/tonne) in feed. Resistant strains will develop.
Monensin	100 ppm in feed for 56 days
	Followed by 50 ppm from 56–84 days, and 25 ppm until 112 days
	Toxicity if used with pleuromutilins
Arsenicals (formerly in common use)	
Sodium arsanilate	In water at 175 ppm for 6 days
Arsanilic acid	500 g/tonne for 21 days in feed (monitor for signs of toxicity)

BW, body weight; IM, intramuscularly; MIC, minimum inhibitory concentration; ppm, parts per million.

In experimentally induced swine dysentery using colon from affected pigs, oral inoculums such as tiamulin in the drinking water at 45 mg/L or 60 mg/L for 5 days were also effective in treating clinical disease. However, diarrhea commonly recurred 2 to 10 days after withdrawal of the drug and repeated medication of the water with tiamulin was necessary to reduce the severity of diarrhea and prevent deaths. After one to three retreatments, the pigs were immune to experimental exposure and there was a significant increase in their serum anti-B. hyodysenteriae antibodies. This supports the observation that when certain antimicrobial agents such as dimetridazole, which are highly effective in preventing the development of diarrhea, are withdrawn, the affected pigs do not become immune.

Drug-diminished swine dysentery occurs when suboptimal levels of the drug are used. The severity of the diarrhea is reduced and deaths do not occur, but the disease is not eliminated. However, severe disease may follow withdrawal of medication.

The feeding of ronidazole at 60 ppm for 10 weeks, or carbadox at 55 ppm or lincomycin at 110 ppm for 6 weeks eliminated an experimental infection, and swine dysentery did not recur during a 9-week period after withdrawal of the medication. The feeding of sodium arsanilate at a level of 220 ppm for 3

weeks to pigs, which had been fed ronidazole for only 6 weeks, did cause the development of swine dysentery.

In both drug-delayed and drug-diminished swine dysentery, there are chronic lesions in the colon. In drug-resistant swine dysentery, medication of the feed is not effective and diarrhea and deaths occur. Certain outbreaks of the disease may be resistant to both tylosin and sodium arsanilate. The sensitivity of B. hyodysenteriae to dimetridazole has not decreased significantly following use of the drug over several years.

Drug-augmented swine dysentery is a more severe form of the drug-resistant disease in which affected pigs are more severely affected than nonmedicated controls. The cause is unknown. The disease occurs in a severe form several days or weeks following withdrawal of successful medication for a previous outbreak of the disease. This form appears to occur most commonly in pigs that did not have clinical disease during an earlier outbreak but received medication. The concentration of the drug administered was sufficient to prevent diarrhea, but not sufficient to eliminate the spirochetes from the colon. During the delay of the initial diarrhea by the drug, there may have been intraglandular recolonization of spirochetes throughout the colon. After withdrawal of medication, rapid intraglandular multiplication of the large spirochetes may occur and result in clinical disease. Drug-delayed augmented dysentery usually occurs only in those pigs that have been infected but did not develop clinical disease, which usually results in immunity. The occurrence of diarrhea is necessary for its development, which occurs 4 to 13 weeks after infection. Treatment of swine dysentery with the more efficacious drugs has been shown to inhibit the development of this immunity and serum antibody to B. hyodysenteriae. However, the clinical significance of this is undermined, and at present it is suggested that outbreaks of swine dysentery be treated vigorously.

It should be possible to minimize these drug-related problems of swine dysentery by the use of therapeutic levels of effective drugs in the drinking water for short periods followed by prophylactic levels in the feed for 3 weeks or more. This must be combined with proper management techniques and waste disposal systems that minimize or prevent reexposure.

Regardless of the drug used, many pigs are reinfected following withdrawal of medication because of the continual presence of the organism in the environment. The sources of the organism include in-contact carrier pigs shedding the organism and survival of the organism in waste materials (see the section Epidemiology).

Cleaning and Disinfection

After the institution of treatment, thorough cleansing of the contaminated pens is necessary to prevent reinfection or the transmission of infection to new groups of pigs. This is usually done after 3 to 6 days, when all diarrhea has ceased. The decision to continue with prophylactic medication depends on the hygiene and a knowledge of past patterns of the disease on the farm. It is generally recommended to continue prophylaxis for at least 2 weeks. Swine housing units with open gutter-flush systems in which swine dysentery-infected pigs have been maintained should remain idle for a longer period than 5 or 6 days to eliminate B. hyodysenteriae.

CONTROL

Experimentally, a highly digestible diet can protect pigs from swine dysentery. Diet cannot influence the colonization of B. hyodysenteriae.[28] Diets containing inulin but not lupins helped to prevent swine dysentery in experimentally challenged pigs.[18]

Effective control of swine dysentery is dependent on the control of infection in the herd and the limitation of reinfection, eradication by depopulation, and repopulation or mass medication without depopulation.

Control of Infection/Limitation of Reinfection

Control of the clinical disease can be achieved by early treatment with adequate levels of antimicrobials for a sufficient length of time. This must be combined with adequate removal of fecal wastes to prevent reinfection. Pigs destined for market should be moved out as a group and their pens cleaned, disinfected, and allowed to dry for a few days before pigs are restocked. Where possible the purchase of feeder pigs should be restricted to private sales from herds with no history of the disease. Communal trucks should not be used for transport. Where this is not possible pigs should be placed in isolation pens for 3 weeks and provided with medicated feed or water to eliminate the carrier state in infected pigs. Every effort should be made to avoid potential fecal–oral cycles and contamination by feces between pens. Preventing the buildup of fecal wastes is also of paramount importance. Pigs from different source farms should not be grouped in the same pen. It is also necessary to reduce the stress of transportation and overcrowding on the pigs.

In farrowing-to-market enterprises where the disease is always a threat, routine prophylactic medication may also be necessary. This is commonly performed following weaning and during the early growing phase. In countries where withdrawal periods are in force, the use of certain microbials is precluded for this purpose.

The feeding of tiamulin at a dose of 20 mg/kg BW to pregnant sows, beginning 10 days before farrowing and continuing until 5 days after farrowing when the piglets are weaned and transferred to an isolation unit, has been successful in the prevention of infection of newborn piglets. This is known as the "barrier method," which can be an efficient method of eradicating endemic infections. To reduce the risk of postnatal infection of the progeny, the piglets should stay with the latently infected sows for the shortest time possible. Furthermore, early weaning is necessary, and strict isolation is an important condition to success. The disease is spread primarily by carrier pigs, and contact between infected and uninfected pigs must be avoided.

The administration of tiamulin at 10 mg/kg BW IM daily for 5 days to all animals in a large herd, combined with cleaning, disinfection, and rodent control, was effective in controlling the disease, and no further clinical signs occurred in the subsequent 2.5 years.

Mass Medication and Sanitation Program Without Depopulation

With the strategic use of antimicrobials, effective sanitation, serial depopulation of possible carrier animals, and the introduction of infected animals, it is possible to virtually eradicate the infection from a herd.

Elimination of infection from closed swine herds is possible using antimicrobials (see the section Treatment), and there are various options.

Dietary Modification

Experimentally, modification of the diet can assist in the control of swine dysentery. Feeding a highly digestible diet reduces fermentation in the large intestine and is associated with a failure of colonization by B. hyodysenteriae when challenged orally. Pigs fed on a diet based on steam-flaked maize and steam-flaked sorghum had a decreased incidence of disease. Pigs fed on a diet based on cooked white rice were fully protected from experimental infection with B. hyodysenteriae.

Depopulation and Repopulation

The infection can be eradicated by depopulation of the entire herd and repopulation with breeding stock free of infection. However, this can be uneconomical unless it is part of the long-term plans for the herd and the producer.

The disease can be eradicated through the use of minimal disease or high-health–status herds that are free of several infectious diseases and maintain disease-free status. In such herds, diseases such as swine dysentery occur only rarely and almost never over a period of several years.

Biosecurity

Strict biosecurity measures are necessary to prevent introduction of infected carrier pigs. This requires knowledge of the infection status of the herd of origin. It also requires a highly reliable test to detect the infected pig. Particular attention should be paid to the state of vehicles visiting the farm. The farm staff and the truck drivers should not cross over the gate at the loading point. The

loading gate should be at the perimeter of the unit.

Monitoring of the herd for continuous freedom is essential. This includes clinical observations, examination of colons at abattoir, culture of feces, ELISA monitoring,[23] and PCR examination of feces.

Vaccines

Pigs that have recovered from clinical swine dysentery may be protected against subsequent challenge, but attempts to immunize pigs with B. hyodysenteriae have been proven to provide incomplete protection and involve complex procedures that may have limited practical value. The development of effective vaccines will require attention to serospecificity of the organisms used to formulate the vaccines.

Effective vaccines are not widely available as yet. A commercial vaccine using a protein-digested bacterin has shown efficacy in the reduction of disease caused by B. hyodysenteriae. It produced both a systemic and mucosal immunity. Both IFN-γ and lymphocyte blastogenesis responses were stimulated. A recombinant outer membrane lipoprotein has also been shown to be a hopeful vaccine.

An inactivated, adjuvant, whole-cell vaccine against B. hyodysenteriae has been tested experimentally. The vaccine provided significant protection in two small trials, but some of the vaccinated and unvaccinated pigs developed late-onset swine dysentery, which is unexplainable. Field trials to test the vaccine are required. An experimentally inactivated B. hyodysenteriae vaccine with mineral oil adjuvant resulted in exacerbation of the clinical disease following challenge; a majority of the vaccinated pigs developed the disease earlier and to a more severe degree than the unvaccinated pigs.

BRACHYSPIRA HAMPSONII

In every respect *B. hampsonii* produces the same clinical and pathologic syndrome as *B. hyodysenteriae*. It is possible that several unrecognized *Brachyspira* species play an important role in clinically relevant swine intestinal disease. Recently a novel strongly hemolytic *Brachyspira* species was encountered in North America in cases similar to those caused by B. hyodysenteriae[1] and subsequently found in Spain. In other words, swine dysentery was caused by an entirely different agent. The isolates were found to be different from all known *Brachyspira* spp. on the basis of the *nox* gene, 16S ribosomal RNA sequencing, and biochemical testing. The organism is called *B. hampsonii* after David Hampson, who contributed so much to the study of *Brachyspira.* To identify the organism, the duplex PCR was first used to differentiate or eliminate B. hyodysenteriae and BP, and then PCR was used to identify the *nox* gene. The PCR products were then sequenced and then multilocus typing was used.[2,3] The results of this typing grouped the isolates into two clades (I and II), which formed a cluster independent of each other. Most of clade I was positive for β-glucosidase and clade II negative for this enzyme. This organism is strongly β-hemolytic but is indole negative, which distinguishes it from B. hyodysenteriae and *B. suanatina,* which are the other β-hemolytic *Brachyspira.*

The disease has been almost absent from the United States until quite recently, but a number of recent outbreaks of severe bloody diarrhea have been seen in the United States and Canada.[4] Since 2008, more than 50% of isolates from query swine dysentery cases have been nontypeable at the Minnesota laboratory,[1] and only 36% at the Iowa laboratory[4] in the first 9 months of 2010 were typeable to the species level. The others may turn out to all be *B. hampsonii.* All the isolates were associated with severe bloody diarrhea in the field.

In October 2009, two herds in Saskatchewan in Canada had a disease indistinguishable from swine dysentery. All pigs had characteristic lesions in the large bowel, and abundant spirochetes were seen in smears from the colonic mucosa of affected pigs but not from the nonaffected pigs. They were unable to identify B. hyodysenteriae. A quantitative (q)RT-PCR was developed, and it showed that 10^5 to 10^6 organisms per gram of tissue or cecal contents were found.[5] In 2011 a similar condition was reported in Iowa and Minnesota.[6] Recently the organism was found in Spain and isolated from geese and ducks, which suggests that wildfowl may transmit the organism around the world to pigs.

NONSPECIFIC COLITIS IN PIGS

This condition is found worldwide and as yet has no known definitive causes. It can be found in all ages from weaning to slaughter but particularly from weaning to 40 kg. Nonspecific colitis was first seen in the UK in intensive management systems.

ETIOLOGY

At the moment the role of the various possible players is not clear. It might involve feed ingredients, feeding practices, predisposing viral enteritis, poor management, poor hygiene, or even sudden changes in husbandry.

The condition is ill defined but nutrition and infection are thought to be important. Undigested food ingredients reach the colon as a result of poor digestion of feed. This undigested feed allows fermentation in the colon, and all these factors may not allow the colon to absorb water. Sometimes the condition is found on feeding pellets but not on meal. The pelleting has the capacity to caramelize carbohydrates, alter particle size, and destroy micronutrients.

It may be associated with variations in a wide variety of factors including feed ingredients, feed formulations, feed availability, absence of fiber, or high salt in the water.[1]

EPIDEMIOLOGY

The epidemiology may be individual farms, breeding stock suppliers, unhygienic conditions, and different suppliers of feed involved in the spread of the condition.

PATHOGENESIS

Many infections may contribute to disorders of the colon, particularly brachyspirae and *Lawsoniana* and those organisms that contribute to villous atrophy in the small intestine.

Any abnormalities of the small intestine will further increase the amount of undigested and harmful food entering the large intestine. It has now been shown that some diets induce a colonic acidosis and enhance colonization by spirochetes. Many of these cases have no involvement of any of the brachyspirae, and the possibility exists that there may be a syndrome of colonic dysfunction without direct spirochetal involvement.

It is possible that any event that leads to the disturbance of colonic microflora may lead to colonic lactic acidosis and damage to the colonic mucosa and then a reduction in colonic fluid absorption, resulting in diarrhea.

CLINICAL SIGNS

The clinical signs of nonspecific colitis are mild and characterized by mild persistent diarrhea in pigs 5 to 14 weeks of age. Growth retardation and partial anorexia are common. Morbidity and mortality data are not available.

Pigs showed a sporadic diarrhea with soft, wet feces, which may bubble on passing, occasional mucus in the stools, growth depression, and hollow flanks in 18- to 35-kg pigs and with a morbidity of 20% to 30%. Pigs may be ill for up to 3 weeks. Most pigs continued to thrive but some grew poorly.

PATHOLOGY

Pigs had enlarged colons with frothy contents and most had a reddened mucosa. In a study of nonspecific colitis there was increased crypt depth in the colon of weaned pigs with diarrhea.[2] There was no association with any of the common infectious causes of colitis, but there was an association with a diet high in protein and wheat. The total level and digestibility of protein is believed to affect the intestinal microbiota. The further fermentation of the undigested protein in the colon may then result in the production of toxic by-products, and this may be the explanation for protein-associated diarrhea. The increased crypt depth in the colon may result from the protein degradation in the colon as well as the more usual diet rich in dietary fiber and coarsely ground cereals. In this study[2] it is possible that the increased crypt depth may be associated with the feed particle size. Microscopically, they have a mild erosive colitis. A grossly distended large intestine is sometimes seen. The contents are fluid, contain bubbles, and sometimes seem oily. An increased crypt depth was discovered in these colitis cases.[1] Sometimes there may be colonic lesions.

DIAGNOSIS

Clinical signs may indicate nonspecific colitis, and the absence of any positive diagnostics on laboratory testing may further suggest this.

TREATMENT

Identify any specific causes and treat these, and provide general antibiotic treatment such as oxytetracycline.

CONTROL

Control coincident infections such as PCV2 and porcine reproductive and respiratory syndrome virus (PRRSV) through vaccination.

Introduce a general cleanup of the hygiene and in particular use all-in/all-out by age and then thorough cleaning, disinfection, and drying. Examine the nutrition and in general change from pelleted feed to meal. Also eliminate or reduce the antitryptic factors in the food (reducing trypticase in soya meal) and reduce indigestible carbohydrates. Some varieties of wheat and peas should be avoided, and wheat can be replaced by barley. Enzymes can also be used to reduce nonstarch polysaccharides entering the colon.

PORCINE INTESTINAL SPIROCHETOSIS (SPIROCHETAL COLITIS, PORCINE COLITIS, AND PORCINE COLONIC SPIROCHETOSIS) AND NONSPECIFIC COLITIS

INTRODUCTION

Porcine intestinal spirochetosis is a nonfatal, colonic disease of recently weaned, grower and finisher pigs. The causative organism, BP, was first recognized in 1980 and is a gram-negative, anaerobic, but oxygen-tolerant spirochete found in the colon.

It is found in a wide variety of hosts including immunocompromised humans, primates, dogs, opossums, commercial chicken production, and various species of birds. There appears to be no risk to pig workers. The human strains can cause colitis in pigs, and the wide species occurrence may cause concern for zoonotic risk but this has not yet been confirmed. A cause of special concern is that in some parts of the world the level of infection in humans is quite high, and this may be an indicator that spread is possible from some of the other species to humans.

Porcine colonic spirochetosis (PCS) and nonspecific colitis may be two different syndromes, or the former may contribute to the latter with other organisms and nutritional contributions. Even now the effect of various intestinal combinations of flora and fauna to the pathogenicity of various organisms is unknown. As yet, there is no way to introduce a known intestinal microbiota that encourages well-being. The interrelationship between what goes on in the small intestine and the results in the large intestine in pigs is still largely unknown.

A nonspecific colitis can be part of *Brachyspira, Salmonella, Lawsoniana, Trichuris,* or *Balantidium* infections. PCS is certainly associated with BP, formerly known as *Serpulina pilosicoli*. B. hyodysenteriae and BP are the only two confirmed pathogens of the brachyspirae group together with the newly described *B. hampsonii, B. innocens, B. intermedia,*[1] *B. suanatina,*[2] and *B. murdochii,*[3,4] which are still considered nonpathogenic for the most part.

Large, anaerobic weakly β-hemolytic non-B. hyodysenteriae spirochetes have been associated with porcine colitis and are capable of inducing disease in gnotobiotic pigs, but their role as primary or opportunistic pathogens in colitis in conventional pigs is uncertain.

ETIOLOGY

BP is the cause of PCS. It is a weakly β-hemolytic spirochete usually typed by PFGE. It has 4 to 7 flagella and no plasmids.[5] The outer membrane has LPS, which are serologically heterogeneous. There are a number of outer membrane proteins. The organism is more tolerant of oxidative stress than B. hyodysenteriae.

Swedish workers grouped the intestinal spirochetes isolated from pigs into four groups based on phylogenetic studies, although they are closely related. Groups I and II were isolated only from pigs with dysentery or diarrhea. Group II was differentiated from Group I only by weak β-hemolysis. In Sweden, members of Group II are often isolated from young weaned pigs up to 25 kg in herds where a nonspecific diarrhea, which is clinically distinct from swine dysentery, occurs frequently. These strains seem to be absent or rare in herds without such diarrheic pigs. Group III included the type strain for *B. innocens.* Group IV (detected by PCR) included the pathogenic, weakly β-hemolytic strain P43 (BP) shown to cause spirochetal diarrhea in pigs. Most farms have distinct *BP* genotypes, and common genotypes between and among herds are rare.

A complex investigation of 20- to 40-kg pigs (8–16 weeks of age) on 85 pig units in Scotland from 1992 to 1996 showing diarrhea and slow growth provided much needed information on the occurrence of mixed infections. BP was found on 25% of the units; atypical brachyspirae on 7%; B. hyodysenteriae on 6%; with *S. typhimurium* on 4%, *Y. pseudotuberculosis* (YP) on 4%, and LI on a mere 3%. Mixed infections of BP with *Yersinia, Salmonella,* other combinations, and B. hyodysenteriae were found on 27%. On 6 of the 85 units no pathogens were detected.

Occurrence

PCS probably has a worldwide occurrence. Herds using carbadox had a lower prevalence of *Brachyspira* species than the ones using olaquindox. It has been seen in minimal disease herds in which no antibiotics are used, and it is also seen in herds where no growth promoters are used. There may be multiple strains on a farm or a farm with just one strain.

Risk Factors

Transmission

PCS is usually introduced into herds by other pigs. The shedding may be continuous over

several weeks or intermittent. It is likely that the common route of transmission is fecal–oral but there may be a role for mice and birds. It has been recorded in a wide range of species that may be naturally infected (pigs, dogs, and birds), but rodents are probably not a long-term host.[6] It is possible that feral water birds may be a reservoir.

Managemental and Environmental Factors

The organism has a greater environmental survival than B. hyodysenteriae, particularly in slurry lagoons and manure heaps and the soil itself. It will survive in lake water at 40°C for 66 days and remains viable at 10°C for 119 days in soil and 210 days in soil with 10% pig feces added. It is susceptible to most disinfectants, but not when there is organic matter present.

There may be a close association between this agent and other nonspecific factors in the gut. Changes in colonic microenvironment may predispose to colonization and damage associated with BP. There is a lower incidence if antibiotics are fed compared with no antibiotics.

Feed

Consumption of a rice-based diet significantly reduced the onset of excretion of BP after experimental challenge. In a recent set of experiments five diets were used in conjunction with BP. They included pelleted feed, nonpelleted standard food, standard diet plus lactic acid, formulated liquid diet, and a diet based on cooked rice. The group of pigs that were fed rice did indeed excrete BP for less time in their feces and in fewer numbers than the other groups. The pigs on the pelleted diet were worst. Nonpelleted and home-mixed diets were better.

PATHOGENESIS

The initial colonization of the colon appears to be mediated by the motility-regulated mucin association in which there is a positive chemotaxis toward mucin. Galactosamine and glucosamine are important constituents of intestinal mucin, and BP uses both of these substrates when it is grown in vitro. The organisms penetrate the mucus. This is followed by the multiplication of the spirochetes in close proximity to the mucosal surface and inside the lumen of the crypts. Intimate attachment of BP to the apical membrane of the colonic enterocytes occurs and causes destruction of the enterocyte microvilli. The cell junctions are the target. No receptors have been found as yet. These lesions are only seen in the first three weeks postinoculation in the experiments that have been performed. There may be a specific spirochete ligand and host cell membrane receptor interaction. BP can invade between the enterocytes and reach the lamina propria, where it may remain extracellularly or be seen in macrophages. BP can virtually eat its way through from the lumen to the lamina propria. They spread extracellularly in the underlying lamina propria and are phagocytosed by the macrophages and also enter the capillary blood vessels. They are taken up by a novel mechanism called coiling phagocytosis in which the BP are localized and replicate in the endoplasmic reticulum (ER) of the infected cells, which suggests intracellular trafficking.

Penetration of the epithelium may involve disassociation of the intercellular junctional areas by the action of a subtilisin-like serine protease present in the outer membrane of the spirochete. The proliferation of the organism raises the levels of IL-1β and IL-8.

CLINICAL FINDINGS

Porcine colonic spirochetosis is characterized by mild persistent diarrhea in pigs and loss in weight and increased days to slaughter. It affects mostly young weaned animals of 20 to 40 kg but can occur in finishers and sows. There is believed to be an incubation period of 5 to 20 days. It occurs often after a change in diet. There may a slight fever (40°C), and growth retardation and partial anorexia occur commonly.

The clinical signs of porcine intestinal spirochetosis (PIS) are difficult to distinguish from nonspecific colitis (NSC) and are similar to those seen in other forms of colitis, including early swine dysentery. In one study, prevalence was found to be 5% to 15% and the mortality <1% in affected batches.

Typically, PIS occurs 7 to 14 days after weaning or after they have been mixed. Morbidity is in the region of 5% to 30%, and the signs last for 2 to 6 weeks. It is distinct clinically and pathologically from swine dysentery. Clinical findings include a mucoid nonbloody diarrhea, which is greenish or gray, often soft and wet to start, forming puddles like "wet cement," and then becoming watery. It is usually self-limiting and lasts 2 to 14 days. There may be a stained perineum. During recovery and in chronic cases there may be large amounts of mucus. Affected pigs are usually alert and active but may become depressed, gaunt, and found with starry, rough coats. Affected pigs rarely die and eventually recover. Chronic infection and relapses are sometimes recorded. Mixed infections took longer to recover and had a more profound effect on growth rates and often persisted unless there was medication.

PATHOLOGY

Gross lesions are usually subtle or not recognized. They are restricted to the cecum and colon in all species. The spiral colon is flaccid and full of watery contents with a variable amount of mucus. The large bowel is usually full of content. Mucosal lesions are most obvious in the midregion of the spiral colon followed by the proximal spiral colon. The cecal mucosa is usually not involved or only mildly. The mucosa is reddened or thickened by edema, and it may even form ridges. There are a variable number of erosions. If there are a few erosions, then there appears to be nothing visible, but if they are many erosions then the surface appears granular, and it may be necessary to gently wash the mucosa with water to see these erosions. Fibrin may be mixed with mucus or blood, and there may be variable amounts of either loose in the lumen of the colon. In mixed infections with BP the lesions were more extensive and sometimes affected the cecum as well as the colon.

Microscopically, with time the surface epithelium becomes eroded and attenuated, but these changes are not specific to BP. There is a mild to moderately severe erosive colitis that can be multifocal or diffuse. The extent and severity of this is probably a function of the colonic microflora. The lesions may extend to the muscularis. There are often adherent fibrinonecrotic exudates and feed particles. Goblet cell hyperplasia with distended mucous-filled crypts, mucosal edema, and lymphoplasmacytic infiltrates are also found. Crypt abscesses are not uncommon.

The characteristic histologic feature is a dense mat or false brush border of spirochetes that are closely packed parallel to one another and are attached by one end to the colonic epithelium resembling a brush border. This may be a feature only in the first 2 to 3 weeks of infection. With time the spirochetes persist in the lumen of the colonic glands, which are dilated and filled with mucus. In chronic infections there may be a large increase in chronic inflammatory cells. On EM spirochetes can be seen in the epithelial cells.

IMMUNOLOGY

Immunity to BP is not understood. There is a low level of IgG produced after 2 to 3 weeks. BP may be able to evade the immune system. Recovered pigs may have serum immunoglobulins, but in experimental infections there seems to be a lack of a systemic response.

LABORATORY DIAGNOSIS

The laboratory diagnosis of PCS is similar to that for swine dysentery. The identification of spirochetes in fresh wet smears of feces viewed by phase contrast microscopy may provide evidence of spirochetal infection, but this method alone is not reliable and cannot differentiate between the various groups of pathogenic and nonpathogenic spirochetes. It can be improved with fluorescent-labeled antibodies.

Primary isolation is the technique of choice for confirmation of the disease, and it is then necessary to show BP in the mucosa or feces by culture or PCR. The weakly β-hemolytic BP organisms can then be demonstrated and provisional identification is done by hippurate hydrolysis, although there are organisms that are hippurate negative, but have been confirmed as BP by

16S ribosomal DNA analysis. Most have the hippurate cleaving capacity. It is safer to remember that biochemical analysis is not definite as they can be both hippurate negative or positive. For this reason, it is worth checking on their reaction with β-glucuronidase because they should be negative if they are true BP.

Microscopic lesions are not diagnostic because they may be confused with salmonellosis or swine dysentery but the organisms in the hematoxylin and eosin sections can be seen, and they may be confirmed in Warthin–Starry silver-stained sections. Specific identification requires IHC staining with BP-specific mouse monoclonal antibodies. Fluorescent ribosomal RNA can also be detected in ISH. Scanning EM shows degenerating epithelial cells and spirochetal colonization of the epithelium with BP but nothing with *B. intermedia.* The presence of *B. intermedia* can then be detected by PCR using 23S rDNA genes. Specific PCRs targeting 16S RNA or 23S RNA or *nox* genes[7] are available. The duplex and multiple PCRs have been designed to differentiate BP from B. hyodysenteriae and *Lawsoniana.* RT-PCR is available, and restriction fragment length polymorphism analysis can be used to identify the BP isolates. There are no antibody detection systems as yet.

TREATMENT

Treatment and control uses the same principles as those used for swine dysentery. In an old study in the United States, all isolates were susceptible to tiamulin and carbadox; over 50% were resistant to gentamicin; and 42% were susceptible to lincomycin, 15.8% resistant, and 42% had an intermediate susceptibility. Few strains are susceptible to tylosin. In all time-related studies of resistance there seems to be an increasing resistance. In those countries where olaquindox can be used 100 ppm is useful.

In experimental infections when given after challenge valnemulin significantly reduced diarrhea and colonization by spirochetes. More recently in-feed valnemulin has also been shown to be useful at 25 ppm for 14 to 27 days giving lower lesion scores and less widespread colitis.

CONTROL

An effective rodent control policy and prevention of bird entry is probably essential for the control of PSC. Treatment and control of PIS and PSC are achieved using the same principles as those used for swine dysentery. Control can produce significant savings where there is all-in/all-out management and multiple site production. Improving hygiene and reducing contact with feces are the essential ingredients for successful control. If there is a lot of contamination then it is always better to allow exposure for about a week before giving antibiotics because this allows at least some immunity to be produced. Because other species may be a source of infection it is necessary to control mice and birds. Rational use of antibiotics may be useful. Rotation of antibiotic usage may make the occurrence of resistance less likely. The three most likely successful treatments are valnemulin, carbadox, and tiamulin, although carbadox cannot be used in many countries.

- Rations shown to contain 33 and 110 ppm of lincomycin provided an effective control.
- In Finland the use of tiamulin at 200 ppm for 18 to 30 days combined with thorough cleaning removed PCS from a 60 farrow-to-finish operation.
- Valnemulin at 25 ppm (1.25 mg/kg) was shown to be effective in controlling spontaneous PCS.

Vaccination

Vaccination seems to induce a primary and secondary serologic response to BP, but an experimental whole-cell bacterin was not protective when administered parenterally. There is no vaccine in widespread use.

YERSINIOSIS IN PIGS

The principal disease of pigs is caused by *Y. enterocolitica* (YE) as well as YP. It causes enteritis and typhlocolitis in pigs and similar conditions occur in man. Contamination of carcasses during the slaughtering process may lead to carcass contamination and problems in the food chain (biotypes 4, 2:O9, and 1:O3), and may pose a threat to abattoir workers. *Yersinia* also has significance in that cross-reactions of O9 with *Brucella* are a frequent cause of problems in *Brucella* testing.

ETIOLOGY

The organisms are gram-negative coccobacilli. There are biotypes and serotypes and some of the human food-poisoning types have virulence factors.

EPIDEMIOLOGY

Both species are widespread in pigs[1] and carriage may persist for a long time in both tonsils and feces. Shedding is low in weaners (30%), increases in growers, reaches a peak in finishers (70%), declines in gilts (20%), and is usually absent in sows and boars. Antibody has a similar trend, and is low in neonates and weaners and increases so that usually 100% of sows have antibodies. It can survive in the environment and infects other species including rats, mice, flies, and humans.

PATHOGENESIS

Infection is carried in the tonsils where it sometimes may lodge, and multiplication occurs in the ileum and large intestine. Shedding occurs between 5 and 21 days post infection (DPI) and may continue for up to 10 weeks. Antibodies appear after about 18 days and may also last about 10 weeks. Septicemia may occur with YP, and in these cases there may be abscesses in the liver, spleen, lymph nodes, and guts, as well as the enteritis.

CLINICAL SIGNS

There may be mild fever, watery diarrhea (3–5 days), dark-colored feces, and blood-stained mucosa and soft feces in YE cases. Rectal stricture may also be seen. In YP cases there may be dullness, inappetence, edema, and bloodstained diarrhea, and it has also been isolated from rectal stricture cases.

PATHOLOGY

In former clinical cases at necropsy there may be a catarrhal enteritis. In YP cases the lesions are perhaps more severe with button ulcers in the colon, gut, mesenteric lymph nodes, and liver.

DIAGNOSIS

Clinical signs do not make a provisional diagnosis of yersiniosis likely, but the organism is usually found at postmortem or on bacteriologic testing. They can be isolated on culture from enrichment media or broths. DNA probes or PCR will also detect both organisms, and YE can also be detected in feces by PCR in feces at 5 CFU/mL feces. Diagnosis usually depends on the pathology associated with demonstration of the organism by culture or PCR. Serology (ELISAs) can be useful for detecting herd infection from 2 weeks after infection to a peak at around 30 to 35 days and disappearance at around 70 days.

TREATMENT

If there is a problem it will usually respond to antimicrobial treatment in water or feed, particularly tetracyclines, synthetic penicillins, fluoroquinolones, and furazolidone (not in the EU).

CONTROL

Hygiene and biosecurity are the best controls, aided by rodent and fly control.

VIRAL DIARRHEA IN NEONATAL PIGS

Neonatal diarrhea in the pig involves principally viruses such as PED, rotaviruses, and the TGE virus, probably in that order of

importance, since 2013. In addition, there are several other viruses of lesser or unknown importance.

Additional major groups in neonatal pigs include the bacterial diseases and principally clostridial infections (*C. perfringens* type A and C and *C. difficile*). In addition, there are the protozoal conditions of coccidiosis and cryptosporidiosis to further complicate the situation. Multiple infections are probably more common than realized because there is a temptation to not look for a further diagnosis once the initial culprit is found.

OVERVIEW OF VIRAL DIARRHEA

Emerging and reemerging swine viruses have been reviewed.[1] The etiologic agents of diarrhea are varied but the predominant group are the viruses. These include TGE and PED, which are the most severe infections causing considerable mortality. The latter is a cause of much recent disease in Asia (China, Thailand, Vietnam, and Korea) in which 50% of the cases may be caused by this agent[2-5] and the mortality approached 100% and now, since May 2013, a large epizootic has occurred in North America.

The most common agent is porcine rotavirus. In addition there are several newly emerging agents including porcine kobuvirus and porcine bocavirus.[6-9]

A systematic study was made in China of these viruses.[10] In finishing pigs, 5% to 10% had diarrhea and usually recovered within 1 week. Sows had diarrhea in 15% to 20% of cases when pregnant and were usually well within 1 to 3 days. Piglets were ill within 1 week of farrowing. These outbreaks spread rapidly within 3 to 5 days. Clinical signs included yellow, watery diarrhea, vomiting, depression, anorexia, and death from dehydration from within 2 to 3 days. The stomach contained a mass of curdled and undigested milk. The small intestine was thin walled and almost transparent. Mortality often reached 80% to 100% but supportive therapy might reduce this to 20% to 30%. If piglets were infected at >14 days then mortality was low. The pathologic changes were mostly in the jejunum and the ileum with little change in the duodenum. There was often villous atrophy.

The pathogens causing diarrhea are diverse with over 96% of the cases having at least one cause in Korea,[4] in Italy,[8] and in Thailand.[11]

In this Chinese study from 2013,[10] not surprisingly 82% had PED. Kobuvirus was frequently detected in single infections but more importantly in mixed infections. Bocavirus and rotavirus were also often detected in mixed infections and only occasionally in single infections. Over 75% in this study were mixed infections. Dual infections were 43.9%, triple 26.1%, and quadruple 2.3% of cases.

Various viruses may coexist with PED. Different infection patterns are observed in different age groups. The viral load of PED tended to be higher in the infected pigs than in the healthy. TGE and rotavirus were not detected in healthy pigs. The viability of enteric viruses after waste treatments has been examined.[12]

PORCINE ROTAVIRUSES

This virus is a major cause of diarrhea in the pig. The zoonotic potential is unknown, although pig and human strains do reassort.[1] In a recent case in an infant in China it was shown that the rotavirus responsible was a pig–cattle reassortant.[2]

ETIOLOGY

The virus has 11 segments of double-stranded RNA (dsRNA), and each segment encodes for a viral structural protein (VSP) or a nonstructural protein except segment 11, which encodes for both.[3] The virus is a triple-layered particle, and if the outer proteins are removed (VP4 and VP7) by a disinfectant then there is a double-layered particle remaining; in an EM picture both particles can be seen. Only the triple-layered are infectious.[4] There are seven groups that are morphologically similar but antigenically different based on the VP6. Of these Group A is the most important in the pig,[4] but Group C has become more of a problem recently[5-7] and Group E was detected in the UK many years ago. The classification of rotaviruses has been the subject of much discussion.[8,9] In the United States, there has been a substantial diversity.[10]

The Group A rotaviruses are a common cause of diarrhea in nursing pigs from 1 to 5 weeks of age with peak occurrence from 1 to 3 weeks of age, and weanling pigs at 3 to 5 weeks of age and within 3 to 5 days of weaning. Groups A, B, and C occur in diagnostic surveys with about 90% belonging to Group A. Substantial diversity of Group B viruses has recently been described in the United States.[10] Group C rotavirus has also been found to be the cause of enzootic neonatal diarrhea in a minimal disease herd. They are divided into two serotypes, G (15+) and P (25), and different types predominate in different outbreaks.

Multiple rotavirus G serotypes and P types have been detected in swine. In a recent survey in Europe 14% of the pig samples were positive for rotavirus and the number of G–P combinations was high and confirms the high diversity of genetic diversity.[11] New combinations are being discovered all the time, for example, the discovery of a G2-like virus with a novel VP4 type P32 in Ireland[12] and the G9 P[13] in Ohio in nursing piglets. There is little or no cross-protection between porcine rotaviruses with distinct G and P types, but viruses that share common G and P types induce at least partial cross-protection in experimental studies. This is why it is sometimes essential to know which types are present on the farm. The most common are G3, G4, G5, and G11.

In some countries a certain genotype may be more common, e.g., P23 in Thailand.[14] Variant serotypes of porcine rotavirus such as G3 may cause severe outbreaks of diarrhea in piglets. Subclinical infections are common, and age resistance to rotavirus infection may not occur.

EPIDEMIOLOGY

The serotypes are present worldwide, and up to 100% of adult pigs may be serologically positive for Groups A, B, C, and E, and multiple serogroups and serotypes have been found in the pig.[15-18]

Fecal–oral transmission is common and possibly by aerosol, although this is not confirmed. In the past most infections were Group A, but recently in the United States[6] and Brazil[19] Group C has flared up. The infection dynamics on farms have been described.[20] Reassortants have occurred between pigs on one hand and cattle, horses, and humans on the other.[9,21-23]

In an infected herd, piglets become infected between 7 and 35 days of age, and the virus cannot be detected usually in piglets under 10 days of age, presumably as a result of protection by lactogenic antibody. Virus shedding can occur from 1 to 14 days for the Group A viruses and rather less for the Group B viruses. It is suggested that in an intensive piggery, with a constant shedding of viruses in feces of sows before and after farrowing leads to a continuing cycle of rotavirus infection, with a buildup of host immunity against a circulating strain in the pig population. A virus such as CRW-8 probably could undergo changes through mutations over a period of time, leading to antigenic drift.

In piglets, rotaviral diarrhea is most common in pigs weaned under intensive management conditions, and the incidence increases rapidly from birth to 3 weeks of age. There is no age-dependent resistance up to 12 weeks of age. The disease resembles milk scours, or 3-week scours of piglets. Mortality caused by rotavirus varies from 7% to 20% in nursing pigs and 3% to 50% in weaned pigs, depending on the level of

sanitation. In the United States the peak incidence occurs in February and a moderate rise occurs in from August to September.

A case-control epidemiologic study examined the relationship between Group A rotavirus and management practices in Ontario over a 5-year period. In rotavirus-positive herds, herd size was larger and weaning age was younger compared with rotavirus-negative herds. Pigs raised in all-in/all-out nurseries were three to four times more likely to have a positive Group A rotavirus diagnosis than pigs in a continuous flow system. Pigs in the all-in/all-out system were weaned at an earlier age.

The sow is the source of infection. Seropositive sows can shed rotavirus from 5 days before to 2 weeks after farrowing, when piglets are most susceptible to infection. There are increased secretory IgA and IgG antibodies to rotavirus in the milk of sows after natural rotavirus infection or following parenteral inoculation of pregnant or lactating sows with live attenuated rotaviruses. The early weaning of piglets at a few days of age or at 3 weeks of age results in the removal of the antibody supplied by the sow's milk and predisposes to infection.

Continuous transmission of the virus from one group to another is an important factor in maintaining the cycle of rotaviral infection in a piggery. The virus can be found in dust and dried feces in farrowing houses that have been cleaned and disinfected. This suggests that the environment is also an important source of infection. The porcine rotavirus can survive in original feces from infected pigs for 32 months at 10°C. Gilts and sows shed virus antigen before farrowing and during lactation, which makes it next to impossible to eliminate the infection from a herd. As sows increase in age they develop increasing levels of lactogenic IgA rotavirus antibodies but do not transfer increasing levels of protection to their piglets.

Different electrophore types of Group A rotavirus and different groups of rotaviruses may occur at the same time in a single piggery, which must be considered when developing vaccines. The subgroups of Group A porcine rotaviruses have been classified, and there are differences in virulence of isolates. Most isolates from outbreaks of diarrhea belong to Group A, whereas a small percentage are atypical rotaviruses. Some porcine rotaviruses are related antigenically to human rotavirus serotypes 1 and 2. Porcine rotaviruses displaying the typical bovine P[1], P[5], P[11], G[6], and G8 genotypes have been detected in pigs, which indicates the high frequency of rotavirus transmission between cattle and pigs. The various G and P types of the virus have been examined and compared in Poland and the United States.

Atypical rotaviruses and other enteroviruses are often present in preweaning and PWD in swine herds and should be considered as potential pathogens. Some atypical rotaviruses are associated with villous epithelial cell syncytia in piglets with enteritis. Single and mixed infections of neonatal piglets with rotaviruses and enteroviruses have been described. Combined rotavirus and K99 + *E. coli* infection causes an additive effect when induced experimentally in gnotobiotic pigs. The inoculation of calici-like viruses into gnotobiotic piglets can result in diarrhea and villous atrophy. Diarrhea in unweaned piglets 1 to 3 weeks of age has been associated with a combined infection of rotavirus and *Isospora suis*. There can be an important synergistic effect with other viruses such as PED.[24] The combined effect of a dietary change at weaning and rotavirus infection in gnotobiotic piglets is a temporary villous atrophy, and there is no evidence of persistent atrophy of the small intestine.

PATHOGENESIS

They replicate in enterocytes of the small intestinal villi and the cecal and colonic epithelial cells. Jejunum and ileum are the most affected. Within 12 to 48 hours of an experimental inoculation, the affected cells lyse and disruption of villous architecture follows. To some extent this is age dependent and strain and serogroup dependent. Groups A and C produce the most serious effects. Malabsorption results as a result of impaired glucose-regulated sodium transport, impaired disaccharidase production, and increased thymidine kinase activity.

CLINICAL SIGNS

The incubation period may be 18 to 96 hours. Rotaviral diarrhea may occur in nursing piglets from 1 to 4 weeks of age and in pigs 1 to 7 days following weaning. If the condition is uncomplicated by other agents then the disease is often mild. Lactogenic immunity is very protective. Direct experimental infections are always more severe than the natural infections. In older piglets it is less severe, and in pigs of 4 to 5 weeks it produces only a very slight diarrhea. The disease in nursing piglets resembles milk scours or 3-week scours. Most of the pigs in the litter are affected with a profuse liquid to soft diarrhea with varying degrees of dehydration. Recovery usually occurs in a few days unless complicated by ETEC or unsatisfactory sanitation, overcrowding, and poor management. The disease is often most severe in herds in which there is continuous farrowing with no period of vacancy for cleaning and disinfection in the farrowing barn. The disease may also occur in pigs a few days after weaning and may be a major factor in PWD of piglets weaned at 3 weeks of age, or earlier in the case of weaning pigs at 1 to 2 days of age.

PATHOLOGY

Gross lesions are most severe in 1- to 14-day-old pigs when the stomach is empty and the intestine is thin walled, flaccid, and full of watery flocculent fluid. The lacteals in the mesentery are empty and the lymph nodes are small. In pigs older than 21 days there are no gross lesions in the uncomplicated cases.

Histologically, there is loss of the villi tips within 16 to 18 hours postinoculation. Significant villous atrophy occurs within 24 hours and reaches its height at 24 to 72 hours. Then there is a flattened squamous epithelium and crypt hyperplasia.

DIAGNOSIS

Porcine rotaviruses grow in cell cultures with a characteristic rounding of the cells, and the virus can be detected in these cultures by immunofluorescence or IHC. The latter is also used directly on tissue sections from the small intestine.

A whole variety of methods are used to detect rotavirus, but many rely on the commercial ELISA kits for rotavirus A, and monoclonal antibody capture ELISAs have been developed for Groups B and C. Nucleic acid hybridization and viral RNA have been detected by RT-PCR. The latter is often used for the detection of serogroups and genotyping.[1,6,15-17,25]

Because the infection is so widespread there is little point in measuring antibodies, but a whole variety of techniques can be used to detect high levels of IgA and IgM, which will indicate recent infection.

IMMUNITY

The immune response appears to be specific for either the P or G type. There appears to be little cross-protection between the groups. The presence of a neutralizing IgA antibody in the small intestine appears to be the most important feature in the immune response. This is the reason the pig is most prone to infection when the level of maternal antibody has decreased.

DIFFERENTIAL DIAGNOSIS

Transmissible gastroenteritis is most common in piglets under 1 week of age and explosive outbreaks are common. There is acute profuse diarrhea and vomiting. Affected piglets may continue to nurse for several hours after the onset of the diarrhea. The case–fatality rate is high in piglets under 7 days of age; older pigs usually survive.

Porcine epidemic diarrhea type I affects piglets under 4–5 weeks of age and is characterized by profuse watery diarrhea, high morbidity, and low mortality.

Porcine epidemic diarrhea type II causes a profuse fluid diarrhea in pigs of all ages, including nursing piglets. Explosive outbreaks may occur and the morbidity may reach 100%. Mortality is usually restricted to piglets under 3 weeks of age.

Enteric colibacillosis usually occurs in piglets under 3 days of age. There is acute diarrhea, dehydration, and rapid death. Pigs with coliform septicemia may die without

Continued

obvious diarrhea and usually appear cyanotic. Entire litters may be affected and the case–fatality rate may be 100%. Early treatment with antibiotics and subcutaneous fluids will result in recovery. Coccidiosis occurs in piglets from 5 to 10 days of age and is characterized by an acute diarrhea in which the feces are foul smelling and vary in consistency from cottage cheese–like to liquid, and gray or yellow and frothy. The diarrhea is persistent for several days and nonresponsive to antibiotics. Some pigs recover spontaneously, whereas others die in 2 to 4 days. Coccidial oocysts can be detected in the feces. The morbidity rate varies from 50% to 75% and the case–fatality rate from 10% to 20%.

Hemorrhagic enterotoxaemia caused by *Clostridium perfringens* type C affects entire litters of pigs under 1 week of age; is characterized clinically by severe toxemia, dysentery, and rapid death; and at necropsy there is a hemorrhagic enteritis.

Coccidiosis

C. perfringens type A

C. difficile

Other pig diarrhea viruses (calicivirus, sapovirus, norovirus, adenovirus, etc.)

TREATMENT

Diarrhea causes dehydration and electrolyte imbalance, so rehydration and energy provision is essential using oral electrolytes. The younger the pig is, the worse the effect, because in these animals reserves of energy and cold tolerance are largely reduced. It is therefore essential to maintain a warm environment and to provide the correct creep feeds for young piglets to encourage food consumption. Regular cleaning and disinfection will reduce the level of virus challenge.

CONTROL

A variety of disinfectants including phenols, formalin, and chlorine have been used to deal with a virus that is resistant to a variety of environments. It can survive for 9 months at the temperatures normally found in a farrowing house. As yet there is no good porcine rotavirus vaccine.[26]

PORCINE HEMAGGLUTINATING ENCEPHALOMYELITIS VIRUS

Porcine hemagglutinating encephalomyelitis virus (HEV) is also known as vomiting and wasting disease. It is also a disease of neonatal pigs. It can be seen as different manifestations, and there is no public health significance.

ETIOLOGY

The cause is a Betacoronavirus of the *Coronaviridae,* and the natural host of the virus is the pig. It was originally described in the UK and Canada, and there is only one serotype. There are mostly inapparent infections with occasional outbreaks in nonimmune herds,[1,2] and it has a tropism for neural tissues.

EPIDEMIOLOGY

The condition occurs worldwide. The condition affects neonates and is maintained by the infection of piglets from sows. Because most sows are protected there are few outbreaks. A new herd of 6000 sows with 55% gilts and first or second litter sows was severely affected.[2] The piglet is affected before 3 to 4 weeks of age if born to nonimmune sows. It is transmitted in nasal secretions probably resulting in nose-to-nose transmission and possibly aerosols. Excretion of the virus following infection probably lasts 8 to 10 days. The presence of maternal antibody, which lasts up to 15 weeks, protects the piglet against neural damage. Pigs over 3 to 4 weeks do not get nervous signs.

The virus will also spread rapidly among newly weaned finishing pigs, and immunity develops within 8 to 16 weeks. The virus is rapidly destroyed by ultraviolet light.

PATHOGENESIS

After oronasal infection signs begin within 3 to 5 days. These signs are affected by age at infection and possibly also by any strain differences in the virus. Replication is widespread in the respiratory tract, particularly lungs, tonsils, and small intestine. It may spread to the CNS via the peripheral nervous system, particularly the trigeminal, vagus, and intestinal plexuses to the spinal cord. On reaching the brain it particularly affects the vomiting and appetite centers to produce wasting. Virus replication in the gastric nerve plexi causes damage and disturbs gastric emptying and starvation. Viremia is of no importance.

CLINICAL SIGNS

Piglets between 5 days and 3 weeks are affected. They will often try to suckle, then stop and vomit. The first signs are vomiting and huddling together, which indicates a raised temperature that may last 1 to 2 days. Anorexia, dehydration, and constipation follow, and the vomiting increases in frequency and is usually followed by death or wasting. Nervous signs may follow in some pigs with hindleg weakness, difficulty in swallowing, and persistent retching and vomiting. Older pigs nearer 3 weeks may just lose their appetite and become emaciated, and may require euthanasia. Morbidity may be 100% if totally susceptible, and mortality may also be high under similar circumstances. Pigs in outbreaks of the so-called motor encephalomyelitic form may huddle, sneeze, cough, and vomit as early as 7 days after birth. They may then huddle, show tremors, hyperesthesia, jerky gait, walk backward, or adopt a dog-sitting posture. Blindness, opisthotonus, nystagmus, and paddling on the side in lateral recumbency, followed by coma and death, are also seen.

PATHOLOGY

There are usually no gross lesions. The abdomen may be swollen. The intestinal tract and particularly the stomach are usually empty. There may be intestinal dilatation.

Histologically, there may be nonsuppurative inflammation in the tonsils or lungs. In the V and W form there may be degeneration of the ganglia in the stomach and perivascular cuffing in the stomach. If there is an encephalitic form, a nonsuppurative encephalitis is found that is most pronounced in the pons, medulla, and the dorsal horns of the spinal cord with perivascular cuffing, gliosis, and neuronal degeneration.

DIAGNOSIS

The clinical signs in young pigs less than 3 weeks of age are highly suggestive. Virus isolation in the first 2 to 3 days of an acute infection is possible using PK cells and then using hemadsorption, immunofluorescence, neutralization or hemagglutination, or the presence of syncytia to confirm. IHC on tonsils, brainstem, and lungs will also confirm the diagnosis.

RT-PCR on tonsils, brainstem, and lungs will also demonstrate the agent. An antibody that arises 7 to 10 DPI can be detected by plaque reduction, virus-neutralization (VN), or hemagglutination inhibition tests. Antibody concentrations increase rapidly after infection but there presence does not indicate active disease.

DIFFERENTIAL DIAGNOSIS

The most likely differential diagnoses are pseudorabies or Teschen–Talfan.

TREATMENT AND CONTROL

There is no treatment or control. If you know the herd is free, keep it so by biosecurity, purchase new stock from a known-free source and quarantine on arrival, and then adapt to the unit to encourage immunity to the strains present on the farm; otherwise maintain a high herd immunity by mixing ages of sows to encourage circulation of the virus, increasing colostral immunity.

PORCINE ADENOVIRUSES

Porcine adenoviruses cause mild diarrhea and pneumonia in pigs.

ETIOLOGY

Porcine adenoviruses are DNA viruses and can be cultured in cells to show cytopathic effects and intranuclear inclusions. They are resistant to the environment and may live up to 1 year at 4°C but are susceptible to most disinfectants. Seven types have been found in pigs and types 1 and 4 are the most common.

EPIDEMIOLOGY

Porcine adenoviruses are found worldwide; for example, antibodies have been found in 80% of slaughter pigs in the UK and similarly in Japan. Antibody positivity increases with age. Virus has been isolated from nasal discharges, abortions, and from stillborn piglets following transplacental infection, and from normal animals. In one herd 24% of piglets to 8 weeks were positive as well as 60% of finishers and 90%+ of the sows.

PATHOGENESIS

Intestinal strains colonize the tonsils and the intestines and infect the intestinal cells of the villi of the lower jejunum and the ileum. Intranuclear inclusions can be seen in the cells that have nuclear swelling and lose microvilli, and then villous shortening follows. The affected cells migrate to the tips of the villi.

Type 4 also has a predilection for the respiratory tract, where it causes interstitial pneumonia and occasionally encephalitis.

CLINICAL SIGNS

Pigs less than 3 weeks of age are affected in the main, but there can be infection from 5 days to 24 weeks. The incubation period is 3 to 5 days, and the diarrhea lasts for 3 to 6 days. It is yellow, intermittent, and of variable consistency. Dehydration does occur but death is rare.

PATHOLOGY

There is thinning of the intestinal wall in the jejunum and ileum. Histologically, there are intranuclear inclusions in the enterocytes, particularly over the Peyer's patches, and these are of the Cowdry type (eosinophilic or amphophilic surrounded by a clear halo).

DIAGNOSIS

Diagnosis is based on the detection of virus particles in the gut contents by EM, demonstration of inclusions in histologic sections, and the detection of the virus by PCR and qPCR.

PORCINE CALCIVIRUSES

Porcine enteric caliciviruses[1,2] have been found in Europe,[3] Korea,[4] and Japan.[5,6] They are common and of unknown pathogenicity. It is not known if they are zoonotic, but they are of no public health concern at the moment.[7,8] They are RNA-containing viruses. Infection of gnotobiotic piglets causes diarrhea lasting 3 to 7 days. The viruses are found in the usual place on the sides and base of the villi and caused significant villous atrophy.

The family Caliciviridae is divided into four genera: *Norovirus, Sapvirus, Lagovirus,* and *Vesivirus.* An unassigned fifth genera[9] and both the sapoviruses and noroviruses are of uncertain pathogenicity in the pig.[8] The pig viruses are called porcine sapoviruses (PoSaVs) and the porcine noroviruses (PoNoVs). The prevalence and molecular characteristics of these viruses has been studied in the United States.[9]

No clear relationship between diarrhea and infection has been demonstrated,[10] and they are often recovered from normal pigs.[11,12,13]

PORCINE SAPOVIRUSES

The first of the PoSaVs was isolated in 1980 in a diarrheic piglet using EM. The prototype was known as the Cowden virus, and most of the ones studied since are similar to this virus. It was originally known as the porcine enteric calicivirus. Experimental infections with this virus produced severe diarrhea, anorexia, and intestinal lesions.

They are found in all age groups of pigs including those with diarrhea and those without clinical signs. It is suggested that sapoviruses play a part in enteritis in piglets.[1] A Korean-like sapovirus was recently identified in the United States.[2] Sapovirus characterization has been described.[3]

A survey of pigs with diarrhea showed that 32.5% had sapoviruses, but there was no proof that these were the cause of the problem.[4] They have evolved by recombination.[5]

Both sapoviruses and noroviruses are resistant to environmental conditions. At least six sapovirus genotypes have been identified and they are widespread on European farms.[3] They also have been identified in Japan.[6] They are highly diverse, but PoSaVs belong to genotypes GIII, GVI, GVII, GVIII, and GIX, and GX and GIII are the most common in pigs. Double infections with two or more sapoviruses are common.

In experimental infections sapoviruses do produce diarrhea. The virus produces lesions in the small intestine and replicates in the enterocytes. When given orally to piglets the virus is shed for up to 9 days.

In histologic examination it produces shortening, blunting, and fusion or destruction of the villi in the duodenum and the jejunum. There is crypt cell hyperplasia and reduction of the villus:crypt ratio (villous atrophy).

The incubation period with the original Cowden virus was 2 to 4 days after oral inoculation, and diarrhea and anorexia persisted for 3 to 7 days.

In another study, the viruses were homogenously distributed among the different age groups of pigs and were not associated with disease.[4]

In a serologic survey in Spain,[6] 85 samples from pigs of 8 to 34 weeks were examined and 62% were positive.

A high maternal antibody is probably developed in the first few weeks of life, which then falls, and by 3 months has risen again (active immunity).

No human sapoviruses were detected in pigs by the authors who analyzed sapoviruses across Europe.[3] They detected the virus in 80/1050 samples (7.6%) collected from 39 farms in 6 countries. The highest prevalence was in 2- to 8-week-old pigs, and there was no difference in prevalence between healthy and diseased piglets. Six old genotypes and two new types were discovered.

Diagnostic tests are available in research laboratories (e.g., EM PCR, RT-PCR).[7,8]

Little is known about immunity, although it is assumed that sows produce colostral antibodies.

PORCINE NOROVIRUS

It is not certain whether the pig and human noroviruses are antigenically distinct or related. These viruses have not been detected in nursery or postweaning pigs but have been found in healthy finishing pigs.[1,2]

A PoNoV was found in asymptomatic finishers and adult pigs.[1] It has positive sense single-stranded (ss)RNA viruses with three ORFs. Genetically diverse, they have five genotypes[3] and G11 is the one found in pigs and humans. There are three separate genotypes (11, 18, and 19) in pigs, and they have a worldwide distribution.[4-11] Epidemiologically, it will survive waste treatments. Little is known about their pathogenicity.

In an experiment with human norovirus in gnotobiotic pigs, a mild diarrhea was produced with lesions in the proximal small intestine.[12] It replicated in some pigs and produced antibody in some pigs. No diagnostic tests are available commercially, but a variety have been used in research laboratories (e.g., EM, RT-PCR, and PCR).[9]

PORCINE ASTROVIRUSES

Porcine astroviruses, although isolated from pigs, are of unknown importance. They are not zoonotic, and they were first isolated from pigs in the 1980s.

ETIOLOGY

The viruses from the different species are probably antigenically different, and five types have been recognized.[1-5] All five types have been found in the United States,[6] and in some cases more than one type was found in a pig. The porcine strains are different from the human strains.[7] They are members of the family Astroviridae and of the genera *Mamastrovirus*; are positive sense, ssRNA viruses; and are highly diverse. They have partially clustered genomes[4,8] and are of two different lineages (PAST-1 and PAST-2).

EPIDEMIOLOGY

Porcine astroviruses have a worldwide distribution. A recent survey[9] suggested that perhaps 62% of pigs had astrovirus (260 pigs with diarrhea were studied). The transmission is presumed to be the usual fecal–oral route such as for most enteric pathogens.

PATHOGENESIS

The viruses are only known to cause disease in association with other agents. In an experimental infection given with PAST-1, only mild diarrhea was produced, which occurred within 1 day and continued for 5 to 6 days.

CLINICAL SIGNS

The association between these viruses and clinical disease is obscure because they are found in pigs with diarrhea and in healthy pigs. The clinical signs are more likely to be found in association with simultaneous infection with rotavirus, coronavirus, or calicivirus.[9]

DIAGNOSIS

EM, cell culture, and RT-PCR have been used to detect the antigen. VN and IFA techniques have been used to detect antibodies.[10]

TREATMENT AND CONTROL

Treatment and control are probably not possible, and if affected then supportive therapy may be instituted.

PORCINE TOROVIRUS

The link between these viruses and clinical disease is obscure. They are probably found worldwide and most recently have been found in Spain.[1,2] These kidney-shaped viruses are members of one of the four species within the *Torovirus* genus of the Toroviridae subfamily of the Coronaviridae [3] and have been identified in a variety of pigs with diarrhea including the following:

- A 3-week-old pig with diarrhea
- Four-week-old pigs from Italy had greenish-yellow diarrhea and 30% morbidity and 8% to 10% mortality.
- Korean torovirus strains cause sporadic infections.
- In South Africa, 6- to 8-week-old pigs showed a sudden increase in mortality with piglets showing a reduction in appetite, weakness, tremors, recumbency, and death.

Generally, they are probably endemic in most pig herds and probably occur in closely related clusters in an area. Most pigs are affected postweaning. There is a high prevalence in subclinically infected weaned pigs.[4,5] There is probably endemic subclinical infection in neonates and young pigs and possibly there is a low incidence in adults.[4] In Korea, they are genetically diverse.[5]

Toroviruses can be demonstrated by PCR, RT-PCR, and qRT-PCR for antigen, and ELISA and VN for antibodies.

Antibodies can be demonstrated using ELISAs using recombinant viral proteins.

PORCINE ORBIVIRUSES

Porcine orbiviruses have been found in porcine feces and seem to have no clinical significance.

PORCINE PICOBIRNAVIRUSES

Porcine picobirnaviruses have been found in the UK, Argentina, Venezuela, and Hungary. Their clinical significance is unknown, but on one farm 11% of the samples from 15- to 35-day-old pigs were positive. Excretion has been followed from birth to slaughter.[1]

PORCINE KOBUVIRUSES

The virus was first identified in Hungary in 2008.[1] These viruses are also Picornaviridae and belong to the genus *Kobuvirus,* and the virus is found in pigs with diarrhea and in healthy pigs.[1,2] No significance has as yet been attributed to them. They have been found worldwide by RT-PCR, and infection rates seem to vary from 45% to 99%. It has been reported that as many as 84.5% of pigs have the virus.[3] These infections are most commonly observed in nursery pigs and also as single infections. The viral load in healthy and infected pigs is also similar. They have been found in Brazil and the Netherlands,[4] Thailand,[5] Japan,[6] Korea,[3] and China.[7,8] They have also been found in the Czech Republic[9] and in 2013 found in the United States.[10]

PORCINE BOCAVIRUS

Studies have indicated that Bocavirus,[1] which has a close relationship with enteric disease in domestic animals, had a high prevalence in stool samples of pigs.[2,3] It is commonly found in grower pigs,[4] and the level of virus load is not different between healthy and infected pigs. It can be detected using TaqMan-based RT-PCR.[5] A bocavirus causing respiratory tract signs has been found in China.[6] It has been found in pigs in Sweden,[7,8] China,[9,10] and in Northern Ireland.[11]

A NEW NEONATAL DIARRHEA SYNDROME

A French study[1] has suggested that there is a new neonatal diarrhea syndrome (NNDS) in France and Denmark characterized by a mortality rate of up to 40% in suckling pigs, of unknown cause, with 15% to 20% of French herds supposedly having experienced this outbreak and with over 80% of submissions to Danish laboratories having been associated with this outbreak. It has been suggested that the herds are mainly the high-yielding well-managed herds. There is considerable variability between the litters; particularly the gilts and second litter sows may be affected. The length of parturition in the affected litters was longer than in the unaffected herds. The proportion of piglets born late was higher. Levels of antibodies in colostrum varied, but there was no evidence of differences in quality of colostrum. No consistent pattern emerged in the herds, and no consistent pattern of microbiological observations has been found. Piglet serum IgG is a reflection of the rate of absorption from the gut, which depends on the level of IgG in the colostrum and in turn depends on the level of maternal antibody in the sow. There were normal amounts of milk in the stomach of affected pigs; there were no obvious gross lesions; they were not dehydrated; the small intestines were contracted, or atonic, and dilated; hyperemia was rare, and intestinal contents were yellowish and aqueous. The intestinal mucosa was not inflamed and the lymph nodes were reactive. The colon had no changes, and the contents were creamy or watery. In the Danish laboratories 55% of the cases had nonhemolytic *E. coli* and 7% hemolytic *E. coli* that was mostly O7, 16% had ETEC, *C. perfringens* type A was found in 80%, *C. difficile* was found in 12%, and rotavirus was also found in 12%. Only 1/220 samples had *C. perfringens* type C.

Four Danish pig herds with NNDS were investigated.[2] This has occurred since 2008 and is characterized by a nonresponse to treatment or to management therapies. No pathogens have been detected in the past, and in this investigation no pathogens were detected either. Macroscopically, these pigs had filled stomachs and flaccid intestines without mucosal changes. The predominant histologic changes were villous atrophy in the jejunum and ileum. Epithelial lesions were seen in the colon in one-third of the cases. In the Danish cases it was found that (1) microbiological testing was not sufficient to explain the problem, (2) histopathology was generally inconclusive, (3) *E. coli* and *C. perfringens* type A are found in normal pigs and are therefore not considered to be important, and (4) the role of *C. difficile* under Danish conditions has not been elucidated.

A suggested case definition was nonhemorrhagic diarrhea during the first week of life without detection of known infectious pathogens characterized by milk-filled stomachs and flaccid intestines at necropsy.

TRANSMISSIBLE GASTROENTERITIS IN PIGS

SYNOPSIS

Etiology Transmissible gastroenteritis virus, member of the Family Coronaviridae

Epidemiology Highly contagious disease of newborn piglets but may affect pigs of all ages in susceptible herds. High morbidity and high case-fatality rate in piglets under 10 days of age. Over 5 weeks of age, mortality is low. Large economic losses. Epidemics of disease occur in susceptible herds. Transmission by oral and aerosol routes. Recrudescence of infection and endemic disease commonly follows epidemics. Infection of pregnant sows results in protection of piglets by secretory IgA in milk. Porcine respiratory coronavirus mutant of transmissible gastroenteritis (TGE) virus has reduced the incidence of TGE.

Signs *Epidemic disease*: Acute diarrhea, vomiting, dehydration, and death in piglets under 10 days of age. Less severe diarrhea in older pigs of all ages.

Endemic disease: Diarrhea in young pigs 6 days of age and older, including weaned pigs.

Clinical pathology Detection of virus in tissues. Serology.

Lesions Fluid-filled intestines. Villous atrophy.

Diagnostic confirmation Detection of virus in mucosal scrapings of intestine.

Differential diagnosis list

- Enteric colibacillosis
- Coccidiosis
- *Clostridium perfringens* types A and C; *Clostridium difficile*
- Rotavirus enteritis
- Porcine epidemic diarrhea, especially new strains
- Vomiting and wasting disease
- Diarrhea of adult sows, gilts, and boars

Treatment Supportive therapy. Fluids and electrolytes. No specific treatment.

Control Isolation of sows due to farrow. Planned exposure to virus. Biosecurity and acquisition of virus-free replacement stock. All-in, all-out management system. Vaccination.

ETIOLOGY

Gastroenteritis is associated with the transmissible gastroenteritis (TGE) virus, an alphacoronavirus 1 and member of the Family Coronaviridae[1] belonging to the Order Nidoviridales. The nucleotide sequences from 20 TGE virus isolates obtained from eight countries between 1946 and 1996 have been compared. The virion is an enveloped, large, single-stranded RNA genome with positive polarity. It has three major structural polypeptides: 200-Kda spike protein (S protein), 30-Kda membrane protein (M), and a minor 10-Kda protein (E). These are produced by open reading frames (ORFs) 2, 5 and 6. The function of ORF products from 3a and 3b are not known, but they have been postulated as an important determinant of virulence.

In Europe, TGE-like strains of coronavirus have recently emerged.[2] These might be novel recombinants and are associated with the winter season, possibly occur in nonporcine hosts (cats, dogs, and foxes), and can be spread by starlings and houseflies.[3]

EPIDEMIOLOGY

Occurrence and Prevalence of Infection

The disease occurs in pig-producing areas of North America, Europe, and many parts of Asia, principally in the northern hemisphere. During the past three decades, TGE has changed from a sporadic disease that historically occurred in the midwestern United States to an endemic disease in most countries of the northern hemisphere. It can cause severe disease even in seronegative herds, especially if the protection of porcine respiratory coronavirus (PRCV) is missing. In Asia, TGE and porcine epidemic diarrhea

(PED) often cocirculate. In densely swine-populated areas, such as the midwestern United States, the disease is one of the major causes of morbidity and mortality in young pigs. The disease has not been diagnosed in Australia and New Zealand. In 1990, the prevalence of infection in the United Kingdom was low, with 0.6% of sows sampled being seropositive compared with 3% in 1984. No major epidemics have occurred since 1981. In 1984, a seroconversion to the TGE virus occurred in a closed herd in the absence of any clinical disease. The TGE virus was not isolated, and it is possible that the seroconversion resulted from the emergence of PRCV throughout Europe and the United Kingdom beginning in 1986. PRCV is a deletion mutant of the TGE virus, and its high rate of prevalence has markedly reduced the number of TGE outbreaks in European swine herds. The TGE virus probably coexists in these herds together with PRCV. In 1999, a single case was diagnosed in East Yorkshire as a one-off. Other isolated outbreaks in herds that were seropositive for PRCV were also reported. An outbreak of TGE occurred in the United Kingdom in 1996 in which the virus was a variant with an intact spike gene but with a large deletion in ORF 3a, which therefore may not be necessary for enteric virulence.

The **prevalence of infection** with the TGE virus based on serological surveys of swine herds varies with the size of the herd, the distance between herds, and the purchase of breeding stock from nonspecific pathogen-free herds. Depending on the geographical location, up to 50% of herds may be seronegative, and in 45% of herds, the prevalence of infection in sows will vary from 10% to 80%. In the United States in 1990, a national survey of swine herds found that 36% of herds were positive for the TGE virus, and 24% of the producers' herds were vaccinated for the virus. By 1997, up to 100% of surveyed herds and 91% of the sampled sera were positive for both the TGE virus and PRCV, which indicates a marked increase, probably as a result of subclinical infections.

The disease is highly contagious and affects piglets primarily under 10 days to 2 weeks of age. Pigs over 5 weeks of age often have milder clinical signs. **Epidemic TGE** occurs when the virus is first introduced into a susceptible herd and is usually of short duration and no longer clinically evident after herd immunity develops. Epidemics of the disease occur most commonly during the winter months. **Endemic TGE** occurs when the virus persists in a partially immune herd into which susceptible swine are introduced or if the epidemic form is not well managed. Endemic TGE is a common sequela to a primary epidemic in herds of more than 300 sows in which diarrhea occurs in piglets from 6 days of age to approximately 2 to 3 weeks after weaning. Recurrence of clinical TGE often occurs in endemically infected herds approximately 9 months after the first outbreak as the piglets of susceptible sows are exposed to the virus. Recurrence has been associated with the following factors:

- Breeding herd sizes of over 100 sows
- Presence of finishing pigs in large herds
- Introduction of purchased gilts

Morbidity and Case Fatality

Typically, an epidemic in a herd is explosive and dramatic. Rapid spread and high morbidity occur in pigs of all ages within 2 to 3 days, but major clinical disease is restricted to pigs prior to weaning and lactating sows. Case-fatality rates can approach 100% in pigs under 10 to 14 days of age but are much lower with increasing age, and mortality is low in postweaned and adult pigs. The epidemic commonly terminates in 3 to 5 weeks with the loss of young, susceptible pigs and the development of herd immunity, and, generally, the disease does not recur again for a 3- to 6-year period.

Risk Factors

Animal Risk Factors

Level of Herd Immunity. Epidemics of clinical disease occur following the introduction of the virus into a **susceptible herd with no previous exposure** to the virus. All age groups will become infected, and most pigs will be affected clinically to variable degrees. Nursing piglets under 2 to 3 weeks of age are most susceptible to clinical disease and experience the highest case-fatality rate. Clinical disease disappears when the herd becomes immune. Endemic TGE develops when the virus and clinical disease persist within partially immune herds, as a result of continual or periodic introduction of susceptible pigs. In endemic situations, diarrhea is generally observed in pigs from the age of approximately 6 days until approximately 14 days after weaning. Overall pig mortality is lower and generally occurs in recrudescent episodes. After weaning, piglets no longer have the protection provided by TGE-specific secretory IgA antibody in milk and are susceptible to infection and clinical disease if the infection rate in the weanlings is high. Thus, weanling pigs serve as a major reservoir of infection.

Sow parity may be a risk factor. Parity-1 sows with no previous exposure to the virus may be a risk factor on some farms. On other farms, parity-3 sows were at increased risk for unknown reasons. A single boar may be a high-risk animal on some farms.

Herd Size. There is a higher likelihood that sows will be seropositive if the herd size exceeds 500 sows and if more than 25 replacement breeding animals are purchased from nonspecific pathogen-free herds. A mathematical model of the detection and dynamics of the disease in Australia indicates that the disease is likely to be established in breeding and finishing swine herds of average size. The threshold number of susceptible pigs for establishment of the infection is 90 to 160. Swine herds most at risk are those with large numbers of susceptible pigs, continuous breeding of susceptible pigs, high numbers of purchased pigs, and close contact between feral pigs and susceptible domestic pigs. The risk is highest in herds that do not receive a rapid diagnosis, such as when there is little or no veterinary involvement in health and disease management. In small farms (containing 15-40 sows), outbreaks of TGF are characterized by rapid spread of infection to most animals of all ages but a duration of only 3 to 5 weeks.

Environmental and Management Risk Factors

Climatic factors appear to be important in the occurrence and establishment of the disease. Climate does not yet have significance in the tropics or southern hemisphere, and there is evidence that spread of the disease is limited in hot climates. In areas where the disease is endemic, it has a distinct seasonal occurrence, with the majority of outbreaks occurring from midwinter to spring, and cyclic occurrence has been recorded. The virus is labile above 21° C and is very sensitive to sunlight. It is also killed by most disinfectants. The disease tends to occur in area outbreaks in which herds in close proximity are affected within several weeks. Within swine barns, the location of the farrowing crates may be a risk factor if the cold-air inlets are directly above the crates.

The use of a continuous-flow system of production in a herd is a major risk factor. The constant overlap of farrowing sows in farrowing rooms, overlap of weaned pigs in nursery rooms, and a continuous flow of finishing pigs without adequate cleaning and disinfection between each group of pigs are major risk factors and perpetuate persistent infection and the endemic form of the disease. An all-in, all-out system for each group of pigs reduces the risk of infection between pigs.

Lack of adequate biosecurity is a major management risk factor. Infection can be introduced into herds by the importation of infected breeding stock, by contaminated trucks and other vehicles, or on workers' clothing and boots.

Pathogen Risk Factors

The virus has a long survival in slurry, water, and sewage. It is readily destroyed by standard solutions of phenol and formalin, by boiling, and by drying but not by freezing. The virus is highly photosensitive, which may account for the more frequent occurrence of the disease during the winter and spring months. The virus survives freezing, and infected pork scraps or offal may provide

a source of infection either directly through feeding of uncooked garbage or possibly indirectly via dogs. Purposeful infection by the feeding of frozen infected piglet intestine to sows to induce immunity can also be a significant source of continued infection of a herd or area.

The genome and the genetic basis for the pathogenesis of the virus have been described. Antigenic differences between TGE viruses have been examined, and the nucleotide sequences of isolates from various countries have been compared.

The TGE virus is not antigenically related to the two other porcine coronaviruses, hemagglutinating encephalomyelitis virus and porcine epidemic diarrhea virus, but it is related to PRCV.

Porcine Respiratory Coronaviruses

PRCV is a deletion mutant of the TGE virus with altered tissue tropism to the respiratory tract, first recognized in Belgium in 1984. It has a partially deleted receptor binding protein. The virus closely resembles the TGE virus antigenically, and pigs infected with PRCV develop a serological response that cannot be distinguished by virus-neutralization tests from the response of pigs infected with the TGE virus. In other words, it provides cross-protection. Infection with PRCV produces high levels of interferon and nitric oxide in the lungs.[4,5] Despite the antigenic relation of PRCV and the TGE virus, they can be differentiated with monoclonal antibodies. All PRCV strains have around 600 to 700 nucleotide (nt) deletions within the amino-terminal S gene, resulting in the loss of hemagglutination activity and two antigenic sites. European PRCVs have an identical deletion of 672 nt at the same position, whereas U.S. strains have 621 to 681 nt deletions located at different positions, which suggests that they arose separately. Natural infection of the sow with PRCV induces natural antibodies that neutralize classic TGE. The virus has spread throughout Europe and has been identified in the United States and Canada. Spread of the virus has been explained in part by airborne transmission, and infection shows a seasonal pattern, affecting farms during winter and spring. Seroprevalence studies in Belgium indicate that 95% of sows are PRCV positive. Nearly all piglets are infected by 10 to 15 days of age. The infection is widespread in swine herds in Spain. The risk factors associated with seropositivity in Danish swine herds include (a) increasing herd size, (b) certain geographical locations, (c) presence of a slurry system with slatted floors, and (d) purchase of pigs. The serological status of neighboring herds is also a risk factor; closeness of a seropositive herd has been associated with an increased risk of a herd becoming serologically positive.

PRCV replicates in the respiratory tract of pigs and to a very limited extent in the intestines.[6,7] Its pathogenicity is controversial. Some studies indicate that the virus causes only subclinical respiratory infections, whereas others have linked the virus with field outbreaks of respiratory disease. Experimentally, inoculation of the virus intratracheally into 8-week-old piglets resulted in clinical respiratory disease and bronchointerstitial pneumonia, and the virus was recovered from the respiratory tract. Some isolates of the virus produce interstitial pneumonia in neonatal piglets with no recognizable clinical respiratory disease. The administration of dexamethasone will produce severe lung lesions,[8] as will concurrent infection with porcine reproductive and respiratory syndrome virus (PRRS). In a recent study in Japan, it was shown that most pigs are seropositive for PRCV, but TGE is present on some of the farms.[9]

Methods of Transmission

The exact mode of transmission of the TGE virus is uncertain. Virus shedding in the feces of infected pigs usually ends at or within a few weeks of recovery, although recovered pigs may harbor the virus in pulmonary or intestinal tissue for periods of more than 100 days. The shedding period is thought to be 14 days. After weaning, the pig is no longer protected by specific secretory IgA antibody of the sow's milk and is highly susceptible to infection if the rate of infection is high in the weanling population. The weanling pig is a major reservoir of infection for continuous infection in the herd. Feeder pigs with no clinical signs can be an important reservoir of the virus. The virus has also been isolated from pharyngeal swabs taken from farm-raised sows sent to slaughter.

Epidemics commonly follow the introduction of pigs into a herd, and the carrier pig is a major source of infection. Frequently, the disease first appears in older pigs in the herd and then subsequently spreads to newborn pigs and sows in the farrowing area. **Spread is much more rapid in a continuous-flow system of production compared with an all-in, all-out system, whereby groups of pigs of the same age or production stage are handled as groups and their housing facilities are cleaned and disinfected before and after being occupied.** Visitors and their boots, transport vehicles, equipment, and starlings have also been incriminated in the transfer of infection to new locations. Starlings may act as vectors in spreading the disease to adjacent farms. The virus can also multiply in houseflies (*Musca domestica*), and they may be a vector. Feral pigs are not a significant reservoir for the TGE virus in the southern United States but are capable of becoming infected and developing virus-neutralizing antibodies against the virus. Subpopulations of infected pigs may exist within the herd, and although shedding normally lasts for 14 days, it is possible for animals to be infected for 100 days.

Once the infection has gained access to a herd, transmission occurs by both oral and respiratory routes. The speed of spread without direct contact indicates that the virus can be spread by aerosol. Respiratory transmission appears significant in adults, and replication in the respiratory tract is followed by excretion in nasal secretions and milk within 1 day of infection and also in feces. Excretion in milk results in rapid transmission to suckling piglets, which in turn may excrete large quantities of the virus within 2 days of infection.

Immune Mechanisms

Immunity to clinical disease in newborn piglets is dependent on the level of TGE-specific secretory IgA antibody in the colostrum of the sow and is known as **lactogenic immunity**. When pregnant sows are infected orally with the virulent TGE virus, specific IgA precursor cells are sensitized in the intestine. These sensitized cells migrate to the mammary glands and differentiate into plasma cells that secrete IgA-class TGE virus antibody in colostrum and milk. This immune mechanism to induce protective antibody for suckling pigs is termed the *gut–mammary gland link* or the *gut-associated lymphoid tissue* (GALT) system. Following natural infection with TGE during pregnancy, the recovered sow or gilt is capable of protecting her litter against the disease. After farrowing, the colostrum contains antibodies of the IgG, IgM, and IgA isotypes derived from serum. After the third day, milk is produced, and the only antibody it contains is the IgA antibody, which is synthesized in the mammary gland. The IgA antibodies of immune sows are the most critical in the protection of mucosal surfaces such as the gastrointestinal tract, and this immunoglobulin is the most abundant isotype in porcine milk. These IgA antibodies are not induced after the parenteral administration of viral antigens, which explains the relative ineffectiveness of parenteral vaccines. Serum antibody induced by vaccination of the pregnant sow does not provide protection of piglets through colostrum or milk.

Secretory IgA is the predominant antibody class in milk and is responsible for lactogenic protection of pigs and active protection of the intestine. It is stimulated by oral inoculation with nonattenuated TGE virus, but it is not associated with attenuated TGE virus. Although high concentrations of IgA and IgG originating from the serum are present in colostrum, IgG does not persist in the milk, whereas IgA does persist because of local mammary secretion. After the first week of lactation, secretory IgA constitutes 50% to 60% of the total immunoglobulin concentration in swine milk, and IgG makes up 20% to 30%.

Suckling pigs are protected from infection by continued ingestion of antibody of the IgA class secreted in milk. The level of

serum IgA antibody as an indicator of immunity to transmissible gastroenteritis can be measured using the indirect immunoperoxidase antibody test. Young pigs of 6 weeks of age that are exposed to experimental infection with the virus develop both a humoral and cellular immunity, which reach peaks at 21 and 28 days, respectively.

In recent years, less typical forms of the disease have been observed. With continuous farrowing and the continual introduction of susceptible pigs into an infective environment, outbreaks may be considerably prolonged, and prolongation or recrudescence is more likely than when pregnant sows are kept in relative isolation on pasture or elsewhere. Atypical endemic forms of the disease with a low morbidity and mortality and frequently with the onset of clinical disease delayed until piglets are 2 to 4 weeks of age have been observed and may go unrecognized because of the atypical clinical findings. They are more likely to occur in large continuous-farrowing units and may be associated with partial herd immunity and low-virulence strains. Some sows do not develop a significant immunity following a single infection, and in large herds, there may be a sufficient number of these to allow the disease to perpetuate in a low-incidence, endemic form.

A recrudescence of the disease may occur after a period of several months and is thought to result from inadequate exposure and immunity of some pigs, particularly dry stock during the initial outbreak followed by reinfection from a carrier pig. Recrudescence of clinical disease is usually of much shorter duration than the primary outbreak and commonly lasts only 6 to 10 days. The periods of recrudescence are commonly precipitated by the simultaneous farrowing of several susceptible gilts in the same farrowing room. Of greater long-term concern is that approximately 50% of some large herds continue to experience clinical recrudescences for almost 2 years or more. The endemic form of the disease appears to be correlated with herds of more than 100 sows and herds in which finishing pigs were kept. In large herds, the virus may spread more slowly, and replacement gilts entering the herd may take several months to become infected and to seroconvert. In large herds, the rapid turnover of breeding stock, continuous farrowing, and early weaning also contribute to the perpetuation of an endemic infection, and thus TGE can maintain itself through the slow and incomplete spread of the virus among adult pigs, particularly herd replacements. Joint infection with PRRS and TGE does not appear to affect the clinical effects, shedding, or persistence of either virus.

Economic Losses

A herd epidemic of TGE causes economic losses through the following routes:

- Death of pigs
- Increased downtime of the swine enterprise
- Increased labor
- Disturbance of the breeding program
- Subsequent reduced growth of young pigs destined for slaughter
- Curtailed performance of older pigs

The economic losses can be very large. Simulation of the economic losses resulting from an outbreak of disease in Australia, where the disease is exotic, estimated a reduction in net revenue of 70% in the 6 months after a moderate outbreak (50% mortality of piglets under 1 week of age) and 100% for a severe outbreak (95% mortality of piglets under 1 week of age). An analysis of the economic losses resulting from the disease in swine farms in some areas in the United States over a 2-year period estimated the average loss to be between 13% and 18% of the average return earned above total production costs. It has been assumed that the growth of surviving pigs was depressed by 10% and their feed conversion by 18%, but pigs surviving or born shortly after an epidemic of TGE are profitable to raise.

PATHOGENESIS

The S protein of the viral membrane of the TGE virus (TGEv) has four major antigenic sites and is the major inducer of neutralizing antibodies. The protein mediates the binding of the virus to the cell surface and the subsequent fusion of the viral and cellular membranes.[3] High titers of serum IgG and virus-neutralizing antibody to TGEv probably reflect the amount of S protein the pig has received. Two different ligands have been shown to interact with the S protein, and binding to the porcine aminopeptidase N, the cellular receptor for TGEv, is essential for infection of the cells. TGEv is also able to recognize sialic acid residues and attach to sialylated macromolecules. A second binding site on the N-terminal division of the S protein allows TGEv to interact with terminal sialic acid residues on glycoproteins or glycolipids and to agglutinate red blood cells (RBCs). TGEv also recognizes a porcine intestinal brush-border protein called mucin-type glycoprotein (MEP), and TGEv binds to this mucin produced by goblet cells. A mutant virus that has lost its sialic acid binding capability is not pathogenic because it is unable to attach to goblet cells. Sialic acid binding activity is a pathogenicity factor for TGEv, and it is important to note that the sialic acid binding sites for TGEv and *Escherichia coli* are different.

The virus infects the upper respiratory tract and the intestines, but the major clinical effects result from intestinal infection. Following oral challenge of susceptible piglets, the incubation period may be as short as 24 hours. After 12 to 24 hours, there is massive necrosis, and no enzyme activity in the epithelium remains. The virus infects mature differentiated columnar epithelial cells of the intestinal villi but not the undifferentiated cells of the crypts. Replication occurs within 4 to 5 hours, with sloughing of the infected cells and release of the virus, and after several replication cycles, there is a marked reduction in villous size with villous atrophy. The loss of epithelial cells results in increased migration of undifferentiated cells from the crypts to line the shortened villi. With virulent virus, epithelial cells at all levels of the small intestine are infected, with major lesions occurring at the proximal jejunum and, to a lesser extent, at the ileum. In most cases, the duodenum is not affected. The lesser virulence of attenuated strains of the virus may be associated with their inability to infect and produce lesions in the villi of the more cranial portions of the jejunum. Gnotobiotic pigs inoculated orally with a TGE vaccine will develop lesions similar to those in the naturally occurring disease.

Diarrhea results from a combination of malabsorption, the osmotic effects subsequent to the loss of intestinal surface area and disaccharidase activity, and impaired lumen-to-extracellular fluid flux of sodium caused by the occurrence of undifferentiated cells lining the stunted villi. The virus invades the villus, but not the crypt epithelium of the small intestine, within hours after experimental administration. The infected villus cells are quickly shed and replaced by relatively undifferentiated enterocytes. As infected cells are shed, the epithelium proliferates, and migration of cells from the crypts accelerates. There are marked abnormalities in ion transport function in the jejunum and ileum at the peak of the diarrhea. There is a failure of the intestine to actively transport sodium and chloride, and there is a defect of glucose-mediated sodium ion transport. Macromolecular hyperpermeability of the small intestine also occurs, but its significance is uncertain. Experimentally induced infection of 3-week-old pigs results in villous atrophy, crypt hyperplasia, and a marked decrease in the secretory response of the villous epithelium to *E. coli* enterotoxins. The disease is more severe in gnotobiotic pigs that are infected with *E. coli* in addition to the TGE virus, suggesting that bacterial factors also influence the severity of the diarrhea.

In the experimental disease in 2-day-old pigs, vomiting and diarrhea occur 12 to 24 hours after oral inoculation of the virus, and affected piglets are moribund 1 or 2 days later. Before becoming moribund, most piglets become lethargic and comatose. In addition to dehydration and metabolic acidosis, there is a severe hypoglycemia resulting from a combination of inadequate glucose metabolism inherent to neonatal piglets and the acute maldigestion and malabsorption from the diffuse and severe villous atrophy. The high death rate is attributable to a combination of dehydration, acidosis, and severe hypoglycemia.

The age-dependent resistance to TGE can be explained in part by a decreased susceptibility of the epithelial cells of older pigs to infection and by an increased proliferative capacity of crypt cells with much more rapid

regeneration of atrophic villi in pigs over 2 weeks of age. It may be that the virus has developed strategies to evade apoptosis in intestinal enterocytes by producing huge amounts of the virus.

A recent experiment comparing a Korean strain with two U.S. strains showed that the progression of the Korean virus was much slower (i.e., much less virulent), possibly because there was only replication in the ileum and jejunum, whereas the U.S. strains also replicated in the duodenum. The more virulent strains attack a wider area of enterocytes. Most only attack the villous rather than the crypt enterocytes. An outbreak of reduced-virulence TGEv was associated with the presence on the farm of three strains of PRCV that had variable-sequence changes in ORF 3, 3a, and 3b.

CLINICAL FINDINGS

In a primary or epidemic outbreak, the clinical findings of typical acute TGE are characteristic. The appearance of the disease is not significantly altered by a concurrent infection with PRRS. Sows may become ill when lactating and may develop anorexia and agalactia, further contributing to piglet mortality.

Piglets

After an incubation period of 18 to 72 hours, there is a sudden onset of vomiting and diarrhea. The diarrhea is profuse and frequent; the feces are watery and usually yellow-green in color. The feces may contain clots of white undigested milk and have an offensive odor. The vomitus is yellow, foamy, and slimy. There may be a transitory fever, but in most cases the temperature is normal. Depression and dehydration are pronounced, the hair coat is ruffled, and weakness and emaciation progress to death on days 2 to 5. Some piglets may continue to suck to within a few hours of death; those that survive are severely emaciated and gain weight slowly. The illness may commence as soon as 24 hours after birth. It is not uncommon on an individual farm for the disease to become less severe (endemic), and in these cases, it resembles rotavirus infection and spreads more slowly with the passage of time.

Older Pigs

In older pigs, there may be signs similar to those that occur in piglets, but many animals become infected without clinical abnormalities. Diarrhea may occur first in the dry sows. In older pigs, recovery is much more likely to occur, with the illness lasting for up to 10 days. Lactating sows may or may not be affected clinically. Fever and inappetence occur, with or without diarrhea, and agalactia is a common complication in sows. In endemically affected herds with continuous farrowing and partial sow immunity, the disease is milder, with diarrhea affecting piglets approximately 6 days of age or older and diarrhea in weaned pigs. Brief periods of clinical disease occur in some parts of the herd, mortality is low, and affected pigs subsequently grow poorly.

CLINICAL PATHOLOGY

Serum Biochemistry

Severe dehydration with metabolic acidosis and marked hypoglycemia is common.

Detection of the Virus

TGE virus can be grown in pig kidney (PK) cells and PRCV in PK cells and swine testicle cells.

The virus can be detected in the mucosal scrapings and feces using an enzyme-linked immunosorbent assay (ELISA), immune electron microscopy, fluorescent antibody staining, or the immunoperoxidase test. A capture-enzyme immunoassay has also been developed. A reversed passive hemagglutination test for detection of the virus in feces is also available. A solid-phase immune electron microscopic technique for detection of the virus in feces is also useful for diagnosis in living animals. PRCV can be isolated by tissue culture.

DNA Probe

DNA probes can differentiate PRCV from TGEv. Polymerase chain reactions (PCRs) were described quite early on for identifying TGE. The real-time PCR (RT-PCR), a rapid RT-TaqMan, has been shown to be a very good sensitive test for TGEv in pig fecal samples.[10] Tests are now available to differentiate PRCV from TGEv.

In situ hybridization (ISH) has been described, and a nested RT-PCR has been developed that is very sensitive. A multiplex RT-PCR for differentiating the PED virus (PEDv) from TGEv in clinical samples has been described. It has also proved possible to use formalin-fixed tissue for multiplex PCR, nested-PCR, and ISH with 100% conformity.

A multiplex RT-PCR has been developed for the simultaneous detection of both TGEv and PEDv.[11] A multiplex microassay can be used for the rapid differential diagnosis of eight viruses, including TGEv.[12]

Serology

Several serological tests can detect and measure antibody to the virus in live animals. The serum neutralization test is sensitive and reliable, but it is time-consuming and requires facilities for cell culture techniques. Neutralizing antibodies appear in the serum 7 to 8 days after infection and persist for at least 18 months. An ELISA is more sensitive than the virus neutralization test, and a competitive ELISA differentiates between TGEv and PRCV. A blocking ELISA to differentiate TGEv and PRCV has also been described.[13,14]

NECROPSY FINDINGS

The lesions are confined to the intestine and stomach, although he changes may be minor in many field outbreaks and in the experimental disease. The intestinal wall is thin and translucent, and the intestine is distended with fluid ingesta. Despite the presence of milk in the intestine, there is little evidence of fat absorption in the draining lymphatics. The important histopathological change is atrophy of villi with failure of epithelial cell differentiation in the small intestine. The atrophy is evident 24 hours after infection, and regeneration occurs 5 to 7 days later. The marked reduction in the size of intestinal villi may even be detected at low magnification with a stereomicroscope. In the stomach, there may be engorgement of vessels and necrosis of the epithelium deep in mucosal crypts. No inclusion bodies are detectable. When secondary pathogens contribute to the disease, there may be inflammatory lesions in the intestines. In chronic cases, a thickening of the intestinal wall identical to that seen in terminal (regional) ileitis has been described.

In Europe, the disease is characterized by more severe mucosal lesions, often including fibrin exudation. There is also degeneration of the heart muscle and, in some cases, of the skeletal muscle.

A simple test for the presence of intestinal lactase in intestinal washings may assist in the laboratory diagnosis. Examination of frozen sections of jejunum from acutely ill piglets by the fluorescent antibody technique is a rapid and effective method for the detection of virus in tissues. The intestine may be segmentally affected, so multiple areas must be sampled. Viral antigen is detectable for only 24 to 36 hours when utilizing most fluorescent antibody (FA) conjugates. This makes the selection of acute cases critical. Electron microscopy is often utilized to identify the presence of coronavirus, but this method is not specific for TGEv. PCR methods for TGEv detection are being developed, and immunohistochemical techniques are available for use in formalin-fixed tissues.

The use of apoptotic markers shows that most of the cells are undergoing apoptosis but are not infected with TGEv; they are termed *bystander cells*. It has been previously suggested that apoptosis does not occur in the enterocytes of piglets infected with TGEv. An accumulation of interferon-alpha-producing cells occurs in the GALT of TGEv-infected piglets. It has been suggested that these are the mucosal counterparts of the dendritic cells recently shown to produce interferon (IFN) alpha after in vitro viral induction. The TGEv challenge of pigs produces an increase in CD4+/CD8+ cells, an increase in natural killer cells and cytotoxic T cells, an increase in the expression of IL-2 receptors, and a decrease in null cell phenotypes.

Samples for Confirmation of Diagnosis

- **Histology**—several segments of jejunum and ileum, stomach (LM, IHC)
- **Virology**—several segments of jejunum and ileum (FAT), feces (EM)

DIFFERENTIAL DIAGNOSIS

The epidemiological and clinical characteristics of transmissible gastroenteritis (TGE) should make possible a presumptive diagnosis, but confirmation must depend on the finding of compatible histological lesions, the detection of antigen, transmission experiments, and evidence of seroconversion. It is unusual to encounter outbreaks of diarrhea in piglets that appear to be typical of TGE where there is porcine respiratory coronavirus (PRCV) on the same farm. Either the virus can be demonstrated in the tissues by fluorescent antibody test (FAT), but serum antibodies cannot be detected in the breeding animals; or serum antibodies can be detected in the adults, but the virus cannot be demonstrated in the tissues by either immunofluorescence or tissue culture.

Villous atrophy is not pathognomonic for the disease because it occurs in 3-week-old piglets affected with diarrhea and steatorrhea, in rotavirus infections of piglets, in coccidiosis, and in some herds for undetermined causes immediately following weaning. In some instances, diagnosis in suckling or recently weaned pigs is difficult.

In piglets, TGE must be differentiated from the following:

- **Enteric colibacillosis** A common disease of piglets under 10 days of age with profuse diarrhea, no vomiting, dehydration, and a good response to therapy if treated early.
- ***Clostridium perfringens* type C** Enterotoxemia occurs in piglets under a few days of age and causes marked depression, diarrhea, dysentery, reddening of the anus, and rapid death. Lesions at necropsy are characteristic.
- ***Clostridium perfringens*** type A
- ***Clostridium difficile***
- **Coccidiosis** Affects newborn piglets 5 to 15 days of age, causing profuse diarrhea, depression, dehydration, and unthriftiness. Affected piglets may continue to suck. There is high morbidity, low mortality, and oocysts in the feces.
- **Rotavirus enteritis** Rotavirus causes diarrhea in suckling and weaned piglets, with a high morbidity and low mortality. Most affected piglets recover in a few days, and epidemics are commonly associated with continuous farrowing.
- **Porcine epidemic diarrhea** A coronavirus-like virus causes diarrhea in pigs similar to that in TGE, except much less severe and with reduced mortality. **Porcine epidemic diarrhea type I** causes diarrhea only in pigs up to 4 to 5 weeks; whereas porcine epidemic diarrhea type II causes diarrhea in pigs of all ages. The morbidity may reach 100%, but mortality is low. The disease may start in the finishing pigs and spread rapidly to pregnant sows and their nursing piglets. The diarrhea may persist in the 6- to 10-week-old pigs, and seronegative gilts introduced into the herd may become infected and develop profuse diarrhea lasting a few days. The recent strains appearing in Korea, Vietnam, China, and now the United States are much more similar to TGE.
- **Vomiting and wasting disease** Affects piglets under 10 days of age in epidemics similar to TGE. However, vomiting is characteristic, diarrhea is not a feature, and laboratory differentiation is necessary.

In adults (gilts, sows, and boars), TGE must be differentiated from diarrhea resulting from the following diseases:

- Swine dysentery
- Salmonellosis
- Porcine proliferative enteritis

TREATMENT

There is no specific treatment, but good husbandry in the form of warm, dry, draught-free conditions with ad lib water and nutrient provision helps. Treatment aims at alleviating starvation, dehydration, and metabolic acidosis, which result in hypoglycemia. Treatment with fluids and electrolytes containing glucose is indicated. Because there is loss of intestinal villi and the enzyme lactase, the ideal treatment would be to reduce the intake of milk for up to 5 days and administer a glucose–glycine–electrolyte solution orally every few hours to maintain hydration. However, removal of affected piglets from the sow is impractical and not recommended. Oral fluid therapy should improve the survival rate, with affected piglets recovering in a few days following treatment. In experimentally induced TGE, removal of the milk diet and the use of an oral glucose–glycine–electrolyte solution plus a 5% dextrose solution given intraperitoneally at the rate of 25 mL/kg body weight (BW) once daily decreased the severity of the diarrhea, dehydration, and metabolic acidosis but did not prevent or significantly improve the renal failure and severe hypoglycemia. A newborn piglet weighing 1.25 kg has an energy expenditure of approximately 170 kcal/d (711 kJ) if maintained at 30°C (86°F); 30 mL of a 5% dextrose solution supplies 1.5 g of glucose for a total of approximately 5.6 kcal/d (the gross energy of glucose is 3.74 kcal/g). Because the volume of 5% dextrose solution injected daily into piglets should not exceed 8% of their body weight, it is unlikely that the hypoglycemia can be prevented or treated.

The use of natural human interferon given orally to piglets 1 to 12 days of age affected with the disease increased survival rates compared with placebo-treated piglets.

CONTROL

Endemic infection will persist as long as susceptible or partially immune sows are exposed to the virus.

Control of the disease is complex because it is so highly contagious and because of the dynamics of infection between the different age groups of animals within large swine herds. Although there is considerable information available about the biology of the virus and the nature of the disease, there is little documented reliable information about the control in a swine-breeding herd. Most of the recommendations for control are empirical and based on clinical experience without any controlled field trials to evaluate the different strategies. The following guidelines for the control of TGE are based on the characteristics of the virus and the disease:

- The disease is highly contagious and spreads rapidly between groups of pigs in a herd. Most epidemics last 6 weeks.
- Newborn piglets are highly susceptible to disease if the sow's milk does not contain specific TGE secretory IgA antibody.
- Infection of pregnant sows with the virulent virus results in protective immunity for their piglets. Recovered sows are immune, usually do not harbor or shed the virus, and need not necessarily be culled.
- Weaned pigs are a major reservoir of infection in farrow-finish herds.
- Vaccination of pregnant sows with any of the available vaccines is not as effective as natural infection in providing protection for piglets.
- The disease is controlled either by elimination of the virus from the herd or by controlled natural immunization and use of the all-in, all-out system of production.

Control During and After an Outbreak

The highly contagious nature of the disease makes the immediate control of an outbreak in a herd virtually impossible. Epidemics usually last approximately 6 weeks, during which time many piglets die, and the herd eventually becomes immune. Successful control depends on planning and implementation of certain strategies, which must be understood and implemented by the producer and monitored by the veterinarian. Failure of the producer to fully understand or accept the diagnosis and apply the principles of control will result in failure to control the disease and the persistence of an endemic form of the disease in the herd. Several strategies are used to control the infection pressure and to enhance immunity where possible.

Isolation of Sows Due to Farrow

To avoid further new infections of newborn piglets, sows due to farrow within 2 to 3 weeks should be isolated under strict hygienic conditions. However, this is usually impractical in most intensive swine production enterprises, where isolation facilities are usually not available. The disease is so highly contagious that isolation is ineffective. There should be no movement of pigs between the farrowing or nursery rooms. An all-in, all-out system for movement of pigs,

especially in the farrowing rooms and nurseries, with complete cleaning and disinfection between groups should be established (see later discussion of all-in, all-out practices).

Discontinuation of Breeding Stock Sales and Purchases

Once a diagnosis of TGE has been confirmed in a breeding herd that sells breeding stock, all sales should be discontinued. Likewise, all purchases of breeding stock from other herds should be discontinued for a few months until the epidemic has subsided and the future production plans of the herd, including disease control, are reviewed.

Partial Depopulation and Culling

If possible and feasible, all weaned pigs ready for finishing units should be moved off the farm to contract finishing units. This allows for a general cleanup of facilities, a break in the production cycle, and an intensive all-in, all-out system. All culled pigs should be destroyed to prevent a reservoir of pigs actively shedding the virus.

Planned Exposure to Virulent Virus

To minimize the duration and severity of the outbreak, all pregnant sows due to farrow more than 3 to 4 weeks ahead should be given an inoculum of virulent TGEv obtained from virus-infected intestines, ideally from piglets in which the disease began within the last 12 to 24 hours. The piglets should be submitted for necropsy and TGE confirmed by a diagnostic laboratory. It cannot be assumed that all piglets that die in an epidemic of TGE will be infected with the virus. The intestines of the confirmed cases should be homogenized in special media and centrifuged, and supernatants should be poured into capsules and frozen for storage. The contents of the capsules are then thawed and poured onto the feed of the sows. The inoculum is given daily for 3 days. Preparation and use of the inoculum will ensure adequate uniform inoculation of sows, compared with earlier recommendations to feed feces and intestines of piglets that died of the disease to the other pigs. More inoculum can be prepared by inoculating weaned piglets in isolation and collecting their small intestines 1 to 2 hours after onset of diarrhea, which is usually 16 to 21 hours after inoculation. The boars are also fed the inoculum. An alternative to the inoculum is to mix the intestines from two affected piglets in 25 L of water and feed 50 mL of the solution daily for 3 days.

If there is sufficient time for immunity to develop, the piglets born 3 to 4weeks later will be protected through the colostrum and milk, which will contain the TGEv-specific IgA antibodies. Piglets sucking such sows are resistant to infection while sucking, but they become fully susceptible if transferred to a nonimmune sow. Natural infection by mouth produces a high level of secretory antibody, particularly IgA, in the colostrum and milk, whereas vaccination produces a good IgG response but a much lower IgA response. The newer recombinant vaccines have also been shown to be immunogenic but are still not able to produce lactogenic immunity.

An alternative to the feeding of infectious material to pregnant gilts and sows is vaccination using the available vaccines. The gilts, sows, replacement stock, boars, and newborn piglets are vaccinated according to the indications of the vaccines used. However, the efficacy of the vaccines is questionable. Over the last two decades, the aim has been to produce TGEv protein subunit vaccines. The most novel approach has been to feed recombinant immunoproteins (capable of neutralizing TGEv in vitro) to confer protective immunity.[15]

Biosecurity and Acquisition of Replacement Breeding Stock

Following recovery from an epidemic in a herd, replacement breeding stock should be introduced as a group at one time and exposed to animals in the herd, monitored for clinical disease, and tested. Serological testing using paired sera at 30 and 60 days after entry will indicate seroconversion to the virus. The usual precautions to prevent transmission of infection between units of the herd and between herds are necessary, including the following:

- Washing of boots
- Sanitation of trucks
- Use of separate clothing for each unit of large herds
- Showering of personnel moving between units

Washing hands and changing into clean outerwear or showering and changing into clean outerwear after being in contact with TGEv-infected pigs was found to be sufficient to prevent mechanical transmission of TGEv to susceptible pigs.

All-in, All-out Management System

The all-in, all-out management and production system is based on the principle of handling, feeding, and housing pigs in small subgroups as they move through the various stages of production. These subgroups either remain free of certain infectious agents, if absent, or all animals in the group become infected and immune to the infectious agents that are present in some pigs and transmitted to others in the subgroup but not to other subgroups. With this system, breeding gilts and sows are handled and bred as subgroups, kept in the gestation units as subgroups, farrowed as subgroups, and nurse their pigs as subgroups. The pigs are weaned as subgroups at the same time, the weaned pigs are placed in the nursery facilities as a subgroup at the same time, and all of the pigs are moved out of the nursery to the finishing facilities at the same time. The pigs are handled in finishing units as subgroups, and all pigs are marketed as a subgroup. At each stage of production, the housing facilities should be cleaned and disinfected following removal of the pigs and left vacant for a few days before a new subgroup of pigs is introduced into the previously cleaned rooms. This system avoids the mixing of pigs back and forth between groups and ages, which is often done to maintain uniformity of size and age of pigs. During an epidemic, the use of a strict all-in, all-out system in the farrowing and nursery units will aid in the control of clinical disease. Approximately 2 months after the epidemic and the absence of clinical disease, sentinel seronegative pigs of 2 to 4 months of age can be introduced to each part of the herd and monitored serologically for evidence of viral activity.

Complete Depopulation and Repopulation or Establishment of New Herd

In some situations where the disease cannot be controlled, complete depopulation of the herd is the best option. This should be followed by repopulation with breeding stock derived from specific pathogen-free herds or minimal disease-free herds that are known to be free of the virus. Serological testing can be used to test the animals before they are moved into the facilities. The establishment of new swine herds now commonly depends on the acquisition of breeding stock from disease-free herds.

TGEv Vaccines and Vaccination

In many instances, TGEv vaccines do not provide reliable, complete protection for suckling pigs against a challenge exposure. However, priming piglets with PRCV was shown to be very beneficial in providing resistance to TGEv and also resulted in a much better maternal antibody response.

Vaccination of Pregnant Sows

Because of the effectiveness of acquired immunity following natural infection, vaccination of the pregnant sow would appear to be the method of choice for control of the disease. However, the available vaccines have not been efficacious enough to be a reliable control strategy. Circulating virus-neutralizing (VN) antibodies, acquired actively or passively, provide insufficient protection against clinical disease, and parenteral vaccines have been relatively ineffective. Protection against the disease requires the presence of secretory IgA antibody, either actively or passively acquired, in the intestine (see "Immune Mechanisms").

TGE Vaccines

Several live-attenuated and inactivated virus vaccines are available for use in pregnant sows and neonatal pigs. Vaccines for oral and intranasal administration were developed on the basis that vaccination by the oral or intranasal route would induce the production of secretory IgA antibody. However, these vaccines have not been efficacious.

The vaccination of pregnant sows with attenuated strains of TGEv by either the parenteral or oral route does not provide sufficient lactogenic immunity to protect their piglets against virulent strains of TGEv. Some litters sucking vaccinated sows may achieve partial protection in which the onset of diarrhea is delayed, the diarrhea is less severe, and the case-fatality rate is decreased. Villous atrophy is inhibited to varying degrees in pigs sucking immunized sows, depending in part on the antibody titer in the colostrum and milk.

The severity of the losses in a vaccinated herd after exposure to the virus will vary, depending on the following factors:

- Herd management
- Environmental conditions
- History of previous exposure
- Severity of viral exposure

After natural infection or experimental oral infection of pregnant sows with a virulent strain of TGEv, lactogenic immunity is highly protective for piglets, and neutralizing antibodies in milk are mainly associated with the IgA fraction. Vaccination of sows orally with a nonattenuated vaccine provides greater levels of lactogenic protection than does orally or parenterally administered attenuated-virus vaccine. In vaccinated sows, the levels of colostral antibody correlate with the percentage of survivability of their piglets when challenge-exposed at 3 to 5 days, whereas the serum antibody to TGEv does not. There is also a significant relationship between milk antibody and percentage survivability when pigs are challenge-exposed at 5 days of age but not at 3 days of age. There is a need to develop an attenuated virus strain that is completely avirulent for pigs but that also replicates sufficiently in the small intestine of sows after oral administration and induces secretory IgA antibody. It appears that no strains of the virus have been identified that are sufficiently attenuated and safe for pigs while still being able to provide a sufficient immune stimulus in the intestine of the sow. The Nouzilly strain, which is a mutant type of TGEv resistant to acidity and the proteases of the digestive tracts of adult pigs, is being evaluated as a vaccine.

Vaccine Schedule

If vaccines are used, it is generally recommended that the two vaccinations, 14 days apart, be given during the last trimester of pregnancy. Vaccines are available for vaccination of neonatal piglets, weaner pigs, and finishing pigs, but there is insufficient published information available on the efficacy of the vaccines based on randomized clinical trials using controls under field conditions.

Subunit TGEv Vaccine

Experimentally, a recombinant TGE virus S glycoprotein subunit vaccine given subcutaneously or intramammarily to pregnant sows induced colostral and milk IgG, but not IgA, antibodies to the virus. Piglets born from vaccinated sows were challenged at 4 to 5d ays of age with the virulent virus, and the morbidity was 100%, with mortality ranging from 20% to 80%. The same vaccine given subcutaneously to 11-day-old piglets induced VN antibodies. This is consistent with the well-known observation that secretory IgA antibody in the milk is necessary for protection in piglets. Compared to VN antibodies, antibodies of the secretory IgA class are more effective at neutralizing TGEv because they are at higher titers in milk, are more resistant to proteolytic enzymes, and bind to gastrointestinal enterocytes. Protective immunity to transmissible gastroenteritis correlates with milk whey secretory IgA antibody titer to the TGE virus when pigs are challenge-exposed with the virulent virus at 3 to 5 days of age.

Immunity to PRCV

There is considerable cross-protection between TGEv and PRCV. There is indirect evidence that a bronchial-associated lymphoid tissue (BALT)–mammary gland link similar to the gut-associated lymphoid tissue (GALT)–mammary gland link described for TGEv may exist in pregnant, multiple-PRCV-exposed sows. In herds infected with PRCV, multiple exposures of pregnant sows are associated with higher IgA and IgG antibody titers to TGEv in milk, and these titers contribute to protection against TGEv. The immunization of pregnant gilts with PRCV induces lactogenic immunity and partial protection of piglets from challenge with TGEv. An overall survival rate of 70% was found for piglets nursing PRCV-infected gilts compared with a 16% survival rate for piglets nursing control gilts. The highest degree of protection occurs in sows primed with PRCV, then given a booster vaccination with TGEv 2 weeks later. Infection of pigs with PRCV primes the systemic and mucosal humoral immune system against TGEv, and subsequent challenge with TGEv results in a secondary antibody response and decreased duration of excretion of the virus. Protective immunity to TGEv infection can also be induced in piglets exposed to PRCV at 2 to 6 days of age.

PORCINE EPIDEMIC DIARRHEA

PED was first described in Britain in 1977, although it probably first appeared in 1971, and spread globally and rarely occurred after the 1970s and 1980s. It is a highly contagious disease in pigs of all ages but particularly young pigs. It was thought to be similar but not as severe as TGE. Before 2012 in Asia and 2013 in the United States and then Canada, the disease was sporadic in Asia and Europe. It was not found in the Western Hemisphere before May 2013.

Recently in a new wave of severe infections it was mostly associated with Asia, particularly China,[1,2] Vietnam,[3] Thailand,[4] and Korea (originally but has recently reappeared in Europe[5]).

It was detected for the first time in U.S. swine in May 2013[6] and by November 9, 2013, 1069 PED virus (PEDV) cases had been found in over 19 states (www.aasv.org/pedv).

The 2013 outbreak in the United States of this Chinese strain is particularly severe because within 3 to 4 months of the start of the outbreak there may have been 250,000 to 300,000 deaths in Oklahoma, Indiana, and Iowa. The total number of deaths between April 2013 and June 2014 may have been 7 million.

ETIOLOGY

There are several porcine coronaviruses: TGE was described in 1946, HEV in 1962, PEDV in 1977, PRDC in 1984, and the newly discovered Deltacoronavirus described in Hong Kong in 2012. They are the largest RNA viruses. All of the coronaviruses are very closely related. They are subject to deletions and insertions of their genetic material, and two of these may have occurred in the new PEDV in the United States.

PEDV is a positive-sense RNA virus of the family Coronaviridae and subfamily Coronavirinae and the genus *Alphacoronavirus*, which contains PEDV, TGE, and PRCV.

It is a coronavirus with three major nonstructural protein antigens. The virus genome is similar to that of TGE and is composed of seven ORFs that encode four structural proteins. It can be cultured in Vero cells. Chinese and Korean isolates form clusters distinct from European isolates.[7-10] Recent Chinese strains[2] differ from Korean isolates. It has also been found in India and reemerged in Thailand,[5] where it is now endemic. It caused massive losses in Vietnam in 2009. Recent Korean strains differ from European and vaccine strains.

The complete genome sequence of the virus been described from a pig infected with the PEDV strain USA/Colorado/2013.[11] It has 96.5% to 99.5% homology with other PEDV in the gene bank and 99.5% homology with a recent Chinese strain. Thus far, the initial cases in Colorado, Oklahoma, and

Kansas have similar S gene sequences (99.8–100%).

The genetic properties of endemic Chinese strains of PEDV have been described.[12] The study showed that 10 post-2010 isolates shared high homology with each other and were clustered together with the virulent DR13 strains from South Korea and one earlier Chinese strain.

This virus has been observed in various parts of China since December 2010. Ten post-2010 isolates showed homology with one another.[12] They were all clustered close to the Korean strain and to an earlier strain from China. It is suggested that the current strains are derived by similar genetic changes from the Korean strains or earlier Chinese strains.

Viruses recently isolated in Iowa (five cases) have a different gene sequence from those investigated from April 2013 showing greater similarity to strains isolated from China between 2004 to 2012. The first isolate has been described.[11] They show only 93.9 to 94.6% nucleotide identities to those previously found since April 2013 but are 99.5% to 100% similar to each other.

The virus causes a distinct cytopathic effect with characteristic cell fusion, syncytia formation, and eventual cell death. The U.S. isolates are closely related to one another and are 96.3% to 99.5% related at the nucleotide level to the 23 non-U.S. PEDV strains, and are closest to the Chinese 2011 to 2012 strains.[16]

Recent studies suggest that there are two distinctly different groups of PEDV circulating in the United States. The first group has a 99.1% to 100% identity with the initial Chinese strains. The second group has a 99.6% to 100% identity with each other but only 93.4% to 94.4% nucleotide identity with the original U.S. strain, showing that mutation has already started to occur.

A new virus, porcine Deltacoronavirus, closely related to avian coronaviruses, was discovered in Hong Kong in 2012.[19] It causes severe diarrhea and vomiting in mature pigs but is not so severe in suckling pigs. Recovery seems to follow. It is not cross-protective. It was found in the United States in August 2013.[20,21]

EPIDEMIOLOGY

The severity and outcome of the disease depend on age, challenge dose, immunity, and other on-farm conditions. Under experimental conditions 4-week-old pigs inoculated with PEDV did not gain much weight for 7 to 10 days after challenge.

The virus is usually introduced by carrier pigs, which is usually new stock coming onto the farm. Pig movements through sale or purchase of pigs are an important source of infection. It is easily spread in markets. Contaminated transport trucks, boots, and other fomites are also a possibility for spread. There is no semen transmission.

The recommendation to use feedback in Asia has probably contributed to it becoming endemic in Asia.

In studies in the United States, in the recent outbreak, larger herds are more likely to be affected, positive sites had more feed truck deliveries, half the frequency of the visits of company service persons were found on the positive sites, and trucks removing pigs (×2) and trucks removing trash were also associated with positivity (×5). Staff or family workers working off the site were also associated with positivity.

Recent studies of the partial S gene have shown that the Thai and Vietnamese strains originated from the original Chinese strain JS-2004-2.

Transmission is by the fecal–oral route, and shedding of the virus begins at the time of the development of the diarrhea. There is a high concentration of the virus in feces and the virus is very stable, so fomites, equipment, and people are easily contaminated. Truck transport of infected feces is a considerable risk.

The virus excretion may be 10,000 to 1,000,000 times more in PEDV compared with a TGE case, and the virus is much more infectious.

The recent epidemic in the United States began in Colorado and Ohio in April 2013 and has rapidly spread to at least 16 states by July 2013, with possibly over 400 cases. The virus is 99.4% similar to the 2012 Chinese virus when sequenced. It has been difficult to find out the origin because it seemed to occur separately in several sites.

A recent study of the original Chinese virus has already suggested that new variants are appearing.

The fecal and nasal shedding was first observed 24 hours postinfection. Some studies have suggested that the greatest virus shedding is greatest at 12 to 18 hours of the onset of diarrhea. Peak fecal shedding occurs 5 to 6 DPI and was much greater than nasal shedding. Some pigs still shed 21 and 28 DPI and even 35 DPI without clinical signs.[17] Pigs remain PCR positive for up to 6 weeks. Only tissues from the gastrointestinal tract appear to be positive. No aerosol transmission was detected but virus was found in the walls, pens, and food bins. The virus is highly infectious and is highly stable in the environment (>28 days in fecal slurry at −20°C, >28 days in wet feed mixture, <2 weeks in dry feed at room temperature, >14 days and <28 days in fecal slurry at room temperature, and 28 days at 40°C in fecal slurry at room temperature). There was no effect of relative humidity on virus survival.

During acute infections in a boar stud the virus has been detected in feces, blood, and semen.[18] There is also evidence for area spread of the virus and it may travel through the area on dust particles and not as a true aerosol. Virus has been detected by PCR in air samples collected up to 10 miles from an infected farm.

In the United States, there has been considerable discussion of how it spreads: air, people, feeds, or fomites. At the moment it seems most likely that it reached the United States either in feeds or in processed plasma. The PCRs are not designed to find the virus in feeds, but spiked feeds have been shown to be capable of infecting pigs in experimental studies. Samples from feed bins have proved positive for live virus. Live virus has also been found in air samples and in bird feces.

Recent studies have suggested that plasma proteins, particularly those that are imported, are a possible means of infection. A statement by the Canadian Food Inspection Agency on February 18, 2014, stated that testing with a swine bioassay has determined that the plasma ingredients contain PEDV capable of causing disease in pigs. The epidemiology clearly links the live PEDV-contaminated plasma shipment to the 18 infected herds in Ontario. These infected imports originated in the United States. As of March 5, 2014, there were 25 pig sites in Ontario with PED. At this date only 6% of the 1063 trailers tested for PED had turned up positive. An assembly yard also tested positive. The Ontario authorities suggested that the virus would not be as easily transmitted in the warmer months as it is in March. The Canadian authorities said that plasma products, spray dried plasma, and feed were PCR positive.

OCCURRENCE

In April 2013 in west central Iowa piglets were described with fetid, watery diarrhea and mortality in 90% of the pigs. It then spread rapidly to sites in northwest and northeast Iowa and then Indiana with a piglet mortality greater than 90%. There was no connection between the production systems, there were no known relationships and no common trucking or feed service. In May, confirmation occurred through EM of the presence of a coronavirus. The virus was then confirmed as being similar to the Chinese 2012 PEDV strain, and PCR and sequencing at the National Veterinary Services Laboratories in the United States confirmed this. On June 13, 2013, it had reached 12 states; by September[15] five more states; by December[15] another nine states; and by July 5, 2014, 29 states had reported infected pigs.

After occurring widely in the United States it has now spread to Canada. In March 2014 there were 25 cases in Ontario and one each in Quebec, Prince Edward Island, and Manitoba.

PATHOGENESIS

The virus appears to need trypsin for its replication to open up the Spike protein, which is why it is particularly attached to the intestinal enterocytes, which are a source of trypsin.

The virus resembles TGE in its behavior but does not replicate in the respiratory tract.

The major structural gene of the 28-kb PEDV genome encodes the multifunctional virulence factor, Spike (S), which is responsible for viral receptor binding, induction of neutralizing antibody and host cell fusion. These S gene sequences are a distinguishing feature of the PEDV strains, which affect virulence and evolution. The new strain began life in China in 2010.

The virus localizes in the porcine intestinal epithelial cells via receptors particularly on the sides and tips of the villi. Porcine amino-peptidase N is a functional receptor for the PEDV coronavirus. The PEDV N protein then localizes in the ER of the cell and inhibits intestinal epithelial cell growth and prolongs the S-phase of the cell cycle. It then causes the expression of IL-8, which further induces ER stress. The N protein also binds to the virion RNA and provides a structural basis for the helical nucleocapsid giving stability to the virus. The level of production of the digestive enzymes is rapidly reduced and malnutrition results in starvation very quickly followed by dehydration. In partially immune pigs only a small portion of the intestine is affected.

IMMUNITY

PEDV antibodies have been reported to persist for at least 1 year. Colostral protection may last for up to 2 weeks in the piglet (specific IgG antibodies). Lactogenic immunity is said to be poor. The length of protection depends on the titer in the dam. Colostral IgA is a better method of assessing protection than serum levels. It is more resistant to enzyme degradation in the gut and therefore better at neutralizing gut infections. It also has greater activity than IgM and IgG. One of the characteristics of the recent Chinese strains is that there is poor herd immunity, with recurrent outbreaks every 6 months.

CLINICAL SIGNS

In the 1970s, when it first occurred in Europe, there were two types described. Epidemic virus diarrhea type 1 occurred in mature pigs and not suckling pigs and was similar to a mild form of TGE. The more severe type, which occurred in suckling pigs and was associated with a much higher mortality, was called epidemic virus diarrhea type 2.

It is exactly the same as a severe TGE outbreak because it spreads very rapidly to affect all nursery pigs. Sows may have anorexia and diarrhea but the picture is more variable in adults. Now with the new strains preweaning mortality will be 100% over a 3.5- to 5-week period. In the nursery, there will be diarrhea with a slight increase in mortality and a reduction of growth rate.

It affects pigs of all ages with an incubation period of 1 to 3 days. Most sows are ill within 12 to 36 hours with diarrhea and sometimes with vomiting. Affected pigs are unwell, dull, and unwilling to rise, but pyrexia is rare. The piglets then produce an extremely watery diarrhea, may vomit, and are inappetent. In the old style PED the morbidity was often 100% but the mortality was low, which distinguished the condition from TGE. It also rarely occurred if there was access to water. The clinical signs may then last 2 to 3 days before death or recovery of the damaged piglets. This recovery may take 7 to 8 days. In older stock there may just be 100% inappetence without other signs. Only 20% to 80% of older stock may have vomiting or diarrhea. Sometimes the piglets under about 30 kg are not affected and this may be because of maternal antibodies, which may last 5 to 13 weeks.

In the United States, the new cases in 2013 have had severe diarrhea and vomiting. The death rate in many cases has been 100% below 7 days of age, and up to 3 weeks of age the morbidity is 90% but falls as the piglets become older.

There is severe watery diarrhea, dehydration, and milk curd in the stomach in all affected naive piglets. Death is caused by dehydration and loss of electrolytes.

In the new outbreaks in Vietnam the morbidity reached 100% and the mortality ranged from 65% to 91%, and the disease appeared milder in Vietnam than in Thailand. In Asia, there appears to be poor herd immunity with outbreaks recurring at 6-month intervals.

In the new outbreaks in the United States the clinical signs are characterized by acute vomiting, anorexia, watery diarrhea, and heavy mortality in pigs less than 10 days old. It is highly contagious and can be seen in all ages of pigs. It took nearly 6 weeks to return to baseline production after an outbreak. (Villous cells are replaced about three times more quickly in 3-week-old pigs than in 1-week-old pigs.)

There was also an effect on the sows with a 12% decrease in farrowing rate if infected in the first 30 days of pregnancy. A 2.2 piglet decrease in born-alive to gilt litters if affected at a similar time and a severe effect on subsequent reproduction in gilts more than sows.

PATHOLOGY

The stomach is usually empty or may be full of undigested milk curd. The intestines are thin walled and pale with watery contents. There is a severe atrophic enteritis with shortened blunted villi (villous atrophy) and fused villi within 24 hours of the onset of clinical signs. The atrophy is as severe as those seen in TGE. The villous height/crypt ratio falls from 7:1-9:1 to 3:1. Under experimental conditions, in weaned pigs, there was severe villous atrophy occurring by 3 DPI and remained until 7 days but was repairing by 14 days. In neonatal pigs the villous atrophy was visible within 12 hours postinfection and was significant at 24 hours.

The pathology is milder than TGE except in the new post-2010 Chinese type outbreaks in which the pathology was as severe as TGE. A study of the U.S. outbreak in 2013 shows that the disease is exactly the same as TGE. Degenerate tips and sides of villi with swollen epithelial cells full of eosinophilic cytoplasm were described. Some cells were loose from their surrounding cells, and sometimes there were syncytia. Initial investigations showed a coronavirus on EM, but the tissues were negative for TGE and rotavirus A on RT-PCR. Subsequent testing by sequencing showed that all the PCR products were PEDV and 99+% similar to the Chinese strains.

DIAGNOSIS

The clinical signs suggest either TGE virus or PEDV and in the past PEDV was mild and differentiated by the lack of mortality. The new strains of PEDV are identical to TGE. TGE and PED have the same morphology under EM, so immunoelectron microscopy is necessary to differentiate the strain, using intestinal contents or feces. Fecal samples from clinically affected pigs are considered the gold standard. The virus is difficult to grow, which is why PCR technology was developed. The virus can be demonstrated by ELISAs; RT-PCR; multiplex RT-PCR,[13] which is rapid, cost-effective, and sensitive; and qRT-PCR.[14] The new multiplex PCRs with specific primers are useful for simultaneous detection of TGE, PED, and rotavirus type A in field samples. Immunoperoxidase techniques can be used to detect virus in the intestinal epithelium. The PCR targets the conserved portion of the N gene.

Most diagnostic labs in the United States now offer a PEDV/TGE differential PCR. It is very sensitive and can be performed on intestinal tissue, feces, or oral fluid samples.

Specific antibodies can be detected by immunofluorescence, and there are ELISAs for the detection of specific antibody in pig sera and milk from recovered pigs.

Very recently, Iowa State University validated an IFA test that measures exposure to the virus, and the best time to test is 3 to 4 weeks after the onset. It is labor intensive and the antibody titers fall very quickly but will rise erratically on reexposure.

There is now a differential multiplex PCR that can be used to differentiate the two groups of virus in the United States.

Oral fluids were as good as fecal samples in a study from the United States.[17] According to PCR results on both oral fluids and fecal swabs, viral shedding began on day one and reached its peak during 3 to 4 DPI. There were no clinical signs of virus infection present 10 DPI. In oral fluids and fecal swabs, viral nucleic acid continued to be found at the limits of detection from 10 to 35 DPI. A slight increase in viral shedding was seen in days 14

to 17 in oral fluids. It was surprising to find that viral shedding occurred for nearly 30 days after the clinical signs ceased.[17] Where the virus is endemic there may be no clinical disease and the PCR may be positive.

TREATMENT

There is no real treatment. You can make sure there is adequate water provision, give milk substitute, and provide glucose : glycine electrolyte solutions for the old style PEDV infection. The new Chinese strains now in the rest of Asia, Europe, and the United States are usually too quickly fatal to necessitate early treatment. Euthanasia is often required for the very badly affected animals and for the lesser affected hospitalization is necessary.

There is no cross-immunity with TGE or PRCV. On a breeding unit the old style PED was self-limiting. Serum antibody titer levels become detectable 2 weeks after infection and rise to levels of 1 : 1000 and then decline to 1 : 20 to 1 : 640. Passive antibody levels from a previously exposed sow may protect piglets for 5 to 13 weeks, but antibody in the sow does not always mean that the piglet is protected.

Immunity from previous natural infections and the previously used Asian vaccines do not appear to give any protection to this recent strain. In China, a bivalent live vaccine has been used for protection against TGE and PED since 1977, but there is little evidence that this works for the new virulent strains of PED.

CONTROL

Disinfectants used for TGE work effectively for PEDV. Heating at 160°F for 10 minutes for trailers will kill the virus as will exposure to 68°F for 7 days.

The key thing for producers to realize is that after the disappearance of clinical signs, the virus may be shed for up to 35 days, and therefore there has to be care when moving pigs (which are then stressed and may well reexcrete the PEDV).

The only control is very tight biosecurity and strict sanitation measures including isolation before integration for new incoming stock.

Authors in the United States have drawn attention to the risk that may be associated with pig diets and their ingredients. Some producers are choosing not to use any porcine products in pig diets and many choose to remove any porcine plasma from the diet and replace it with bovine plasma. Other suitable products would be fermented soybean meal, soy protein concentrate, whey protein concentrate, skim milk powder, and poultry meal among others. Specific use of feedback may be applied with sows when efforts to control sporadic outbreaks of PEDV fail. The material to be used in feedback occurs within 24 hours of the onset of diarrhea when the virus count is very high. Exposure of pregnant sows to virus using feces from infected piglets will stimulate rapid lactogenic immunity and shorten the outbreak on the farm.

The old method for the control of TGE may work for pigs with PEDV. The methods used for the control of TGE are as follows:

- Addition of 4 to 6 months of replacements and then close the herd.
- Feedback (forced exposure) of the entire herd, feces, intestines, and intestinal contents from acute farrowing/nursery cases is used.
- Strict all-in/all-out and one-directional flows should be practiced until after the clinical signs have disappeared.
- Introduction of sentinels about 30 days after the clinical signs have disappeared to confirm there is no circulation of virus
- Strict control of unidirectional flow of pigs and people to allow the PEDV to be walked out of the premises

In another study Dufresne[18] suggested:

- That all piglets down to 10 days of age be weaned off the farm
- Expose all gilts and sows 2 to 5 weeks prefarrow with scours wiped from the heat lamps in the farrowing areas with tissues. This can then saturated in water and placed in the water trough daily for 3 days.
- Delay feedback until they have sufficient intestines from scouring piglets. Ideal material appears to be intestines from euthanized piglets 24 hours after the outbreak has started.
- The author repeats the feedback three times in 2 weeks using one intestine for 10 sows.

This sort of approach seems to lead to a stabilization at around 18 to 20 weeks after commencement of the protocol. The process is more difficult than for PRRSV because there is greater transmission of virus, a greater virus stability, and sow immunity is lower. On the other hand, the persistence of viral infection in the host is much shorter.

Most herds return to normal mortality 5 weeks after exposure. In the experience of one veterinarian,[18] about 70% of herds' prewean mortality remains normal for an extended period but the remainder has varying degrees of clinical relapse. It is believed that the relapse is not just an example of failure of exposure, but it is possible that the relapse occurs because of waning herd immunity. They have seen relapses in herds with little or no closure time, in very large sow farms (5000+), and where there is pen gestation rather than crate gestation.

Control relies only on biosecurity and making sure that all blood products are properly heat treated to 80°F followed by storage at room temperature for 6 weeks. In 2014 the disease was made reportable in the United States so that a record of its spread is possible.

SWINE VESICULAR DISEASE

SYNOPSIS

Etiology Enterovirus of family Picornaviridae

Epidemiology Important because it resembles foot-and-mouth disease. No outbreaks since 2011 in Europe and in Asia since 2000. Transmitted by direct contact, movement of pigs, and feeding uncooked garbage containing pork products

Signs Fever, lameness, vesicles on coronary bands, and recovery in 2–3 weeks

Clinical pathology Demonstrate antigen in tissues.

Lesions Vesicles

Diagnostic confirmation Demonstrate virus in tissues. Isolate virus. RT-PCR

Differential diagnosis

- Foot rot of pigs
- Differentiate from other vesicular diseases by laboratory examination and virus identification.

Treatment None needed

Control Control of garbage feeding and movement of infected pigs

The importance of swine vesicular disease is that the clinical signs of this economically unimportant disease are indistinguishable from those of FMD, which is an economic disaster if it occurs in your country. It can mask FMD as was the case in Taiwan in 1997,

although diagnosis is now easier and possible on farm.[1]

ETIOLOGY

The disease is associated with an enterovirus (family Picornaviridae) related to human coxsackie B5 virus. A variant of this virus may have become adapted to swine. It was once regarded as porcine coxsackie (75%–85% homogeneity with the human virus) virus. Human isolates of coxsackie B5 virus do not cause disease in pigs, although swine vesicular disease virus once infected humans, but this is not considered likely with the current strains. The disease is restricted to pigs, although experimental challenge of sheep has produced subclinical infection.

EPIDEMIOLOGY

Occurrence and Prevalence of Infection

The disease was first recognized as a limited outbreak in Italy in 1966 and was eradicated by slaughter. It then appeared in a variety of countries in Asia (last was in Chinese Taipei in 2000) and in Europe but recently only in Portugal (2007)[2] and Italy (2011). This latter outbreak was associated with the rapid rise in pig numbers in Lombardia and the increase in animal movements combined with weak biosecurity methods.[3] North and South America and Australasia remain free from infection.

Eradication programs based on a slaughter policy were instituted and in most cases were effective. There has been some variation in virulence, which is determined by two amino acids in the capsid, and there may be seven antigenic strains, although there is no wide genetic variation. The epidemiologic pattern of the disease in the various outbreaks is presumably caused by different strains of the virus.

Methods of Transmission

Infection generally occurs through minor abrasions on the feet but may occur through other routes. The incubation period is 2 to 14 days, and the virus may be excreted before the onset of clinical signs. During and for a short period following the viremic phase, the virus is excreted in oral and nasal secretions. It is excreted in feces for periods up to 3 weeks, and vesicular fluid and shed vesicular epithelium are potent sources of infection. A chronic infection with shedding of virus for periods up to 3 months has been described. Contact within a contaminated environment may lead to viremia within 1 day and clinical signs within 2 days.

Large amounts of virus are shed in the immediate vicinity of infected pigs. Transmission occurs by direct contact or contact with infected food or water or infected feces, and the disease spreads rapidly between pigs within the same group. Airborne transmission of the virus is not a feature, and the spread between groups of pigs is less rapid than that which occurs with FMD. The resistance of the virus and its persistence within the environment allows spread by mechanical methods such as trucks and contaminated boots. Areas that have housed infected pigs may remain infective for a considerable period of time. The potential for contaminated communal livestock trucks and markets to spread infection is considerable because of the occurrence of minor foot abrasions that occur during the movement of pigs and the presence of persistently infected organic matter.

In the UK epidemic in the 1970s, the major methods of spread were movement of pigs (48%), contaminated vehicles (21%), feeding contaminated waste (15%), and contact at markets (11%). Other methods included movement of equipment or personnel, local spread, and recrudescence of previous infection. The outbreaks were fewer in the summer when less pork was consumed, and this resulted in much reduced pig movements.

The disease may be sufficiently mild to escape clinical detection. This, plus the occurrence of subclinical infection, and the reluctance of farmers to report suspicions of its occurrence, facilitates spread by the movement of infected pigs to other farms or through markets. Vertical transmission has not been demonstrated.

The disease may also be spread by the feeding of uncooked garbage, but it is believed that more of the virus is needed to infect pigs via this route. Pigs killed during the incubation period of the disease or with subclinical infection possess a considerable amount of virus in body tissues. There is little reduction in infectivity with cold storage, and the virus can persist in pork and pork products indefinitely.

Risk Factors

Pathogen Factors

There are minor antigenic differences and variation in virulence between some isolates of swine vesicular disease virus from different countries and two genetically and antigenically distinct variants exist in Europe. Swine vesicular disease virus can be grown in tissue culture and has characteristics distinguishing it from the viruses associated with FMD, VS, and vesicular exanthema. The virus is extremely resistant to chemical and physical influences, which has made control of the disease very difficult. It is inactivated only at extremes of pH (it can survive at pH 2–12) and temperatures. It may remain infective in the environment and in manure for periods of at least 6 months. It is resistant to the action of many disinfectants, and recommendations for disinfectants include 2% sodium hydroxide, 8% formaldehyde, and 0.04% sodium hypochlorite if organic material is not present. It is easily transmitted in infected meat. The virus survives the processing of pork and pork products, especially salami, except when heated at greater than 68°C (154°F). It can persist in these products indefinitely (salami, 40 days).

Infected carcasses can be held in cold storage for months and then released at neutral pH and 40°C and the virus can still be found after 160 days. It is very stable and therefore difficult to decontaminate the environment, particularly where swine are housed on the soil. The virus can be found in earthworms from above the burial pits.

Economic Importance

Although the economic effects of the primary disease are minor, the cost of the slaughter method for eradication is high. Although the morbidity rate with most strains is high, the disease generally runs its course in 2 to 3 weeks and produces a negligible mortality and only a minor setback to production. The major importance of the disease is its close clinical similarity to other vesicular diseases and the effects of a ban on export animals to other countries. The necessity for immediate differentiation of an outbreak from FMD and the problem of having such a similar clinical entity present in the pig population has made eradication of the disease desirable. In most countries this has proved extremely expensive.

PATHOGENESIS

There is variation in the susceptibility of different sites of the body to invasion by swine vesicular disease virus, and in natural outbreaks initial infection is most likely through damaged skin, particularly damaged feet. It has been suggested that 90% of the infection may be through the tonsil. A large amount of virus is in the tissues before the clinical signs develop. Once infection is established in a pig, virus excretion is so massive it results in infection of others in the group through the tonsil and gastrointestinal tract as well as through skin abrasions. Massive amounts of the virus are excreted in the feces. Experimentally, the disease can be reproduced by intravenous, intramuscular, subcutaneous, and intradermal inoculation of virus. Virus spreads at the site of infection and enters the bloodstream through the lymphatics. It is followed by viremia, which may last 2 to 3 days. Recent research has suggested that the virus can persist for a longer length of time for up to 63 days, but at 119 DPI the virus was again found in feces when two groups of pigs were mixed. This suggests that the virus and RNA can persist for a long time and possibly suggests a carrier state, but the same authors also suggest that persistent infection is rare. Most virus is produced during the first week, but lesions are infective for a long time. The virus has a special affinity for epithelium of the coronary band, tongue, lip, and snout, and for myocardium. Lesions in the brain, especially the brainstem, are seen histologically, but nervous signs are not a common clinical finding.

CLINICAL FINDINGS

The incubation period varies from 2 to 14 days. The disease is usually mild or even inapparent. It may be seen initially just as lame pigs. The morbidity rate varies from 25% to 65% and up to 100% of pigs within a pen may be affected. A transient fever (40–41°C; 104–105°F) and temporary mild inappetence may be seen. Lameness, arching of the back, and other signs of foot discomfort are evident but are less severe than with FMD. Very occasionally they walk on the knees or scream. The incidence of lameness and of foot lesions are influenced by management and are less severe on bedding or with soft conditions underfoot. Characteristic vesicles occur at predilection sites frequently associated with trauma. They are most common on the coronary band of the claws, especially at the heel, and of the supernumerary digits. They start as areas of blanching and swelling and progress in 1 to 2 days to thick-walled vesicles that rupture, giving the appearance of an ulcer. Sometimes pigs may have a retracted recovery. In severely affected pigs, the lesions will encircle the coronary band and the horn may be shed as in FMD. Lesions also occur on the tongue, lips, and snout and the skin of the legs and belly. They are much less frequent in these areas and frequently do not progress to typical vesicles. An examination of the feet of other apparently normal pigs within the group will often reveal the presence of minor lesions, and the extent of involvement of pigs within the group may be underestimated without careful examination. In some outbreaks, the incidence of clinical lesions has been minimal and even a single vesicle on the pig's foot should be treated as suspect. Some pigs show no clinical signs but develop significant titers of neutralizing antibody. The course of the disease within a group is generally 2 to 3 weeks, mortality is very uncommon, and there is only a minor setback to production unless complete separation of the horny foot occurs. Nervous signs with ataxia, circling, head pressing and convulsions, and paralysis have been observed rarely. Recovered pigs have immunity that protects against reinfection.

CLINICAL PATHOLOGY

Tests for the identification of swine vesicular disease include the demonstration of antigen in tissue and the detection of antibody. Vesicular epithelium provides the best material for direct antigen demonstration, and it may be present even in the remnants of 10-day-old lesions. The virus can also be grown on tissue culture and identified. An RT-PCR has been developed, and PCR and PCR-ELISA have been described including those to differentiate between the various vesicular diseases.[4,5] A lateral flow device for the detection of swine vesicular disease and differentiation from FMD in clinical samples has also been developed.[6] It has potential for being used next to the animal in providing a rapid support to clinical diagnosis as a rapid pen-side test.

Specific antibody is produced within 4 to 6 days and may be demonstrable before clinical disease is evident. With FA or direct CF, a result may be obtained within 8 to 12 hours. Antibody may be detected by VN or ELISA for the diagnosis and surveillance of the disease. Isotype-specific ELISAs have been described. The direct liquid-phase blocking ELISA (LP-ELISA) correlates well with the neutralization test, which is used by the European Community authorities. Monoclonal antibody trapping ELISA was used in Canada, Italy, and England to test results against other tests, and it was found that VN should be used as a definitive test. Virus isolation and RT-PCR are the first choices for detection of swine vesicular disease virus in feces or organs.

NECROPSY FINDINGS

There are no gross or histologic findings that differentiate swine vesicular disease from FMD. Lesions in the skin consist of areas of coagulative necrosis with intraepithelial vesicle formation. Additional necrotic foci are present in the tonsils, renal pelvis, bladder, salivary glands, pancreas, and myocardium. There is also nonpurulent meningoencephalitis. Intranuclear inclusions are present in the ganglion amphicytes. An ELISA used on vesicular fluid or epithelium can give a result in 4 to 24 hours. It grows well in culture in swine kidney cells and may show effects within 6 hours. The intracerebral infection of mice causes paralysis and death.

DIFFERENTIAL DIAGNOSIS

The occurrence of vesicles differentiates this disease from other nonvesicular diseases of pigs. So-called foot rot in pigs is associated with lesions on the sole and horn of the claw rather than the epithelial area of the coronary band. The differentiation of swine vesicular disease from other vesicular diseases relies on laboratory examination and virus identification as detailed previously.

TREATMENT AND CONTROL

No treatment is described and none is warranted. In most countries where outbreaks have occurred, control has been attempted or achieved by slaughter eradication. Depopulation is followed by thorough cleansing and disinfection and limited repopulation effected after a period of 2 to 3 months. The disposal of infected carcasses can be important because the disposal site may remain infective.

The detection of infected herds can be a problem. The mild nature of the disease means that it can easily escape detection, especially in darkened pig houses or where conditions underfoot obscure observation of the feet. Mild infections may produce little clinical disease and any vesicular lesions should be treated with suspicion. The reluctance of some farmers to report suspicious lesions can also be important, and it is essential to institute educational programs that emphasize the necessity for early detection and diagnosis of outbreaks. Serologic surveys to identify present or past infections have proved of value in aiding detection of the disease. Serologic single reactors cause a lot of trouble in trade. Piglets receive maternal antibodies from the sow and these may last for 30 to 50 days.

The three most important methods of spread are

1. Feeding of garbage containing infected pig meat
2. Movement of pigs from infected farms either directly from farm to farm or indirectly through markets
3. Movement of pigs in contaminated transport vehicles

Control of these methods of spread must include:

- Strict enforcement of garbage-cooking regulations
- Closing of markets, except perhaps for holding areas for pigs going directly to slaughter
- Strict control of movement and sale of pigs
- Adequate cleansing and sanitation of infected areas and transport vehicles

Transmission through feeding of infected meat in garbage appears the most difficult to control, and the latent period of this cycle means that outbreaks can recur at a time when eradication was thought to be complete. Disinfection of slurry is also difficult but can be attempted by treatment with sodium hydroxide.

In the UK, the most crucial item for control was the introduction of a 21-day movement prevention after the initial movement. Sentinels are put in after 8 weeks after the initial disinfection and are observed for about 3 weeks. If they are free after this time they are allowed to restock.

Vaccination has not been used for control in most countries, although experimental vaccines are available but not commercially.

VESICULAR EXANTHEMA OF SWINE

VES is an acute, febrile, infectious disease of swine associated with a calicivirus. At least 34 types of calicivirus have been recognized in the ocean and new outbreaks continue to occur. The relationship between these viruses and VES is a continual source of speculation. The virus isolated in 2000 from sea lions was shown to be infectious for swine. It is indistinguishable clinically from FMD in swine, VS, and swine vesicular disease. It has not been a problem for the pig industry for over 50 years.

ETIOLOGY

The causative virus is a calicivirus, and 13 antigenic strains have been isolated with some variation in virulence between strains. Even in one herd the virus isolated may have been antigenically different from others. At least 17 antigenic types have been isolated since 1972. Only pigs are susceptible, although experimental transmission to horses can be effected with some strains. All ages and breeds of pigs are susceptible to infection. The initial outbreak in pigs was traced to the feeding of meat from sea mammals.

EPIDEMIOLOGY

Occurrence

VES was first diagnosed in Southern California in 1932. In 1952 it was diagnosed outside California and by 1953 had occurred in 42 states. However, rigid control eradicated it by 1956 with particular importance being paid to garbage-feeding control.

Except for isolated outbreaks in Hawaii and Iceland, the disease has occurred only in the United States. This is important because of its direct effect and because of its resemblance to FMD. Although VES is a mild disease with a low mortality rate (usually less than 5% and there may be many deaths in unweaned pigs), affected animals may suffer a severe loss of BW and convalescence may require several weeks. Pregnant sows may abort and lactating sows may go dry with resultant heavy losses in baby pigs. The disease was eradicated from the United States in 1959, 27 years after its initial appearance.

Methods of Transmission

The sources of infection are infected live pigs and infective pork. Infected pigs excrete the virus in saliva and feces but not in the urine for 12 hours before vesicles develop and for 1 to 5 days afterward. Raw garbage containing infective pork scraps is the most common medium of spread from farm to farm. On infected premises the disease is spread by direct contact and, although the virus is resistant to environmental influences, spread by indirect means does not occur readily. Pigs frequently become infected, as evidenced by the development of immunity, without evidence of clinical disease. Ingestion of infected material is sufficient to produce infection.

The isolation from marine animals of an identical virus, which is capable of producing a disease identical to vesicular exanthema when inoculated into pigs, has led to the hypothesis that the primary reservoir for vesicular exanthema is in marine animals. Epizootics in pigs may have been initiated by the feeding of marine meat or garbage containing marine animal products.

Risk Factors

Pathogen Risk Factors

The virus is resistant to environmental influences and persists in frozen and chilled meats. It is readily destroyed by several different commonly used disinfectants including sodium hypochlorite, sodium hydroxide, and phenol. A good immunity develops after an attack and persists for about 20 months. There is no appreciable cross-immunity between the strains of the virus, and a series of outbreaks, each associated with a different strain of the virus, may occur in the one herd of pigs.

A similar if not identical virus, San Miguel sea lion virus, has been isolated from sea lions and fur seals off the coast of California in the United States. It is physically, chemically, and morphologically identical to the vesicular exanthema virus, although the same antigenic types have not been found. The virus produces an identical disease to vesicular exanthema when inoculated into pigs and appears to have a similar host range. The VES virus is infective for the harp seal, but the disease is inapparent and self-limiting. The intradermal inoculation of VES into otrariid (fur) seal pups will result in plaque-like lesions. Feeding swine the seal tissues from the inoculation experiments resulted in seroconversion in swine that were fed tissues from seals infected with VES virus but not in those fed tissues from seals infected with the San Miguel sea lion virus. Antibody to this virus has also been detected in California gray whales and in feral swine inhabiting coastal areas.

PATHOGENESIS

As in other vesicular diseases there is a viremia, lasting for 72 to 84 hours and commencing 48 hours before vesication, with localization occurring in the buccal mucosa and the skin above the hooves. The intradermal inoculation of the VES virus and the San Miguel sea lion virus into swine results in fluid-filled vesicles at the sites of inoculation in the snout, coronary band, and tongue. Lesions are usually limited to the nonhaired portions of the integument and tongue. A mild viral encephalitis occurs in pigs inoculated with the swine virus, and the sea lion virus can be recovered from the brain tissue of pigs infected with the virus.

CLINICAL FINDINGS

The incubation period varies with the virulence of the causative strain of virus but is usually 1 to 3 days. Morbidity is always high but mortality is low. There is an initial high fever (40.5–41°C; 105–106°F) followed by the development of vesicles in the mouth, on the snout, on the teats and udder, as well as on the coronary skin, the sole, the heel bulbs, and between the claws. This is accompanied by extreme lassitude and complete anorexia. The initial lesion is a blanched area that soon develops into a vesicle full of clear fluid. The vesicles rupture easily leaving raw, eroded areas. This usually occurs about 24 to 48 hours after they appear and is accompanied by a rapid fall of temperature. Secondary crops of vesicles often follow and may cause local swelling of the face and tongue. Lesions on the feet may predominate in some outbreaks, whereas in others they may be of little significance. The affected feet are very sensitive and there is severe lameness. Healing of the oral vesicles occurs rapidly, although secondary bacterial infection often exacerbates the lesions on the feet. Recovery in uncomplicated cases is usually complete in 1 to 2 weeks. It may occasionally cause encephalitis, myocarditis, and diarrhea as well as failure to thrive. When sows become infected late in pregnancy, abortion frequently occurs and lactating sows may go dry.

CLINICAL PATHOLOGY

Fluid from the vesicles is used in transmission experiments and for tissue culture. Blood serum is used for the CF, viral neutralization in cell culture, and gel diffusion precipitin tests.

NECROPSY FINDINGS

Postmortem examinations are not of much value in the diagnosis of vesicular exanthema, but the pathology of the disease has been defined. The lesions are limited to epithelial lesions in which there are vesicles, necrosis, sloughing, and rapid healing with mild scarring. Diagnosis involves virus isolation in cell culture, with EM as a possibility and various serologic tests including FATs for the antigen. PCR tests have also been developed.

DIFFERENTIAL DIAGNOSIS

Because of its case-for-case similarity to foot-and-mouth disease (FMD), prompt and accurate diagnosis of the disease is essential. In most countries the **disease is notifiable**.

All species

- FMD and other vesicular diseases

Cattle

- Bovine virus diarrhea
- Bovine malignant catarrh
- Pseudocowpox

Horses
- Blister beetle toxicosis
- Bullous pemphigoid
- Phenylbutazone toxicity
- Grass seed awns

TREATMENT

There is no effective treatment. The immunity is solid following infection, but heterologous infection is possible.

CONTROL

Eradication of the disease should be attempted whenever practicable. In most instances it is essential to report to the regulatory authorities. The first step is to quarantine infected premises and restrict movement of pigs in the area. Infected animals should be slaughtered, but the carcasses may be salvaged for human consumption provided the meat undergoes special treatment to ensure destruction of the virus. Normal freezing and chilling procedures are not sufficient to destroy it. All garbage fed to pigs must be boiled. Infected premises should be thoroughly cleaned and disinfected with a 2% sodium hydroxide solution before restocking. The implementation of these measures was eminently successful in eradicating the disease from the United States.

In view of the reservoir of virus in marine animals and apparent infection in feral swine in the coastal areas of California, it is possible that the disease could recur in domestic swine in the United States. Possible methods of reintroduction that need to be guarded against have been described.

Active immunization may be practicable if the disease reappears and other control measures fail. A formalin-killed virus preparation produces an immunity lasting for at least 6 months. Multivalent vaccines may be required if more than one strain of the virus is involved.

Recently the pathogenic class of VES virus–like caliciviruses (genus *Vesivirus*) endemic in certain ocean species and U.S. livestock has possibly caused vesicular disease on the hands and feet of humans.

SALMONELLOSIS IN RUMINANTS AND HORSES

SYNOPSIS

Etiology *Salmonella* spp. Cattle: *S.* Typhimurium, *S.* Dublin, and *S.* Newport. Sheep and goats: *S.* Typhimurium, *S.* Dublin, *S.* Abortusovis, and *S. enterica* subsp. *diarizonae*. Horses: *S.* Typhimurium and *S.* Enteritidis. Differentiation between host-specific, host-restrictive, and ubiquitous serovars

Epidemiology Worldwide occurrence. Important zoonosis and food-borne illness. Prevalence of infection in healthy animals varies according to species and country. Incidence of clinical disease lower than prevalence, and outbreaks occur precipitated by stressors. Spread by direct or indirect means; the infected animal is the source of organism, which contaminates feed and water supplies.

Disease may become endemic on farm. Carrier animals shed organism and may introduce infection into herd. Deprivation of feed and water, transportation, drought, intensive grazing and housing, and mixing animals from different sources contribute to onset of disease. Antimicrobial resistance is a major public health issue and is more common in isolated sick animals than from healthy carriers.

Signs Septicemia in neonatal ruminants and foals with a high case–fatality rate. Acute diarrhea and dysentery, fibrinous fecal casts, fever, marked dehydration, and toxemia; chronic enteritis; abortion; dry gangrene of extremities; and arthritis and foci of osteomyelitis. Severe diarrhea and dehydration characteristic in the horse

Clinical pathology Culture of organism from feces, repeated culture of feces required to identify carrier animals, serology in blood or milk, use hematology for changes in leukon and clinical chemistry for electrolyte changes

Lesions Septicemic hemorrhages. Mucoenteritis to marked fibrinohemorrhagic necrotic enteritis; enlarged mesenteric lymph nodes. Foci of necrosis and thickened intestinal wall in chronic enteritis

Diagnostic confirmation Culture of organism from feces, tissue, or body fluids; polymerase chain reaction and antigen-ELISA to detect specific DNA

Treatment Antimicrobials in cases of bacteremia, antiinflammatory therapy, and supportive fluid and electrolyte therapy

Control Prevent introduction of infection into herd. Limit spread of infection within the herd by identification of carrier animals, prophylactic antimicrobials, restricting movement of animals, clean water supply, hygiene, and disinfection of buildings. Avoid spread of infection in veterinary clinics and dispose of infective materials. Vaccines for immunization are available but not effective.

ETIOLOGY

Salmonella are gram-negative, rod-shaped bacilli belonging to the family Enterobacteriaceae. *Salmonella* spp. belong to the most important food-borne pathogens causing human infection. The bacterium is a facultative intracellular organism with worldwide occurrence in all mammal species. The genus *Salmonella* consists of only two species, *S. enterica* and *S. bongori*. Based on molecular characteristics *S. enterica* is further divided into six subspecies that are subsp. *enterica* (formerly subgenus I), subsp. *salamae* (formerly subgenus II), subsp. *arizonae* (subgenus IIIa), subsp. *diarizonae* (subgenus IIIb), subsp. *houtenae* (subgenus IV), and subsp. *indica* (subgenus VI). Subgenus V is now assigned to *S. bongori* to avoid confusion with serovar names of *S. enterica* subsp. *enterica*.[1] Within each subspecies different strains are classified into serovars (or serotypes) based on their LPS antigen (O) and flagellar antigen (H) characteristics according to the Kauffmann–White scheme. Currently over 2600 serovars are recognized, of which most of the ones causing infection in people and mammals belong to *S. enterica* subsp. *enterica*.[2] In practice for *S. enterica* subsp. *enterica*, the subspecies name does not need to be indicated as only serovars of this subspecies bear names. Serovars of the other subspecies are designated by their antigenic formula. The name of the serovar is no longer italicized but is capitalized.[1]

Before this novel taxonomy and nomenclature for the genus *Salmonella* was introduced in 1986, subspecies were treated as subgenera and serovars were considered species. This change in taxonomy has caused and will be causing confusion as long as both terminologies appear in the medical literature. The way former *Salmonella* species and now serovars were designated changed with time. Initially the serovar name denoted a syndrome (e.g., *S. typhi*) or host-syndrome combinations (e.g., *S. abortus-ovis, S. abortus-equi*). Later serovars were designated by the geographic origin of the first identified strain of the serovar in question (e.g., S. *dublin,* S. *london*). When the new nomenclature was introduced names were retained for serovars of subspecies *enterica,* which comprises the great majority of isolated serovars, because these names were so familiar. In contrast, serovars of other subspecies are now designated by their antigenic formula.[1]

Salmonella serovars differ in the range of hosts they can infect and in the nature of disease that may result: this difference is referred to as **serovar–host specificity**. So-called **ubiquitous serovars** such as *S.* Typhimurium or *S.* Enteritidis can affect a wide range of hosts and produce acute but self-limiting illness. **Host-specific serovars**, such as *S.* Typhi in humans or *S.* Gallinarum in poultry affect only a single species, and are associated with severe illness that does not necessarily include diarrhea. **Host-restricted serovars** primarily affect one specific species, but can also cause illness in a limited number of other species. Such serovars are, for example, SD, primarily affecting cattle or SCS, primarily affecting pigs.[3] The serovars that most commonly cause salmonellosis in farm animal species are as follows:

- **Cattle**: *S.* Typhimurium, SD, *S.* Newport, *S.* Enteritidis

- **Sheep and goats**: *S.* Typhimurium, SD, *S. enterica* subsp. *diarizonae, S.* Abortusovis
- **Horses**: *S.* Typhimurium, *S.* Abortusequi, *S.* Newport, *S.* Enteritidis

EPIDEMIOLOGY

The epidemiology of salmonellosis is complex, which often makes control of the disease difficult. The epidemiologic patterns of prevalence of infection and incidence of disease differ greatly between geographic areas depending on climate, population density, land use, farming practices, food harvesting and processing technologies, and consumer habits. In addition, the biology of the serovars differs so widely that consideration of salmonellosis, *Salmonella* infection, or *Salmonella* contamination are inevitably complex.

Prevalence of Infection

Surveys investigating the prevalence of fecal shedding indicate considerable variation between countries and animal species. In the following section the literature of the prevalence of infection or fecal shedding in healthy animals is reviewed by species.

Cattle

The prevalence of positive culture results in feces from dairy cattle in the United States has been studied in three comparable studies conducted in 1996, 2002, and 2007 and including over 90 operations from at least 17 states.[4] In the most recent study, 39.7% of participating herds and 13.7% of tested animals were culture positive for *Salmonella* spp., which is double the herd and animal prevalence reported in the first study of 1996.[4] Overall larger herds with more than 500 cows were found to be more likely to have culture-positive fecal samples (61.0%) than smaller herds with less than 500 cows (41.5%). The most common serovars isolated in the 2007 study were, in descending order, *S.* Cerro, *S.* Kentucky, *S.* Montevideo, *S.* Muenster, *S.* Meleagridis, *S.* Mbandaka, and *S.* Newport.

A study conducted in one large U.S. feedlot receiving calves from the Midwest and High Plains found a prevalence of culture-positive environmental samples in cohorts at the time of feedlot entry of 64.7%.[5] The predominantly isolated serotypes in this study were *S.* Anatum, *S.* Montevideo, *S.* Orion, *S.* Kentucky, *S.* Mbandaka, and *S.* Newport. The geographic distribution of the serotypes differs: *S.* Typhimurium has a universal distribution and SD has a patchier habitat. In the United States, up until 1948, it was limited to California and as recently as 1971 it had not been reported in cattle east of the Rocky Mountains. In 1980 the first case of SD occurred in Indiana. The movement of infected adult cattle and calves is responsible for the introduction of infection to areas in which it had not previously been diagnosed. In a California survey of 60 dairy herds, milk samples and serum samples tested with an ELISA for antibodies against *Salmonella* serogroups B, C1, and D1 antigens found that 75% of dairy herds surveyed had cows with serologic evidence of recent exposure to salmonellas, especially *S.* Typhimurium and SD.

Data from bacteriologic monitoring of *Salmonella* in cattle herds were reported by several member states of the European Union (EU) in 2009.[6] Finland and the Netherlands reported a herd prevalence of 0% and 5.5% of culture-positive fecal samples, respectively. Animal prevalence levels determined either at the farm or at the time of slaughter between 0% and 3.4% were reported from 8 European member states and Norway. The results of microbiological examinations of bovine meat conducted in Denmark, Germany, Ireland, Italy, and the Netherlands indicate that the most prevalent serovars, in descending order, were *S.* Typhimurium, SD, *S.* Infantis, *S.* Derby, and *S.* Enterididis.[6]

An Australian study investigating the prevalence of culture-positive fecal samples in slaughter age cattle reported an estimated animal level prevalence of 1.7% for dairy, 0.8% for feedlot beef, and 0.5% for pasture beef cattle.[7] The determined herd level prevalence for non-Dublin *Salmonella* spp. positive fecal samples in this study was 17% for dairy, 13% for feedlot beef, and 5.5% for pasture beef herds.[7] The most prevalent serovars in cattle were SD, *S.* Typhimurium, and *S.* Anatum.

The prevalence of culture-positive fecal samples from cattle and calves hospitalized in a veterinary teaching hospital in the United States that were cultured as part of a *Salmonella* surveillance program but were not clinical *Salmonella* suspects was 3.2% for calves and 2.3% for adult cattle.[8] The most prevalent serotypes in these non–*Salmonella*-suspect patients were, in the order of occurrence, *S.* Newport, *S.* Typhimurium, and *S.* Agona.[8]

Sheep

The literature on infection prevalence in sheep is scant. The recent U.S. Department of Agriculture-Animal and Plant Health Inspection Service (USDA-APHIS) "Sheep 2011" study included 247 sheep operations from 22 states to investigate the prevalence of enteric pathogens and commensal organisms in the U.S. sheep population.[9] In this study a herd prevalence of culture-positive fecal samples of 66.4% was determined. The proportion of positive composite fecal samples stratified by sheep type was 38.2% for ewes nursing lambs; 30.9% for the group of nursing lambs, market lambs, and replacement ewes; and 29.1% for pregnant ewes and others.[9] By far the most prevalent serovar was *S. enterica* subsp. *diarizonae* IIIb:61 -:1,5,7 accounting for 94.6% of all isolates. *S.* Enteritidis and *S.* Newport combined accounted for only 4% of all isolates, whereas *S.* Typhimurium was not isolated.[9]

Abattoir studies conducted in different countries reported prevalences of culture-positive samples of sheep between 0.1% in the UK and 40% in Australia.[10] In a recent Australian abattoir study, *Salmonella* spp. were isolated from 20% of fecal samples and 13% of fleeces in slaughtered sheep.[11] Another Australian study used a multiplex qPCR to determine the prevalence of *S. enterica* in fecal samples collected from lambs at weaning, postweaning, and preslaughter from eight farms across four states. The overall prevalence of *Salmonella*-positive fecal samples was 5.0%, but wide variations among states were found. Highest prevalence rates were determined in New South Wales in lambs at weaning (18.1%) and postweaning (23.8%).[10]

S. Abortusovis is an ovine-restricted serovar that represents a common cause of abortion and mortality in newborn lambs in Western Asia.[12] Infections have been reported from France, Spain, Germany, Cyprus, Italy, Switzerland, Russia, and Bulgaria, but few infection prevalence studies are available. A recent Swiss study determined the seroprevalence of *S.* Abortusovis infection in sheep flocks in 2007 after a series of abortion storms that had occurred between 2003 and 2007 throughout the country. Before 2003 abortion caused by *S.* Abortusovis had not been reported for several decades in this country. Overall an animal seroprevalence of 1.7% and a flock prevalence of 16.3% were found.[13]

Horses

Few infection prevalence studies conducted in nonclinical horses have been conducted. The National Animal Health Monitoring System Equine 1998 study that included over 8000 horses on nearly 1000 operations across the country reported prevalence of culture-positive fecal samples of 0.8%. At least one horse on 1.8% of operations was estimated to shed salmonellas in feces.[14] A total of 14 different serotypes were isolated with the most common serotype being *S.* Muenchen.

Four percent of specimens of equine origin submitted to a diagnostic laboratory in the United Arab Emirates were found to be *Salmonella* positive. The two predominant *Salmonella* serovars were *S.* Typhimurium and *S.* Kentucky, followed by *S.* Anatum and *S.* Agona.[15]

Occurrence

Salmonellosis occurs universally in all species.

Cattle

The disease has assumed major importance, particularly for the dairy industry. Apart from having implications for health and productivity on an individual animal and on a herd level, infections and outbreaks in dairy cattle present an important risk of zoonotic transmission. Remarkably the prevalences of

the different *Salmonella* serovars isolated in samples in clinically healthy animals differ considerably from the prevalence rates of serovars isolated in fecal samples from sick animals.

A recent U.S. field study conducted in 831 dairy herds from New York, Pennsylvania, Vermont, Massachusetts, and Connecticut that agreed to submit fecal samples of *Salmonella*-suspect clinical animals to a diagnostic laboratory reported culture-positive results in 22.5% of over 2500 cultured samples.[16] The herd level incidence rate was 8.6 positive herds per 100 herd years, and the animal-level incidence rates for preweaned heifers, postweaned heifers, and adult cows was 8.1, 0.04, and 1.8 cases per 1000 animal years, respectively.[16] In this study *S.* Newport was the most prevalent serovar with 41%, followed by *S.* Typhimurium (including var. Copenhagen) with 19.1%, *S.* Infantis (8.2%), 4,5,12:i:- (6.1%), *S.* Agona (5.2%), and *S.* Muenster (4.2%).[16]

Among 768 *Salmonella* suspect clinical cases of a veterinary teaching hospital in New York State 6.5% were identified as fecal shedders based on culture results.[8] The prevalence of culture-positive fecal samples of clinical cases was 9.1% in calves and 3.6% in adult cows with highest proportions of positive samples in the fall and lowest during spring.[8] The most common serovars were *S.* Typhimurium, *S.* Typhimurium var. Copenhagen, and *S.* Newport with similar numbers of isolates.[8]

In the UK, with a cattle population of 8.26 million in 2013, a total of 52.922 samples from clinical cases have been submitted for diagnostic purposes; salmonellas were isolated from 604 samples. The most prevalent serovars isolated in cattle were SD (72.5%), *S.* Mbandaka (7.5%), *S.* Typhimurium (5.0%), and *S.* Montevideo (3.3%).[17] SD was the most common serovar isolated from cattle with clinical disease for the past 15 years in the UK. The prevalence of *S.* Typhimurium, which was the most prevalent serovar with over 60% at the end of the 1990s in the UK and other countries, has continuously declined over the past years, and in particular *S.* Typhimurium definitive type (DT)104 that was associated with outbreaks of salmonellosis in dairy cattle and humans in the UK and the United States subsided.

In Germany the number of outbreaks of bovine salmonellosis has decreased over the past years from 258 outbreaks in 2002 to 81 outbreaks in 2009. From 2009 to 2011 this number had increased again to 109 outbreaks of bovine salmonellosis in 2011.[18] *S.* Typhimurium (including var. Copenhagen) was the most common serovar associated with approximately 40% of all outbreaks between 2009 and 2011, followed by SD (22%), *S.* Enteritidis (6.4%), and *S.* Abony (5.5%).[18]

A recent study investigated the prevalence of different serovars of culture-positive fecal samples from diarrheic calves in Australia including a total of 597 samples from 84 herds.[19] The most common serovars in these diarrheic calves were SD (27.4%), *S.* Typhimurium (14.5%), *S.* Zanzibar (11.3%), and *S.* Bovismorbificans (9.7%).

S. Montevideo has been the cause of large economic losses from abortion and cow mortality in an outwintered beef herd in Scotland. Up to 25% of the cows aborted and the overall herd mortality was 7%. The organism had been the cause of abortion in a neighboring sheep flock.

Sheep

Salmonellosis is commonly encountered when sheep are assembled at high stocking rates. In the UK, with a sheep population of 30.95 million, approximately 9500 ovine samples from *Salmonella*-suspect clinical cases have been processed by official diagnostic laboratories in 2013.[20] The most common serovars were *Salmonella enterica* subsp. *diarizonae* 61:k:1,5,(7) and variants (36.6%), followed by *S.* Montevideo (32.1%), SD (11.6%), and *S.* Agama (8.9%).[20] There were no *S.* Typhimurium or *S.* Abortusovis cases in sheep in the UK in 2013.

Serovar Dublin can cause both enteritis and abortion in adult sheep, and the disease is often associated with metritis, anorexia, and loss of wool. Newborn lambs may develop diarrhea with a high mortality rate. Serovar Typhimurium is associated with acute disease, enteritis but not usually abortion. *S.* Brandenburg has affected livestock and humans in the South Island of New Zealand. The strain has caused abortions in sheep and cattle as well as gastroenteritis in calves and adult cattle. The same strain also caused disease in horses, goats, deer, pigs, and humans. Spread of the disease on farms was strongly associated with aborting ewes, which resulted in considerable environmental contamination. During the abortion season, black-backed gulls appeared to spread the disease to other farms. Other potential sources of infection were carrier sheep, contaminated water sources, and contaminated sheep dust.

Outbreaks of *S.* Abortusovis infections causing abortion storms in sheep have occurred in different European and West Asian countries. Most recently such outbreaks occurred in Switzerland during the lambing seasons of 2003/2004 to 2007/2008 with up to 70% fetal losses in affected flocks.[13]

Horses

The incidence of salmonellosis has been increasing in the horse population, particularly where horses are assembled at large clinical centers and breeding farms. Nosocomial salmonellosis is an important problem for horses in veterinary hospitals.[21] It is also possible that many of the unidentified enteritides of horses may have been associated with *Salmonella* spp.

In the UK 44 isolations of *Salmonella* spp. from clinical cases were reported in 2013. Unlike previous years *Salmonella* 4,5,12:i:-, and not *S.* Typhimurium was the most commonly isolated serovar (25%).[22]

Morbidity and Case Fatality

The morbidity rate in outbreaks of salmonellosis in calves and sheep is usually high, often reaching 50% or more. Morbidity and mortality are usually highest in calves under 12 weeks of age. In all species the case–fatality rate often reaches 100% if treatment is not provided. In outbreaks in outwintered suckler cattle herds, the morbidity varied from 14% to 60% and mortality in adult cattle from 0% to 14%. In a review of 40 cases of clinical salmonellosis in horses that were diagnosed in one clinic, the case–fatality rate was 60%. Epidemics of salmonellosis affecting up to 40% of foals under 8 days of age on one Thoroughbred horse farm have been reported.

Methods of Transmission

Salmonellas are spread by direct or indirect means. Infected animals are the source of the organisms; they excrete bacteria and infect other animals, directly or indirectly, by contamination of the environment, primarily feed and water supplies. The farm animal may be infected in different ways: by animal-to-animal transmission, especially of host-adapted serovars; by contaminated animal feed; and by a contaminated environment (soil, birds, rodents, insects, and water supplies). Liquid wastes from infected animals may contaminate the environment directly, including streams, rivers, and pastures. Bacteria may also be disseminated during the transport of infected animals and during the holding of animals in a lairage before slaughter. In these situations, the excretion of salmonellas is exacerbated by the stress imposed.

The mixing of young susceptible calves and their subsequent transportation is an efficient mechanism for the rapid dissemination of *Salmonella.* Saleyards and dealers' premises can serve as reservoirs of infection despite cleaning and disinfection. Many vehicles and markets are contaminated with *Salmonella.* The introduction of infected carrier animals into a herd is a common cause of outbreaks of clinical salmonellosis in dairy herds that are expanding in size.

The organism can persist for an average of 14 months in the environment where calves are reared. *Salmonella* spp. do not survive for more than 5 days in bovine urine not mixed with feces but will survive in dried bovine feces for up to 6 years. After a clinical outbreak of salmonellosis, for example, in a dairy herd raising its own replacements, the premises cannot be declared to be *Salmonella* free solely on the basis of freedom from clinical cases over the next few years or on the basis of comparatively high herd

performance. In large dairy herds with modern free stalls that recycle water in their manure flush systems, it may be possible to isolate *Salmonella* serovars for several years following an outbreak of clinical salmonellosis. The organisms may be found in recycled water samples, bulk tank milk filters, and the feces of calves and adult cows.

During slaughter, fecal contamination of the carcass commonly occurs and can be carried through all slaughter procedures up to the processing of the raw products. Milk can be contaminated directly by cows that excrete the organism in the udder, especially those cattle infected with SD and *S.* Muenster, both of which have adapted to colonize the bovine mammary gland. Although *S.* Typhimurium is not usually excreted in milk, except during the febrile stage of clinical disease, it has been reported to have been persistently isolated from the milk of a healthy cow. *S.* Enteritidis has been isolated from milking filters, milk from a bulk tank, and milk from one-quarter of a 5-year-old dairy cow that persistently shed the organism in the milk for several months. Milk is most likely to become contaminated by feces, either from an animal with clinical salmonellosis or from a healthy carrier animal, during the milking process. Additional sources of contamination during milking are use of polluted water or contaminated equipment. Workers who lack personal hygiene skills and have clinical salmonellosis or are chronic shedders of the organism may also contaminate milk supplies.

Airborne transmission can be a primary mode of infection of *S.* Typhimurium. Studies have shown that the organism can survive in air sufficiently long to present a significant hazard of airborne spread.

Carrier State

Because salmonellas are facultative intracellular organisms that survive in the phagolysosome of macrophages and other cells, they can evade the bactericidal effects of antibody and complement. Thus persistence of infection in animals and in the environment is an important epidemiologic feature of salmonellosis. A cow infected with SD may become a clinical case or an **active carrier,** shedding organisms constantly or intermittently in the feces. It may alternatively become a **latent carrier** with infection persisting in lymph nodes or tonsils but no salmonellas in the feces, or even a **passive carrier,** which is constantly acquiring infection from pasture or the calf-pen floor. In passive carriers invasion of tissues does not occur, and when the animal is removed from the environment the infection disappears. However, passive carriers probably multiply the salmonellas, contributing to the epidemiology of the pathogen. Latent carriers can become active carriers or even clinical cases under stress, especially at calving time or during illness. A major problem with the control of SD infection is that latent carriers of the organism, unlike persistent excreters, cannot be readily identified by fecal culture or serologic methods. In a 3-year study of one dairy herd, the organism was isolated occasionally from the feces of adult cattle, from some cattle after parturition, and from some calves within 24 hours after birth. In some dairy herds, the organism may persist for many years with a low incidence rate of clinical disease.

For *S.* Typhimurium, which is one of the most common serovars associated with human disease, the donor can be any domestic animal species, including humans, or any wild animal or bird. Although all infected adults become carriers, it is rarely for any length of time, and calves rarely become carriers. In sheep and cattle the carrier state may persist for as long as 10 weeks, and in horses up to 14 months.

Risk Factors Predisposing to Clinical Disease

The clinical characteristics of salmonellosis in large animals vary depending on the various management systems used, the intensity of stocking, whether or not the animals are housed, and the epidemiologic characteristics of the different *Salmonella* species. Thus salmonellosis in cattle is a very serious and persistent disease in areas where it is caused principally by the host-adapted serovar SD. In contrast bovine salmonellosis associated with *S.* Typhimurium is sporadic and, even though it is fatal to individual animals, it is not a serious disease. Although there are probably similar differences with the other species, they are not particularly well defined. The difference between the diseases associated with SD and *S.* Typhimurium is the marked tendency for SD to persist in adult cattle and create a significant reservoir of carrier animals. *S.* Typhimurium does not do so as much, so that the disease is likely to subside after an initial exposure and to recur only when the source of infection, from rodents or feedstuffs, or sewage or slurry, reappears. This does not preclude the disease from persisting in a flock or herd for long periods. *S.* Typhimurium infection persisted in a large dairy herd for 3.5 years. Although the incidence rate of clinical disease declined over the study period, the organism could still be cultured from the bulk tank milk filters, which may have been associated with one cow identified as a milk excretor. Several incidents of human illness associated with *S.* Typhimurium infection following the consumption of raw milk are documented.

In hospitalized horses several studies determined an increase of developing a nosocomial *Salmonella* infection following treatment with antimicrobial drugs or nasogastric intubation as well as in horses presenting with colic at the time of admission.[21] Other studies reported an increasing risk of developing salmonellosis with prolonged duration of parenteral treatment with penicillin G potassium.[21]

Animal Risk Factors

Except in the newborn, especially foals, infection with a *Salmonella* sp. is usually not sufficient to cause clinical salmonellosis. The response to infection with a *Salmonella* sp. varies depending on the size of the challenge dose and the immunologic status of the animal, itself dependent on colostrum intake in neonates, as well as previous exposure to infection and exposure to stressors, particularly in older animals. It is generally accepted that the intervention of some precipitating factor such as transport, intercurrent disease, anesthesia and surgery, dosing with antimicrobials or anthelmintics, acute deprivation of food, or parturition is usually necessary to cause clinical disease distinct from infection with *Salmonella* spp.

The portal of infection in salmonellosis is almost always the mouth, so that the severity of the disease in an individual, or of an outbreak in a group, depends on the degree of contamination and the environmental conditions of temperature and dryness that determine the survival time of salmonellas. Just as important is the influence of the host on the outcome of the infection. Many animals become infected naturally and are passive carriers; they shed salmonellas in their feces without clinical disease but only for the duration of their cohabitation with other infected animals. It is possible to reproduce salmonellosis experimentally in most animals using a sufficiently large dose of a virulent strain of the organism. There still remains the common occurrence of the animal that is a subclinical carrier of the infection but develops clinical salmonellosis when exposed to stressors such as long transportation, hospitalization, severe feed deprivation, or parturition.

Genetic Resistance to Salmonellosis in Domestic Animals

There is evidence of a strong genetic association with resistance to salmonellosis in several economically important domestic animal species. However, selective breeding for resistance traits is not used in control of diseases or the carriage of *Salmonella* in any of these species. The value of a particular resistance trait in reduction of disease must be balanced against other factors, such as productivity of meat and milk. The control of *Salmonella* colonization of the gastrointestinal tract of food animals would appear to be a particularly useful objective with enormous potential public health benefits. There may be a role for several inherited immunologic traits, including polymorphonuclear leukocyte function and lecithin-induced mitogenic proliferation.

The interrelationships between the risk factors of the host, the environment, and the

pathogen are described here according to species differences.

Dairy Cattle

In calves, the disease is usually endemic on a particular farm, although outbreaks can occur.

S. Typhimurium is commonly associated with enteritis or septicemia in calves younger than 2 months, whereas serovar Dublin is identified with similar frequency in young (>2 months) and adult cattle.[23] Spread between calves of a group is by the fecal–oral route. Infection of the newborn calf may be from the dam because many cows that are latent shedders become active shedders at parturition. The calves are not infected at birth but become infected from the environment.

In adult cattle, SD is the common infection and occurs sporadically, but as outbreaks when stressors occur. Spread is usually by the oral route and in cattle at pasture is greatly enhanced by persistently wet conditions. Wild mice are potential reservoirs of SD in dairy herds.

Beef Cattle Herds and Feedlots

Although salmonellosis can cause significant economic losses in beef herds and feedlots, it is not as important as in dairy cattle. Low numbers of beef cattle are found to shed *Salmonella* at the time of slaughter, and beef cattle do not appear to be a major risk of carcass contamination.

Sheep

Salmonellosis in sheep may occur with a range of different syndromes of variable severity, depending mainly on the particular serovar involved. *Salmonella enterica* subsp. *diarizonae* are most commonly found in sheep. Serovars of *Salmonella enterica* subsp. *enterica* commonly found in sheep include *S.* Montevideo, SD, *S.* Typhimurium, and *S.* Agama.

Horses

Horses are frequently passive carriers, hosting *Salmonella* in internal organs such as lymph nodes but not or only intermittently shedding them in feces. Accordingly the search for a carrier can be laborious and even fruitless. At least five negative cultural examinations of feces should be made before acquitting a suspected donor.[21]

As in other species age is an important risk factor for developing clinical diseases, with foals at increased risk of developing severe clinical disease and septicemia. Risk factors in foals include a history of dystocia, immaturity or prematurity, FTPI, an unsanitary environment, infection with a concomitant pathogen, or other debilitating disease and poor health of the dam.

The occurrence of salmonellosis in horses hospitalized for another disease has become a major problem and can at least in part be attributed to increased stress and immune suppression caused by illness and debilitating procedures such as anesthesia or surgery.

Immune Mechanisms

Most information on the mechanisms of immunity to *Salmonella,* including the safety and immunogenicity of most *Salmonella* vaccines, has been found experimentally in mice. In primary infections in mice, early bacterial growth in the reticuloendothelial system is controlled by the contribution of both macrophages and polymorphonuclear cells and is affected by the virulence of the strain. In lethal infections, the early growth of the bacteria in the tissues results in high bacterial numbers that lead to death of the animal. Following natural infection with *Salmonella* antibody, responses to LPS and protein determinants can be detected. Anti-*Salmonella* IgM appear in serum early after infection followed by IgG. T-cells have a critical role in the later stages of primary infection.

Environmental and Management Risk Factors

Cattle

Intensification of husbandry in all species is recognized as a factor contributing significantly to an increase in the new infection rate. Any significant change in management of the herd or a group of animals can precipitate the onset of clinical salmonellosis if the infection preexists in those animals. The risk factors for fecal shedding of *Salmonella* and clinical salmonellosis in dairy herds were herd size, rodent activity in housing and feed areas, use of flush water systems, and feeding brewers' products to lactating cows. Large herd size and intensive management are likely to provide an environment conducive to *Salmonella* shedding and chronic dairy herd infection.

Nutritional stress caused by transition diets and heat stress was associated with outbreaks in some herds. Feed withdrawal, transport stress, and the commingling of animals before slaughter can affect the number of cattle that are contaminated with bacterial pathogens such as *Salmonella.* However, none of the risk factors evaluated before or throughout the transport process had an impact on fecal shedding and hide or carcass contamination. The pH of rumen contents has been shown to affect the number of salmonellas surviving passage through the rumen. A high volatile fatty acid content and a low pH, such as prevails when a ruminant is on full feed, is unfavorable to salmonellas passing through the forestomachs. Feed intake depression as a result of transportation or around calving may further contribute to the risk of clinical or subclinical infection. In some herds there are sporadic cases in periparturient cows, usually within 1 week of calving.

Pastures contaminated by the feces of infected animals present an important source of infection for grazing animals. In grazing cattle there is a distinct seasonal incidence in late summer, fall, and early winter, probably because of greater exposure to infection at pasture. Temperature and wetness are most important, as salmonellas are susceptible to drying and sunlight. *S.* Typhimurium can remain viable on pasture and in soil, still water, and feces for up to 7 months. The use of "slurry" as a means of disposal of animal manure from cow housing is a highly efficient means of spreading *Salmonella* infections. The chance of cows becoming infected increases considerably if they are grazed soon after the slurry is applied, and is less likely during dry, sunny periods and when there is sufficient pasture growth to avoid it being eaten right down to the ground surface. The survival time of *Salmonella* spp. in cold liquid manure depends on several factors, including pH of the slurry and the serotype of the organism. It can be as long as 28 weeks.

Salmonella contamination of water supplies of calves and cows was identified as a potential source of exposure. Water offered to weaned dairy calves in a continuous water-tank–filling method was a risk factor compared with a valve on demand and a water pH of more than 8. Drinking water can remain infected for long periods, as long as 9 months, and in cattle at extensive pasture infected drinking water in stagnant ponds is a significant source of infection. Feedlot playas (temporary shallow lakes) are frequently contaminated with many *Salmonella* serotypes. Using playas as a source of water for feedlots can be a source of *Salmonella,* and they should not be used to cool cattle in the summer months, or for dust abatement, or for irrigation of crops. Wildlife, birds, and migratory waterfowl have access to these bodies of water and, because of their size and number, there is little that can be done to prevent them from becoming contaminated.

Infection can be introduced by infected domestic animal carriers. For example, in large-scale calf-rearing units many of the calves are infected when they are picked up from their home farms and, if they are penned in groups, all calves in the group are soon infected. The infection can spread among calves penned individually, which suggests that aerosol spread may occur. *S.* Typhimurium can survive for several months in calf-rearing premises despite depopulation, cleansing, and disinfection. However, because of the failure of most calves to continue as carriers, they are usually free of infection within 6 weeks of arrival.

Contaminated feedstuffs, carrier animals, and infected clothing of visitors and casual workers are the most common methods of introducing infection. Less common methods include free-flying birds and nematode larvae that are already infected with salmonellas. Salmonellas have been isolated from a wide variety of wild animals that

could act as reservoirs for infection of domestic animals under certain conditions.

Previous antimicrobial treatment of cattle or calves with laboratory-confirmed *Salmonella* infections increases the probability of isolating salmonellas. Vaccination with a modified-live vaccine producing a systemic reaction, treatment with irritant compounds such as carbon tetrachloride for fluke, and fluke infestation can also precipitate clinical disease.

Sheep

In range sheep, the most common occurrence of the disease is during a drought when sheep are concentrated in small areas of surviving grass heavily contaminated by feces. Sheep held in holding yards or transport vehicles previously occupied by sheep for long periods are also susceptible to clinical disease. This is most likely to occur when they drink from puddles of water, especially in heavily contaminated yards, or when they are exposed to recycled dip wash. In sheep, the disease is commonly associated with deprivation of feed when animals are assembled for vaccination, anthelmintic administration, or shipment over long distances. Lambs in feedlots are susceptible to salmonellosis within a few weeks after arrival in the lot.

The modern development of pen lambing, in which ewes about to lamb are brought into small pens, is also a means of potentiating spread from a chronic shedder. In all these situations feed stress by deprivation is likely to contribute to susceptibility. Field outbreaks in range sheep have been recorded. In some instances they have been caused by the use of unsterilized bonemeal as a phosphorus supplement. Outbreaks occurring in sheep on a number of farms in the same area at the same time have been ascribed to contamination of drinking water by birds eating carrion. Heavy dosing with zinc oxide as a prophylaxis against facial eczema is also credited with precipitating outbreaks of salmonellosis in young sheep.

Horses

In adult horses, most clinical salmonellosis occurs after the stress of transport and mostly in horses that are overfed before shipment, receive little or no food or water for the duration of a protracted journey, and are fed excessively on arrival. Cases can appear 1 to 4 days later. Groups of horses that have been exposed to a contaminated environment, such as saleyards or railroad yards, may experience outbreaks in which up to 50% are affected. Multiple serotypes of *S.* Enteritidis have been isolated from the mesenteric lymph nodes of 71% of healthy horses examined at an abattoir, which indicates that extraintestinal infection occurs in the horse as it does in other species. In the light of the high carrier rate in this species, it is surprising that there are not more outbreaks.

The occurrence of salmonellosis in horses hospitalized for another disease has become a major problem for veterinary teaching hospitals and private equine practices that provide surgical veterinary care. In these circumstances there is a constant reintroduction of carriers of the disease, a persisting contamination of the environment, and a large population of horses, all of which are under stress because of anesthesia, surgical invasion, or intercurrent disease and many of which are exposed to oral and parenteral treatment with antimicrobials, which appears to greatly increase their chances of acquiring salmonellosis. Horses in which nasogastric tubes were passed were at 2.9 times greater risk of having salmonellas isolated than horses that did not undergo this procedure. Horses treated with antibiotics parenterally were at 6.4 times greater risk, and those treated with antimicrobials orally and parenterally were at 40 times greater risk of developing salmonellosis, compared with horses not receiving such treatment. In hospitalized horses, the factors found to be associated with fecal shedding of salmonellas included diarrhea at the time of admission as well as fever and a change of diet while hospitalized.

Outbreaks of nosocomial salmonellosis among horses in a veterinary teaching hospital have been described. Case–fatality rates may be high, necessitating closure of the hospital for complete disinfection and systematic sampling of the environment to detect the presence of persistent *Salmonella.* Strict isolation of hospitalized horses that have been shedding *Salmonella* and the planning and implementation of infectious disease control (IDC) throughout the hospital are necessary. Bleach is an effective disinfectant on the largest number of surfaces. The factors potentially associated with *Salmonella* shedding among horses hospitalized for colic at a veterinary teaching hospital were examined. *Salmonella* spp. were detected in the feces of 9% of patients at least once during hospitalization. They were more likely to shed *Salmonella* if diarrhea was evident 6 hours or less after hospitalization and the duration of hospitalization exceeded 8 days (OR 20.3), laminitis developed during hospitalization (OR 12.0), results of nasogastric intubation were abnormal (OR 4.9), leukopenia was evident 6 hours or less after hospitalization (OR 4.6), or travel time to the teaching hospital exceeded 1 hour (OR 3.5). Horses treated with a probiotic did not differ from control horses in likelihood of fecal shedding of *Salmonella* (OR 1.5) or prevalence of clinical signs.

Salmonellosis is also one of the common causes of neonatal septicemias of foals, and the disease may occur as endemic on particular studs, or there may be outbreaks with many foals being affected at one time. The common management strategy on "visiting stud-farms" of bringing mares and newborn foals to communal studs and then bringing them daily to a central point for observation and teasing is also likely to facilitate spread of an infection through a group of foals.

Contaminated Feedstuffs

Housed animals are generally more susceptible to infection from purchased feeds containing animal by-products than are pastured animals, which are again more susceptible to animal-product–based fertilizers. Organic feedstuffs, including bonemeal, are being increasingly incriminated in the spread of salmonellosis. Most of the contamination of meat and bonemeal occurs after heat sterilization, especially if the material is left in digester tanks. Fishmeal is one of the most frequently and badly contaminated feedstuffs. These feed meals need to be heated at 82°C (180°F) for an hour to be sterilized. The contamination of these materials may derive from antemortem infections in the animals used to make the by-product, but soiling of the material at the preparation plant or abattoir or during storage may also occur. Stored feed not of animal origin, especially grain, is also commonly contaminated by the droppings of rodents that infest it and this can lead to sharp outbreaks of salmonellosis caused by *S.* Typhimurium. Of special importance is colostrum stored without refrigeration. If the colostrum is contaminated initially, multiplication of salmonellas may occur and transmission of the infection is likely. Dried milk products appear to be relatively safe.

Pathogen Risk Factors

Salmonellas are facultative intracellular organisms that survive in the phagolysosome of macrophages and other cells and can therefore evade the bactericidal effect of antibodies. Compared with other organisms of the same family, salmonellas are relatively resistant to various environmental factors. They multiply at temperatures between 8°C and 45°C, at water activities above 0.94, and in a pH range of 4 to 8. They are also able to multiply in an environment with a low level of or no oxygen. The bacterium is sensitive to heat and will not survive temperatures above 70°C. It is sensitive to pasteurization. Salmonellas have been shown to be resistant to drying, even for years, especially in dried feces, dust, and other dry materials such as feeds and certain foods. Prolonged survival in water and soil has also been described. They are quite sensitive to beta- and gamma-irradiation.

Salmonella spp. have 13 predicted fimbrial loci, of which most are deployed in vivo. **Fimbriae** are required for the attachment onto host cells, colonization, and biofilm formation, but not specifically for intracellular survival.[24]

Flagella have been implicated as virulence factors because they may enhance motility and the invasiveness of the bacterium. This view, however, remains controversial because flagella that consist of flagellin

monomers are potent inducers of innate immunity. In the intestinal epithelium flagellin induces inflammation while inhibiting apoptosis.[24]

Like in other gram-negative bacteria, the cell membrane of salmonellas contain LPS (endotoxins), which on release, can induce shock in the host organism, contributing to its virulence. The O-antigen LPS of salmonellas is toxic and an important virulence factor, and immunity directed against the :LPS is thought to be of major importance in the host defense against salmonellosis.

Salmonellas possess a **type three secretion system (TTSS)** that is required for invasion of epithelial cells of the intestine. The TTSS functions like a needle allowing the bacterium to inject its outer proteins, the so-called effector proteins, into the host cell to which it is attached. Effector proteins signal the host cell to take up the bacterium, which consequently is engulfed into the host cell encased in a vesicle called the *Salmonella*-containing vacuole.[25]

Salmonellas have acquired at least five **SPIs** through horizontal gene transfer. SPI-1 and SP-2 in particular are important determinants of the pathogen's virulence.

The capacity to produce **superoxide dismutase** is another virulence factor that protects salmonellas from reactive oxygen species produced by the host cells to kill intracellular pathogens.[24]

In states of iron deprivation salmonellas have the capacity to produce two potent siderophores, **enterobactin** and salmochelin, allowing them to overcome this limitation.[24]

Antimicrobial Resistance of *Salmonella*

Strains of *Salmonella* spp. with resistance to antimicrobials are now widespread in both developed and developing countries. Since 1990 there have been considerable increases in the occurrence of multiply-resistant strains of *Salmonella* spp. in many developed countries.

AMR of salmonellas has been and is a major point of concern and controversy in veterinary medicine and human public health. The continued use of antimicrobials in veterinary medicine, and in food animals in particular, is believed to be a major cause of selective pressure that leads to the appearance and persistence of resistant strains. The resistance is usually to multiple antimicrobials and its existence is considered as a potential risk factor. The significance of AMR is most obvious in its impact on the treatment of human infections. AMR of *Salmonella* spp. causing clinical disease leads to increased morbidity, mortality, and treatment costs and limits the choice of antimicrobials for the treatment of systemic salmonellosis in humans.[26] Antimicrobial-resistant *Salmonella* infections can further complicate antimicrobial therapy of other infections; prior antimicrobial therapy allows fewer numbers of antimicrobial-resistant salmonellas to cause symptomatic infections, and an increase in the proportion of salmonellas that are antimicrobial resistant will increase the overall frequency of salmonellosis. Infections in humans associated with antimicrobial-resistant salmonellas are increasing and have become a cause for public health concern. Resistance to third- and fourth-generation cephalosporins and fluoroquinolones is considered of greatest public health importance, because these are the antimicrobials of particular relevance for the treatment of human salmonellosis.[27]

The prevalence of *Salmonella* isolates that are antimicrobial-resistant varies widely between countries, animal species, and serovars. National and species-specific differences have been attributed to differences in the practice of antimicrobial use between animal species, production systems, and countries. Generally, AMR among salmonellas is higher in the United States than in other countries, is more common in isolates from swine than from other species, and is more common in serovar Typhimurium than in other *Salmonella* serovars. The comparison of AMR levels in different studies consistently showed that AMR is much less common in isolates from healthy individuals than in isolates from diseased animals.

During the 1990s AMR of *Salmonella* became an important issue because of a global epidemic of the *S.* Typhimurium DT104 in animals and humans that was frequently resistant to a wide range of commonly used antimicrobials for the treatment of salmonellosis in humans. Multidrug-resistant *S.* Newport has been spreading on an epidemic scale in both animals and humans throughout the United States. In addition to the resistance to five drugs found in *S.* Typhimurium DT104, *S.* Newport, called Newport MDR-AmpC, is also resistant to amoxicillin–clavulanic acid, cephalothin, cefoxitin, and ceftiofur and exhibits decreased susceptibility to ceftriaxone. The emergence of Newport MDR-AmpC strains in humans has coincided with the emergence of Newport MDR-AmpC infections in cattle. Although the role of farm animals as a primary source of *Salmonella* infection in humans is not undisputed, it should be noted that transfer of AMR between species does not necessarily require pathogen transfer.[28] Resistance genes can be carried on plasmids or integrons, which are potentially independently mobile DNA elements encoding a site-specific integration system responsible for the acquisition of multiple small mobile elements called gene cassettes which, in turn, encode antibiotic resistance genes. Integrons have also been described on plasmid DNA in *S.* Enteritidis. Plasmids and integrons can be transferred between animal-associated *Salmonella* and *E. coli,* and identical *CMY-2* genes carried by similar plasmids have been identified in humans, suggesting that the *CMY-2* plasmid has undergone transfer between different bacterial species and may have been transmitted between food animals and humans.

A survey including 380 *Salmonella*-positive samples from diseased animals submitted to different diagnostic labs in the United States revealed that 82% of the samples were resistant to at least one antimicrobial and 70% to at least three antimicrobials.[29] When stratified by animal species the highest prevalence rates of resistance to at least one antimicrobial were found for swine (92%), followed by cattle (77%), chickens (68%), and horses (29%).[29] Approximately 35% of cattle isolates and 10% of equine isolates were resistant to over 9 antimicrobials. The serovars showing resistance to 5 to 8 antimicrobials were *S.* Typhimurium (71%), SD (69%), and SCS (40%). In this study resistance was most often observed to tetracyclines (78%), streptomycin (73%), sulfamethoxazole (68%), and ampicillin (54%).[29] Worryingly, 36% of cattle isolates exhibited resistance to ceftiofur, a third-generation cephalosporin extensively used in cattle practice in the United States. Resistance to nalidixic acid, a compound used to detect emerging resistance to fluoroquinolones, was observed in isolates from chicken (9%), cattle (8%), and turkeys (6%).

The annual UK survey of 2013, including a total 2886 isolates from submissions of clinical cases to diagnostic laboratories, reported resistance to at least one antimicrobial in 35.8% but 87.1% of swine isolates.[27] When stratified by serovar 69.7% of *S.* Typhimurium but only 5.1% of SD isolates were resistant to at least one antimicrobial. Of the serovars other than *S.* Typhimurium and SD 38.8% were resistant to at least one antimicrobial substance.[27] AMR was most often observed to tetracyclines (26.1%), sulfonamide compounds (24.8%), streptomycin (18.8%), and ampicillin (13.2%). Resistance to nalidixic acid was observed in 5% of all isolates and was most common in turkeys (20.2%), other avian species (14.6%), chickens (8.0%), and dogs (6.0%). Isolates from cattle were resistant to this compound in 1.4%. Resistance to ceftazidime occurred in 0.03% of all samples.[27]

A smaller study from Australia including 76 *Salmonella*-positive fecal samples from diarrheic calves reported resistance to at least one antimicrobial in 27.6% of all isolates. Resistance to over four antimicrobials occurred in 14.3%.[19] Most common resistance was to streptomycin (25.5%), a combination of sulfonamides (21.1%), and ampicillin (18.4%). Resistance to nalidixic acid was not observed in this study.

Zoonotic Implications

Salmonellosis, a common human intestinal disorder primarily associated with *Salmonella*-contaminated meats and poultry, causes over 90 million human cases every year. Annual costs of human salmonellosis

have been estimated to be approximately €3 billion in the EU and $2.7 billion in the United States.[30] The Centers for Disease Control estimate approximately 1 million illnesses per year, 19,000 hospitalizations, and 380 annual deaths.[31] In the EU approximately 109,000 confirmed cases of human salmonellosis have been reported in 2009, corresponding to 23.7 cases per 100,000 population.[30]

The disease has assumed increasing importance in recent years because of the much more frequent occurrence of human salmonellosis, with animal salmonellosis as the principal reservoir. *S.* Enteritidis and *S.* Typhimurium are the serovars most commonly associated with human illness. Human *S.* Enteritidis cases are most commonly associated with the consumption of contaminated eggs and poultry meat, whereas infection with *S.* Typhimurium is typically associated with the consumption of pig, poultry, or bovine meat.[30] The most serious risk is that the transmitted bacteria will have acquired resistance to specific antibiotics because the animals from which they originate have been treated with the particular antibiotics repeatedly or over a long period.

Various clinical forms of salmonellosis can occur in veterinarians working with *Salmonella*-infected animals. Gastroenteritis, bacteremia, and other systemic abnormalities can occur. Cutaneous salmonellosis has been reported in veterinarians attending to infected cattle at the time of parturition. The disease was characterized by pustular dermatitis from which *S.* Virchow and SD were isolated. Veterinarians may develop skin lesions after obstetric deliveries, even after hygienic precautions and the use of abundant amounts of disinfectant creams and careful washing of the arms and hands.

Salmonella Typhimurium DT104

Throughout the 1990s there was a global epidemic of multidrug-resistant *S.* Typhimurium DT104 (DT stands for definitive phage type) in animals and humans. It was important because of its widespread prevalence, its presumed zoonotic nature, and the high frequency of multiple AMR. *S.* Typhimurium DT104 was first reported in the UK in 1984 and emerged in the 1990s as an increasing cause of *Salmonella* infections in humans and animals in England, Wales, and Scotland, as well as other European countries such as Germany, France, Austria, and Denmark and Canada. A wide range of potential reservoirs is associated with this infectious strain, from humans to the traditional food animals such as poultry, cattle, sheep, and pigs. Over a 1-year period in Scotland it was the predominant *Salmonella* isolated from nine species of animal (cattle, pigs, sheep, chickens, pigeons, horses, cats, dogs, and rabbits). A large outbreak of salmonellosis caused by multiply-resistant (mr) DT104 occurred in people in England who had consumed milk from a dairy that received raw milk supplied by two farms. The DT104 was isolated from the milk filter, and failure of on-farm pasteurization was thought to be the cause. Strains of the organism from humans, the dairy cattle, and the milk filter showed decreased susceptibility to ciprofloxacin.

All isolates were resistant to at least one antimicrobial and 98% were resistant to multiple antimicrobials, with R-type ACTSp being the predominant resistance pattern. In the UK, a clonal strain of mrDT104 resistant to at least five antimicrobials (ampicillin, chloramphenicol, streptomycin, sulfonamides, and tetracycline; R-type ACSSu T) was detected in humans in 1984 and cattle in 1988. The organism has emerged as an important cause of diarrhea in horses in Ontario.

The organism has been found in a variety of human foods, including salami, sausages, chicken, burgers, oysters, and vegetables. Human infections have been associated with contact with farm animals and from consumption of contaminated foods such as chicken, pork, sausages, meat pastes, and beef. The organism's ecology, its precise reservoirs, and its distribution in the human food chain are unclear. Clinical signs in humans infected with DT104 include diarrhea, fever, headache, nausea, and vomiting. Septicemia may develop in a small percentage of cases with potential complications of meningitis and foci of infection in bones and joints.

Economic Importance

Salmonellosis is a significant cause of economic loss in farm animals because of the costs of clinical disease, which include deaths, diagnosis, and treatment of clinical cases, diagnostic laboratory costs, the costs of cleaning and disinfection, and the costs of control and prevention. In addition, when the disease is diagnosed in a herd it can create considerable apprehension in the producer because of the difficulty in identifying infected animals. The veterinarian is also often in a difficult position because the diagnosis, treatment, and control of the disease are less than reliable, and it is difficult to provide advice with confidence. An estimation of the economic impact of an outbreak of SD infection in a calf-rearing unit indicated that the cost of disease represented a substantial proportion of the gross margin of rearing calves. The losses incurred by livestock producers include reduced feed efficiency and reduced weight gains or deaths because of salmonellosis.

PATHOGENESIS

The pathogenesis of salmonellosis is a complex and multifactorial phenomenon. The nature of the disease that occurs following infection is dependent on the specific combination of serovar and host known as serovar–host specificity. A range of infections is included in the term *salmonellosis*. The most common type of infection is known as "the carrier state," in which carriage of the organism is not accompanied by clinical abnormalities or clinical disease. In production animals, these carriers are of importance because they may serve as reservoirs for further spread of infection through shedding and may be present as contaminated food products.

The evolution of host-specific *Salmonella* serovars is considered to be associated with an increase in pathogenicity for the specific host. The hypothesis is based on the fact that broad-range serovars (Typhimurium and Enteritidis) are generally associated with severe disease only in young animals, whereas host-restricted serovars cause high mortality in both young and adult hosts.

The pathogenesis of different *Salmonella* serovars possessing different degrees of host restriction have been studied in young lambs to evaluate the basis of the serovar–host specificity in sheep. Infection with *S.* Abortusovis resulted in clinical signs of salmonellosis, including a fever and bacterial dissemination to systemic tissues. This confirms the virulence of the strain with sheep. *S.* Gallinarum caused relatively mild disease but is virulent in chickens. SD was virulent in sheep, confirming its association with ovine salmonellosis. The apparent specificity of a serovar for a particular host or range of hosts as defined by epidemiologic data is influenced not only by bacterial virulence but also by the ability of the serovar to circulate within the population of the host.

Infection

Salmonella infects animals and humans by the oral route. Following ingestion, a proportion of the organisms resists the low pH of the stomach, reach the distal ileum and the cecum, invade the mucosa, and replicate in the submucosa and Peyer's patches.

In young animals, and in adults whose resistance has been lowered, spread beyond the mesenteric lymph nodes occurs, and the infection is established in the reticuloendothelial cells of the liver, and from there it invades the bloodstream. These steps in the infection process can occur very rapidly. For example, in newborn calves, SD when taken by mouth can be found in the bloodstream 15 minutes later. In older calves bacteria can be isolated from the intestinal lymph nodes 18 hours after their oral administration. Provided a sufficient number of a sufficiently pathogenic serotype is used, the disease is reproducible with pure cultures, for example, of *S.* Typhimurium in lambs, SCS in pigs, SD, *S.* Typhimurium, and *S.* Enteritidis in calves, and *S.* Typhimurium in horses. Once systemic infection has been established, salmonellosis as a disease can develop. Its principal manifestations are as septicemia, enteritis, abortion, and a group of localizations in various tissues as a result of bacteremia.

Septicemia, Bacteremia, and the Carrier State

After invasion of the bloodstream occurs, a febrile reaction follows in 24 to 48 hours, and the acute phase of the disease, similar to that seen in natural cases, is present 3 to 9 days later. The early septicemia may be rapidly fatal. If the systemic invasion is sufficient to cause only a bacteremia, acute enteritis may develop, and abortion is a common final sequel in sheep and cattle. Many animals survive this stage of the disease, but localization of the salmonellas occurs in mesenteric lymph nodes, liver, spleen, and particularly the gallbladder. In healthy adults there may be no clinical illness when infection first occurs, but there may be localization in abdominal viscera. In either instance the animals become chronic carriers and discharge salmonellas intermittently from the gallbladder and foci of infection in the intestinal wall into the feces and occasionally into the milk. For this reason, they are important sources of infection for other animals and for humans. Carrier animals may also develop an acute septicemia or enteritis if their resistance is lowered by environmental stresses or intercurrent infection. Salmonellas can reside intracellularly where they are able to escape antibody-mediated killing, and the numbers of organisms are controlled by cellular defense mechanisms involving the macrophages in which they reside.

Enteritis

Enteritis may develop at the time of first infection or at some other time in carrier animals. The best information available on the pathogenesis of enteritis is derived from the experimentally produced disease. In most instances the disease is produced by the administration of massive doses of bacteria, and this may result in the production of a different syndrome from that which occurs naturally. The pathogenesis of enteric salmonellosis is much more complex than cholera, involving an increase in mucosal cell cyclic AMP content and prostaglandin concentration as well as an inflammatory response to the invading bacteria. Intestinal invasion is a characteristic feature of *Salmonella* pathogenesis. Within minutes of injecting ileal loops in calves, *Salmonella* can be seen to invade both M-cells and enterocytes that overlie domed villi associated with lymphoid follicles and absorptive villi. The organism must invade the intestinal mucosal epithelium to cause disease.

After oral infection with SD, invasion occurs through the intestinal wall in the terminal ileum and cecum and progresses only as far as the mesenteric lymph nodes. Progress beyond this point, and the development of salmonellosis, is determined by factors such as immune status and age of the animal, whether or not it is exposed to stress, and the virulence of the strains. A number of characteristics of the bacteria influence their virulence, including the presence of adhesin pili and flagella, cytotoxin, enterotoxin, LPS, and the inflammatory response that they initiate in the intestinal wall. The effects of some of these factors are not limited to the intestinal tract and also contribute to the systemic complications of salmonellosis. The SD virulence plasmid mediates systemic infection in cattle by causing macrophage dysfunction.

SD infections in calves have been used to create the disease experimentally. In calves 6 to 7 weeks of age, an oral dose of the organisms is fatal within 24 hours, with the animals dying of septicemia and an acute necrotizing panenteritis. Calves 12 to 14 weeks of age developed a progressive fatal diarrhea within 1 week following infection. Experimental infection of ligated ileal loops from calves with *S.* Typhimurium results in an acute neutrophilic inflammatory response associated with invasion of Peyer's patches.

In calves, infection is initiated by bacterial invasion of the mucosal epithelium of the distal ileum or proximal colon causing extensive local tissue damage that leads to shortening of the villi and degeneration of the enterocyte layer. *Salmonella* invasion induces potent inflammatory response characterized by a massive infiltrate of polymorphonuclear cells into the lamina propria and submucosa and secretion of fluid into the intestinal lumen. Damage to the enterocyte layer and the secretion of fluid into the intestinal lumen results in diarrhea, and the fever is caused by circulating inflammatory cytokines.

Experimentally induced *Salmonella* infection in calves results in an increase in serum haptoglobin levels within 3 days of challenge. By day 3 after experimental infection the serum haptoglobin levels increased to a median level of 212 μg/mL, whereas placebo controls had median levels of 0 μg/mL. The increased levels closely reflected the clinical findings of infection and are considered useful markers of infection severity in salmonellosis in calves.

In **sheep**, the experimental disease produced by oral dosing with *S.* Typhimurium includes an early acute enteritis of the small intestine at 24 hours. At 5 to 8 days there is hemorrhagic and necrotic typhlitis and the infection is established in mesenteric lymph nodes and the liver. Experimental SD infection of the mammary gland of dairy cattle results in a persistent infection associated with a chronic active mastitis similar to carriers with naturally acquired SD infection.

In ponies with experimental infection with *S.* Typhimurium orally, there is much variation in the time after infection that the various signs appear. Pyrexia, neutropenia, and high fecal *Salmonella* counts coincided on the second and fourth days, but diarrhea occurred in only some ponies and then on the third to eleventh days after inoculation. Positive agglutination tests were recorded from day 1 but were mostly during the period 6 to 12 days postinoculation. The neutropenia of the early stages of the disease is transient, and neutrophilia occurs when diarrhea commences.

The characteristic **fever** and **leukopenia** of **equine salmonellosis** have been attributed to the release of endotoxin from the bacteria during invasion of, and replication within, the intestinal epithelium. The equine colonic mucosa can respond to cholera toxin, which causes an increased secretion of chloride, sodium, and water into the intestinal lumen. The enterotoxin activity of *S.* Typhimurium of equine origin has been compared with cholera enterotoxin.

Although there is sufficient obvious enteritis to account for the diarrhea that characterizes the disease, there appear to be other factors involved. For example, it has been shown experimentally that in *Salmonella* enteritis there is stimulation of active chloride secretion combined with inhibition of sodium absorption, but invasion of the mucosa is not essential for these changes to occur. These observations are of interest in light of the known hyponatremia that characterizes the disease. Studies of calves with salmonellosis have shown that the fluid loss associated with the diarrhea of this disease is much greater than in other calf diarrheas. This, together with a large solid matter output, contributes to the significant weight loss occurring in salmonellosis.

Abomasitis

S. Typhimurium DT104 has been associated with some independent outbreaks of abomasitis in veal calves. Abomasitis was reproduced experimentally by oral infection of calves.

Abortion

Abortion is a common manifestation of salmonellosis in cattle between days 124 and 270 of gestation. When infection is associated with SD, the organism multiplies in the placenta, having been seeded there from a primary lesion in other maternal tissues. Fetal death has already occurred in many cases, because of its invasion by bacteria, but live calves also occur, suggesting that the placental lesion is the critical one. *S.* Montevideo, *S. enterica* subsp. *diarizonae*, and *S.* Abortusovis all are frequently associated with a significant number of outbreaks of abortion in ewes.[13,20] Abortion caused by *S.* Abortusovis infection typically occurs during the second half or last third of pregnancy. In horses *S.* Abortusequi is typically associated with late abortion (7–8 months of gestation).

Terminal Dry Gangrene, Osteitis, and Polyarthritis

Terminal dry gangrene caused by endarteritis of the extremities of the limbs, ears, and tail may occur in calves with SD infection. Epiphyseal osteomyelitis affecting the metaphyses, and polysynovitis and arthritis are also possible sequelae.

CLINICAL FINDINGS

The most common clinical manifestation of salmonellosis is enteritis, but a variety of other conditions including acute septicemia, abortion, arthritis, and respiratory disease are frequently observed.

The disease is most satisfactorily described as three syndromes classified arbitrarily according to severity as **septicemia, acute enteritis, and chronic enteritis.** These are described first, but the differences between the animal species are sufficiently significant to justify describing the disease separately in each of them.

Septicemia

This is the characteristic form of the disease in newborn foals, calves, and lambs. Commonly, there is profound depression, dullness, prostration, high fever (40.5–42°C, 105–107°F), and death within 24 to 48 hours.

Acute Enteritis

This is the common form in adult animals of all species. There is a high fever (40–41°C, 104–106°F) with severe, fluid diarrhea, sometimes dysentery, and occasionally tenesmus. The fever often subsides precipitously with the onset of diarrhea. The feces have a putrid smell and contain mucus, sometimes blood, and fibrinous casts, which may appear as complete tubular casts of intestine, and intestinal mucosa in sheets or casts. There is complete anorexia but in some cases increased thirst. The heart rate is rapid, the respirations are rapid and shallow, and the mucosae are congested. Pregnant animals commonly abort. The case–fatality rate without early treatment may reach 75%. In all species, severe dehydration and toxemia occur and the animal loses weight, becomes weak and recumbent, and dies in 2 to 5 days. Newborn animals that survive the septicemic state usually develop severe enteritis, with diarrhea becoming evident at 12 to 24 hours after the illness commences. If they survive this stage of the illness, residual polyarthritis or pneumonia may complicate the recovery phase.

Chronic Enteritis

This is a common form in pigs following a severe outbreak, and occurs occasionally in cattle and adult horses. In calves there is intermittent or persistent diarrhea, with the occasional passage of spots of blood, mucus, and firm fibrinous casts; intermittent moderate fever (39°C, 102°F); and loss of weight leading to emaciation. Although chronic enteritis may occur initially, it usually succeeds an acute episode.

Bovine Salmonellosis

The disease associated with SD is usually endemic on a particular farm, with sporadic cases occurring when individual animals are exposed to stress. Severe outbreaks are rare but do occur when there is severe stress, usually acute nutritional deprivation, applied to the entire herd.

When *S.* Typhimurium is the cause, it is usual to have a single animal or a small number of animals affected at one time. When the disease is in the calf population it is usual for it to be much more severe, with many affected, either as a point outbreak or, when there is a succession of calves, a continuing occurrence of the disease. The emphasis therefore is generally on the occurrence of individual, sporadic cases in newborn calves and recently calved cows. Depending on the geographic region other less commonly occurring serovars that have been associated with clinical disease in cattle and calves include *S.* Newport, *S.* Agona, *S.* Infantis, *S.* Enteritidis, *S.* Mbandaka, *S.* Muenster, and *S.* Bovismorbificans.[16-19] *S.* Muenster in a dairy herd has been associated with abortions, diarrhea in adults and calves, and shedding of the organism in the milk of about 8% of the cows.

Septicemia is the common form of the disease in newborn calves under a few weeks of age. There is depression, toxemia, fever, dyspnea, and weakness, and nervous signs, including incoordination and nystagmus, may occur. Diarrhea and dysentery may occur but are not common.

Calves older than a week and adults are usually affected by **acute enteritis**, followed in survivors by abortion in pregnant cows and polyarthritis in calves. In severe cases of enteritis, there is often dysentery, with whole blood passed in large clots, and complete agalactia in lactating cows. Abdominal pain, with kicking at the abdomen; rolling; crouching; groaning; and looking at the flanks, may occur in adult cattle. Rectal examination at this stage usually causes severe distress.

Chronic enteritis with inappetence, reduced weight gain, and unthriftiness may follow an attack of acute enteritis or be the only manifestation of the disease. Abortion is a common sequel in pregnant cows that survive an attack of acute enteritis. However, infection with SD is also a significant cause of abortion in cattle without there having been any clinical signs other than retained placenta. A sequel to some cases of apparent enteric salmonellosis is the development of terminal dry gangrene caused by endarteritis of the extremities, including ear tips, tail tips, and the limbs from the fetlock down.

Terminal dry gangrene of the extremities of calves is characterized by lameness, swelling of the hindlimbs below the fetlocks, and separation of the skin above the fetlock. The distal portion of the limb is cool, not painful, and the skin is dry or moist. There is a clear line of demarcation of the skin at the level of the fetlock joints between the normal proximal skin and the distal necrotic tissue. The phalanges may be separated from the metatarsus. The tips of the ears may be indurated and deviated medially, and the distal aspect of the tail may be dry and shriveled.

Abortion caused by SD may occur spontaneously without any previous clinical evidence of salmonellosis in the herd and occurs from days 124 to 270 of gestation. Cows that abort may be ill with a fever, anorexia, and hypogalactia, and some will retain fetal membranes. In a number of cases, calves may be born shortly before term and die in the perinatal period. *S.* Muenster has also been implicated in abortions in a dairy herd.

The experimental disease produced by infecting adult cattle with SD by mouth varies from no clinical illness to fatal dysentery. Abortion occurs in some pregnant females. Many suffer pyrexia, anorexia, and mild diarrhea. Experimental infection of calves with *S.* Typhimurium has the same general effect, with more severe syndromes occurring in younger calves. Chronic cases may develop bone lesions, including osteoperiostitis and osteomyelitis, sometimes with epiphyseal separation. Experimental infection with *S.* Enteritidis causes profuse yellow diarrhea, fever, dehydration, frequent cough, and a mucopurulent nasal discharge.

Ovine and Caprine Salmonellosis

Depending on the geographic region the serovars most commonly associated with clinical disease in sheep include *S.* Typhimurium, *S. enterica* subsp. *diarizonae,* *S.* Montevideo, SD, *S.* Abortusovis, and *S.* Enteridiidis.[13,20,32] Salmonellosis in sheep may occur as acute enteritis or abortion on a flock scale. However, in the early stages of the outbreak and young lambs the infection may present as septicemic form. After experimental infection of sheep with SD, fever and diarrhea are followed in pregnant ewes by abortion. Abortion is also common in the naturally occurring disease associated with all serovars causing clinical disease, not just *S.* Abortusovis. Some ewes die after abortion, and many of the lambs born alive die subsequently. Fever and diarrhea, followed by abortion, have also been produced experimentally in sheep by the administration of SD.

In goats, naturally occurring cases are not often reported. SD is the usual pathogen in those countries where it is a resident, but *S.* Typhimurium is also recorded as a cause. Peracute septicemia, in newborn animals, and acute enteritis occur with signs and lesions similar to those in cattle.

Equine Salmonellosis

Salmonellosis is one of the common causes of infectious diarrhea in horses, and *S.* Typhimurium and *S.* Agona are the most commonly isolated serovars from clinical cases. The disease in horses usually occurs in a single animal and is sporadic. However, outbreaks do occur in newborn foals, in groups of horses recently transported, and in horses hospitalized in veterinary clinics. Analysis of spatial and temporal clustering of horses with salmonellosis in an intensive

care unit of a veterinary teaching hospital suggested that affected horses were grouped in time. Experimental infection of horses by oral administration of *S.* Typhimurium produces a disease similar to the natural disease. The incubation period may be as short as 24 hours. The following four syndromes occur:

- **Asymptomatic shedding** of *S.* Typhimurium in feces intermittently or continuously for short periods of 4 to 6 days
- A **subacute enteric form in adult horses** on farms in which the disease is endemic, with fever, depression, and anorexia but without severe diarrhea, although the feces may have the consistency of soft bovine feces. There is no other obvious intestinal abnormality. There may be a neutropenia with a left shift.
- Severe, acute fulminating enteritis with diarrhea, fever, dehydration, and neutropenia occurs. There is abdominal pain, which may be sufficiently severe to stimulate violent actions. This is the common form of the disease, occurring commonly in adults that are exposed to stress in one form or another. Newborn and young foals up to 8 days of age also often have this form of the disease, characterized by depression, anorexia, and diarrhea.
- **In foals up to about 2 days of age there is a highly fatal septicemia.** Localization in survivors includes lesions in the brain, causing meningoencephalitis and polyarthritis. Fatal meningoencephalomyelitis caused by *S.* Agona has been described in a 7-day-old foal. Clinical findings included head tilt, seizures, and diarrhea.

S. Abortusequi has become a rare, only occurring in few countries worldwide. Infection with this serovar is associated with abortion in the last third of gestation, followed by retained placenta and metritis. Foals born alive may develop acute septicemia in the first week of life or polyarthritis in the second week of life. In stallions orchitis, pneumonia, arthritis, and more rarely tendovaginitis have been described.

CLINICAL PATHOLOGY

A definitive etiologic diagnosis of salmonellosis depends on the isolation of the organism from tissue aseptically collected at necropsy and from feces, blood, milk, and other body fluids. In the case of abortion suitable material for culture include placenta, vaginal swabs, and fetal stomach contents.[33] Feed, water, and environmental samples may be cultured to confirm the presence of the pathogen in a herd or flock or to determine the source of the organism. The type of sample required and frequency of sampling will largely depend on the objective of the testing strategy, the clinical presentation (if any), and the degree of precision of prevalence estimates that is required. Samples from individual animals should be obtained as aseptically as possible to prevent cross-contamination. Clinical cases are best sampled during the acute phase of the disease and before initiating antimicrobial therapy. In the case of herd/flocks testing environmental samples, such as pooled feces or swabs from floor swabs or boots, may be most cost effective.[33] Identifying subclinical infection may require repeated sampling and a larger sample size because so-called carrier animals may shed the bacterium only intermittently and in low numbers.

The diagnostic techniques available are as follows.

Bacterial Culture

Bacterial culture is the only way to make a definitive etiologic diagnosis of salmonellosis and to exactly determine the serotype. However, culturing the organism, particularly from feces, is unreliable for various factors including the method used to collect samples, the amount of material submitted, variation in the fecal shedding of the organism, and the bacteriologic method used. A major complicating factor is the occurrence of apparently healthy carriers, which shed the organism intermittently and in low numbers, and silent carriers, which do not shed *Salmonella* in feces but harbor the organism in mesenteric lymph nodes or in the mucosa of the cecum and colon. The difficulty varies according to genotype. Host-adapted serovars (e.g., SD in cattle or *S.* Abortusovis in sheep) are more difficult to isolate from feces than serovars with a broader host range such as *S.* Typhimurium. In cattle with SD infection, the bacteria are present in the blood and milk for a very brief period during the bacteremic phase and before diarrhea commences. Cows near calving are most likely to be shedding *Salmonella* in the feces. Multiple cultures at 24-hour intervals were found to be superior to single fecal cultures for the diagnosis of clinical salmonellosis in horses; currently at least five consecutive fecal samples are recommended to rule out the carrier state in an individual animal with over 95% confidence.[21]

The organism can be cultured from tissue, body fluids, fecal samples, bulk tank milk, milk filters, water, feed, and environmental sites. When sampling dairy farms weekly for 7 to 8 weeks, the prevalence of fecal shedding from different groups of cattle may vary widely among herds, indicating that herds with infected cattle may be classified incorrectly if only one group is tested.

Clinical laboratories generally require at least 48 hours for presumptive diagnosis of *Salmonella* spp. in feces because of required preenrichment and enrichment steps. Biochemical and serologic confirmation of the genotype and the following susceptibility testing may require an additional 24 to 48 hours.

There are numerous methods to culture *Salmonella*, and the choice of the appropriate method depends on the suspected serovars, the source and type of the sample, and the affected animal species.

Preenrichment Media

The use of preenrichment media, such as buffered peptone water or preenrichment broth, can increase the sensitivity of the fecal culture by resuscitating severely damaged salmonellas that may otherwise not grow on selective culture media. The use of preenrichment media may, however, not be ideal to isolate host-specific serovars that are less vigorous and may suffer from overgrowth of competing bacteria during this nonselective enrichment process.[33]

Enrichment Media

Enrichment media contain additives that selectively stimulate growth of *Salmonella* while inhibiting the growth of competing organisms. Examples of selective growth media include sodium tetrathionate, selenite cysteine, or brilliant green broth. Some of these specific enrichment media are, however, toxic to the certain *Salmonella* serovars; for example, brilliant green is toxic to many SD strains.[33]

Selective Plating Media

Selective media are solid agars inhibiting growth of bacteria other than *Salmonella* spp. while giving information on some of the principal biochemical characteristics, such as nonlactose fermentation and hydrogen sulfide production of *Salmonella* spp.[33] Selective agars are usually incubated for 24 to 48 hours at 37°C and *Salmonella* are present as characteristic colonies on these agars that can be differentiated from colonies of other bacteria. There are, however, certain organisms such as *Proteus, Pseudomonas,* or *Citrobacter,* which may be difficult to differentiate from *Salmonella* on selective agars. In positive samples additional biochemical tests are required to identify specific serovar variants.

DNA Recognition and Immunologic Methods

A variety of rapid *Salmonella* detection methods such as electrical conductance/impedance immunomagnetic separation, ELISA, and DNA probe PCR methods are available. Many of these methods have been developed for the use in human foodstuffs but have not been fully validated for environmental or fecal samples. Samples containing fecal material present a problem for PCR-based methods because of the presence of inhibitors of the PCR reaction in the test sample matrix.[33] In most cases selective or nonselective enrichment stages and DNA extraction techniques are required when using DNA-based methods, resulting in

more steps and operator time for the isolation procedure.

Serology

Serum Enzyme-Linked Immunosorbent Assay

Serologic testing using ELISA tests on serum or milk can be used in herds to identify *S.* Typhimurium or *S.* Enteritidis infections in farm animals and has also been used as a diagnostic aid to identify SD carriers. The test is based on immunoglobulins to the O antigens of the LPS of the organism and is usually designed to detect a limited range of *Salmonella* serovars or serogroups.[33]

Salmonella antibody ELISAs are now in routine use and are widely available commercially. The tests can be run on individual blood or milk samples to identify potentially infected individuals or to determine a vaccine response; it can also be used to identify infected herds or flocks by determining the presence or absence of antibody in bulk milk samples.[33] Bulk tank milk testing for antibodies to SD is used as a national screening diagnostic aid in some countries. Using a variety of ELISA tests, muscle fluid samples from cattle taken at slaughter can be used as an alternative to serum to detect antibodies to *Salmonella* polysaccharide.

Serologic results of individual animals should be interpreted cautiously because serologically positive animals may no longer be infected with *Salmonella.* On the other hand, infected and shedding individuals may not have seroconverted. Particularly in regions with low prevalence of *Salmonella* infection the specificity issue means that most positive results will be false.[33] Repeated positive serology in individual animals may, however, be used as a diagnostic aid to selective culling of chronic carrier animals.

Laboratory Diagnosis in a Suspected Sick Animal

A positive diagnosis depends on culture of the organism, usually from feces but possibly from blood in the septicemic stage. In case of abortion fetal material and placenta should be submitted for culture. If serologic diagnosis is available a serum sample should also be submitted. Indirect tests are very valuable and, if laboratory availability is good, a total white cell count and estimation of serum sodium levels should be undertaken. A presumptive diagnosis is often all that can be stated, and this may be supported by a herd diagnosis.

Herd Diagnosis

A serologic examination of a sample of animals is a first step. A completely negative serologic test would indicate that the infection is not present. Positive results indicate a need for further examination, and periodic fecal cultures at 15-day intervals should be undertaken. When *S.* Typhimurium is the causative bacteria, the feces of other species of animals on the farm should be examined, because ducks, dogs, horses, pigs, sheep, and cattle may be sources of infection for each other. It is always advisable to examine the drinking water and feed for evidence of infection.

Detection of Clinically Normal Carrier Animals

The most difficult diagnostic problem in salmonellosis is the detection of the clinically normal carrier animal. The recommended procedure is to do fecal cultures on all cows at 14-day intervals for three examinations and repeat the examination on the day of calving. At that time, swabs are taken from feces and the vagina of the cow and the feces of the calf. The sampling should preferably be done when the cows are tied in stanchions and not grazing pasture, because of the large number of passive carriers of the infection in the latter circumstance. In horses at least five samples should be submitted for fecal culture as a diagnostic procedure to identify carrier horses to have over 95% confidence that the tested animal is negative for *Salmonella* spp.[21]

The reliability of diagnosis based solely on culture of fecal swabs is not high and represents the major difficulty in detecting carriers. A combination of fecal culture and serologic tests offers some improvement in accuracy, but even with the agglutination or CF tests accuracy is insufficient.

Determination of Prevalence of Infection in Population of Animals

In food-producing animals it is particularly important to determine the prevalence of *Salmonella* infection in a population of cattle.

NECROPSY FINDINGS

Septicemia

There may be no gross lesions in animals that have died peracutely but extensive submucosal and subserosal petechial hemorrhages are usually evident. In some cases the necropsy findings may include splenomegaly and pinpoint white foci in the liver (paratyphoid nodules). The histologic lesions are nonspecific, with the exception of the somewhat granulomatous character of the older paratyphoid nodules. The placentas of cattle and sheep aborting because of *Salmonella* spp. often contain very large numbers of intravascular bacteria.

Acute Enteritis

Some of the changes associated with the septicemic form are often present, but the most consistent damage is found in the large and small intestines. The character of the inflammation here varies from a mucoenteritis with submucosal petechiation to diffuse hemorrhagic enteritis. Similar lesions may be present in the abomasum, and in SD infections in calves multiple mucosal erosions and petechiation of the abomasal wall are common. Infections with *S.* Typhimurium are characterized by severe necrotic enteritis in the ileum and large intestine. The intestinal contents are watery, have a putrid odor, and may contain mucus or whole blood. In cases that have survived for longer periods, superficial necrosis and fibrin exudation may proceed to the development of an extensive diphtheritic pseudomembrane and fibrin casts. The mesenteric lymph nodes are enlarged, edematous, and hemorrhagic. The wall of the gallbladder may be thickened and inflamed.

Chronic Enteritis

In cattle, the chronic form is usually manifested by discrete areas of necrosis of the wall of the cecum and colon. The wall is thickened and covered with a yellow-gray necrotic material overlying a red, granular mucosal surface. Less commonly the lesions are discrete in the form of button ulcers, occurring most frequently in the cecum around the ileocecal valve. The mesenteric lymph nodes and the spleen are swollen. In all species, chronic pneumonia and a variety of other localized inflammatory processes such as polyarthritis and osteomyelitis may be found.

*Salmonella*s are present in the heart, blood, spleen, liver, bile, mesenteric lymph nodes, and intestinal contents in both septicemic and acute enteric forms. In the chronic form, the bacteria may be isolated from the intestinal lesions and less commonly from other viscera. Culture is more successful if enrichment media such as tetrathionate broth are used. Surveys that set out to determine the percentage of carriers in animal populations by examining abattoir material show that by far the largest number of isolations are made from the lymph nodes draining the cecum and lower small intestine.

Samples for Confirmation of Diagnosis

- Bacteriology: Ileocecal lymph node, ileum, colon, spleen, lung, liver, and culture swab from gall bladder (CULT)
- Histology: Formalin-fixed samples from these tissues plus kidney, stomach, and brain (LM)

Note the zoonotic potential of these organisms when handling carcasses and submitting specimens.

DIFFERENTIAL DIAGNOSIS

The clinical diagnosis of salmonellosis is difficult because of the number of other diseases that resemble each form of the disease. Salmonellosis is characterized by septicemia in young animals and acute and chronic enteritis in adults, although acute enteritis can occur in neonates. Thus the septicemic form of the disease must be differentiated from all other causes of septicemia, and the enteric forms

differentiated from all other causes of diarrhea in both young and adult animals. At necropsy the isolation of salmonellas from tissues and intestinal contents, although suggestive of the presence of salmonellosis, does not of itself confirm the diagnosis, and care must be taken to ascertain whether other disease is present.

Cattle

Septicemia

The septicemic form of salmonellosis in calves resembles coliform septicemia, and differentiation is possible only by bacteriological examination of blood, feces, and tissues. Salmonellosis occurs most often during the second and third weeks of life in contrast to coliform septicemia, which occurs most often in the first few days of life. Both are characterized by weakness, depression, polypnea, tachycardia, fever or hypothermia, scleral injection and hemorrhages, diarrhea, and rapid death.

Acute enteritis

Acute enteric salmonellosis in adult cattle or calves is characterized by fever, anorexia, toxemia, abdominal pain, diarrhea and dysentery, excessive mucus and fibrinous casts and strands in the feces, and dehydration.

- **Coccidiosis** is most common in young cattle 2–8 months of age and is characterized by diarrhea with frank blood in the feces, tenesmus, only occasionally systemic signs of dehydration and anemia, and spontaneous recovery in a few days; rarely there are nervous signs and death.
- **Acute intestinal obstruction** is characterized by abdominal pain, scant or absent feces, bloodstained feces, tenesmus, anorexia, and palpable abnormalities on rectal examination.
- **Hemorrhagic bowel syndrome** is characterized by acute onset and pronounced abdominal pain associated with signs of systemic disease but no fever. Feces contain large amounts of dark red, partially or entirely clotted blood resembling blackberry jam. The condition typically affects individual adult midlactating cows.
- **Winter dysentery** occurs in explosive outbreaks in housed adult cattle; the feces are gray with flecks of blood, there is no toxemia, no dehydration, and the disease is self-limiting in 24–48 h.
- **Mucosal disease** is characterized by typical oral erosions, anorexia, fever, persistent diarrhea, dehydration, lesions in the interdigital clefts, and a high case–fatality rate.
- **Bracken fern poisoning** is characterized by dysentery, scleral hemorrhages, and a history of access to the bracken plant.
- **Other poisonings**, especially arsenic and to a lesser extent lead and a number of miscellaneous weeds, may cause a similar acute enteritis.

Chronic enteritis

Chronic enteric salmonellosis may resemble **paratuberculosis (Johne's disease)** or **chronic molybdenum poisoning**, but dysentery and epithelial casts do not occur in these diseases. Massive **stomach fluke infestations** may also cause diarrhea and dysentery.

Abortion

Abortion caused by salmonellosis requires laboratory examination of the fetus, fetal fluids, vaginal mucus, feces, and milk of the aborting animals.

Sheep

Diarrhea associated with infections with coccidia or *Campylobacter* spp. or by parasitic infestation may resemble enteric salmonellosis in sheep, but the latter is usually more acute with a higher fatality rate. *Salmonella*-related abortion requires laboratory examination of the fetus, fetal fluids, vaginal mucus, feces, of the aborting animals.

Horses

Septicemia

Septicemic salmonellosis in foals may resemble the septicemias associated with *Escherichia coli* and *Actinobacillus equuli.*

Acute enteritis

Acute enteric salmonellosis in adult horses causes profuse diarrhea, dehydration, severe depression, and weakness. A history of recent transportation often helps in suggesting the diagnosis of salmonellosis in adult horses, in which colitis X is the important differential diagnosis.

Idiopathic equine colitis X is a severe enterocolitis of adult horses characterized by profuse diarrhea, marked dehydration, and a high case–fatality rate in spite of intensive fluid therapy. Many cases are considered to be enteric salmonellosis, but the definitive etiological diagnosis is often not obtained.

Other diagnoses that must be considered include:

- **Clostridiosis** caused by *C. perfringens* type A and *C. difficile* may result in peracute hemorrhagic diarrhea, marked dehydration, and rapid death.

Chronic enteritis

Chronic diarrhea caused by salmonellosis may resemble **parasitism**, **granulomatous enteritis**, or **lymphosarcoma.**

TREATMENT

Primary Treatment: Antimicrobial Therapy

The use of antimicrobials for the treatment of clinical salmonellosis is controversial. Concerns with this treatment approach include the risk of creating so-called carrier animals and the selection for AMR particularly when using antimicrobials not only on clinically affected individuals but metaphylactically on a group of exposed animals. Issues are in part derived from experience in human medicine where invasive infection with *Salmonella* is uncommon and antimicrobial therapy is discouraged.[23] However, bacteremia is frequently encountered in cattle with acute enteritis, and septicemia is a feature of clinical salmonellosis in foals, calves, and lambs. In acute cases of clinical salmonellosis with suspected or confirmed bacteremia it would be professionally negligent not to treat affected animals with appropriate antimicrobials. There is indeed evidence that antimicrobials can prolong the duration of the period after clinical recovery from acute and in particular from chronic enteritis in humans and animals during which the causative bacteria can be isolated from the intestine. It is accepted that this can occur and that the use of antimicrobials may contribute to the spread of disease.

Another related issue is the creation of drug-resistant strains. The problem with resistant strains would not have become a significant one if only individual animals had been treated, but mass medication of in-contact animals and prophylactic treatments have generally resulted in a large population of resistant strains.

Oral treatment in cattle and pigs is recognized as a satisfactory treatment, but it is not recommended in horses in which an immediate worsening of the diarrhea, or its prolongation as a persisting chronic diarrhea, may be encountered. It is thought that both sequelae result from an alteration of the normal population of intestinal microflora resulting from the 8 to 10 times greater concentration of drug that occurs in the intestine after oral treatment, compared with the concentration resulting from parenteral injection.

If antimicrobial therapy is considered, the choice of antimicrobials should be based on antimicrobial susceptibility testing whenever this is possible. Because salmonellas are facultative intracellular pathogens, it is critical to choose an antimicrobial with good tissue penetration that attains adequate intracellular concentrations.

Ruminants

Currently many countries lack antimicrobials labeled for treatment of bovine salmonellosis. In cases of acute and severe disease in which antimicrobial therapy is most appropriate and treatment cannot be delayed, broad-spectrum antibiotics are often used because of the considerable turnaround time of bacterial culture and susceptibility testing in the case of *Salmonella.* As a result, treatment of salmonellosis in cattle is largely empirical, and extralabel use of certain antimicrobials is common in veterinary practice.

Salmonella spp. are gram-negative bacteria that are generally resistant to penicillin, erythromycin, and tylosin. Resistance to other antimicrobials such as ampicillin, amoxicillin, ceftiofur, florfenicol, sulfonamides, ceftiofur, trimethoprim-sulfas, and tetracyclines is variable.[16,23] Multidrug resistance is encountered more often in strains isolated from calves than from adult cows.[16]

Historically ampicillin, chloramphenicol, and trimethoprim-sulfas have been widely

used for the treatment of salmonellosis in cattle, but with resistance to these compounds becoming increasingly common and food safety concerns with the use of chloramphenicol in food-producing animals the use of ceftiofur has become more common, particularly in the United States. Chloramphenicol is now banned for use in food-producing animals in many countries. Nitrofurazone given orally to calves and adult cattle was commonly used for the treatment of salmonellosis but is now similarly banned. In countries where it is permitted fluoroquinolones are widely used for the treatment of clinical cases. The use of third- and fourth-generation cephalosporins and fluoroquinolones that are considered critically important antimicrobial agents in human and veterinary medicine for veterinary use is, however, discouraged by the World Organization of Animal Health (OIE); the use of these compounds should be limited to cases in which resistance to other antimicrobials is confirmed or at least must be assumed.

Horses

As in other species antimicrobial therapy in horses infected with *Salmonella* is controversial. Although antimicrobials are indicated in cases of bacteremia or septicemia as it occurs in foals, their efficacy for the treatment of enterocolitis or healthy shedders is questionable. In any case the choice of an antibiotic should be based on drug sensitivity of the organisms isolated whenever possible. Based on some studies of isolates from horses, gentamicin at 3 mg/kg BW combined with ampicillin at 20 mg/kg BW given intravenously at 8- to 12-hour intervals has been recommended. An alternative is trimethoprim-sulfonamide given twice daily intravenously at a combined dose of 30 mg/kg BW or ceftiofur at 2 to 4 mg/kg BW, twice daily. Sulfadiazine, sulfadoxine, and sulfamethoxazole are the best sulfonamides to combine with trimethoprim for salmonellosis in the horse. Care needs to be exercised when treating adult horses for salmonellosis because of the tendency for antimicrobials, especially tetracyclines, to precipitate attacks of diarrhea.

Foals with septicemic salmonellosis are usually treated both systemically and orally with antimicrobials, sometimes a different one by each route. Treatment must be given at least at 6-hour intervals and accompanied by a supportive fluid therapy. Antimicrobials recommended include gentamicin, ampicillin, sulfonamide combinations, and chloramphenicol.

Supportive Therapy

Supportive therapy includes the use of oral electrolyte solutions and polyionic ion fluids administered intravenously to replace fluid and correct electrolyte and acid-base imbalances (see Chapter 5).

NSAIDs have been recommended to alleviate endotoxin-related symptoms, control pain, and possibly prevent the risk of laminitis in horses. Maintaining adequate hydration is particularly important when using NSAIDs that decrease renal perfusion and may become nephrotoxic in dehydrated individuals. Prolonged use of NSAIDs has been associated with gastric/abomasal ulceration in different species and colonic ulceration in horses. Their use should therefore be limited in time and at the lowest possible dose.

TREATMENT

Antimicrobial therapy in cases of suspected/confirmed bacteremia

The use of antimicrobials for the treatment of chronic enteritis or healthy shedders is highly controversial.

Cattle/calves

Trimethoprim-sulfonamide (20 mg combined/kg) IV/IM every 12–24 h) (R2)

Amoxicillin (10 mg/kg IM every 12 h) (R2)

Amoxicillin-clavulanate (12 mg combined/kg IM every 12 h) (R2)

Ampicillin (10 mg/kg PO/IM every 12 h) (R2)

Enrofloxacin* (2.5–5.0 mg/kg SC/IM every 24 h) (R2)

Ceftiofur* (1.1–2.2 mg/kg BW every 24 h SC/IM for 3 days) (R2)

Horses/foals

Trimethoprim-sulfonamide (30 mg combined/kg IV/IM/PO every 12 h) (R2)

Ampicillin (20 mg/kg IV/IM every 8–12 h) (R2)

Amoxicillin trihydrate (20 mg/kg IM every 12 h) (R2)

Ceftiofur* (2–4 mg/kg every 24 h SC) (R2)

Fluoroquinolones* (R3)

Foals

Gentamicin 6.6 mg/kg IV every 24 h or 4.4 mg/kg IV every 12 h, ensure adequate hydration (R2)

Chloramphenicol (50 mg/kg IV every 6–8 h) (R2)

Antiinflammatory therapy

Flunixin meglumine (2.2 mg/kg IV as a single dose) (R2)

Meloxicam (0.5 mg/kg SC/IV as a single dose) (R2)

Fluid therapy

Oral and parenteral fluid therapy to substitute water and correct acid-base and electrolyte imbalances†

IM, intramuscularly; IV, intravenously; PO, orally; SC, subcutaneously.
**Are classified as critically important antimicrobials in human and veterinary medicine. Use as first line treatment is discouraged.*

CONTROL

Prevention of Introduction of Infection (Biosecurity)

Avoidance of infection is the major objective but is not easily achieved. The principal sources of infection are carrier animals and contaminated feeds containing foodstuffs of animal origin. There is a critical need to develop methods to control the spread of *Salmonella* infections on dairy farms by instituting biosecurity and biocontainment practices in addition to enhanced farm management. This would result in a reduction in the use of excessive antibiotic treatment of individual animals or herds.

A closed herd minimizes the risk of infection but is not a practicable procedure for the types of animal producer (the calf-rearer and the commercial pig fattener) for which salmonellosis is a major problem. For such producers the following rules apply:

- Introduce the animals directly from the farm of origin. Avoid auction marts, saleyards, and public transport, all of which are likely to be sources of infection. Ensure that the farm of origin is free of salmonellosis.
- If possible, purchase animals when they are older, such as 6 weeks of age for calves, to provide an opportunity for specific and nonspecific immunity to develop. Animals from vaccinated herds are desirable.
- The premises of dealers, saleyards, and transport vehicles must be under close surveillance and the need for frequent vigorous disinfection must be stressed. The infection rate in calves delivered to calf-dealers' yards in the UK was less than 1%, but the infection rate increased to 36% if the calves were kept on the premises over the weekend.
- Introduce only those animals likely not to be carriers. Unfortunately the detection of carriers is inaccurate and expensive. To have any confidence in the results, fecal samples for culture must be submitted on at least three occasions. Even then, occasional carriers with lesions in the gallbladder or tonsils will escape the net and be capable of reviving the disease on the farm or transferring it to another one.

Management practices to reduce the risk of *S.* Brandenburg on a sheep farm include reducing stocking density; avoiding strip grazing; maintaining adequate nutrition; minimizing yarding of ewes and the time spent in yards; dampening down yards before yarding; providing stock with a fresh clean source of drinking water; avoiding the purchase and/or grazing of stock from known affected farms, as they may contain carrier animals; preventing dogs from scavenging; and preventing scavenging by black-backed gulls by removing and burying aborted fetuses frequently during the lambing season.

Limitation of Spread Within a Herd

When an outbreak occurs, procedures for limiting spread, as set out next, need to be strictly enforced, and medication of affected groups, and of susceptible groups at high risk, must be performed.

- **Identify carrier animals and either cull them or isolate and treat them vigorously.** Treated animals should be resampled subsequently to determine whether a "clean" status has been achieved.
- **The prophylactic use of antimicrobials** is used but **not recommended** because results are poor and there is a risk of developing resistant strains. Probiotics intended for the prevention of shedding of *Salmonella* in the postoperative period in horses with colic have been evaluated and found to be ineffective.
- **Restrict the movement of animals around the farm** and limit the infection to the smallest group. Pasture and permanent buildings are both important, although the major source of infection in most cases is the drinking water.
- **The water supply should be provided in troughs that are not susceptible to fecal contamination.** Static drinking water or pasture may remain infected for as long as 7 months.
- **Rigorous disinfection of buildings is important.** An all-in/all-out policy should be adopted and steam cleaning and disinfection performed after each batch of animals. If economics permit, individual pens for calves are beneficial. Where calves are reared indoors they are common and economical. Dirt yards present a problem, especially those used for sheep and calves, but, provided they can be kept dry and empty, two sprayings, 1 month apart, with 5% formalin is recommended.
- **The control of salmonellosis in veterinary clinics and veterinary teaching hospitals** requires special attention to the possible sources of infection and containing and preventing the spread of infection. Following the diagnosis of the disease in a clinic, an environmental survey should be performed using bacteriologic culturing of stalls, wall padding, stomach pumps, nasogastric tubes, alleyways, water drains, and other equipment used routinely. This is followed by a thorough cleaning and disinfection of the entire animal-holding premises. The surfaces are then recultured to determine the presence of residual contamination. Medical and surgical equipment are cleaned and sterilized. Traffic flow patterns in the clinic are reviewed and modified accordingly. Use of disposable gloves and thorough washing of hands after handling suspect animals are recommended. Stalls in which horses with salmonellosis were housed should only be used to accommodate newly hospitalized horses after samples (collected after two cycles of cleaning and disinfection) from stall drains, cracks, and corners yield negative results on bacteriologic culture. Using PCR assay for *Salmonella* DNA, samples from floor drains and drainpipes yield the greatest proportion of positive results. The PCR results should be confirmed by bacteriologic culture, because a positive PCR in itself is not considered to pose a risk of salmonellosis to hospitalized horses. When a hospitalized horse leaves its stall permanently, it should be cleaned of organic matter using a cold water hose and scrubbed with a steel wool mop. This is followed by an application of generic bleach solution. This is then followed 24 hours later by another cleaning and disinfection with a peroxygen solution (Virkon) and allowed to dry. Virkon is a balanced stabilized blend of peroxygen compounds, surfactants, organic acids, and inorganic buffer system. Active ingredients are potassium peroxymonosulfate, sodium chloride, and other ingredients. It is effective against a wide range of bacteria, virus, and fungi, including: *S. pyogenes, C. pyloridis, Klebsiella pneumoniae, E. coli,* and *S.* Typhimurium.
- **Suitable construction of housing is important.** Impervious walls to stop spread from pen to pen, pen design to permit feeding without entering the pen, avoidance of any communal activity, and slatted floors to provide escape routes for manure all assist in limiting the spread of enteric diseases. Pen design and the environment should be such as to encourage proper eliminative behavior and good pen hygiene. Drinkers should be sited at one end of the pen, preferably on a narrow end with oblong pens, to encourage defecation in this area. Wet or damp areas of the floor in other parts of the pen will encourage defecation and urination there and should be eliminated. Drinkers of the nipple type rather than bowls are preferable for hygienic reasons. Communal dunging alleys increase the possibility of spread, especially during the cleaning procedure, and the trend is toward slatted or meshed areas over a channel.
- **Disposal of infective material should be done with care.** Carcasses should be burned or, better still, sent to an institution for diagnosis, rather than to a rendering plant to be converted into still more contaminated bonemeal. Slurry and manure for disposal should be placed on crops rather than on pasture. Slurry does not constitute a danger via hay, and salmonellas do not survive silage making. When slurry is used on pasture it should be stored for at least a month beforehand and even longer if silo effluent is included. Slurried pasture should not be grazed for 1 month, and for young animals a 6-month delay is recommended. Pig slurry is most dangerous and should always be avoided.
- **All persons working on infected premises should be warned of the hazards to their own health.** Other peripatetic species, especially dogs, should be kept under close restraint.

Principles of Infectious Disease Control for Prevention of Nosocomial Gastrointestinal and Respiratory Diseases in Large-Animal Hospitals

The principles of an IDC program for the prevention of gastrointestinal and respiratory diseases in a large-animal hospital have been described and are applicable to the control of salmonellosis. The three basic strategies are reducing exposure to pathogens, avoiding increasing susceptibility to pathogens, and monitoring effectiveness of the IDC program. The major procedures are summarized here.

Reducing Exposure to Pathogens

- Promoting appropriate personal hygiene
- Using effective methods for cleaning and disinfection
- Controlling the flow of human and animal traffic
- Implementing protocols for prompt identification of patients with signs of contagious disease
- Controlling birds, rodents, and flies

Avoiding Increasing Susceptibility to Pathogens

- Controlling ambient temperature
- Using antimicrobials appropriately
- Aiding in establishing normal intestinal or rumen flora
- Controlling endotoxemia

Monitoring Effectiveness of the Infectious Disease Control Program

- Bacterial culture of fecal samples of animals admitted to the hospital
- Regular culture of environmental samples.

Recommended Steps in Developing an Effective Infectious Disease Control Program for a Large-Animal Hospital

An effective IDC program is necessary for all large-animal veterinary teaching hospitals and private veterinary clinics. The recommended steps are outlined here.

- Have all clinicians work together to develop and approve the IDC program, because grassroots buy-in is vital.
- Develop a specific, written IDC program and disseminate it widely among staff members.
- Identify a veterinarian who is active in the large-animal hospital to serve as the IDC officer; this individual will oversee

the IDC program and should report to the hospital director and practice partners.
- Provide the resources, both human and monetary, needed for the IDC officer to effectively perform the approved IDC program; prevention costs less than the alternatives.
- Make students, residents, and staff aware of the key points of the IDC program and the importance that clinicians place on compliance.
- Teach the barn crew, particularly those actually responsible for cleaning, disinfecting, and feeding, about the goals of the IDC program and the methods to be used.
- Monitor the effectiveness of cleaning and sanitation by means of bacterial culture of environmental samples and give regular feedback to the barn crew, staff, students, and clinicians.
- Hold a seminar at least yearly to distribute written information about the IDC program and results of monitoring.

Animals Being Transported

Animals being transported are a special case. They should be unloaded or exercised at least once every 24 hours and given water and feed, with the feed provided first and at least 2 hours before watering. Hay or chopped hay is preferred to succulent feeds. All railroad cars and feeding and watering troughs should be properly cleaned and disinfected between shipments. Horses that are to be transported should be yarded and hand-fed on hard feed for 4 to 5 days beforehand. If the disease is likely to occur, prophylactic feeding with sulfonamides or antimicrobials has been shown to decrease the incidence in all species. Apart from the risk that this practice will produce resistant bacteria, there has been a suggestion that it may so change the normal bacterial flora of the gut as to encourage the proliferation of salmonellas and lead to the development of the clinical disease.

Immunization

Salmonella Vaccinology

Host resistance to *Salmonella* relies initially on the production of inflammatory cytokines leading to the infiltration of activated inflammatory cells in the tissues. Thereafter, T- and B-cell–dependent specific immunity develops, allowing the clearance of *Salmonella* from the tissues and the establishment of long-lasting acquired immunity to reinfection. The increased resistance that develops after primary infection or vaccination requires T-cells, cytokines such as IFN-γ, TNF, and IL-2, in addition to opsonizing antibody. Seroconversion and/or the presence of detectable T-cell memory do not always correlate with the development of acquired resistance to infection.

Long-term immunity using live attenuated vaccines is serotype specific and involves the recall of immunologic immunity. Killed vaccines induce strong antibody responses but trigger insufficient Th1-cell responses.

Vaccination can decrease the number of bacteria shed in feces and the number of blood-culture–positive calves, thus decreasing the number of carriers and reducing environmental contamination. Many types of vaccines have been developed and tested in cattle and pigs. If vaccination is combined with the hygienic precautions described, the vaccines are an aid to management. Killed bacterins and live attenuated vaccines are available. Either can be used as a prenatal vaccine to provide passive immunization of the newborn. It is now generally accepted that live *Salmonella* vaccines are more effective immunogens in calves than are killed vaccines.

Cattle

In cattle, SD is the infection likely to be endemic in a herd and a commercial vaccine, to be effective, must have a strong SD component. Live organisms are better able to stimulate anti-LPS antibodies and to stimulate cell-mediated immunity. Calves vaccinated at 1 to 3 weeks of age with a modified-live aromatic-dependent SD bacterin have detectable anti-LPS immunoglobulins after immunization. Safe live oral vaccines against *S.* Typhimurium and SD have been constructed and shown to confer protection against experimental infection with virulent wild-type strains of the organism. Vaccination of calves orally with a genetically altered stable nonreverting aro-SD as a modified-live vaccine provided a measurable systemic immune response, but the vaccine volume makes it unlikely to be practical for field use. Vaccinated calves responded with increases in humoral-mediated and cell-mediated immunity, as measured by ELISA and skin testing. It is claimed that the combination of humoral immunity and cell-mediated immunity stimulated by live-organism vaccines provides superior protection. Other genetically altered vaccines consisting of hybrid strains derived from SD and *S.* Typhimurium are being evaluated. An avirulent live SCS vaccine is efficacious experimentally against salmonellosis caused by SD infection in calves.

The vaccine strain 51, produced in the UK from a rough variant strain of this organism, has been found to be efficient and safe and provides good protection against *S.* Typhimurium as well as SD. It has the disadvantages of a living vaccine, but calves can be vaccinated successfully at 2 to 4 weeks of age. In limited experiments other living, attenuated, and killed, adjuvanted vaccines have given calves protection, and a comprehensive program of vaccination, hygiene, and adoption of a closed herd policy has been successful in controlling the disease. Reports on killed *S.* Typhimurium vaccines used in calves indicated good results provided the antigenic mass in the vaccine is kept high, but commercial killed vaccines are of doubtful value.

Attenuated *S.* Typhimurium (strain SL1479) given orally or intramuscularly has shown good efficiency, and attenuated SD (strain SL1438) has been similarly effective. The *S.* Typhimurium vaccine also gives some protection against SD.

The autogenous bacterin, which must be precipitated on aluminum hydroxide to have any significant effect, is given as two injections 2 weeks apart. Good immunity is produced but calves and pigs less than 6 weeks of age are refractory, and anaphylactic reactions may cause the loss of a significant number of animals. To protect young calves the best program is to vaccinate the cows during late pregnancy. This will give passive protection to the calves for 6 weeks, provided they take sufficient colostrum, and the calves can be vaccinated at that time if danger still exists. Vaccination of pregnant cattle with a formalin-killed *S.* Typhimurium vaccine approximately 7 weeks and then 2 weeks before parturition protected their calves against experimental infection. Reports of results have not been enthusiastic, but if proper attention is given to the detail of the program it has been sufficient, in the author's hands, to provide almost complete protection. A similar observation has been made with respect to vaccination of calves against *S.* Typhimurium.

Horses

In horses, a similar regimen with a booster dose for all mares in late pregnancy appears to be effective. In foals, an autogenous *S.* Typhimurium bacterin has been used in several bad field situations and has been credited with preventing further clinical cases and with reducing environmental contamination, in spite of continued poor hygiene and management practices.

Sheep

Results in sheep have been unconvincing. Some live *S.* Typhimurium vaccines are being evaluated for their efficacy against salmonellosis in sheep.

ACUTE UNDIFFERENTIATED DIARRHEA OF NEWBORN FARM ANIMALS (PARTICULARLY CALVES AND PIGLETS)

Diarrhea in newborn farm animals, particularly calves under 30 days of age and piglets in the first week of life, is one of the most common disease complexes that the large-animal clinician encounters in practice. It is a significant cause of economic loss in cattle and pig herds and continues to assume major importance as livestock production becomes more intensified. Considerable progress has been made in the treatment of the effects of diarrhea, such as dehydration and acidemia, but less so in the control of these disease complexes.

The causes of calf and piglet diarrhea are complex and usually involve an interaction between enteropathogenic bacteria, viruses, protozoa, the colostral immunity of the animal, and the effects of the environment (Table 7-27). Thus the term **acute undifferentiated diarrhea of newborn calves** is used to describe the type of acute diarrhea that occurs in newborn calves under 30 days of age, characterized clinically by acute profuse watery diarrhea, progressive dehydration, acidemia, and death within days, or earlier if not treated. Based on clinical findings alone, it is not usually possible to differentiate between the common known causes of diarrhea in newborn calves, which include ETEC, enteropathogenic (attaching and effacing) *E. coli* (EPEC), necrotoxigenic *E. coli*, rotavirus, coronavirus, bovine torovirus (Breda virus), norovirus, *Cryptosporidium* spp., *Giardia* spp., and *Salmonella* spp. The common necropsy findings are dehydration, emaciation, and a fluid-filled intestinal tract, with no other obvious gross lesions. The exceptions are enteritis associated with *Salmonella* spp., *C. perfringens* types B and C, *Eimeria* spp., and EPEC, in which there are usually typical gross lesions at necropsy.

Thus the disease is considered to be a complex syndrome because one or any combination of more than one of the specific etiologic agents is isolated in clinical cases. **Animal and environmental risk factors** play an important predisposing role in the development of clinical disease, and disease may not occur or may occur with lower incidence and/or severity in absence of such predisposing factors.

RISK FACTORS

Many interrelated risk factors have been associated with increased incidence of calf diarrhea and have added to the difficulty of understanding the complexity of the disease and controlling it. The identification and modification or removal of these risk factors can be very effective in the clinical management and control of epidemics of the disease.

Animal Risk Factors

The host risk factors, some of which are interrelated, include the following:

- Primiparous dam (higher risk of dystocia, lower quality of colostrum …)
- Immaturity/low birth weight of the neonate
- Difficult birth (mechanical trauma, asphyxia, acidemia, and impaired vigor)
- FTPI

Table 7-27 Differential diarrhea: Most likely causes of acute neonatal diarrhea in farm animals

Calves	Piglets	Lambs and kids	Foals
Acute neonatal diarrhea			
Enteropathogenic and enterotoxigenic *Escherichia coli*	Enteropathogenic *E. coli*	*C. perfringens* type C	Foal-heat diarrhea
Rotavirus	*Salmonella* spp.	*C. perfringens* type B	Rotavirus
Coronavirus	Transmissible gastroenteritis virus	(lamb dysentery)	*C. perfringens* type B
Bovine torovirus (Breda virus)		Rotavirus	
Bovine calicivirus	*C. perfringens* type C (rarely A)	Caprine herpesvirus	
Bovine norovirus			
Cryptosporidium spp.	*C. difficile*		
Giardia spp.	Rotavirus		
Salmonella spp.	PRRSV		
Eimeria spp. (calves at least 3 weeks old)	*Isospora* spp.		
Clostridium perfringens type C			

PRRSV, porcine reproductive and respiratory syndrome virus.

- Nutrition of the pregnant dam (reduced quantity and altered nutrient content of colostrum)
- Litter size (increased morbidity and mortality with increasing litter size in piglets)
- Disease of the dam around or after parturition (e.g., mastitis–metritis complex in sows)

Colostrum

The role of colostrum in protecting the newborn calf from infectious disease in early life cannot be overemphasized. The failure of the neonate to ingest an adequate quantity of colostrum containing a high level of colostral immunoglobulin within a few hours after birth is a major risk factor contributing to development of diarrhea and other infectious diseases. Complete or partial FTPI occurs with an incidence of between 5% and over 20% in different farm animal species, with highest incidence rates in dairy calves (see also Failure of transfer of colostral immunoglobulins (transfer of passive immunity) in Chapter 19).

Causes for FTPI can be various and include impaired vigor of the calf with low drive to suck (e.g., immaturity, acidemia, asphyxia, birth-related trauma), inadequate immunoglobulin content of colostrum (e.g., colostrum leaking before calving, colostrum collected later than 6 hours after calving), inadequate volume of colostrum available to the calf (e.g., agalactia, mastitis, poor mothering skills of the dam), or delayed ingestion of colostrum.

Cases of diarrhea caused by specific **nutritional deficiencies** are reported rarely and not well documented. However, field observations indicate that outbreaks of diarrhea in suckling beef calves may have been associated with specific nutrient deficiencies such as copper or selenium. These are not documented but should be considered in certain situations in which these deficiencies are known to be present in the herd. An epidemic of intractable diarrhea in 2-month-old beef calves was associated with deficient tissue and plasma levels of vitamin E in the affected calves, which also had lesions of skeletal and myocardial muscular dystrophy with adequate levels of selenium. An inadequate supply of vitamin E and β-carotene to the neonate though colostrum from dams that were vitamin E and β-carotene deficient during late gestating has been incriminated as a predisposing factor for neonatal diarrhea in dairy calves.[1] A combination of low vitamin E status and low immunoglobulin status may contribute to neonatal diarrhea by impairing the immune cell function of calves, but this is not well documented.

Environmental and Management Risk Factors

A number of environmental and management risk factors have been identified as predisposing diarrhea in different farm animal species and different production systems.

Table 7-28 Calf diarrhea risk factors: Risk factors and their role in acute undifferentiated diarrhea of newborn calves

Risk factor	Role of risk factor
Colostral immunity of calf	Low levels of serum immunoglobulins render calves highly susceptible to death from diarrhea.
Dystocia	Calves born at a difficult calving were at increased risk of developing and dying of diarrhea.
Parity of dam	Calves born from heifers may not acquire sufficient levels of colostral immunoglobulins.
Residence time in maternity pen (dairy)	Dairy calves remaining in the maternity pen with their dam for longer than 24 h were found to be at increased risk of developing diarrhea, presumably caused by longer exposure to pathogens and/or lower amounts of ingested colostrum.
Group housing (versus hutches)	Calves housed in groups were at higher risk of developing diarrhea, presumably because of facilitated fecal–oral transmission of pathogen.
Overcrowding	Increased population density increases infection rate and high morbidity and mortality.
Preventive antimicrobial use	Calves with adequate colostrum supply were at higher risk of developing diarrhea when treated preventively with medicated milk replacer.[12]
Meteorological	Changes in weather; wet, windy, and cold weather commonly precedes outbreaks of diarrhea in beef calves; higher mortality in dairy calves exposed to hot environmental temperatures; high environmental temperatures precipitate outbreaks
Quality of diet	Heat denatured skim milk used in milk replacers is less digestible than whole milk and precipitates diarrhea.
Calf rearer	The concern and care provided by the calf rearer will have a direct effect on morbidity and mortality associated with diarrhea.
Herd size	Conflicting reports over the effect of herd size on the incidence rate of calf diarrhea and calf mortality have been published.

Calves

A wide range of management practices from housing and feeding of the pregnant dam, to over calving management, to calf housing and feeding have been associated with an increased risk of enteric disease in dairy calves (Table 7-28).

Nutrition of the Dam in the Preparturient Period

Nutrient deficiencies in cows during the late trimester of pregnancy have been associated with decreased birth weights and impaired efficiency of intestinal IgG absorption of the calves born to cows fed a protein deficient diet.[2,3] Although little effect of the dam's nutrition on the colostral immunoglobulin content has been reported, β-carotene and tocopherol deficiency of the dam during late gestation was associated with deficiency of these substances in their calves. Because deficiencies in β-carotene and tocopherol were more common in herds with high incidence rates of neonatal diarrhea, this has been incriminated as a potential predisposing factor.[1,4]

Calving Management: Dairy

The calving management has a great impact on the calf's health and development during the neonatal period and beyond. Calves born in a separate maternity facility are at decreased risk of developing neonatal diarrhea compared with calves born in regular stalls (either stanchion or free stalls),[5] and calves born in individual maternity pens had a lower risk of diarrhea than animals born in a group maternity pen.[6] Prolonged residence time of the neonate in the maternity pen (over 24 hours) was associated with increased risk of diarrhea and calf mortality. These effects have been attributed to differences in exposure to pathogens and differences in colostrum intake associated with the different management systems.

The degree of calving supervision and quality of obstetric care also affects the disease incidence in neonatal calves. Lack of calving supervision can lead to prolonged calvings resulting in more severe acidemia and asphyxia, which will impair the calf's vigor in early life. Good obstetric technique will reduce stress and reduce the risk of birth-related trauma in dams and calves.[5]

Calving Management: Beef

Crowding of maternity or wintering lots and calving cows and heifers on the same grounds is considered an important risk factor for calf diarrhea in cow–calf operations. A decrease in the surface of the effective calving yard per cow is generally associated with poor drainage and wetness and results in increased pathogen exposure. Similarly, the odds of diarrhea occurring in calves born toward the end of the calving season are twice that of

calves born in the first part of the calving season. This also may be because of increased pathogen exposure as the calving season progresses.

Colostrum Management: Dairy

Although in most farm-animal species adequate colostrum intake can be anticipated in the large majority of spontaneously delivered healthy neonates, this is not the case in dairy calves. Numerous studies have demonstrated that a considerable number of calves allowed to voluntary nurse from their dam after birth suffer from FTPI, which is the major risk factor for diarrhea and other neonatal infectious diseases (see also Failure of transfer of passive immunity).[4,6] Assuring adequate colostrum intake in a timely manner by separating the calf from its dam and hand-feeding colostrum is associated with significantly lower rates of FTPI and a significantly lower risk of neonatal diarrhea.

Other colostrum management practices that can affect the occurrence of disease are avoiding fecal contamination during collection, pasteurization of colostrum, and proper storage.

Calf Housing and Feeding: Dairy

Group housing of calves during their first month of life is associated with higher diarrhea incidence than housing calves in individual hutches, and the overall morbidity rate of neonatal calves is higher when calves are housed in groups of 6 to 30 calves compared with small groups of up to 6 calves.[7] Similarly indoor housing was associated with higher morbidity and mortality rates in neonatal dairy calves than housing calves in outdoor hutches.

Overall disease occurrence and mortality of neonatal calves has been shown to be influenced by feeding practices. Adequate energy and nutrient supply are critically important for proper immune function. In the dairy industry it is customary to limit the daily feed supply of unweaned calves to 10% to 15% BW, a procedure also known as "restricted feeding." The objective of restricted feeding is to facilitate early weaning and to decrease the risk of diarrhea. Notwithstanding the voluntary intake of calves fed whole milk ad libitum can easily exceed double this amount, and it was shown that calves can safely ingest milk equivalent to 20% of their BW and achieve markedly higher daily weight gains than calves on restricted feeding.[8] The effect of feeding larger amounts of milk on the incidence of diarrhea was studied with inconsistent results; some studies have reported higher diarrhea incidence when feeding larger volumes while others did not.[8]

Feeding milk replacer instead of whole milk also presents a form of undernutrition, particularly during the cold season of the year, when the energetic requirements of the calf are increased. The energy density and the digestibility of proteins contained in commercial milk replacers are generally speaking lower than in whole milk, which has been proposed to predispose to impaired immune function and thus to disease. A study comparing calves fed the same amount of whole milk or milk replacer in a commercial dairy farm found that mortality rates in both groups were similar during summer but differed dramatically during winter between calves fed whole milk (2.8%) and milk replacer (21.0%).[9]

Some studies have shown that the major contributing factor to dairy calf mortality is the care provided by the calf attendant.

Calf Housing and Feeding: Beef

In beef herds veterinarians have commonly observed a relationship between adverse climatic conditions and epidemics of diarrhea in calves. During inclement weather, such as a snowstorm, a common practice in beef herds is to confine the calving cows in a small area where they can be fed and watered and observed more easily. The overcrowding may be followed by an outbreak of calf diarrhea.

Disease Control and Management: Dairy

Antibiotics are widely used for the control and treatment of diarrhea and other diseases, particularly in dairy and veal calves. A common practice is feeding medicated milk or milk replacer during the first weeks of life, which is a practice that has been associated with reduced calf morbidity and mortality and increased daily weight gains particularly in herds with a high prevalence of FTPI and high infectious pressure.[10] In contrast, this effect was much less pronounced over even the opposite in a well-managed herd with low FTPI prevalences. In well-managed herds calves fed a medicated milk replacer had over 30% more days with diarrhea than herd mates receiving nonmedicated milk replacer.[10]

Although antimicrobial therapy is clearly indicated in diarrheic calves with signs of systemic disease, antibiotics may be counterproductive in scouring calves without systemic illness.[11] Scouring calves without systemic illness that were treated with antibiotics in addition to oral rehydration had 70% more days with diarrhea than calves without systemic disease that received oral rehydration without antibiotics.[12]

Other Environmental and Management Factors

Cold, wet, and windy weather during the winter months in temperate climates and hot humid weather during the summer months may be associated with an increased incidence of dairy calf mortality caused by diarrhea. Changes in weather and wet, windy, and cold weather are commonly associated with subsequent outbreaks of the disease in beef calves raised outdoors. Increases in population density in calf barns, and on calving grounds, resulting in highly contaminated calving grounds, are important risk factors.

Increasing the percentage of heifers calving in the herd is associated with an increased risk of diarrhea because calves born to heifers may be about four times greater than in calves born to cows.

Large herd size was found to be associated with increased diarrhea incidence and overall calf morbidity and mortality in some studies but not in others.[7]

Piglets

Epidemics of diarrhea in piglets are commonly associated with inadequate sanitation and hygiene in the farrowing facility, which may be under continuous use without sufficient time for cleaning and disinfection between farrowings. Producers that managed their farrowing barns as all-in/all-out facilities had lower diarrhea-related morbidity and mortality rates.[13] Herd size was found to have a positive association with piglet morbidity but not mortality related to diarrhea.[13]

Piglets in litters receiving milk replacer as feed supplement were at increased risk of developing diarrhea (OR 1.9) compared with piglets that did not. Although the explanation for this observation is not evident, it was suggested that feed supplementation might either be associated with increased occurrence of hypogalactia or agalactia in sows, or the provision of milk replacers reduces the voluntary intake of sow's milk.[13]

Other management practices that were associated with reduced diarrhea incidence in piglets were the parenteral administration of iron to piglets and vaccination of the sow herd against *E.coli*.[13] Increasing the percentage of gilts among the sow population was associated with increasing diarrhea incidence in the herd.[14]

Seasonal effects have also been reported with highest diarrhea incidence rates in piglets occurring during the cold season of the year.[15]

Lambs

Management factors associated with diarrhea in neonatal lambs were animal density in pens, cleaning frequency of lambing pens, and the use of anthelminthic drugs.[16,17]

Conflicting results regarding the effect of the flock size on diarrhea incidence in lambs have been published. Although some authors reported an increased risk of diarrhea with increasing flock size, this was not confirmed by others.[17]

Pathogen Risk Factors

Calves

The distribution and occurrence of enteropathogens in the feces of diarrheic and normal healthy calves vary depending on the geographic location, the farm, the age and type of calves being examined, and the extent

to which the diagnostic laboratory is capable of isolating or demonstrating the pathogens. Rotavirus, *Cryptosporidium* spp., coronavirus, and ETEC, collectively, are responsible for 75% to 95% of infections in neonatal calves worldwide. The relative frequencies of each of the four differ between locations and between seasons and years. Any one of the common pathogens may predominate or be absent in a certain group of animals. Mixed infections are common. Rotavirus will be most common in some groups, especially housed calves. Coronavirus may predominate in beef calves in some countries, and *Cryptosporidium* spp. may occur in 30% to 50% of diarrheic calves on a worldwide basis. *Cryptosporidium* spp., rotavirus, and coronavirus are the most commonly identified enteropathogens in intensively reared veal calves. In dairy calves, the prevalence of giardiasis and cryptosporidiosis may be high and both parasites may be associated with diarrhea. *C. parvum* is an important pathogen in calves under 1 month of age, but *Giardia duodenalis* may be more important in older calves. Calves may clear *C. parvum* infections within 2 weeks, whereas *G. duodenalis* infection may become chronic in the same calves. The combination of *Cryptosporidium* spp. and rotavirus may predominate in some situations. *Cryptosporidium* spp. were the second most commonly detected pathogens next to rotavirus, and case–control studies indicated a highly significant association with diarrhea. Enteropathogens may not be detectable in up to 30% of diarrheic calves. *Eimeria* spp. can cause coccidiosis in calves any time after about 21 days after birth, but the disease is more common in calves several months old.

In some countries, enterotoxigenic F5 ($K99^+$) *E. coli* may occur in 30% to 40% of diarrheic calves, whereas in others the incidence may be as low as 3% to 6%. AEEC that causes hemorrhagic colitis and blood in the feces of diarrheic calves about 2 weeks of age is being recognized with increasing frequency. It may occur concurrently with other enteropathogens (cryptosporidia, rotavirus, coronavirus, ETEC, bovine viral diarrhea virus [BVDV], and coccidia).

The age occurrence of the common enteropathogens associated with diarrhea in calves is shown in Table 7-29. Case–control studies of diarrheic and healthy calves from the same groups indicate that the enteropathogens commonly found in diarrheic calves can also be found in healthy calves but at a lower frequency, with the exception of rotavirus, which may be excreted by up to 50% of healthy calves. It appears that healthy calves may be infected more often with ETEC, *Cryptosporidium* spp., coronavirus, and rotavirus in herds in which some calves have or recently have had enteric disease than in herds free from major enteric disease.

Campylobacter spp. and *Yersinia* spp. are well adapted to the bovine host and can be found in the feces of diarrheic and healthy calves at a similar prevalence. Their significance as pathogens in newborn calves is uncertain. They are probably part of the normal enteric flora of ruminants. However, as they represent a source of gastrointestinal infections in humans, management factors limiting intestinal colonization of these bacteria should be considered in beef cow/calf herds.

Rotavirus and coronavirus occur with almost equal frequency in the intestinal tracts of normal and diarrheic calves of some studies. Intestinal lesions compatible with the viral infection are found in about 70% of diarrheic calves. Thus these viruses are widespread in the bovine population and only under some predisposing circumstances will the infection be severe enough to cause clinical disease. Other viruses, such as parvovirus, astrovirus, Breda virus, and norovirus, have been isolated from the feces of diarrheic calves, but their role in the etiology is yet to be defined.

A necrotizing enteritis of suckled beef calves 7 to 10 weeks of age on pasture in Scotland has been reported. Fever, acute diarrhea and dysentery, and a case–fatality rate of 25% are characteristic. No etiologic agent has been identified.

Table 7-29 Calf enteropathogens: Age occurrence of the common enteropathogens in calves

Enteropathogen	Age (days)
Enterotoxigenic *Escherichia coli*	<3
Attaching and effacing *E. coli*	20–30
Rotavirus	5–15
Coronavirus	5–21
Other viruses (Breda virus, parvovirus, bovine virus, diarrhea virus)	14–30 (and older, up to several weeks)

Lambs and Goat Kids

The *E. coli* strains isolated from diarrheic lambs and goat kids on Spanish farms are not generally toxigenic and belong to a large number of O serogroups.

Piglets

In outbreaks of diarrhea in neonatal piglets during the first 5 days of life, the enteropathogens that are commonly present in the feces include the TGE virus, ETEC, *Isospora* spp., rotavirus, *C. perfringens,* and adenovirus. *C. difficile* has emerged as an important pathogen causing enteritis in suckling piglets. The TGE virus causes diarrhea in piglets under 15 days of age, *Isospora* sp. between 5 and 15 days of age, and rotavirus in piglets over 10 days of age. ETEC was found to be preferentially shed by weaned diarrheic piglets. Suckling diarrheic piglets had a low prevalence of ETEC shedding that decreased from the first to third week of life.[18] During the second and third weeks of life, *I. suis* is the most common pathogen in outbreaks of diarrhea in litters of piglets. Although individual piglets may be infected by a single pathogen, it is common for more than one pathogen to be present in the litter.

A seasonal occurrence of the common enteropathogens has also been observed. The prevalence of the TGE virus may be highest during the fall, winter, and spring months, and coccidia and *E. coli* are more common during the summer, fall, and early winter, with the lowest prevalence in the spring.

Foals

Diarrhea in foals is common but most cases are mild, transient, and not associated with infectious agents. Diarrhea is the most commonly reported disease in foals under 7 days of age. The most common occurrence is associated with "foal heat" in the mare. Diarrhea is a common clinical finding in septic foals and is presumably the result of mucosal hypoperfusion and sepsis-related inflammatory mediators rather than bacterial or viral enteritis.

Rotavirus group A (RVA) is the most common cause of epidemics of diarrhea in foals and most commonly occurs in foals under 30 days of age.[19] Clostridial infection associated with diarrhea is most commonly caused by *C. perfringens* type C or *C. difficile.*[19] *Salmonella* spp. have been associated with diarrhea in foals but can cause diarrhea in horses of any age. A variety of other pathogens have occasionally been isolated from diarrheic foals, such as *E. coli, B. fragilis, Enterococcus* spp., and *Aeromonas* spp.

CLINICAL MANAGEMENT OF EPIDEMICS

When faced with an outbreak of acute diarrhea in neonatal calves (less than 30 days old) in which there is profuse watery diarrhea, progressive dehydration, and death within a few days or earlier, the following steps are suggested:

1. Visit the herd and do an epidemiologic investigation to identify the risk factors that may be responsible for the outbreak. Most outbreaks are multifactorial and an interaction among the environment, management, feeding, and the pathogens is probable. The investigation of the underlying causes of the outbreak should involve an examination of the following:
   - Dry cow management (including vaccination protocols)
   - Calving management
   - Colostrum management
   - Calf management (housing, prophylactic treatments, vaccinations …)

- Calf feeding (whole milk or milk replacer, type of milk replacer, amount fed, feeding frequency, feeding hygiene …)
- History of the present outbreak
- Farm history of previous disease outbreaks (not only affecting neonatal calves)
- The affected calves (which calves are affected?, age, vigor, housing type …)
- Results of necropsy, clinical pathology, and microbiology if available
- Treatments used in the current outbreak and their efficacy
- Recent changes in management and environment or changes of the herd that may be associated with the outbreak

2. Each of the commonly recognized risk factors must be examined for its possible role in the particular outbreak:
   - Overcrowding of calving yards in beef herds
   - Recent changes in incidence rate of dystocia and perinatal mortality in calves and periparturient disease in cows
   - Recent changes in climate and recent stress of any kind on the herd
   - In dairy herds feeding milk replacer, the feeding plan should be investigated.
   - Any recent introductions of replacement calves into the herd should be considered as possible sources of pathogens.
   - Prevalence of FTPI can be crudely assessed by checking 10 to 12 healthy calves between 24 hours and 7 days of age for the serum protein or preferably the serum IgG concentration (see Failure of transfer of passive immunity); the prevalence of FTPI should certainly not exceed 20%.
3. Affected calves should be examined clinically, dead ones by necropsy, and a case definition should be determined to ensure that diarrhea is the major problem.
4. All affected calves should be identified, isolated, and treated immediately with oral and parenteral fluid therapy as indicated. The use of oral fluid and electrolyte therapy for the treatment of dehydration and acidemia as soon as the calves are seen to be diarrheic must be emphasized.
5. Antimicrobial therapy should be considered for diarrheic calves with systemic illness but not for alert calves with diarrhea as the only clinical sign.
6. Fecal samples (30–50 g) should be collected from diarrheic calves at the first sign of diarrhea and from normal calves and submitted to a laboratory for the attempted isolation and characterization of ETEC as well as rotavirus and coronaviruses, *Salmonella* spp., and *Cryptosporidium* spp. A rapid ELISA test is available for the simultaneous detection of *E. coli* F5 ($K99^+$) antigen, bovine coronavirus (BCoV), and rotavirus in the feces of diarrheic calves during the acute phase of the infection. Commercial test kits that can be used calf-side for the detection of BCoV, RVA, F5 ($K99^+$) *E. coli,* and *Cryptosporidium spp.* antigen have become available in recent years.
7. Pregnant cows that are due to calve shortly should be moved to a new calving area. In a dairy herd this means a different, clean calving stall, preferably in another barn not previously occupied by cattle; in beef herds it may mean moving a large number of cows to a new, uncontaminated calving pasture.
8. The control of the disease in future calf crops will depend on application of the principles of control, which are described under Acute undifferentiated diarrhea of newborn farm animals and Viral diarrhea of calves, lambs, kids, piglets and foals. If a significant number of cows are due to calve in more than 3 to 6 weeks, vaccination with the calf diarrhea vaccines can be considered.
9. A report should be submitted to the owner that records the observations made at the farm visit and outlines specific recommendations for clinical management of affected calves and for control of the disease in the future.

CONTROL

The principles of control are presented in detail in the sections on colibacillosis of newborn calves, piglets, lambs, kids, and foals, and viral diarrhea in calves, lambs, kids, piglets, and foals, using the following principles:

- Reduction of the degree of exposure of the newborn to the infectious agents
- Provision of maximum nonspecific resistance with adequate colostrum and optimum animal management
- Increasing the specific resistance of the newborn by vaccination of the dam or the newborn

ENTEROCOLITIS ASSOCIATED WITH *CLOSTRIDIUM DIFFICILE*

SYNOPSIS

Etiology Toxigenic strains of *Clostridium difficile.* Common bacterial etiology in antibiotic-associated diarrhea. Fecal–oral spread

Epidemiology Horses: occurs in foals and adults. Commonly precipitated by therapy with antimicrobial agents and/or hospitalization. Pigs: diarrhea and death in piglets in first week of life

Clinical findings Profuse watery diarrhea, tachypnea, dehydration, and metabolic acidosis. High case fatality, especially in very young foals

Necropsy findings Fibrinous to necrotic enterocolitis. Edema of mesocolon in pigs

Diagnostic confirmation Demonstration of organism and toxins

Treatment Fluids and electrolytes. Horses: metronidazole, if sensitive, or vancomycin (noting public health concern)

Control Isolation and barrier protection and prophylactic metronidazole

ETIOLOGY

C. difficile is a gram-positive, spore-forming, anaerobic bacterium. It is a recognized cause of antibiotic-associated diarrhea and pseudomembranous colitis in humans suffering perturbation of the bowel flora from antibiotic therapy or other causes. *C. difficile* causes enterocolitis in horses of any age and is associated with diarrhea in neonatal pigs.

Strains of *C. difficile* pathogenic to horses produce two toxins, A and B, and the degree of pathogenicity is related to the capacity for toxin production.[1] There are numerous strains of *C. difficile* (>50 ribotypes by one estimate), although a much smaller number (~4) constitutes the predominant isolates in animals.[2] Ribotype 078 is the most commonly reported in animals, especially in pigs and cattle,[3] although common human ribotypes (014/020 and 002) also occur in animals. *C. difficile* is isolated commonly from cattle. All *C. difficile* isolates from pigs, cattle, and poultry in the Netherlands were toxinogenic.[3]

EPIDEMIOLOGY

Occurrence

Horses

The disease can occur as outbreaks or, more commonly, is sporadic and associated with the risk factors of antimicrobial administration, hospitalization, or both.[1] It appears to occur worldwide. In young foals within the first 2 weeks of life it may occur without apparent predisposing causes but in adult horses it commonly follows the use of antimicrobial agents.[4] Case–fatality rates are highest in very young foals, in which the disease can be complicated by other existing neonatal diseases.

The microbiota of horses is complex and clostridial species are common in the feces of healthy horses, although *C. difficile* (mostly nontoxinogenic) is isolated from <10% of horses on single sampling.[5-7] However, monthly sampling of 25 healthy horses for 1 year detected toxinogenic *C. difficile* in 40% of horses at least once,[8] and toxinogenic *C. difficile* was detected in 7 of 55 healthy race horses examined once during summer in Ohio, suggesting that asymptomatic carriage of toxinogenic strains by some populations of healthy horses is relatively common.[9] Detection of toxigenic *C. difficile* is often, but not always, associated with disease in horses of any age, as demonstrated by the disproportionate representation of this organism in feces of horses with diarrhea.[6-8,10-14] Seven of 14 foals with diarrhea had *C. difficile* toxin (A/B) identified in feces, whereas none of 139 healthy foals were positive.[15] *C. difficile* was detected only in foals with gastrointestinal disease, and not in healthy foals (OR 5.4), in central Kentucky.[14] *C. difficile* toxin(s) is detected in approximately 5% of hospitalized foals with diarrhea,[10] and *C. difficile* was isolated from 10 of 73 hospitalized horses, 7 of which were positive for toxin A and/or B.[16] There was no association of *C. difficile* with a particular disease in this study.[16] One or both animals in mare–foal pairs can be subclinically infected with *C. difficile* and are potentially a source of infection for the other.[11] This is exemplified by the development of acute *C. difficile* enterocolitis in mares of foals treated with erythromycin and rifampin. Both *C. perfringens* (type A) and *C. difficile* can simultaneously infect foals with severe enterocolitis not associated with administration of antimicrobials, suggesting the potential for an interaction resulting in more severe disease.[4]

There is a strong anecdotal association of *C. difficile*-associated enterocolitis in horses with the administration of antimicrobials. Although most clinicians would agree that this association exists, there is no evidence that quantifies the increase in risk of a horse developing *C. difficile*-associated disease with the administration of antimicrobials or particular antimicrobials. Antimicrobial administration was not significantly more likely in horses with *C. difficile*-associated diarrhea than in horses with diarrhea from which *C. difficile* was not identified, and only 26% of hospitalized horses with *C. difficile*-associated diarrhea had been administered antimicrobials.[17] Thirty-two of 33 (97%) horses and all adult horses with *C. difficile*-associated diarrhea had been administered antimicrobials before onset of diarrhea compared with 48% to 79% of horses with diarrhea of other causes.[18]

Horses with longer duration of hospitalization before onset of diarrhea are more likely to develop *C. difficile*-associated diarrhea.[18]

Pigs

C. difficile has increasing reportage, or recognition, and occurs predominantly in young piglets but also is recorded as a major cause of disease and mortality in sows.[19] The disease occurs worldwide and is an important cause of loss of young piglets.[20,21] The disease in piglets occurs predominantly in the first week of life, when the majority of the litter can be affected, and the case fatality can approach 50% but is usually lower. Stunting is a common sequel. Outbreaks occur with or without a history of processing with antibiotics.

The disease has not been effectively reproduced with simple challenge of conventional animals, suggesting that *C. difficile* in itself is not a sufficient cause. Challenge of adult horses with *C. difficile* with and without pretreatment with penicillin did not result in clinical disease in any of the horses, but *C. difficile* was subsequently isolated at greater frequency from the feces of the horses pretreated with penicillin. Challenge of newborn foals with *C. difficile* has resulted in enteric disease and diarrhea, but only in foals not receiving adequate transfer of colostral antibodies. *C. difficile* has been reproduced in gnotobiotic but not conventional pigs.

Routine prophylactic antimicrobial treatment of periparturient sows for diseases such as mastitis–metritis–agalactia has resulted in outbreaks of enterocolitis.

Pathogen Risk Factors

Pathogenic strains of *C. difficile* produce an enterotoxin (toxin A) and a cytotoxin (toxin B). There are degrees of virulence between strains, but nontoxigenic strains are considered nonpathogenic. Other virulence factors, including an actin-specific adenosine diphosphate-ribosylating toxin and an outer cell surface coat S layer, have been proposed as additional virulence factors.

The organism can be isolated from a number of environmental samples, including soil and the environment of veterinary hospitals. Although it appears that the organism is not commonly present in the feces of normal horses, it can be isolated from those of other animal species and has high prevalence in the feces of dogs and cats. The organism can survive in feces for at least 4 years. Spores are resistant to common disinfectants, but a 5% bleach solution is stated to be effective for disinfection.

Zoonotic Implications

C. difficile is a cause of diarrhea in humans and most commonly occurs following the administration of antibiotics, although sporadic cases without these risk factors also occur. The disease in humans may be mild and self-limiting or develop to severe pseudomembranous colitis with risk of intestinal perforation. In one study using molecular typing, 25% of isolates from humans were indistinguishable from isolates from animals. The risk for zoonotic infection should be considered, but barrier protection and attention to personal hygiene when handling animal cases should limit the risk for infection. Veterinarians and animal handlers undergoing antimicrobial therapy are particularly at risk.

PATHOGENESIS

The disease is associated with severe watery diarrhea and a hemorrhagic necrotizing enterocolitis. The enterotoxin A damages villous tip and brush border membranes and causes necrosis and increased intestinal permeability. The cytotoxin B is lethal to cells once the gut wall has been damaged. Complete erosion of the mucosa may result. Both toxins induce the production of TFN and proinflammatory interleukins, with a resultant inflammatory response and pseudomembrane formation. Lactose intolerance may develop secondary to infection.

CLINICAL FINDINGS

Horses

C. difficile occurs in horses of any age. In foals, it is part of the complex of diseases causing diarrhea and with a variety of clinical severity characteristic of these diseases.[10,14] In adults, infection causes hemorrhagic or necrotizing enterocolitis with classical signs of that syndrome.[22]

The disease in foals ranges from mild, self-limiting diarrhea to acute, rapidly fatal enterocolitis. Disease occurring with onset in the first 2 weeks of life is initially manifested with a decreased interest in suckling, often with signs of colic with increasingly prolonged and severe episodes of rolling and kicking at the abdomen and the occurrence of profuse watery and occasionally hemorrhagic diarrhea. Rectal temperatures are within the normal range but there is severe dehydration, an elevation of heart rate and respiratory rate, acidemia attributable to metabolic acidosis, and the development of septic shock. There is progressive enlargement of the abdomen, and transcutaneous ultrasound shows thickened, fluid-filled loops of intestine and fluid in the ventral abdomen.

In adult horses the disease is manifested with acute and often fatal colitis with profuse

diarrhea, toxemia, hypovolemia, and metabolic acidosis and is reported in individuals and as outbreaks in horses hospitalized and treated for various diseases.[13,17,18] The clinical signs of horses with *C. difficile*-associated disease are not distinguishable from those with non–*C. difficile*-associated disease,[17] although horses with *C. difficile*-associated diarrhea have higher rectal temperatures, band neutrophil counts, hematocrit, and hemoglobin concentration than do horses with diarrhea not associated with toxinogenic *C. difficile*. Horses with *C. difficile*-associated diarrhea have longer duration of hospitalization after onset of diarrhea than do horses with diarrhea of other causes.[18] The case–fatality rate for adult horses is approximately 25%.[18]

Pigs

Affected piglets are depressed and have a yellow, mucoid diarrhea with occasional piglets passing feces with specks of blood. As the condition progresses, affected pigs show abdominal distension and tachypnea, and some have scrotal edema. There is progressive dehydration and hypoglycemia.

CLINICAL PATHOLOGY

There is a leukopenia, a toxic left shift, a high hematocrit, and hyperfibrinogenemia. Plasma protein may be normal to low and there are high bilirubin and elevated liver enzyme values. Metabolic acidosis, as evidenced by an increase in anion gap and decrease in total CO_2 concentration, hyponatremia, and azotemia are present.[17,18] Blood IgG concentrations of affected foals are commonly within the normal range.

Classic methods of diagnosis are by examination of feces by culture of the organism and demonstration of toxins A and B by cytotoxin assays and enzyme immunoassays, some of which have been validated for use in horses with acute diarrhea and in foals.[12,23] Cycloserine–cefoxitin–fructose agar is commonly used to isolate *C. difficile* from feces, and detection is improved by use of PCR technology.[24] The isolation of *C. difficile,* in itself, is generally not considered to be diagnostic and should be accompanied by demonstration of toxin A in the feces by ELISA, or by tissue culture cytotoxin assays, to allow a putative diagnosis. Fecal toxin testing in live animals is an effective method of diagnostic conformation and correlates highly with toxin tests on intestinal contents at postmortem.

The organism, but not the toxins, is labile when kept aerobically at 4°C, with a significant decrease in recovery after 24 hours. Consequently, samples for culture should be taken in anaerobic transport media and shipped on ice.

PCR can provide a more reliable method of detection of genes encoding toxin A and toxin B.[11,13,15] Feces, or isolates, can be tested for genes encoding toxins A and B by PCR, and PCR can also be used retrospectively following postmortem for diagnosis in formalin-fixed tissues.

Human assays are not all suitable for diagnosis of the disease in piglets, with performance of molecular tests designed for humans being inadequate for diagnosis of disease in pigs.[25]

NECROPSY FINDINGS

Horses

Gross findings are of necrotizing or hemorrhagic enterocolitis with histologic findings that vary from a superficial fibrinous colitis with hemorrhage and edema to a severe hemorrhagic multifocal necrosuppurative and ulcerative enterocolitis.[22]

Pigs

The contents of the small intestine are scant and those of the large intestine yellow to dark yellow in color. Edema of the mesocolon is a common finding, along with increased fluid in the peritoneal and pleural cavities. Histologic findings vary from necrosis and exfoliation of the intestinal mucosa to segmental transmural necrosis in the large intestine.[11,15]

DIFFERENTIAL DIAGNOSIS

- Horses: See Table 7-5.
- Swine: See Table 7-6.

TREATMENT

Horses should be aggressively treated with fluids, plasma, and pressors to correct the fluid and electrolyte imbalance, correct the metabolic acidosis, and control pain. Antimicrobial therapy should be based on sensitivity testing if possible, but most isolates of *C. difficile* are susceptible to commonly used antimicrobials.[26] Isolates are usually resistant to trimethoprim-sulfamethoxazole and bacitracin, variably resistant to rifampicin, and susceptible to vancomycin. Metronidazole, 10 mg/kg intravenously four times daily or 15 mg/kg orally four times daily, has been commonly used for therapy, but there is geographic variation in sensitivity and there are reports of clinically important resistant strains.[27] Metronidazole and vancomycin are not approved for use in food animal species in most countries, and use of vancomycin is not prudent on public health grounds. Pharmacokinetics of metronidazole in foals are highly age dependent, and dosing should be adjusted in foals by increasing the period between administration of the drug from every 6 hours to every 12 hours until foals are 2 to 3 weeks of age.[28]

In vitro studies have shown that di-tri-octahedral (DTO) smectite can bind *C. difficile* toxins A and B, and that this can occur without inhibiting the antibacterial action of metronidazole. Clinical trials of efficacy have not been conducted but pharmacologic considerations indicate that an initial dose of 1.4 kg of DTO smectite, administered by stomach tube, followed by 454 g every 6 to 8 hours, could be of therapeutic value. Experimental studies in hamsters indicate promise for the use of immune sera and vaccines, but these are not currently available in agricultural animals.

CONTROL

There is no definitive control procedure. The organism is commonly present in veterinary environments and equine environments where there are foals. Foaling areas should be clean and disinfected with a sporicidal disinfectant. Metronidazole, 500 mg administered orally twice a day for 2 weeks, may be indicated for at-risk horses. Clinical cases should be isolated and, in a veterinary environment, strict barrier protection established between them and other animals under antimicrobial therapy. Orally administered probiotics and lactic-acid–producing bacteria are in use as an aid to prevention, but there are data indicating lack of efficacy.[29]

PROLIFERATIVE ENTEROPATHY IN HORSES

ETIOLOGY

Proliferative enteropathy is associated with LI, an obligate intracellular gram-negative

bacterium associated with proliferative enteropathy in pigs, horses, hamsters, dogs, deer, rabbits, rats, camels,[1] and ratites. The disease in foals can be reproduced by experimental oral infection of foals with a virulent organism.[2] The organism can be isolated from feces of a large number of mammalian species including striped skunks, Virginia opossums, jackrabbits, and coyotes.[3] There is close similarity in DNA among isolates from a variety of species, although strains of the organism isolated from one species vary in their capacity to produce disease in other species. Infection of foals with an organism derived from clinically affected foals, foals with an organism derived from pigs, pigs with an organism derived from foals, and pigs infected with an organism derived from pigs demonstrated more severe disease in species-specific isolates. Such isolates resulted in the development of clinical signs, longer fecal shedding of the organism, and high serologic response than non–species-specific isolates.[4] There is also evidence of varying infectivity and pathogenicity in laboratory animals (hamsters and New Zealand rabbits) of equine or porcine isolates from clinically affected foals or piglets.[5]

EPIDEMIOLOGY

The disease was initially reported from North America and has subsequently been detected in most, if not all, areas of the world with commercial horse studs, including Japan, Europe, South America, Australia, and Israel.[6-11] Prevalence of serum antibodies against the organism increases with increasing age, for instance, 15% of foals before weaning, 23% in weanlings, 89% in yearlings, and 99% in horses >2 years of age.[8] Serum antibodies are detected, by ELISA, in 14% to 100% of horses on individual farms in Kentucky, with seroprevalence positively related to occurrence of the disease. Farms without evidence of endemic clinical disease had lower mean titers and lower maximal titers in individual horses than did farms on which the disease was endemic. Whether this finding is a reflection of prevalence of the disease (i.e., a consequence of high disease prevalence on some farms) or reflects greater exposure of horses that subsequently develop disease is unclear.[12] Approximately 50% of mares on farms with endemic disease are seropositive and ~50% of foals acquire passive immunity (become seropositive after nursing) from mares, and these maternally derived antibodies persist for 1 to 3 months.[13] Thirty percent of foals have evidence of infection, but not disease.[13]

The organism was not detected in foals with signs of gastrointestinal disease in Kentucky in one study,[9] although the disease is endemic in the area.[14] The disease occurs almost exclusively during late summer and early winter in Kentucky.[14]

Affected foals are usually 3 to 13 months of age and disease in adults is rare.[15] There is insufficient information to determine whether there is a breed predisposition to the disease. The disease is presumably transmitted by the fecal–oral route, with mares a potential, but unproven, source of infection.[16]

Proliferative enteropathy in foals occurs as isolated cases and as outbreaks on breeding farms. There is evidence that outbreaks begin after introduction of foals or weanlings to farms with no history of the disease, although whether this is coincidence or represents the mechanism of introduction of infection to the farm is unknown. Morbidity among foals and weanlings on affected farms is 20% to 25%, although this is based on disease outbreaks on only two farms. Case–fatality rate is as low as 7% in treated foals.[14]

PATHOGENESIS

The pathogenesis of the disease in foals has not been determined, but it is probably similar to that of the disease in pigs. Infection results in development of an enteropathy characterized by proliferation of intestinal crypt epithelial cells and infiltration of the lamina propria with mononuclear inflammatory cells. Subsequent malabsorption of small-intestinal contents and protein loss from diseased intestine cause weight loss and hypoproteinemia characteristic of the disease in foals. There is decreased or absent absorption of glucose in foals that can persist, with decreasing severity, for >2 months.[17] Colic and diarrhea result from intestinal dysfunction and malabsorption. Hypoproteinemia and the subsequent decrease in plasma oncotic pressure result in edema and signs of hypovolemia. Death is associated with severe hypoproteinemia, inanition, and colic.

CLINICAL SIGNS

The disease may present as one with a short course characterized by rapid weight loss, colic, and death within 2 to 3 days of onset of clinical signs or as a more chronic disease characterized by gradual development of weight loss and depression. Weight loss and poor body condition are consistent findings among foals affected by the chronic disease. Most affected foals have diarrhea that ranges in severity from acute profuse watery diarrhea to, more commonly, excessively soft feces. Foals are often depressed although they continue to nurse. Edema of the ventral abdomen and intermandibular space is common.[14] Fever is not a consistent feature of the disease.

An acute form of the disease results from ulcerative and necrotizing hemorrhagic enteritis.[18,19] Affected foals might be found dead or die after a brief illness (usually <8 hours) characterized by mild fever and rapid development of mild to severe colic and signs of sepsis.

Ultrasonographic examination of the abdomen reveals multiple loops of mildly distended small intestine with thickened walls. Loops of intestine can have walls of 5 to 8 mm thick (normal <3 mm; Fig. 7-8).

Many affected foals, and especially those that die of the disease, have concurrent diseases including parasitism and pneumonia.

The incubation period in pigs is 2 to 3 weeks but that in horses is unknown. Foals that recover from the disease may take several weeks to regain normal BW. Recovered foals that recover sell for approximately 70% of the sale price of unaffected siblings and peers.[14]

CLINICAL PATHOLOGY

Hypoproteinemia with moderate to severe hypoalbuminemia is present in most affected foals. Serum albumin concentrations can be as low as 0.6 g/dL (6 g/L). Hyperfibrinogenemia and mild anemia are common but not consistent findings. White cell count is elevated (>14 × 10 cells/L) in most foals. Serum sodium and chloride concentrations are lower than normal and serum creatinine concentrations higher than normal in about 50% of affected foals.

Detection of exposure can be by detection of antibodies in serum (IPMA or ELISA) or detection of LI DNA in feces or rectal swabs.[12-14,20,21] PCR examination of feces for LI is specific for detection of the organism in affected foals. Examination of feces detects LI in approximately 80% of samples, of rectal swabs approximately 75%, and of both combined approximately 90% of samples from affected foals.[21] An indirect immunofluorescent assay detects serum IgG antibody to LI in foals, although the specificity of this finding for detection of the disease in foals is unknown. Foals with proliferative enteropathy have titers of 1:30 or greater.

NECROPSY

Gross lesions are mainly thickening and irregular corrugation of the small intestine. There is proliferation of intestinal crypt epithelium with projection of crypt cells into the intestinal lumen. The lamina propria is infiltrated by mononuclear inflammatory cells. Silver staining of intestinal sections reveals numerous short, curved bacteria in apical cytoplasma of crypt epithelial cells.

Samples for Confirmation of Diagnosis

- **Histopathology** of small intestine
- **Silver staining** of small intestine to demonstrate intracellular bacteria associated with hyperplastic cryptic cell
- **Bacteriology** is culture (which can be difficult as it requires cell cultures) and PCR examination of small-intestinal tissue

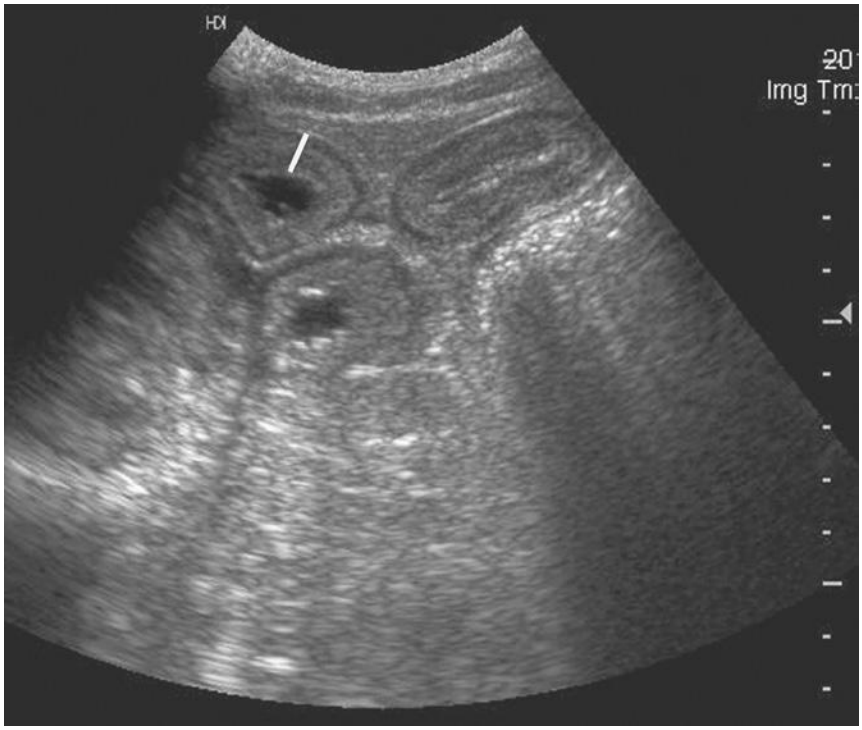

Fig. 7-8 Percutaneous ultrasonographic image of an 8-month-old filly with enteritis caused by Lawsonia *intracellularis* and demonstrating markedly thickened small-intestinal wall (9 mm; normal <3 mm). (Reproduced with permission. Arroyo LG, et al. *Can Vet J.* 2013;54:853.[18])

DIFFERENTIAL DIAGNOSIS

Antemortem diagnosis of proliferative enteropathy in foals should be based on the presence of characteristic clinical, hematologic, and biochemical signs; positive serology; and detection of Lawsonia *intracellularis* DNA in feces by polymerase chain reaction.

The primary differential diagnosis is **parasitism** by *Parascaris equorum*, cyathostomes, and large strongyles (in older foals). Examination of feces for helminth ova is diagnostic in cases with patent infections, but parasite infestations are often not patent in young foals. A history of an adequate parasite control program makes parasitism less likely but does not rule it out. **Malnutrition** caused by inappropriate or inadequate feeding practices or agalactia should be ruled out as a cause of failure to thrive.

Protein-losing enteropathy secondary to **enteritis and colitis** may be associated with *Salmonella* sp., *Rhodococcus equi,* or *Cryptosporidium* sp. Other intestinal diseases that cause enteritis but less often cause protein loss include the intestinal clostridioses, equine granulocytic anaplasmosis, and *Bacteroides* sp. infection. Intraabdominal abscesses associated with *R. equi* or *Streptococcus* sp. can cause chronic weight loss and hematological signs similar to proliferative enteropathy.

Hypoproteinemia can occur secondary to gastrointestinal ulceration. Neoplasia is rare in foals of this age, but intestinal lymphosarcoma can cause hypoproteinemia and weight loss.

Intoxication by **nonsteroidal antiinflammatory** drugs can cause a protein-losing enteropathy.

Diarrhea and ill-thrift caused by colitis and typhlitis associated with *Brachyspira* sp. (a spirochete) are reported from Japan.

TREATMENT AND CONTROL

Principles of treatment are eradication of infection and correction of hypoproteinemia. Administration of **antibiotics** is curative in many foals, and response to treatment does not appear to vary markedly with administration of oxytetracycline, chloramphenicol, or clarithromycin.[14] Isolates of the organism from pigs are sensitive in vitro to a wide range of antimicrobials including penicillin, erythromycin, difloxacin, virginiamycin, and chlortetracycline. Antibiotics used to treat LI infection in foals include oxytetracycline (6.6 mg/kg every 12 hours intravenously), doxycycline (10 mg/kg every 12 hours orally), chloramphenicol (50 mg/kg, every 6 hours orally), clarithromycin (7.5 mg/kg orally), or erythromycin estolate or similar product (15–25 mg/kg every 6–8 hours orally), sometimes in combination with rifampin (5–10 mg/kg every 12 hours orally). Erythromycin or oxytetracycline/doxycycline appear to be effective in the treatment of affected foals. Chloramphenicol is used in place of erythromycin in foals that develop intractable or severe diarrhea when treated with erythromycin, but its use is illegal in some countries and is not recommended because of the risk of aplastic anemia in people exposed to the drug. Enrofloxacin might be effective, based on MIC values, but should be reserved as a drug of last resort because of the arthropathy associated with its use in foals.

Mildly or moderately affected foals require only administration of antimicrobials and nursing care. More severely affected foals can require intensive supportive care including intravenous administration of plasma and/or hetastarch to restore plasma oncotic pressure and minimize edema formation, fluid and electrolyte supplementation because of hypovolemia and abnormalities in serum electrolyte concentration, calorie-enhanced diets or parenteral nutrition, and antiulcer medications if signs of gastric ulceration are present.

Specific **control measures** to prevent spread of the disease among horses have not been developed. Given the putative fecal–oral cycle of infection and association of outbreaks of the disease in pigs after introduction of new stock or mingling of groups, hygiene measures that minimize fecal contamination of the environment by potentially infected foals are sensible. The organism from pigs can survive in feces for up to 2 weeks. Foals with the disease should be isolated from healthy foals, although the duration of this isolation is not known, and should not be transported to other farms until clinical and hematological signs of the disease have resolved. The role for wildlife hosts, if any, in the disease of foals is unknown.

Administration of an avirulent, modified live vaccine intrarectally appears to protect foals from disease after experimental exposure or on farms with endemic disease.[22-24]

EQUINE NEORICKETTSIOSIS (EQUINE MONOCYTIC EHRLICHIOSIS, EQUINE EHRLICHIAL COLITIS, AND POTOMAC HORSE FEVER)

SYNOPSIS

Etiology *Neorickettsia risticii*, which is a rickettsia. Infection occurs by ingestion of infected immature trematodes (the aquatic cercariae), trematode-infected snails, or aquatic insects (including adults capable of flight, e.g., mayflies).

Epidemiology An infectious, but not contagious, sporadic disease of horses in North and South America and parts of Europe. Localized epidemics occur. Disease is most common near large rivers, but can occur elsewhere.

Clinical signs Fever and diarrhea with colic and laminitis in severe cases. Abortion is a sequela of clinical disease in some mares.

Lesions No gross lesions, except for laminitis. Histologic evidence of typhlitis and colitis

Diagnostic confirmation Demonstration of *N. risticii* by polymerase chain reaction or cultivation, in blood or feces of sick horses. More commonly the presence of a high antibody titer in horses with appropriate clinical signs is considered diagnostic.

Treatment Oxytetracycline (6.6 mg/kg, intravenously every 12–24 h), fluids, and supportive care. Prophylaxis for laminitis

Control Vaccination, which is of questionable efficacy and not recommended

ETIOLOGY

The causative agent is *N. risticii*, a small gram-negative coccus that is closely related to the agents of human ehrlichiosis (*Ehrlichia sennetsu*) and salmon poisoning of dogs (*N. helminthoeca*).[1]

EPIDEMIOLOGY

This disease is infectious, but not contagious, and usually has a sporadic occurrence. Localized epidemics occur.

Occurrence

Equine neorickettsiosis is recorded in the United States, Canada, Europe, Uruguay, and southern Brazil**.** Although it might have wider occurrence, evidence of infection based on the commonly used indirect FAT should be interpreted with caution because of the high rate of false-positive results. The highest prevalence of disease is near large rivers, apparently related to the infection of horses by ingestion of infected aquatic insects, although the disease can occur elsewhere, for instance, when strong winds carry infected insects (mayflies, *Hexagenia* spp.) from water sources.[2]

Clinical disease is sporadic and seasonal, with the predominance of cases occurring during the summer and the autumn periods in areas with cool to cold winters. In warmer areas, such as Florida and Texas, cases occur year round. The prevalence of horses in the Midwest and East Coast of the United States with antibodies to *N. risticii* varies with geographic region, but can be as high as 86% of horses tested, although the overall rate appears to be closer to 25%. The prevalence of horses with serologic evidence of exposure is much less in California. There is a marked seasonal variation in the prevalence of seropositive horses, with the highest prevalence in the summer months (July and August) and the lowest prevalence in the winter.

Animal Risk Factors

Clinical disease is believed to be uncommon in horses under 1 year of age (14% in one case series),[3] although peracute disease can occur in foals, and there is no age difference in prevalence of disease in adult horses. Similarly, there is no evidence that breed and sex influence susceptibility to disease. The risk for disease is greater in horses housed on premises with a history of previous infection or those that have other livestock.

The clinical attack rate varies considerably, but estimates range between 0.44 and 19 cases per year per 1000 horses at risk. During epidemics, the clinical attack rate may be as high as 20% to 50% of horses on affected farms. **Case–fatality** rates range from 7% to 30%.[3]

The risk of horses being seropositive in some areas is related to breed (Thoroughbreds are three times more likely to be seropositive than are non-Thoroughbreds and non-Standardbreds), sex (females are 2.7 times more likely to be exposed than are stallions and geldings), and age (increasing risk up to 12 years of age). Horses that have had clinical signs compatible with neorickettsiosis are more likely to be seropositive than are horses with no such history.

Transmission

The disease is infectious but not contagious. Horses develop infection and disease after ingestion of aquatic insects including caddisflies (*Dicosmoecus gilvipes*) or mayflies (*Hexagenia* spp.).[1,2] The disease can be transmitted experimentally to horses by parenteral administration of *N. risticii* or blood from infected horses. Studies of a tick (*Dermacentor variabilis*), black flies (*Simulium* spp.), fleas, flies (*Tabanus* spp., *Hybomitra* spp., *Stomoxys* spp., *Haematobia* spp.), and mosquitoes have failed to demonstrate transmission of infection.

N. risticii infects trematodes stages (cercariae and xiphidiocercariae) found in freshwater snails (*Juga yrekaensis* and *Planorbella subcrenata* in California and northwestern United States and *Elimia* sp. including *E. livescens* and *E. virginica* in the eastern United States).[4] *N. risticii* infects metacercariae found in adults and juveniles of aquatic insects including caddisflies (Trichoptera), mayflies (Ephemeroptera), damselflies (Odonata, Zygoptera), dragonflies (Odonata, Anisoptera), and stoneflies (Plecoptera). *N. risticii* DNA has been detected in trematodes (Lecithodendriidae) infecting bats and swallows. *N. risticii* DNA is present in eggs of the trematodes (*Acanthatrium oregonense*) found in bats demonstrating vertical (adult to egg) transmission of infection in trematodes. Furthermore, *N. risticii* DNA was detected in the blood, liver, or spleen of bats infected with the trematode, suggesting that *N. risticii* can also be transmitted horizontally from trematode to bat. These results indicate that the trematode *A. oregonense* is a natural reservoir and probably a vector of *N. risticii.* This information suggests that insectivorous bats and birds are the definitive hosts of trematodes that maintain the natural reservoir of *N. risticii.* Briefly, it appears that horses are accidentally infected by *N. risticii* that normally cycles between trematode life stages in bats, freshwater snails, and aquatic insects. Infection by horses occurs when they ingest *N. risticii*-infected immature trematodes (the aquatic cercariae) directly while drinking from waterways or trematode-infected snails or aquatic insects while drinking or feeding.

Infected horses develop a sterile immunity and so are unlikely to be a source of subsequent infection.

PATHOGENESIS

Infection is followed by monocyte-associated bacteremia and the organism is present in monocytes, macrophages, and the glandular epithelial cells of the intestinal tract. The number of *N. risticii* in blood is greatest before the development of clinical signs, which in experimentally infected horses and ponies occurs approximately 19 days after infection by ingestion of infected aquatic insects. The prominent clinical sign of diarrhea is caused by colitis and typhlitis and is associated with a neorickettsia-induced disruption of sodium and chloride absorption by the large colon. Fluid and electrolyte losses associated with diarrhea cause dehydration, hyponatremia, and acidosis.

Transplacental infection with *N. risticii* occurs and causes abortion, which can be weeks to months after resolution of clinical disease in the dam.[5]

CLINICAL FINDINGS

The classic manifestation of *N. risticii* infection in horses is fever, depression, anorexia, diarrhea, colic, and laminitis. A retrospective review identified diarrhea (66% of 44 horses), fever (50%), anorexia (45%), depression (39%), colic (39%), and lameness (18%) as the most common clinical signs of the disease in horses at each of two referral clinics.[3] However, infection can result in a variety of clinical abnormalities ranging

from inapparent infection, through transient fever and depression, to the severe signs described earlier. Equine neorickettsiosis should be considered in any horse living in an endemic area that demonstrates fever and depression.

In naturally occurring cases of severe clinical disease there is typically an acute onset with depression, anorexia, tachycardia, congested mucous membranes, and fever. There are decreased intestinal sounds on abdominal auscultation in the early stages of the syndrome and subsequently tinkling sounds before the onset of diarrhea, which usually occurs 24 to 72 hours later. The severity of the diarrhea varies, but it is usually profuse and projectile. It persists for up to 10 days and there can be sufficient fluid loss resulting in severe and rapid dehydration and hypovolemic shock. Colic is a presenting sign in some horses and may be mild or present as an acute abdomen. There can also be subcutaneous edema in the ventral abdomen and limbs. Less severe clinical manifestations of infection include the occurrence of fever and anorexia without other signs or the occurrence of mild colic or subcutaneous edema.

Laminitis occurs in up to 40% of horses and is usually apparent within 3 days of initial signs of disease.[3] One retrospective review of 44 cases identified laminitis present on admission (12 hours to 5 days after first developing clinical signs of equine neorickettsiosis) in 18% of cases with a further 18% developing laminitis during hospitalization (0–4 days after admission, median of 24 hours).[3] Laminitis is often severe, involving all four feet in most horses (88% of those with laminitis) and with rotation of the distal phalanx in 60% of cases that had radiographic examination of the feet (likely the most severely affected horses).[3]

Abortion occurs as a result of *N. risticii* infection and, in experimental and natural infections, occurs 65–111 days after infection of the dam.[5] The dams that aborted all became clinically ill after infection, but clinical signs of disease had resolved at the time they aborted. Abortion was presaged by ventral edema and enlargement of the udder in experimental disease, and placenta was retained in some cases including that with natural infection.

CLINICAL PATHOLOGY

Hematological examination usually reveals leukopenia (<5000 leukocytes per microliter) with neutropenia (74% of cases) and a marked left shift, mild thrombocytopenia, and hemoconcentration (hematocrit 50%–60%, 0.5–0.6 L/L) in 38% of cases.[3] **Serum biochemical analysis** often reveals hypocalcemia (76% of 32 horses), hyponatremia (64%), hyperglycemia (59%), hypochloremia (53%), azotemia (50%), hyperbilirubinemia (50%), and hypoalbuminemia (34%).[3] Hyperlactatemia and metabolic acidosis are common. **Peritoneal fluid** is usually normal. Horses with hemoconcentration are less likely to survive.[3]

Diagnostic confirmation is achieved by demonstration of *N. risticii* in blood or feces, or serologic evidence of infection, in horses with clinical signs compatible with the disease. Routine diagnosis is based on demonstration of a high serum antibody titer on the IFA test. Most horses with disease caused by *N. risticii* have titers ≥1:80 at the onset of clinical signs, whereas horses with titers ≤1:40 probably do not have the disease. The presence of a high titer at the time of onset of clinical signs is a result of the 8- to 12-day incubation period during which there is a high level of neorickettsemia and the production of a strong IgM antibody response. The IgM antibody response wanes rapidly and can be undetectable by 60 days after infection, although a prominent IgG response occurs. Therefore by the time clinical signs are apparent the horse has a high titer that might decline, making the use of acute and convalescent (2 weeks after clinical signs resolve) serum titers potentially misleading. A rising titer in samples collected several days apart soon after the onset of disease is indicative of the disease, but a declining titer does not rule it out. The IFA test performed in some laboratories has a high rate of false-positive reactions and should be interpreted with caution. The preferred diagnostic test is a demonstration of antigen or DNA of *N. risticii*.

Detection of the organism in white blood cells by microscopic examination of stained blood smears is usually not possible because of the low level of infection of blood monocytes. The organism can be cultivated, but this is time-consuming and expensive. However, nest PCR detects the presence of *N. risticii* nucleic acid with a sensitivity similar to that of blood culture in experimental infection. PCR testing depends on the presence of the organism in the blood and could lack sensitivity because of variables levels of the organism in blood.[3] The specificity of the test, in the presence of compatible clinical signs, is assumed to be high.

Similarly, *N. risticii* can be detected by a PCR test in feces of horses. The sensitivity is not reported, but specificity is assumed to be high in the presence of compatible clinical signs.

NECROPSY FINDINGS

The gross changes in horses dying of equine neorickettsiosis usually include subcutaneous edema of the ventral body wall and a very fluid consistency to the contents of the large bowel. Congestion, hemorrhage, and mucosal erosions can occur throughout the alimentary tract but are concentrated in the cecum and colon. The mesenteric lymph nodes are often swollen and edematous. There may be lesions of laminitis. Histologic examination confirms the alimentary mucosal erosion and ulceration, which is accompanied by an infiltrate of a mixed population of leukocytes within the lamina propria and submucosa. The causative organisms can be demonstrated in tissue sections using Steiner's silver stain. Detection using EM or PCR techniques are other options.

Fetuses that are aborted as a result of *N. risticii* infection of the dam have gross lesions consisting of enlarged liver, spleen, and mesenteric lymph nodes and histologic evidence of enterocolitis, hepatitis, myocarditis, and lymphoid hyperplasia with necrosis of mesenteric lymph nodes.[5]

Samples for Postmortem Confirmation of Diagnosis

The parasite can be demonstrated in cecum, colon, and mesenteric lymph node by a polymerase reaction test or EM. Formalin-fixed tissue for light microscopy should include cecum, colon, liver, and mesenteric lymph node.

DIFFERENTIAL DIAGNOSIS

The main differentials are as follows (Table 7-5):

- Diarrhea caused by salmonellosis, *Clostridium difficile* colitis, massive emergence of hypobiotic cyathostomes, colitis X, and antibiotic-induced colitis
- Abortion caused by equine herpesvirus-1, leptospirosis, congenital anomalies, and *Salmonella abortusequi*

TREATMENT

TREATMENT AND PROPHYLAXIS

Treatment of equine neorickettsiosis

- Oxytetracycline 6.6 mg/kg intravenously every 12–24 h for 5 days (R1)

Prophylaxis

- Vaccination (R3)

The specific treatment of equine neorickettsiosis is oxytetracycline (6.6 mg/kg BW intravenously every 12–24 hours for 5 days), and horses treated early in the disease respond well. Administration of oxytetracycline increases the likelihood of survival by nine times (OR 95% CI 1.2–70), with 6/14 horses not treated with oxytetracycline (usually treated with another antibiotic) surviving compared with 26/30 oxytetracycline-treated horses.[3] Administration of metronidazole with oxytetracycline offers no clear survival advantage.[3]

Given the effectiveness of oxytetracycline in the treatment of the disease and the lack of clear evidence that oxytetracycline at the recommended dose induces or exacerbates diarrhea, this drug should be administered to all horses that live in an endemic area and that develop signs consistent with equine neorickettsiosis. Treatment does not

interfere with the development of immunity. Other antibiotics that have been used include combinations of a sulfonamide and trimethoprim or rifampin and erythromycin. Doxycycline has been used, but intravenous administration is associated with cardiovascular abnormalities and sudden death.

Treatment of horses with acute diarrhea is discussed in Chapter 7. Prophylaxis for laminitis is indicated in Chapter 15.

CONTROL

Control centers on vaccination, although this is inadequate in controlling disease in field situations.[6] The apparent lack of efficacy of vaccination in the United States might be caused by the inclusion of only one strain of *N. risticii* in the vaccine, and this strain is immunologically distinct (based on the P51 surface protein) from most strains from the eastern or midwestern United States and from most strains isolated after 2000.[6] There are a number of strains of the organism, with associated variation in surface-expressed proteins and in particular P51, and the vaccine might not confer immunity to all these strains.[1,6] P51 is strongly recognized by sera from horses with IFA titers of 1 : 80 and above, and it could be useful for inclusion in vaccines or diagnostic tests.[6]

Infection is followed by the development of a neutralizing antibody response that is associated with clearance of *N. risticii* and the presence of a sterile immunity to the homologous strain, which persists for at least 20 months. An inactivated whole-cell adjuvanted vaccine is available, and vaccinated animals have resistance to experimental challenge. However, protection from vaccination is not complete and wanes within 6 months. Survival rate of horses with clinical equine neorickettsiosis is not different among horses that were vaccinated (7 of 9, 78%) before development of the disease from that of all horses studied (n = 44, 79% survival rate).[3] In an area with a low attack rate of the disease (0.44–1.7 horses/1000 per year) the risk of neorickettsiosis in horses vaccinated once per year is almost identical (OR 0.93) to that of unvaccinated horses, and there is no difference in the severity of the disease in vaccinated and unvaccinated horses. Furthermore, it is more economical *not* to vaccinate horses in areas with a low attack rate. In areas with a high attack rate it may be appropriate to provide an initial vaccination of two doses 3 weeks apart, with revaccination at 4-month intervals during the disease season.

Current recommendations from the American Association of Equine Practitioners included details on vaccination of horses against equine neorickettsiosis.[7] Because of evidence demonstrating the limited, or lack of, efficacy of vaccination with the currently available product, routine vaccination of horses is not recommended at this time.

EQUINE CORONAVIRUS INFECTION

Coronavirus infection is associated with diarrhea in foals, although rarely,[1] and is also incriminated as a cause of acute lethargy, fever, and signs of gastrointestinal dysfunction in adult horses. The putative causative agent is equine coronavirus (ECoV), and the strains identified in Japan, France, and the United States are virtually identical to the strain initially isolated from foals in North Carolina.[1-4] There is some variation in the virus, principally within p4.7 and the noncoding region following the p4.7 gene.[5] ECoV is of the genus *Betacoronavirus* and the species *Betacoronavirus*-1, which includes BCoV, porcine HEV, and canine respiratory coronavirus.[6] Experimental inoculation of adult horses reproduces the disease.[7]

The association between coronavirus infection and clinical disease in adult horses is reported in Japan, North America, and Europe.[1-5,8] Animal risk factors have not been identified, and the disease occurs in horses from 1 to 29 years of age.[2,5,8] The disease in adult horses is most commonly reported as an outbreak in stables affecting 15% to 60% of horses.[2,4,5] The case–fatality rate is approximately 0% to 7% with deaths caused by acute, profuse diarrhea; septicemia; or signs of neurologic disease.[2,5,8] A case–fatality rate of 27% is reported in two outbreaks of disease in Miniature horses and Miniature donkeys.[8]

Transmission is assumed to be fecal–oral, but the importance of fomites is spread within a stable, and longevity of the virus in the environment is not reported. The virus can be detected in feces for at least 12 to 14 days after oral inoculation of horses,[7] although the median shedding time from onset of clinical signs in horses with spontaneous disease is 4 days.[8]

The incubation period for horses experimentally infected with ECoV is 2 to 4 days before development of fever or anorexia.[7] The main clinical signs are anorexia, lethargy, and fever (43). Approximately 10% of affected horses have diarrhea and colic in approximately 2% of horses.[2,5] Horses that die do so with rapid progression of the disease including profuse diarrhea, septicemia, or neurologic disease. Depression, ataxia, and recumbency with abnormally high blood ammonia concentrations are suggestive of intestinal hyperammonemia.[8] Clinical signs generally resolved within 1 to 4 days with supportive care. Outbreaks last approximately 3 weeks.[2,5]

Affected horses are leukopenic (neutropenic).[2,5] Serum amyloid A concentrations increase in experimentally infected horses 2 to 4 days after inoculation with the virus.[7] Serology is useful for demonstrating seroconversion to ECoV or high titers in recovered horses.[3-5] The virus can be detected in feces and blood, but not nasal discharges, in nonexperimental cases using PCR technology.[2,3] Reverse transcription and loop-mediated isothermal amplification (LAMP) assay are less sensitive but cheaper than RT-PCR technology for detection of the virus.[9] The virus is more frequently recovered from feces of clinically affected horses during outbreaks, and viral load in feces is associated with severity of disease.[2,3,8]

Treatment is supportive. There is no vaccine. Control is facilitated by implementation of measures to reduce viral spread, such as strict limitations on movement of horses within the facility, use of sanitary procedures including disinfectants, and cessation of racing or competition until the outbreak has abated. Most commonly used disinfectants are efficacious in reducing infectivity of coronavirus on surfaces, including benzalkonium and glutaraldehyde as well as alcohol-based hand disinfectants.

VIRAL DIARRHEA IN CALVES, LAMBS, KIDS, PIGLETS, AND FOALS

SYNOPSIS

Etiology Rotaviruses, coronaviruses, toroviruses, and parvoviruses

Epidemiology Common cause of diarrhea in newborn farm animals, usually in calves but also in lambs, kids, piglets, and foals. Rotaviruses ubiquitous in environment and 50%–100% of adults seropositive. Spread by feces. Protection dependent on specific antibody in colostrum in intestinal lumen. Bovine coronavirus is also pneumotropic and causes respiratory disease.

Signs

Calves Outbreaks of diarrhea at 5–14 days of age and older up to 3–4 weeks. Recovery occurs in a few days.

Piglets Outbreaks of diarrhea at 1–4 weeks of age and following weaning. Porcine epidemic diarrhea type I at 4 to 5 weeks of age; type II at all ages. Recovery occurs in a few days.

Foals Profuse diarrhea, slight fever, and dehydration. Recovery occurs in a few days.

Lesions Fluid-filled intestine and dehydration. Villous and crypt atrophy. Diagnostic confirmation. Many diagnostic tests to identify viruses in fecal samples

Treatment Oral and parenteral fluid and electrolyte therapy; correction of acid-base disturbances

Control Reduce infection pressure, ensure adequate transfer of passive immunity, and vaccination of dam to provide specific colostral antibody.

ETIOLOGY

Several families of viruses cause diarrhea in neonatal farm animals, and occasionally in adults. These include Reoviridae, Coronaviridae, Toroviridae, Parvoviridae.

Rotaviruses

Rotaviruses are nonenveloped, dsRNA viruses pertaining to the family Reoviridae and are a primary cause of diarrhea in humans, calves, lambs, kids, piglets, and foals. All members of the group of viruses share a common morphology and were previously designated as reovirus-like viruses. Rotaviruses of human infants, calves, pigs, and foals are morphologically indistinguishable from each other and from the virus of infant mice; the lamb rotavirus is similar to both calf and pig viruses.

Rotaviruses are assigned to serogroups with group members sharing distinctive common antigens. Currently, seven serogroups (A through G) are recognized, which are antigenically and electrophoretically distinct. Rotaviruses belonging to groups A–C are associated with clinical disease in humans and animals, whereas groups D–G have only been isolated from diarrheic animals. **RVA is by far the most prevalent group in humans and animals.**

Rotavirus serogroups are further classified into serotypes based on specificity of the outer capsid proteins VP7 (G type, for glycoprotein) and VP4 (P type, for protease sensitive protein). At least 27 G serotypes and 35 P serotypes of Group A rotavirus are recognized.[1]

Coronaviruses

Coronaviruses are ssRNA viruses pertaining to the family Coronaviridae. They are associated with acute enteritis in neonatal calves and piglets and possibly also in foals. In ruminants coronavirus infection can be associated with calf diarrhea, calf respiratory disease, diarrhea in adult cattle (winter dysentery), and respiratory disease in adult cattle.[2]

The coronavirus-like virus of pigs is similar to, but distinct from, the virus of TGE and is the cause of PED type II.

Toroviruses

The family Toroviridae includes the Berne virus of horses and the Breda virus, which has been isolated from cattle.

Parvovirus

Parvoviruses have been associated with diarrhea in calves but are not significant pathogens in cattle.

Other Viruses and Mixed Infections

Although the rotavirus and coronavirus are the most common causes of viral diarrhea in newborn farm animals (other than TGE of piglets), the adenovirus and small viruses resembling astroviruses and caliciviruses have been isolated from diarrheic calves and foals, but their etiologic significance is uncertain.[3]

Multiple mixed viral infections are being recognized more frequently as diagnostic techniques are improved. Both rotavirus and coronavirus may occur in the same diarrheic calf with or without the presence of ETEC.

EPIDEMIOLOGY

The general aspects of the epidemiology of viral diarrheas of newborn farm animals are described here, followed by the specific epidemiologic features in calves, lambs and kids, piglets, and foals. The rotavirus is used as a model.

Occurrence

The rotavirus is ubiquitous in the environment of domestic animals, and serologic surveys indicate that 50% to 100% of adult cattle, sheep, horses, and pigs have antiviral antibody. Although different animal species commonly host different coronavirus genotypes there is evidence for interspecies transmission not only between animal species but also between animals and humans. Two routes for interspecies transmission have been proposed, direct interspecies transmission and transmission coupled with reassortment.[4] However, the significance of interspecies infection under field conditions has not been evaluated. Cross-infection between species is not a property shared by all rotaviruses.

Methods of Transmission

The intestinal tract is the site of multiplication of the rotavirus and the virus is excreted only in the feces. Infected feces may contain as many as 10^{10} virus particles per gram. **Rotaviruses** are considered to be **highly contagious**; studies in pigs showed infection can be achieved with as little as 90 virus particles. **Because rotaviruses are stable in feces and relatively resistant to commonly used disinfectants, it is extremely difficult to prevent gross contamination of animal housing once infection has been introduced.** The adult animal is the primary source of infection for the neonate. The survival of the bovine rotavirus in air and on surfaces is directly influenced by the level of relative humidity. The rotaviruses generally survive well in an aerosol state, and medium-range of relative humidity and air may be one of the vehicles for dissemination of the virus.

Immune Mechanisms

An important epidemiologic characteristic of rotavirus and coronavirus infections in newborn farm animals is that protection against disease is dependent on the presence of specific colostral antibody in the lumen of the intestine of the newborn. Colostral antibody in serum does not directly protect but contributes to mucosal immunity through re-secretion into the gut lumen. Protection against clinical disease depends on the amount of immunoglobulin in the lumen of the intestine. The daily oral administration of colostrum containing specific antibody or hyperimmune serum to neonates beyond the time of "gut closure" (intestinal absorption of colostral antibody) will improve resistance to clinical rotavirus enteritis.

The protection is against clinical disease but not necessarily against infection, which means that calves, lambs, and piglets can shed virus in feces while being protected from clinical disease. The protection lasts only as long as colostral antibody is present within the lumen of the intestine, which explains why rotaviral diarrhea occurs commonly after 5 to 7 days of age. Survival from rotavirus diarrhea in calves may be dependent on a high level of serum colostral immunoglobulin.

Calves: Bovine Rotavirus

Many of the epidemiologic characteristics of neonatal calf diarrhea associated with the rotavirus and coronavirus must be considered in the context of "acute undifferentiated diarrhea of newborn calves," because mixed infections are more common than single infections.

Occurrence and Prevalence of Infection

Worldwide prevalence rates for bovine rotavirus infection range from 7% to 94% depending on the geographic region, although most studies report prevalences in the range of 30% to 40%.[5] RVA is by far the most prevalent group and is the group most commonly associated with clinical disease, although serogroups B and C have also been isolated from diarrheic calves. Diarrhea caused by RVA occurs in calves from 1 to 2 weeks of age.

In cattle RVA strains belonging to at least 12 G types (G1–G3, G5, G6, G8, G10, G11, G15, G17, G21 and G24) and 11 P types (P[1], P[3], P[5–7], P[11], P[14], P[17], P[21], P[29], and P[33]) have been identified. Most common strains belong to G6, G8, and G10 in association with P[1], P[5], and P[11].[1] Serotypes G6 and G10 are the most

prevalent RVA serotypes in dairy and beef calves with diarrhea in the United States. Rotavirus strains belonging to G10 P[11] constitute the largest proportion of bovine rotaviruses in cattle throughout India. This has major zoonotic implications because this strain is related to those found in newborn children in India.

The prevalence of subclinical infection may be greater than that indicated by isolation of the virus from feces. Rotavirus–immunoglobulin and coronavirus–immunoglobulin complexes may be present in the feces of 44% and 70% of adult cattle, respectively, whereas the free rotavirus and coronavirus may be absent or present in only 6% of fecal samples, respectively. Clinically normal cows can shed the virus for several weeks in the presence of fecal and serum antibody. Repeated bovine rotavirus infection and reexcretion can occur in calves several months of age, even in the presence of serum antibodies. Clinically normal calves may also shed the virus and there may be histologic evidence of lesions of the small intestine caused by rotavirus infection.

Concurrent Infections

Rotavirus was detected in the feces of 43% of neonatal diarrheic dairy calves in Spain. A concurrent infection was detected in 58% of the rotavirus-infected calves, and the most common mixed infection was rotavirus-*Cryptosporidium*. The detection rates of the other enteropathogens with rotavirus infection were 20% for coronavirus, 85% for *Cryptosporidium* spp., 17% for F5 (K99) *E. coli*, and 2% for *Salmonell*a spp. As the age of the calf increased, the detection rates of other enteropathogens decreased. Similar results were recently reported from dairy calves in the Netherlands.[6]

Risk Factors

Animal Risk Factors

The factors that influence rotavirus infection and its clinical severity include the following:

- Age of the animal
- Immune status of the dam and absorption of colostral antibody
- Ambient temperature
- Degree of viral exposure
- Occurrence of weaning
- Presence of other enteropathogens

Calves are most susceptible to rotavirus diarrhea between 1 to 3 weeks of age. This age occurrence is related in part to the rapid decline in specific colostral antibody to rotavirus.

The mortality is highest in the youngest animals that have received insufficient colostrum and are subjected to severe weather conditions.

Environmental Risk Factors

Although the rotavirus has been most commonly associated with outbreaks of diarrhea in beef calves raised in groups outdoors, it has also been recovered from dairy calves raised together in large groups in large dairy herds. The morbidity rate in beef herds varies from herd to herd and from one year to another.

The survival of the bovine rotavirus in air and on surfaces is directly influenced by the level of relative humidity. Rotaviruses generally survive well in an aerosol state and medium range of relative humidity, and air may be one of the vehicles for dissemination of the virus.

Pathogen Risk Factors

There are differences in virulence among the bovine rotaviruses, which may explain the variability in the severity of disease in natural outbreaks and must be considered when developing vaccines.

Rotaviruses possess two outer capsid proteins, VP4 and VP7. The neutralization specificity related to VP7 is the G (for glycoprotein) serotype and that associated with VP4 is referred to as the P (for protease sensitive protein) serotype. Specific G and P types have been associated with specific animal species. As more rotaviruses have been characterized from diverse locations worldwide, the host species specificity of P and G types has become less distinct. G types 6, 8, and 10, once thought to be specific to cattle, have been found in humans.

In contrast to natural recovery from infection, which results in high titers of P-specific neutralizing antibodies, parenteral administration elicits primarily G-specific neutralizing antibodies. Thus failure in passive protection with a monovalent vaccine for prevention of rotavirus-associated diarrhea in neonatal calves may be less than optimal because of the diversity of P and G types occurring in nature.

Natural subclinical infections are common in calves in the second week of life, which raises doubts about rotavirus pathogenicity. Experimentally, the clinical outcome of infection is dependent on both age and rotavirus isolate. Age-dependent resistance to infection was not found. Bovine rotaviruses differ in virulence for calves in the second week of life, and older calves are susceptible to rotavirus infection and disease.

The calf rotavirus can be experimentally transmitted to piglets and has been isolated from natural outbreaks of diarrhea in piglets. The isolation of a rotavirus from neonatal deer affected with diarrhea in a zoo in Australia raises some interesting epidemiologic possibilities.

Morbidity and Case Fatality

In some herds the disease starts at a low rate of 5% to 10% in the first year, increases to 20% to 50% in the second, and to 50% to 80% in the third year. In other herds, explosive outbreaks affecting 80% of the calves have occurred in the first year. The case–fatality rate has also been variable (in some herds as low as 5%), whereas in other herds it has been as high as 60%. The mortality rate probably depends on the level of colostral immunity in the calves, the incidence of enteric colibacillosis, and the level of animal husbandry and clinical management provided in the herd.

Method of Transmission

The virus is excreted by both calves and adult cattle in large numbers (up to 10^{10}/g of feces) and excretion may last for several weeks. Transmission is by the fecal–oral route via contaminated feces or fomites. The minimal infectious dose in cattle does not appear to have been determined, but as few as 90 virus particles were found to be sufficient to induce infection in piglets, making this a highly infectious pathogen.

Even under open-range conditions, there is a rapid spread of the virus throughout calves that come into frequent contact with each other, particularly during the calving season. Calves are infected after birth from the dam's feces or from other infected diarrheic calves. Pregnant cows excrete the rotavirus intermittently throughout pregnancy, from one calving to the next, and provide a direct source of infection for the newborn calf. Both subclinically infected and diarrheic calves infected by rotavirus can be a source of infection for other in-contact calves.

Immune Mechanisms

Newborn calves are protected from the rotavirus only during the first few days after birth, when colostrum contains a specific rotavirus antibody that is active in the lumen of the intestine. This correlates well with the peak incidence of rotavirus diarrhea, which is at 5 to 7 days of age, and coincides with a marked drop in colostral immunoglobulin by the third day after parturition and an incubation period of 18 to 24 hours for the disease to occur. The serum colostral immunoglobulin of the calf may also be re-secreted from the serum into the intestine and complement the role of colostral and milk antibodies in the lumen of the intestine.

Bovine Coronavirus (Calf Diarrhea)

BCoV is associated with diarrhea in adults (winter dysentery) and calves (calf diarrhea). Diarrhea in both dairy and beef calves associated with BCoV has a worldwide prevalence and occurs from 1 day to 3 months of age but mostly between 1 and 2 weeks of age. Disease is more common during the winter months, which may reflect enhanced survival of the virus in a cool, moist environment. The virus is ubiquitous in cattle populations, and the majority of adult cattle are seropositive. The coronavirus may be present in both diarrheic and healthy calves; the incidence rates range from 8% to 69% and 0% to 24% for diarrheic calves and healthy calves, respectively.

The virus can be shed by up to 70% of adult cows despite the presence of specific antibodies in their serum and feces. The peaks of shedding are during the winter months and at parturition. Calves born to carrier cows are at a higher risk of diarrhea. Subclinical persistence and recurrent infections are also common in both neonatal and older calves, and virus excretion from these animals may maintain a reservoir of infection.

Vaccination of the cows with a modified-live rotavirus–coronavirus–*E. coli* combination vaccine does not influence seasonal shedding, but in vaccinated cows the incidence of shedding does not increase at parturition as it does in nonvaccinated cows. The BCoV isolates all belong to a single serotype as polyclonal sera have detected only minor antigenic variations.

The **BCoV is also a pneumotropic virus** that can replicate in epithelium of the upper respiratory tract. In dairy calves, initial infections occur when the calves are 1 to 3 weeks of age, but there are multiple episodes of shedding of viral antigens or seroconversion when the calves are several weeks of age. Clinical signs of respiratory disease occur between 2 and 16 weeks of age but are mild. A more severe lower respiratory tract infection causing minor lung lesions has been reported but is also not severe enough to warrant treatment. Such infections are probably common in closed herds with recurrent subclinical infections occurring in older calves. Persistence of infection or reinfection of the upper respiratory tract with the virus is also common. The amount and specificity of BCoV maternal antibodies in calves at the time of infection with the virus may interfere with the development of an active antibody response in serum and mucosal secretions. The fecal–oral route is the presumed method of transmission, but aerosol transmission may also occur.

The BCoV has been isolated from wild ruminants with diarrhea. Feces from diarrheic sambar deer, one waterbuck, and one white-tailed deer in wild animal habitats contained coronavirus particles identified as BCoV. Gnotobiotic and colostrum-deprived calves inoculated with the isolates developed diarrhea and shed coronavirus in their feces and nasal discharge. Thus wild ruminants may harbor coronavirus strains transmissible to cattle.

The BCoV of winter dysentery in adult cattle is closely related to the BCoV causing diarrhea in young calves.[2] There is no evidence for serologic or in vivo antigenic differences between these two BCOVs.

Parvovirus

The parvovirus has been associated with outbreaks of PWD in beef calves, but its pathogenicity is uncertain. Seroprevalence studies found 49% to 83% of adult cattle seropositive to the virus over a 2-year period.

Bovine Torovirus (Breda Virus)

Breda virus, a member of the genus *Torovirus,* has been isolated from the feces of neonatal calves with diarrhea in Iowa, Ohio, several areas in Europe, and in Canada. In Ohio, the virus was detected in 9.7% of fecal samples from cattle with diarrhea; it occurred in 26% of the total calf samples. It is a common virus in the feces of calves with diarrhea on farms in Ontario. In veal calf operations in Ohio, 24% of calves shed the virus during the first 35 days after arrival, which was associated with diarrhea. Calves shedding additional pathogens were more likely to have diarrhea than those shedding less than one pathogen. Calves that were seronegative or had low antibody titer to the Breda virus on arrival were more likely to shed the virus than those calves that were seropositive on arrival.

More than 88% of adult cattle are seropositive for the Breda virus. More than 90% of newborn calves have high maternal antibodies to the virus that wane at a few months of age, followed by active seroconversion between 7 and 24 months of age.

Bovine Norovirus

Noroviruses, formerly known as Norwalk-like viruses, are ssRNA viruses belonging to the family Caliciviridae and have been recognized as the most common pathogens involved in outbreaks of acute nonbacterial gastroenteritis in humans. Noroviruses can be genetically classified into five genogroups, GI-GV. Genogroups I, II, and IV are considered as human pathogens, whereas genogroup III is isolated from bovines. The prototype strains identified in cattle are the Newbury-2 strain (formerly Newbury agent 2) and the Jena virus. The seroepidemiologic prevalence of the Jena virus, a bovine enteric calicivirus, is 99% in some selected cattle populations in Germany. In the Netherlands Norovirus is endemic in veal calf operations and in a selected dairy herd. The highest number of norovirus-positive veal calf farms was found in the regions with the highest number of veal calf farms. The virus is endemic in cattle populations and genetically distinct from human norovirus.[7] Norovirus genotype III strains were isolated from healthy and diarrheic calves in Hungary, Italy, and recently in France.[7-9] Although the clinical significance of the presence of norovirus in diarrheic calves remains unclear, a significant quantitative difference in the amount of virus particles shed in feces between healthy and diarrheic calves has been demonstrated in a recent case–control study.[10]

Lambs and Kids

Rotavirus

Rotavirus has been associated with diarrhea in lambs 7 to 30 days of age.[11] Rotavirus infection associated with diarrhea in lambs has been reported from several countries including the UK, United States, Australia, Japan, Spain, Egypt, Morocco, and India. Rotavirus groups A and B have been isolated from diarrheic lambs, but there appear to be geographic differences in the occurrence between groups A and B. Although group B has predominantly been isolated in the United States and the UK, RVA is most common in India.[12]

The prevalence of rotavirus infection in diarrheic lambs was recently assessed in India by screening 500 fecal samples from diarrheic lambs collected over a period of 3 years. RVA was isolated from 13.2% of all samples.[13] A similar study from Egypt reported a prevalence of rotavirus infection among diarrheic lambs of 12.3%.[14]

Atypical rotaviruses, possibly group B, have been isolated from the feces of diarrheic goat kids. Affected kids were 2 to 3 days of age, and the disease was severe with marked dehydration, anorexia, and prostration.

The prevalence of rotavirus infection in lambs appears to be influenced by the season of the year, because an increase in the number of outbreaks with high morbidity and mortality has been reported in the early spring months.[11]

The experimental disease in lambs is mild and characterized by mild diarrhea, abdominal discomfort, and recovery in a few days. The mortality in lambs is much higher when both the rotavirus and EPEC are used.

Piglets

Porcine Rotavirus

Rotavirus is recognized as an important etiologic agent of diarrhea in weaned and unweaned piglets. At least four of the rotavirus groups (A–E) have been associated with diarrhea in piglets, but RVA is by far the most prevalent. Within the RVA the genotypes G3–G5, G9, and G11 in combination with P[6], P[7], P[13], and [P19] are most prevalent in pigs and there are differences in virulence of isolates.[4] Different genotypes of RVA and even different groups of rotaviruses may occur at the same time in a single piggery. Some porcine rotaviruses are related antigenically to human rotavirus serotypes. Porcine rotaviruses that display the typical bovine P[1], P[5], P[11], G6, and G8 genotypes have been detected in pigs, which indicates the high frequency of rotavirus transmission between cattle and pigs.

There is little or no cross-protection between porcine rotaviruses with distinct G and P types, but viruses that share common G and P types induce at least partial cross-protection in experimental studies. Variant serotypes of porcine rotavirus such as G3 may cause severe outbreaks of diarrhea in piglets. Subclinical infections are common, and age resistance to rotavirus infection may not occur.

Rotaviruses have a worldwide occurrence and are highly prevalent in the swine population. Infected gilts and sows shed the virus

before farrowing and during lactation, which makes it next to impossible to eliminate the infection from a herd. Continuous transmission of the virus from one group to another is an important factor in maintaining the cycle of rotaviral infection in a piggery. The virus can be found in dust and dried feces in farrowing houses that have been cleaned and disinfected. This suggests that the environment is also an important source of infection. The porcine rotavirus can survive in original feces from infected pigs for 32 months at 10°C (50°F).

In an infected herd, piglets become infected between 19 and 35 days of age, and the virus cannot be detected in piglets under 10 days of age, presumably as a result of protection by lactogenic antibody. There are increased secretory IgA and IgG antibodies to rotavirus in the milk of sows after natural rotavirus infection or following parenteral inoculation of pregnant or lactating sows with live attenuated rotaviruses. Early weaning of piglets at 3 weeks of age results in the removal of the antibody supplied by the sow's milk.

In piglets, rotaviral diarrhea is most common in pigs weaned under intensive management conditions, and the incidence increases rapidly from birth to 3 weeks of age. There is no age-dependent resistance up to 12 weeks of age. The disease resembles milk scours or the 3-week scours of piglets. Mortality caused by rotavirus varies from 7% to 20% in nursing pigs and 3% to 50% in weaned pigs depending on the level of sanitation. In the United States the peak incidence occurs in February, and a moderate rise occurs from August to September.

A case-control epidemiologic study examined the relationship between RVA and management practices in Ontario over a 5-year period. In rotavirus-positive herds, herd size was larger and weaning age was younger compared with rotavirus-negative herds. Pigs raised in all-in/all-out nurseries were 3.4 times more likely to have a positive RVA diagnosis than in pigs in a continuous flow system. Pigs in the all-in/all-out system were weaned at an earlier age.

Concurrent infection of rotavirus with other enteric pathogens such as ETEC, *Salmonella* spp., or TGE virus is common and causes an additive effect resulting in more severe clinical disease and higher mortality rates.

Porcine Coronavirus

The **PEDV** is a corona-like virus that causes diarrhea in pigs. This is similar to TGE except much less severe and with less mortality. Two clinical forms of the disease have been described: PED types I and II. **PED type I** causes diarrhea only in pigs up to 4 to 5 weeks of age. **PED type II** causes diarrhea in pigs of all ages. The morbidity may reach 100% but mortality is low. The disease may start in the finishing pigs and spread rapidly to pregnant sows and their nursing piglets. The diarrhea may persist in the 6- to 10-week-old pigs, and seronegative gilts introduced into the herd may become infected and develop a profuse diarrhea that lasts a few days.

A PRCV with close antigenic relationship to the TGE virus has been identified as enzootic in the UK and in some European countries. A Canadian isolate of the virus inoculated into 8-week-old piglets caused polypnea and dyspnea and diffuse bronchioloalveolar lesions. Seroprevalence studies in Spain revealed that 100% of large herds and 91% of small herds had animals with antibodies. Only mild or inapparent respiratory signs occur and the growth of finishing pigs may be temporarily affected.

Foals

Equine Rotavirus

Rotavirus is the most common viral cause of diarrhea and is endemic in most if not all horse populations, as has been concluded from high seroprevalence rates in unvaccinated adult horses.[15,16] RVA is the group most commonly associated with diarrhea in foals up to 3 months of age. Most equine rotaviruses are distinct from those of other species with a distinctive electropherotype and subgroup reaction. Six G types and six P types have been described among equine rotaviruses thus far; however, the majority of circulating equine rotaviruses are G3 P[12] and G14 P[12].[17]

The virus can be isolated from the feces of healthy foals and from diarrheic foals in outbreaks of diarrhea. Outbreaks of the disease occur on horse farms with a large number of young foals in which the population density is high. A case-control study of foal diarrhea in the UK over a 3-year period revealed rotavirus was a significant pathogen associated with diarrhea in foals. The other common pathogens were *C. perfringens, S. westeri,* and *Cryptosporidium* spp. A survey of the enteric pathogens in diarrheic Thoroughbred foals in the UK and Ireland revealed a prevalence of 37% rotaviruses and 8% in normal foals.

Dual infection with different rotavirus strains as well coinfection with other enteropathogens including *Salmonella* spp., *Cryptosporidium* spp., and ECoV have been reported, but their clinical significance remains to be determined.[15]

PATHOGENESIS

Rotavirus

The rotavirus infects mature brush border villous epithelial cells in the small intestine and to a lesser extent in the large intestine. The infected cells are sloughed, leading to partial villous atrophy, and the atrophic villi are rapidly recovered with relatively undifferentiated crypt cells that mature over a few days and result in the healing of the lesion. The activity of the mucosal β-galactosidase (lactase) in the brush border of the villous epithelium is less than that found in normal animals, which results in decreased utilization of lactose. This reduction in enzymes is associated with immature enterocytes on the villi during rotavirus infection. In vitro studies have suggested that lactase may be the receptor and uncoating enzyme for rotavirus, which may explain the high degree of susceptibility of the newborn with high levels of lactase. The net effect of the morphologic and functional changes in the intestine is malabsorption resulting in diarrhea, dehydration, loss of electrolytes, and acidemia.

The pathogenesis is similar in calves, lambs, pigs, and foals. Lesions occur within 24 hours after infection, villous epithelial cells of the small intestine are infected and become detached, and regeneration occurs within 4 to 6 days after the onset of the diarrhea. The intestinal villi usually return to near normal within about 7 days after recovery from the diarrhea. However, calves and pigs may require 10 to 21 days to fully recover to a normal growth rate following rotavirus infection. Experimental rotaviral infection in 3-week-old piglets results in diarrhea, anorexia, and vomiting. Villous atrophy of the small intestine is the most severe lesion but returns to normal in 6 days. Infection and clinical disease developed in the presence of serum-neutralizing antibody obtained from seropositive sows.

Although it has been generally accepted that lactose malabsorption is an important factor in the pathogenesis of diarrhea, the experimental infection of gnotobiotic lambs with rotavirus did not result in lactose intolerance, as assessed by the measurement of reducing substances in the feces or by the clinical effects and blood glucose levels after a lactose load. Lactose intolerance could be demonstrated by using extremely high doses of lactose, three to four times the normal dietary intake. Thus lactose-containing feeds such as milk are not necessarily contraindicated in rotavirus diarrhea.

A combined infection with rotavirus ETEC may result in a more severe disease than produced by rotavirus infection alone, particularly in calves several days of age when the rotavirus normally produces a mild disease and when calves are resistant to enterotoxigenic colibacillosis. The intestinal lesions of villous atrophy are also more severe and extend into the colon in dual infections. Naturally occurring cases of the dual infection in calves are considered to be more severe than single infections. Under field conditions more than one enteropathogen is likely to be involved in the pathogenesis of the diarrhea.[6,12,15]

Experimentally, in gnotobiotic 1-day-old calves, concurrent infection with BVDV and bovine rotavirus results in a more severe enteric disease than that associated with either virus alone. The BVDV potentiated the effect of the rotavirus. Severe lymphoid depletion was associated with BVDV infection regardless of the concurrent rotavirus infection. The clinical findings of induced

combined BVDV and rotavirus infections in neonatal calves at 8 to 9 days of age are much more severe and the duration of diarrhea much longer than in rotavirus infection alone.

Coronavirus

The pathogenesis of coronaviral enteritis in calves is similar to the rotavirus infection. The villous epithelial cells of the small and large intestines are commonly affected. The crypt epithelium is also affected, which makes regeneration of villous epithelial cells much longer, which in turn results in persistent diarrhea for several days and death from dehydration and malnutrition. Experimental infection of calves with virulent BCoV results in depletion of lymphocytes in the mesenteric lymph nodes and Peyer's patches, low levels of immunoglobulin, and generalized immune suppression. Experimental infection with the attenuated virus results in lower levels of intestinal immunoglobulin titers than with the virulent virus. Experimentally, newborn calves are capable of mounting an intestinal immune response to BCoV and vaccine failures may be the result of overattenuation of the virus. The pathophysiological changes caused by coronavirus-induced diarrhea in the calf have been described and are similar to the changes that occur in acute diarrheal disease in the calf associated with other enteropathogens.

Porcine Coronavirus

This virus replicates in the villous epithelial cells of both the small and large intestine and clinically resembles TGE of piglets. There is no evidence that rotavirus infection in piglets is accompanied by increased permeability of the intestine to macromolecules.

Calicivirus-Like (Norovirus) Agent

Norovirus causes degeneration of the villous epithelial cells of the proximal part of the small intestine leading to villous atrophy, a reduction in disaccharidase activity, and xylose malabsorption. In gnotobiotic calves experimentally infected with the Breda virus, the villous epithelial cells of the ileum and colon are affected, including the dome epithelial cells.

Parvovirus

Experimental infection of calves with the parvovirus results in lymphopenia and viremia and damage to the small-intestinal crypt epithelium and the associated mitotically active lymphoid tissues. Villous atrophy occurs because of failure of replacement of villous epithelial cells. By 5 days after inoculation there was evidence of repair of the intestinal lesions. Following experimental challenge, the tonsillar tissues, intestinal mucosa, and mesenteric lymph nodes all become infected. Subsequent spread also results in greater involvement in the large intestine and the upper jejunum, Peyer's patches, and mesenteric lymph nodes.

CLINICAL FINDINGS

Calves

The naturally occurring disease usually occurs in calves over 4 days of age and is characterized by a sudden onset of a profuse liquid diarrhea. The feces are pale yellow, mucoid, and may contain flecks of blood. Recovery usually occurs in a few days. Explosive outbreaks occur, and up to 50% of calves from 5 to 14 days of age in the affected population may develop the disease. If ETEC are present, the disease may be acute; dehydration is severe and deaths may occur. Multiple mixed infection with *E. coli,* coronavirus, and *Cryptosporidium* spp. are common in calves over 4 days of age; thus it may be impossible to describe a typical case of uncomplicated naturally occurring rotavirus or coronavirus-like diarrhea. There is a tendency for viral diarrhea in newborn calves to occur in explosive outbreaks; the calves are usually not toxemic, but the character of the diarrhea cannot be differentiated clinically from that associated with the other common enteric pathogens of newborn calves.

A coronaviral enteritis affecting calves from 1 to 7 days of age has been described, but there are no distinguishing clinical characteristics. The diarrhea may be persistent for several days, followed by death in spite of fluid therapy and careful realimentation with milk. The feces are voluminous, mucoid and slimy, and may be dark-green or light-brown in color.

Lambs

Experimentally, newborn gnotobiotic lambs develop diarrhea 15 to 20 hours following oral inoculation and show dullness and mild abdominal discomfort. There are only a few documented descriptions of naturally occurring rotaviral diarrhea in newborn lambs. Affected lambs under 3 weeks of age develop a profuse diarrhea, and the case–fatality rate is high. It is not clear if outbreaks of uncomplicated rotaviral diarrhea occur in newborn lambs.

Piglets

Rotaviral diarrhea may occur in nursing piglets from 1 to 4 weeks of age and in pigs following weaning. The disease in nursing piglets resembles milk scours or 3-week scours. Most of the pigs in the litter are affected with a profuse liquid to soft diarrhea with varying degrees of dehydration. Recovery usually occurs in a few days unless complicated by ETEC or unsatisfactory sanitation, overcrowding, and poor management. The disease is often most severe in herds in which there is continuous farrowing with no period of vacancy for cleaning and disinfection in the farrowing barn. The disease may also occur in pigs a few days after weaning and may be a major factor in PWD of piglets weaned at 3 weeks of age or earlier in the case of weaning pigs at 1 to 2 days of age.

PED type I affects piglets only up to 4 to 5 weeks of age and is characterized by profuse watery diarrhea, high morbidity, and low mortality.

PED type II causes a profuse fluid diarrhea in pigs of all ages, including nursing piglets. Explosive outbreaks may occur and the morbidity may reach 100%. Mortality is usually restricted to piglets under 3 weeks of age.

Foals

Affected foals—usually from 3 days to 5 months of age—appear depressed, fail to suck, and become recumbent. The temperature ranges from 39.5 to 41.0°C (103–106°F) and respirations may be rapid and shallow. There is a profuse, watery, nonfetid diarrhea that results in severe dehydration and electrolyte imbalances. Recovery following treatment usually occurs within 2 to 4 days. Death may occur within 24 hours after the onset of diarrhea.

CLINICAL PATHOLOGY

Detection of Virus

Fecal samples (20–30 g) should be collected from affected animals as soon possible after the onset of diarrhea and submitted to the laboratory in a chilled state. Samples of intestinal mucosa from several sections of the small and large intestine should be submitted chilled for virus detection and possible isolation.

Because multiple mixed viral and bacterial infections are common, the request for a laboratory diagnosis must include consideration of all of the common pathogens. The viruses are much more difficult to detect than bacterial enteropathogens. In herd outbreaks, fecal samples from several affected animals and some normal animals should be submitted. The rotavirus will usually be present in both normal and diarrheic animals, which presents problems in interpretation and requires evaluation of the clinical and epidemiologic findings.

Several laboratory tests are available for detection of rotaviruses and coronaviruses in the feces and intestinal contents and tissues. The particular test used will depend on the facilities and equipment available.

Electron Microscopy

Demonstration of the virus in feces using EM has been a standard diagnostic technique. It is easier to see the virus if it has been concentrated by ultracentrifugation or clumped by immunoelectron microscopy using specific antiserum. With EM, the virus can be detected for up to 6 to 10 days after the onset of diarrhea. Protein A-gold immunoelectron microscopy is a valuable test to detect BCoV in the feces and nasal secretions of infected calves. However, because the equipment and expertise necessary for EM are not available in many laboratories, alternative diagnostic techniques have been developed.

Immunofluorescence

Several tests are based on immunofluorescence. These include immunofluorescent

staining of fecal smears and cell culture immunofluorescence of fecal preparations. Immunofluorescent staining of a fecal smear is a more convenient test for diagnostic laboratories because a diagnosis can be made in a few hours, and an EM is not necessary. However, the immunofluorescence tests may not be as reliable as some other tests. The FA technique will only detect the virus within epithelial cells which are present in the feces for 4 to 6h after the onset of diarrhea. In some studies the FA technique detects the virus in only 20% of samples, whereas EM detected the virus in about 60% of the samples.

Immunodiffusion and Electron Microscopy

Immunodiffusion and EM are superior to the FA technique. Treatment of the feces with chymotrypsin improves the detection rate. Monoclonal antibodies to porcine Group C rotavirus can be used in an immunofluorescent test and may have wider applications in the study of Group C rotavirus diarrheas in swine, cattle, and potentially, other species.

Testing immunofluorescent sections of spiral colon is the diagnostic method of choice for the detection of coronavirus in calves; fecal samples are unreliable. Isolation of coronavirus in tracheal organ culture is the most sensitive in vitro culture technique. A hemadsorption–elution–hemagglutination assay test for the detection of coronavirus in the feces of calves is a simple and rapid procedure. A counterimmunoelectrophoresis test is available for the detection of coronavirus in calves. An immunohistochemical technique can be used to detect the virus of PED in the small intestine.

ELISAs are more sensitive and simple than immunoelectroosmophoresis, CF, immunofluorescence on inoculated cell cultures, or EM for the detection of rotavirus in calf feces. The ELISA is effective in detecting the presence of porcine rotavirus in feces and was confirmed in two-thirds of the samples tested using EM, immunofluorescence, and polyacrylamide gel electrophoresis (PAGE). A blocking-ELISA using monoclonal antibodies can detect the PEDV in feces and serum antibodies in both naturally and experimentally infected piglets and earlier than an indirect immunofluorescence test.

A competitive blocking-**ELISA** is considered most suitable for routine detection of porcine epidemic virus in the feces of pigs.

The ELISA and EM of feces are equally reliable in detecting the rotavirus and coronavirus in the feces of experimentally infected calves. The agreement between the two tests was 95% for coronavirus and 84% for rotavirus. There will always be borderline samples containing antigen in quantities near the detection limit for each test. Some samples will be positive for one test and negative for the other and vice versa. This problem can be minimized if several individual samples from a disease outbreak are examined. The morphologic identification of rotavirus is usually straightforward, but the pleomorphism of BCoV can present problems. The ELISA may also fail to detect viral antigen in feces that also contain antibody. The test can provide diagnostic results within 24 hours after collection of the fecal samples.

Reverse Passive Hemagglutination, ELISA, and Polyacrylamide Gel Electrophoresis

The three techniques for the detection of rotavirus in fecal samples from diarrheic calves have been compared. The reverse passive hemagglutination (**RPHA**) was at least as sensitive as the ELISA, and both were compared with the PAGE. The overall agreement between **RPHA** and **PAGE** was 96%; the ELISA was not as sensitive. The commercial ELISA has a slightly higher sensitivity than agglutination, **PAGE**, and concentrated **PAGE**, but the specificity of **ELISA** is lower. The latex agglutination test has a lower sensitivity than ELISA, but its specificity is higher. The latex agglutination test is easy to perform, more sensitive than EM, and more specific for detection of rotavirus. A dot hybridization assay can detect and differentiate two serotypes of porcine rotavirus.

The fast and inexpensive ELISA combined with the highly specific and sensitive RT-PCR is a practical approach in epidemiologic studies of bovine rotavirus.

PCR assays are now available for the detection of BCoV in feces. Nonradioactive PCR-derived cDNA probe assays can be used to detect rotavirus serotypes.

A rapid ELISA using monoclonal antibodies can be used for the simultaneous detection of BCoV, rotavirus serogroup A, and *E. coli* K99 antigen in the feces of calves. The specificity of all of the components was more than 90% specific and the sensitivity for BCoV, F5 (K99) *E. coli,* and rotavirus, 77, 93, and 100%, respectively.

Immunochromatography is used for the detection of RVA in the feces of calves, piglets, and foals, and has a sensitivity of 89% and specificity of 99% compared with ELISA, and its reproducibility is 100%. It is a one-step procedure, simple to use, very rapid, and can be performed on the farm.

A field enzyme immunoassay test (Rotazyme test) is highly accurate and reliable for the detection of rotavirus in the feces of horses with and without diarrhea. The test is a simple, rapid, and specific procedure that can take the place of a more expensive and slower procedure such as EM.

ImmunoCardSTAT Rotavirus is a human group A assay that can be used as an on-site diagnostic test for bovine rotavirus with a sensitivity and specificity of 87.0% and 93.6%, respectively. The assay is a 10-minute one-step test with all the necessary reagents included in the kit and with no need for any laboratory equipment.

Serology

Several serologic tests are available for the measurement of rotaviral antibody in serum and lacteal secretions. An ELISA is used to detect PED coronavirus antibodies in swine sera. The radioimmunoassay is the most sensitive test compared with the agar gel immunodiffusion, CF, hemagglutination, and hemagglutination inhibition tests.

NECROPSY FINDINGS

The pathology of experimentally induced rotavirus and coronavirus diarrhea in colostrum-deprived and gnotobiotic calves, lambs, and piglets has been described. Grossly, the changes are unremarkable and consist of dehydration, fluid-filled intestinal tract, and distension of the abomasum. The microscopic changes consist of shortening of the length of the villi and replacement of the tall columnar villous epithelial cells by cuboidal and squamous cells. Segments of the small intestine may reveal villous fusion, rounded absorptive cells, villous atrophy, and exposure of lamina propria. Crypt hyperplasia occurs in response to the loss of columnar epithelial cells from the villi. Histologic lesions caused by previous rotavirus infection may be present in the upper small intestine of clinically normal calves. The rate at which enterocytes are affected in older disease-resistant calves is caused by the slowing of the virus from entering the cells.

In coronavirus enteritis in calves, there is commonly villous atrophy of both the small and large intestines and destruction of the crypt epithelium; destruction does not occur in rotavirus enteritis. The changes are more severe in field cases of acute diarrhea in calves in which both viruses and ETEC can be isolated. Concurrent infection with BVDV has also been demonstrated to be synergistic in bovine rotaviral diarrhea.

The histologic appearance of the intestinal lesions of experimental infection of calves with Breda virus, calicivirus-like agent, and parvovirus have been described. Generally, the lesions are similar to those associated with rotavirus and coronavirus infection.

The wide array of diagnostic tests available to confirm the presence of enteric viruses has already been discussed. Because of the frequency of subclinical infection with these agents, it is important to histologically confirm concurrent atrophy of villi.

Samples for Confirmation of Diagnosis

- **Histology:** Duodenum, jejunum, ileum, colon (LM, IHC)
- **Virology:** Colonic content (EM, ELISA, latex agglutination); colon, ileum, jejunum (FAT, culture)

DIFFERENTIAL DIAGNOSIS

The cause of acute diarrhea in newborn farm animals cannot be determined clinically. All of the common bacterial and viral enteropathogens can cause an acute profuse fluid diarrhea, with progressive dehydration and death in a few days.

When outbreaks of diarrhea are encountered, a detailed examination of the possible risk factors should be made, and the appropriate fecal samples and tissues from affected animals should be submitted to the laboratory. The most reliable specimens include fecal samples obtained from animals within a few hours after the onset of diarrhea, and untreated affected animals are submitted for necropsy and microbiological examination within a few hours after the onset of diarrhea.

The clinical and epidemiological characteristics of the common acute diarrheas of neonatal farm animals are as follows:

Calves

Enterotoxic colibacillosis occurs primarily in calves under 5 days of age and is characterized clinically by an acute, profuse diarrhea. Recovery following treatment usually occurs in 2 days. Outbreaks occur in beef and dairy calves. Rotavirus and coronavirus diarrhea usually occur in calves over 5–10 days of age and up to 3 weeks of age. Explosive outbreaks occur, characterized by an acute profuse liquid diarrhea with recovery in 2–4 days. Recovery is assisted by oral fluid therapy.

Cryptosporidiosis occurs in calves from 5 to 15 days of age and is characterized by a persistent diarrhea that may last for several days. The cryptosporidia may be detected by Giemsa stain of fecal smears or by fecal flotation.

Bovine viral diarrhea virus (BVDV) Whether or not BVDV causes clinically significant diarrhea with lesions of the small intestine of calves 3–6 weeks of age is unknown. Diagnostic laboratories report the presence of intestinal lesions such as villous atrophy and crypt cell destruction in calves 3–6 weeks of age that have been affected with intractable diarrhea and from which the BVDV was isolated from the feces. However, there is no evidence of a cause-and-effect relationship.

Piglets

Transmissible gastroenteritis is most common in piglets under 1 week of age, and explosive outbreaks are common. There is acute profuse diarrhea and vomiting. Affected piglets may continue to nurse for several hours after the onset of the diarrhea. The case–fatality rate is high in piglets under 7 days of age; older pigs usually survive.

Porcine epidemic diarrhea type I affects piglets under 4–5 weeks of age and is characterized by profuse watery diarrhea, high morbidity, and low mortality.

Porcine epidemic diarrhea type II causes a profuse fluid diarrhea in pigs of all ages, including nursing piglets. Explosive outbreaks may occur and the morbidity may reach 100%. Mortality is usually restricted to piglets under 3 weeks of age.

Enterotoxic colibacillosis usually occurs in weaned and unweaned piglets. There is acute diarrhea, dehydration, and rapid death. Pigs with endotoxemia (Shiga-toxin producing *Escherichia coli*) may die without obvious diarrhea and usually appear cyanotic. Entire litters may be affected and the case–fatality rate may be 100%. Early treatment with antibiotics and subcutaneous fluids will result in recovery.

Coccidiosis occurs in piglets from 5 to 10 days of age and is characterized by an acute diarrhea in which the feces are foul smelling and vary in consistency from cottage cheese–like to liquid and gray or yellow and frothy. The diarrhea is persistent for several days and nonresponsive to antibiotics. Some pigs recover spontaneously; others die in 2–4 days. Coccidial oocysts can be detected in the feces. The morbidity rate varies from 50% to 75% and the case–fatality rate from 10% to 20%.

Hemorrhagic enterotoxemia caused by *Clostridium perfringens* type C affects entire litters of pigs under 1 week of age; is characterized clinically by severe toxemia, dysentery, and rapid death; and at necropsy there is a hemorrhagic enteritis.

Lambs

Enterotoxic colibacillosis occurs in lambs most often under 1 week of age and is characterized by dullness, failure to suck, and acute diarrhea, which responds to antibiotic and fluid therapy.

Coliform septicemia affects lambs under a few days of age and usually causes sudden death. Lamb dysentery occurs most often in lambs under 10 days of age, and there may be sudden death or acute toxemia, tucked-up abdomen, and a severe diarrhea and dysentery. At necropsy the characteristic finding is hemorrhagic enteritis.

Foals

Rotaviral diarrhea occurs in foals from 5 to 35 days of age, but is most common in foals under 2 weeks of age. There is acute profuse watery diarrhea, failure to suck, recumbency, and dehydration. Recovery is common within 1 week. A mild fever is common.

Foal heat diarrhea occurs in foals 6–10 days of age whose dams are in estrus 7–10 days after foaling.

Salmonellosis, *C. perfringens* type B, and dietary diarrhea from excessive consumption of milk are less common causes of diarrhea in newborn foals.

TREATMENT

The treatment of viral diarrheas in newborn farm animals is essentially the same as described for acute undifferentiated diarrhea of newborn calves. There is no specific therapy for viral diarrhea, but antimicrobial agents may be used both orally and parentally for the possible occurrence of secondary enteric and systemic bacterial infections. In the absence of complications, recovery from viral enteritis usually occurs without specific treatment in 2 to 5 days, which parallels the replacement of the villous epithelial cells whose complete replacement and maturation requires several days after the cessation of diarrhea.

Oral and parenteral fluid therapy as indicated is essential (Chapter 5). Affected foals may require fluid and electrolyte therapy for up to 72 hours. A glucose–glycine electrolyte formulation is an effective fluid therapy for pigs affected with experimental rotaviral diarrhea. The formula is glucose 67.53%, sodium chloride 14.34%, glycine 10.3%, citric acid 0.8%, potassium citrate 0.2%, and potassium dihydrogen phosphate 6.8%. A weight of 64 g of this formula is dissolved in 2 L of water to produce an isotonic solution.

When possible, affected animals, particularly calves and foals, should be separated from other neonates. When outbreaks of the disease occur in any species, the principles of good sanitation and hygiene should be emphasized to minimize the spread of infection.

CONTROL

The principles of control of viral diarrhea are similar to those described for acute undifferentiated diarrhea of newborn calves:

- Reduce infection pressure
- Ensure adequate transfer of passive immunity
- Vaccinate the dam to induce specific immunity in the colostrum (passive immunization of the neonate)

Management and Colostral Intake

Colostrum management strategies are discussed in detail (see the section Failure of transfer of Passive Immunity).

Vaccination

Vaccination of the dam before parturition is a common strategy to control rotavirus infection in calves, piglets, and foals.

Two major approaches are used to provide specific immunity for the control of rotavirus and coronavirus diarrhea in calves:

1. Stimulation of active immunity by vaccinating the newborn calf with an oral vaccine containing MLVs
2. Enhancement of lactogenic immunity by vaccinating the dam during pregnancy (passive immunization)

Oral Vaccines to Newborn Calves

An MLV rotavirus vaccine for oral administration to calves immediately after birth has been available commercially for many years. Initially, good results were claimed but vaccine field trials did not include contemporary controls, and the efficacy of the vaccine was uncertain. The incidence of diarrhea in herds not vaccinated in the previous year was compared with the incidence during the year of vaccination, which is inadequate to assess the efficacy of the vaccine.

Field trials using the oral vaccine indicate a failure of protection of calves against rotavirus infection and rotavirus–coronavirus infection. Effective oral vaccination of calves may be hindered by the presence of specific antibodies in the colostrum (the colostrum barrier) and may explain the failure of the vaccine under field conditions. The intestinal antibody response of young calves to an enteric viral infection is associated with the production of IgM and IgA antibodies locally in the intestine. This response is absent or diminished in calves that have ingested adequate amounts of colostrum with specific antibodies to the viruses. Most of the efficacy trials with the vaccine were performed on colostrum-deprived gnotobiotic calves that were vaccinated orally at birth and experimentally challenged a few days after birth. It is probably futile to vaccinate calves orally immediately after birth, particularly in herds in which the disease is endemic, because the colostrum will contain high levels of specific antibodies.

Fecal shedding of oral vaccine rotavirus seldom occurs after oral inoculation of gnotobiotic calves with a commercial modified-live bovine rotavirus-BCoV vaccine. Because of low shedding of virus in gnotobiotic calves that do not have the interfering effects of colostral antibodies, it seems unlikely that vaccine rotavirus will be shed in quantities from orally vaccinated conventional calves that have ingested colostrum containing antibody. Thus detection of the virus by negative stain EM in feces from orally vaccinated calves is most likely to be virulent field virus rather than vaccine virus.

Vaccination of Pregnant Dam (for Passive Immunization of the Neonate Through Colostral Immunoglobulin)

Vaccination of the pregnant dam to enhance specific colostral immunity can provide passive protection against enteric viral infection of newborn farm animals. The success of this method depends on the continuous presence of a sufficient amount of specific antibody to the rotavirus and coronavirus in the intestinal lumen. Normally, the colostral levels of antibody are high in the first few milkings after parturition. However, there is a rapid decline in colostral antibodies to below protective levels within 24 to 48 hours following parturition. Most cases of rotavirus and coronavirus diarrhea occur from 5 to 14 days after birth when the antibody levels in the postcolostral milk are too low to be protective.

The parenteral vaccination of the pregnant dam before parturition with a rotavirus and coronavirus vaccine will usually increase the level and duration of specific antibody in the colostrum. The use of a modified-live rotavirus–coronavirus vaccine stimulated a small but insignificant increase in colostral and milk antibodies. However, by 3 days after parturition, the rotavirus and coronavirus antibody titers in the milk of vaccinated heifers had declined to low or undetectable levels.

Inactivated rotavirus vaccines given to pregnant cows in the last trimester will significantly increase rotavirus antibody in colostrum and milk from vaccinated dams compared with controls, but the severity of diarrhea may be the same in calves from both groups. The increased milk antibody delays the establishment of infection but does not reduce the severity of clinical disease that was experimentally induced.

Experimental Studies of Maternal Bovine Rotavirus Vaccines

The use of an adjuvanted rotavirus vaccine given simultaneously intramuscularly and by the intramammary route significantly enhanced serum, colostrum, and milk rotavirus antibody titers, whereas intramuscular vaccination with a commercial modified-live rotavirus–coronavirus vaccine did not. Colostrum supplements, from the cows vaccinated by the intramammary and intramuscular routes, fed to rotavirus-challenged calves at a rate of 1% of the total daily intake of milk, provided protection against both diarrhea and shedding. The 30-day milk antibody titers from these experimental cows were also considered to be protective for calves by which time the calves should have developed a high degree of age-specific resistance to rotavirus infection. The use of an inactivated rotavirus vaccine in an oil adjuvant given to pregnant cows 60 to 90 days before calving and repeated on the day of calving resulted in a significant increase and prolongation of colostral antibodies up to 28 days after calving. Diarrhea in calves from vaccinated cows was less common and less serious. Similar results were obtained with a combined inactivated adjuvanted rotavirus and *E. coli* vaccine. Similar results have been achieved by vaccination of pregnant ewes. Vaccination of ewes can result in an elevation of specific colostral antibody and prolong the period over which the antibody is present in the lumen of the intestines of the lambs. The vaccination of cows with a monovalent vaccine results in a heterotypic response to all serotypes of rotavirus to which the animals have been previously exposed, which suggests that single serotype vaccination may be sufficient.

The lactogenic antibody responses in pregnant cows vaccinated with recombinant bovine rotavirus-like particles (VLPs) of two serotypes or inactivated bovine rotavirus vaccines have been evaluated. Bovine rotavirus antibody titers in serum, colostrum, and milk were significantly enhanced by the use of triple-layered VLPs, and inactivated vaccines but higher antibody responses occurred in VLP-vaccinated cows.

Bovine Coronavirus Vaccine

An oil-adjuvanted vaccine containing BCoV antigen to enhance lactogenic immunity in the calf by vaccinating pregnant cows and heifers between 2 and 12 weeks before calving increased serum antibody in the dams, which was reflected in a similar increase in the titer and duration of specific antibody in colostrum and milk for up to 28 days after calving. The overall response was dependent on an adequate antigen payload being incorporated within the single dose vaccine.

Commercial Bovine Rotavirus–Coronavirus and *E. Coli* F5 (K99) Vaccines

The original rotavirus and coronavirus vaccines for use in pregnant cows to provide passive immunization were not sufficiently efficacious because of the rapid decline in specific colostral antibodies, which renders the calves susceptible to the viral diarrhea several days after birth. The relative success of the enterotoxigenic F5 *E. coli* bacterins has resulted in a shift of the epidemic curve for acute diarrhea in calves under 30 days of age from a few days of age to 2 to 3 weeks of age.

More recently developed vaccines are efficacious. An inactivated combined vaccine against rotavirus, coronavirus, and *E. coli* F5 administered 31 days before the first expected calving date has been evaluated and compared with controls. There was a significant increase in serum antibody against all three antigens in vaccinated animals, which was accompanied by increased levels of protective antibodies to rotavirus, coronavirus, and *E. coli* in their colostrum and milk for at least 28 days. The levels of specific rotavirus and coronavirus antibodies in the milk of vaccinated cows were greater than the fourfold increase seen in the control cows for at least 28 days after calving.

The primary vaccination of pregnant cows with a trivalent commercial vaccine containing live attenuated bovine rotavirus and coronavirus and *E. coli* F5 followed by an annual booster at 6 weeks and 3 weeks before calving, or using the same protocol with an inactivated trivalent vaccine resulted in significant increase in the serum antibody of all vaccinated animals compared with controls. The antibody titers were higher in cows receiving the live vaccine compared with those receiving the inactivated vaccine.

The colostral antibodies against all three antigens increased in all live vaccinated groups, whereas inactivated vaccinated animals had only significant increases in F5 titers. The colostrum of live vaccinated cows contained much higher specific antibody titers. Thus the MLV vaccine can significantly enhance the specific response to rotavirus and coronavirus and *E. coli* F5 after a primary vaccination followed by a booster annually.

Stored Colostrum

The high levels of viral antibody in the colostrum of the first two milkings of cows can be used to advantage in hand-fed calves. The daily feeding of stored colostrum from the first milkings of cows from the affected herd will reduce the incidence of clinical disease in the calves. The colostrum must be fed daily—beyond the time of gut closure (i.e., intestinal absorption of colostral immunoglobulin)—because rotavirus antibody is not retained in the intestinal lumen for more than 2 to 3 days. In affected herds the specific antiviral antibody in the stored colostrum may be sufficient to prevent the disease if colostrum is fed daily for up to 20 to 30 days. If a large number of cows are calving over a short period of time, the colostrum from immunized cows can be pooled and fed to the calves daily. Even small amounts of colostrum from immunized cows are efficacious if mixed with cows' whole milk or milk replacer. This supplemental feeding of colostrum may be required for only 3 to 4 weeks, because older calves generally possess a high degree of age-specific resistance to rotavirus infections.

Systemic Colostral Antibody

For many years it was uncertain if circulating colostral antibody in calves was transferred back into the intestinal tract. Evidence shows that passive immunity to calf rotavirus diarrhea can be achieved by adequate calf serum colostral antibody titers. Calves fed colostrum on the first day of life had significant rotavirus-neutralizing antibody titers in their small-intestinal lumina for 5 and 10 days later. The intestinal antibody titers correlated with the serum antibody titers derived from colostrum and were predominantly of the IgG_1 isotype. Intestinal antibody titers were approximately equivalent in 5- and 10-day-old calves, suggesting that **antibody transfer to the intestinal tract is a continuing process for up to 10 days after birth.** Additional evidence that transfer of passive immunity occurs is that calves can be protected from rotavirus challenge by the administration of colostral immunoglobulin by parenteral injection. This protection was not caused by lactogenic antibody, because the calves received no source of dietary antibody. The transfer of circulating antibody into the intestinal tract may be the mechanism that results in the decreased morbidity and case fatality caused by diarrhea in calves with high concentrations of passive serum immunoglobulin.

Porcine Rotavirus Vaccines

Although oral porcine rotaviral vaccines have been unsuccessful, the use of either modified-live or inactivated rotavirus vaccines for parenteral immunization of the sow before farrowing is common practice. In pigs, as in ruminants, IgG antibodies to rotavirus are predominant in colostrum and decline 8- to 32-fold in the transition to milk. However, secretory IgA is the primary isotype of rotavirus antibody in the milk of pigs. Increased levels of IgA and IgG antibodies to rotavirus occur in the milk of sows after natural rotavirus infection of nursing piglets or following parenteral inoculation of pregnant or lactating sows with live attenuated rotaviruses. But titers decline by the end of lactation, suggesting that repeated natural rotavirus infection of sows or parenteral revaccination may be necessary to maintain high IgA antibody to rotavirus in milk. This observation may account for the higher prevalence of rotavirus infection during the first week of life in pigs born to gilts (38%) than in those born to sows (3%).

Equine Rotavirus Vaccine

Several inactivated equine rotavirus vaccines are available. These vaccines were shown to significantly increase serum antibody concentration in vaccinated mares and their foals. Notwithstanding it was shown that foals can acquire rotavirus infection despite having a high rotavirus antibody titer. The incidence of rotaviral diarrhea was lower in foals born to vaccinated mares, compared with foals born to control mares but the difference was not significant. Because most clinical trials found that foals of vaccinated mares can still contract a rotavirus infection and develop clinical disease, these vaccines can at most be considered to be partially protective.[15] Parenteral vaccination of mares with inactivated rotaviral vaccine stimulates production of high levels of specific IgG, and not IgA, in colostrum and milk.

Subunit Vaccines

Subunit rotaviral vaccines consisting of VLPs given parenterally can enhance bovine rotavirus antibody titers in serum, colostrum, and milk. These vaccines offer advantages over conventional modified-live or inactivated vaccines including:

- Exclusion of adventitious agents associated with live vaccines
- Consistent production of outer capsid proteins
- Genetic engineering to allow updating of efficacious vaccines for boosting lactogenic immunity

VESICULAR STOMATITIS (SORE MOUTH, INDIANA FEVER)

SYNOPSIS

Etiology Vesicular stomatitis virus, genus *Vesciculovirus* in the family Rhabdoviridae

Epidemiology Disease of cattle, horses, and pigs occurring only in the Americas. Affects predominantly adult animals. Seasonal disease occurrence with clustered outbreaks in summer and autumn. Vector-borne, direct, and mediate transmission. World Organization of Animal Health List A disease (reportable in most countries). Prime importance as differential diagnosis for foot-and-mouth disease

Clinical findings Vesicular lesions or healing ulcers on oral mucosa, coronary bands, teats, and prepuce

Diagnostic confirmation Virus isolation, indirect sandwich ELISA, complement fixation, and polymerase chain reaction. Serology (paired samples) via liquid-phase blocking ELISA, virus neutralization, or complement fixation

Treatment None specifically, just supportive

Control Notifiable disease. Quarantine and movement control

ELISA, enzyme-linked immunosorbent assay.

ETIOLOGY

The causative agent of VS is the *vesicular stomatitis virus* (VSV), genus *Vesiculovirus*, pertaining to the family Rhabdoviridae. Two distinct immunologic classes of the virus have been recognized: VSV New Jersey (VSV-NJ) and VSV Indiana (VSV-IND). There are three subtypes of VSV-IND based on serologic relationships, including IND-1

(classical IND), IND-2 (cocal virus), and IND-3 (alagoas virus). The serotype NJ is the most virulent and most common.

The virus is much less resistant to environmental influences than the virus of FMD. It is readily destroyed by sunlight, boiling, and the use of common disinfectants but can survive in the environment for prolonged periods in a dark and cool environment.[1]

VS is listed on "List A" of the OIE and as such is a reportable disease to the OIE for member states. Accordingly it is a **reportable disease** in most countries of the world. The disease is of major importance because it is clinically indistinguishable from FMD in ruminants and swine. It is considered as a minor zoonosis because it can cause disease in humans.

EPIDEMIOLOGY

Occurrence

Geographic Occurrence

The disease is limited to the Americas, although historically it has been reported from South Africa (1896–1897) and France (1915 and 1917). VS is **endemic** in Mexico, Central America, northern South America, and eastern Brazil as well as in limited areas of the southeastern United States in which area outbreaks occur annually.[2] Periodic **incursions** to the north and south of the endemic area into the United States, Brazil, and Argentina produce epizootic disease. It is also enzootic in Ossabaw Island, off the shore of Georgia in the United States. Ossabaw Island is the only recognized enzootic focus of VSV-NJ. The VSV-NJ antibodies have been detected only from feral swine, cattle, horses and donkeys, deer, and raccoons. However, despite high transmission rates, clinical disease is rarely detected.

Strains of VSV-NJ are endemic in southern Mexico, Central America, Venezuela, Colombia, Ecuador, and Peru and account for more than 80% of clinical cases. Sporadic activity of these strains has been observed in northern Mexico and the western United States. Cases of the disease reported from Brazil and Argentina were related to VSV-IN2 and VSV-IN3.[1] VSV-IN2 has only been isolated in these two countries and only from horses. Cattle in close proximity to affected horses neither developed clinical disease nor antibodies against VSV.[1]

In endemic areas, outbreaks are seasonal, often associated with the transitions between rainy and dry seasons. In these regions the disease occurs seasonally every year, emerging from tropical areas to cause sporadic outbreaks in cooler climates during the summer months.

In the **United States** outbreaks occur periodically in the late summer and autumn; a major outbreak occurred in 14 western states from 1982 to 1983, one in 1995 involving six states, and another one in 2005 involving nine states, with sporadic disease in the intervening and following years. The outbreaks occur in the **southwestern and western states**, start in the south and progress northerly, and **cluster** in areas of high livestock density in irrigated and green zone areas.[3]

In the 1995 outbreak the disease occurred in Arizona, Colorado, New Mexico, and Utah. The epidemic curve suggested a propagating epidemic; the number of positive premises peaked during week 39 and then rapidly declined. As in previous outbreaks in the southwestern United States, there was a northerly progression of the disease over time. Nationwide, horses accounted for 88% of examinations done for the disease, and 97% of the premises on which species of infected animals were identified recorded horses to be positive. Cattle accounted for 10% of examinations performed, and 3% positive premises on which species were identified were cattle positive.

The first major occurrence of the disease or "sore tongue" in horses, cattle, and swine in the United States was in 1801. The disease disabled 4000 horses needed to fight the Civil War in 1862. Major epidemics in U.S. cattle and horses occurred in the southwestern states from 1889 to 2005. A major outbreak occurred in military horses in the United States during the 1914 to 1918 war but in recent years, in addition to clinical disease in horses, it has come to assume greater importance in cattle and pig herds.

Host Occurrence

VS primarily affects equids including horses, donkeys, and mules, as well as cattle and swine. Camelids and possibly sheep and goats as well as humans occasionally develop clinical signs. Domestic animals appear to be dead-end hosts in which the virus does not persist and does not return to its natural cycle. Outbreaks of the disease are **most common in horses followed by cattle** and to a lesser extent in pigs. Calves are much more resistant to infection than adult cattle. Serologic surveys have found that in endemic areas of Mexico and Central and South America in addition to domestic livestock, many species of wild animals such as deer, pronghorn antelope, bighorn sheep, bats, raccoons, opossums, bears, coyotes, foxes, dogs, monkeys, rabbits, rodents, turkeys, ducks, and humans are exposed to the infection and develop neutralizing antibodies.[2] Experimental infection is possible in guinea pigs, mice, ferrets, hamsters, and chicken. The reservoir and amplifying host of VSV has thus far not been identified.

Humans are susceptible with the infection causing an influenza-like disease, and the development of high antibody titers in humans often accompanies outbreaks in cattle.

In the 1995 outbreak in the United States, the overall seroprevalence in livestock in Colorado was lower than the seroprevalence in epidemic areas, and seroprevalence rates in epidemic areas were greater for horses than cattle. The seroprevalence results suggest that some animals had subclinical VS infection during epidemics, and that animals may be exposed to the virus between epidemics. Sentinel premises in Colorado visited quarterly during a 3-year period, when there was no clinical disease, found evidence of seroconversion to both serotypes of virus.

Morbidity and Mortality

The morbidity rate varies considerably; 5% to 10% is usual but it may be as high as 80%. There is usually no mortality in horses and dairy herds, but overall case–fatality rates ranging from 0% to 15% are recorded for beef herds. Higher mortality rates than in other species have been reported in pigs infected with VSV-NJ. Most cases occur in adult animals, whereas animals under 1 year of age are rarely affected. Outbreaks in an area are usually not extensive, but the disease closely resembles FMD and has achieved considerable importance for this reason.

Method of Transmission

The mechanisms of VSV transmission are still not entirely understood. **Vector-borne transmission** is considered the epidemiologically most relevant route, although transmission through direct skin-to-skin contact is likely to contribute to the spread of the disease within a herd.[4] There is strong epidemiologic evidence corroborating the assumption of vector-borne transmission. Apart from an obviously seasonal pattern of disease occurrence, the disease incidence was determined to be increased with an increasing population of potential insect vectors, with proximity of affected animals to running water as well as with a lack of use of shelters.[4] Biological transmission by blood-feeding insects, which have been demonstrated repeatedly to be abundant on case-positive premises, also indicates that the insect-vector hypothesis is plausible. **Biological transmission** of VSV has been verified in **blackflies** (*Simulium vittatum*), phlebotomine **sandflies** (*Lutzomyia* spp.), and **biting midges** (*Culicoides* spp.).[4] Mechanical transmission through flies (*Musca domestica,* and *M. autumnalis*) and eye gnats (*Hippelates* spp.) on which the virus has been isolated may also occur. Experimentally, VSV-NJ–infected blackflies readily transmitted the virus to domestic swine. Transmission was confirmed by seroconversion or by the presence of clinical VS.

Vector-borne virus transmission has been debated because viremia, which is considered to be essential for disease transmission by blood-sucking insects, is not commonly observed in animals infected with VSV. As in other domestic animal species in which viremia has not been detected naturally or experimentally, viremia did not occur in the pigs experimentally infected by infected blackflies. Furthermore, the natural vertebrate host required to maintain the

virus between outbreaks has not been identified. Antibody to VSV has been demonstrated in a large number of **wildlife species** in Central America, but their significance as wildlife reservoirs remains to be determined. Feral pigs are believed to be the reservoir and amplifying host on Ossabaw Island.

Another proposed hypothesis is that VSV is actually a plant virus that would be ingested with forages and then undergo an adaption process to infect its host.[1]

Mediate or immediate contagion occurs by contact or ingestion of contaminated materials, especially in large intensive dairies where there is a great deal of communal use of water and feed troughs. It also occurs by the ingestion of contaminated pasture. Spread within dairy herds also appears to be aided by milking procedures. The importation of embryos from infected areas is considered a minimal risk for introduction of infection.

Convalescent cattle have been suspect as perpetuating disease and spreading it with movement to other herds. VSV has been isolated from convalescent cattle 38 days after the disappearance of clinical signs, and disease can recur in convalescent cattle. Viral RNA can be detected in the tongue and draining lymph nodes of cattle 5 months after experimental inoculation, but there is no evidence for the long-term persistence of replication-competent virus in cattle.

Risk Factors

Host Risk Factors

Differences in susceptibility of different species are well established with horses followed by cattle and then swine, which are considered most susceptible to clinical disease.[1] Age is another well-documented risk factor predisposing to clinical disease, with foals and calves less than 1 year old being less likely to develop clinical disease, although infection and seroconversion still occur.[1] In Costa Rica, which is an endemic area for VS in dairy cattle, parity was associated with clinical disease (animals of parity 4 or 5 were 5.3 times more likely to exhibit clinical signs of VS than animals of parity 3 or lower). Animals of parity 6 and higher had an OR of 4.6 times greater than animals of parity 3 and lower. Factors associated with seropositivity at birth were also found to be breed associated (Jersey calves had an OR of 14.7 times greater than Holstein calves).[5]

Environmental Risk Factors

There is a marked **seasonal incidence** of the disease, with cases decreasing sharply with the onset of cold weather. The disease is enzootic in low-lying coastal countries with tropical climates, heavy rainfall, and high insect populations. There is also a greater incidence in geographically protected areas with heavy rainfall, such as valleys in the mountains and foothills. Areas of low incidence are protected by natural barriers to insect migration. These observations promote the importance of biting insects in the spread of the disease both locally and from infected to clean areas. In enzootic areas there is a much higher risk for dairies in forest land, the presence of sandflies, and a higher risk for clinical disease in older cows and cows in lactation.

The management factors affecting the risk for VS in horses, cattle, and sheep during the 1997 outbreak in Colorado, New Mexico, Utah, and Arizona were examined. Animals with access to a shelter or barn had a reduced risk of developing the disease with an OR of 0.6. This was more pronounced for horses at an OR of 0.5. When horses had access to pasture, the risk of developing disease was increased with an OR of 2.01. On all premises where owners reported insect populations were greater than normal, the OR was 2.5. Premises with animals housed <0.5 miles from running water were more than twice as likely to have clinical signs of VS (OR 2.6). This suggests that rivers are a pathway or a risk factor for VS, which is consistent with outbreaks of the disease following major waterways northward during the summer.

Pathogen Risk Factors

The two major VSV serotypes, VSV-IN and VSV-NJ, are distinct viruses with only 50% similarity in the glycoprotein gene sequence. VSV-NJ is more predominant than VSV-IN in North America.

In the last 70 years, each sporadic outbreak in the southwestern United States has been associated with viral lineages distant from those causing previous outbreaks in the United States but closely related to viruses maintained in endemic areas in Mexico. This pattern of viral occurrence contrasts with that observed in endemic areas in Central and South America where viral genetic lineages are maintained in specific ecological areas over long periods of time. Thus the phylogenetic data and the geographic and temporal distribution of outbreaks indicate that VS does not have a stable endemic cycle in the western United States.

Experimental Reproduction

Livestock can be infected with VSV by injection or aerosol exposure but not by rubbing virus on intact skin. Intradermal injection causes obvious skin lesions at the inoculation site. Experimental inoculation with the virus kills neonatal mice and chick embryos, and most guinea pigs, hamsters, ferrets, and mice, and chicks.

Experimentally, VS-NJ virus-infected blackflies when exposed to the abdomen or snout of young pigs results in lesions developing postinfection day 1. The entire surface of the snout ventral to the nostrils becomes reddened and swollen with pinpoint pale raised areas. This proceeds to vesiculation on day 2, and subsequent rupture, erosion, and crusting by day 3. Erosion persists for several days, and by day 7, the vesiculated area is almost healed. Secondary vesicles develop on the upper lips and the tip of the tongue by day 3. Virus can be recovered from tissues surrounding the snout lesions but cannot be isolated from whole blood or plasma.

Viremia has not been detected in any domestic animal species naturally or experimentally infected with the New Jersey serotype of the virus.

Economic Importance

Most cases of VS recover within days. The economic losses on large dairy farms are largely caused by decreased milk production and mastitis occurring secondary to VSV infection. There is also a great deal of inconvenience and the temporary inability to feed.

There are also losses associated with quarantine such as loss of market opportunities and pasture damage from overgrazing of pastures used for quarantine. Other economic effects result from the cancellation of animal events such as fairs and the cost of loss of international markets.

In the 1995 epidemic of VSV-NJ in the western United States, the direct costs for increased labor and veterinary expenses incurred in caring for horses with the disease were estimated at $382.00 per case. In a dairy herd, losses were estimated at $787.00 per animal from increased culling, and in beef ranches the costs were $15,565.00 per ranch. State regulations restricting the movement of animals within a zone of 10 miles around premises with confirmed cases for 30 days after the last lesion healed, and declaring a quarantine, all added to economic losses.

VS is classified by the OIE as a so-called List A disease, making it a **reportable disease** in all member countries of the OIE.[6] In the United States, all livestock with clinical signs of vesicular disease must be inspected by personnel from USDA-APHIS. Premises confirmed to have VS-positive animals remain quarantined until 30 days after all clinical signs of the disease have disappeared from livestock on the premises. Thus local and national activities involving horses and cattle may be disrupted, and international exports may be prohibited because of meat and livestock embargoes.

Zoonotic Implications

Occasional human infections give the disease some public health significance, but the disease is mild, resembling influenza, and is considered as minor zoonosis.[1]

PATHOGENESIS

Local infection of the mucous membrane of the mouth and the skin around the mouth and coronets is followed by the development of vesicles on the lips, muzzle, tongue, as well as on the teats and interdigital clefts. The frequent **absence of classical vesicles** on the oral mucosa of affected animals in field outbreaks has led to careful examination of the

pathogenesis of the mucosal lesions. Even in experimentally produced cases, only 30% of lesions develop as vesicles; the remainder dehydrate by seepage during development and terminate by eroding as a dry necrotic lesion.

Immune Mechanisms

Following infection, serum-neutralizing antibodies develop within a few days and may persist for 8 to 10 years. Reinfection can occur in the presence of a high antibody titer. In cattle, horses, and swine, high titers of virus are found at the margins of lesions and in vesicular fluids for a short period after infection. However, viremia is undetectable and there is no known carrier state in cattle, horses, or swine.

CLINICAL FINDINGS

Cattle

In cattle after an incubation period of 3 to 15 days, there is a sudden appearance of mild fever and the development of vesicles on the dorsum of the tongue, dental pad, lips, and buccal mucosa. The vesicles rupture quickly and the resultant irritation causes profuse, ropy salivation and anorexia. Confusion often arises in field outbreaks of the disease because of failure to find vesicles. In some outbreaks with thousands of cattle affected, vesicles have been almost completely absent. They are most likely to be found on the cheeks and tongue where soft tissues are abraded by the teeth. At other sites there is an erosive, necrotic lesion. In milking cows there is a marked decrease in milk yield. Lesions on the feet and udder occur only rarely except in milking cows where teat lesions may be extensive and lead to the development of mastitis. Lesions are very painful and cause a decline in feed intake and resistance to be milked in dairy cattle. Recovery is rapid, affected animals are clinically normal in 3 to 10 days, and secondary complications are relatively rare.

Horses

In horses, the signs are broadly similar. There is fever, depression, inappetence, drooling of saliva, and affected horses may rub their lips on troughs and jaw champ. Vesicles coalesce and rupture with detachment of the epithelium and the formation of shallow ulcers. The period of fever and vesicles is short lived. Not infrequently the lesions seen are limited to the dorsum of the tongue or the lips and are in the coalescing ulcer stage. Other less common sites include the udder of the mare and the prepuce of males. Lesions may occur at the coronary band and lead to lameness and deformity of the hoof wall.

Pigs

In pigs, vesicles develop on or behind the snout, the lips, or on the feet, and lameness is more frequent than in other animals.

CLINICAL PATHOLOGY

Vesicle fluid, epithelium covering unruptured vesicles, epithelial flaps of freshly ruptured vesicles, or swabs of vesicles are ideal diagnostic specimens for virus isolation. If unavailable, oropharyngeal fluid from cattle or throat swabs from pigs may be submitted. Samples should be placed in containers with Tris-buffered tryptose broth with phenol red at pH 7.6. Glycerophosphate buffer, pH 7.2–7.6, can be used for specimens intended for CF.[1] Samples need to be kept refrigerated for shipping for up to 48 hours or otherwise frozen.

The **indirect sandwich ELISA** (IS-ELISA) is currently the diagnostic method of choice for identification of viral serotypes of VSV and other causative agents of vesicular diseases. Virus isolation can also be performed by inoculation into Vero **cell cultures** and subsequent staining with anti-VSV FA conjugate. CF is less sensitive than the IS-ELISA and is affected by procomplementary or anticomplementary factors.[1] Nucleic acid recognition by PCR has been used to detect presence of viral DNA.

Serologic tests include VN, CF, and a LP-ELISA, all of which are prescribed tests for international trade. LP-ELISA is currently considered the method of choice for the detection and quantification of antibodies against different VSV serogroups. The ELISA has advantages in speed and expense and has comparable specificity and gives fewer false-negative results than VN.[1]

NECROPSY FINDINGS

Necropsy examinations are not usually undertaken for diagnostic purposes.

DIFFERENTIAL DIAGNOSIS

Because of its case-for-case similarity to foot-and-mouth disease (FMD), prompt and accurate diagnosis of the disease is essential. In most countries the **disease is notifiable**.

Cattle
- FMD
- Pseudocowpox
- Bovine papular stomatitis
- Bovine viral diarrhea/mucosal disease
- Infectious bovine rhinotracheitis
- Bovine malignant catarrh fever
- Bluetongue
- Epizootic hemorrhagic disease
- Rinderpest
- Chemical or thermal burns

Horses
- Blister beetle toxicosis
- Bullous pemphigoid
- Equine infectious arteritis
- Equine herpes virus infection
- Calicivirus infection
- Jamestown Canyon virus infection
- Phenylbutazone toxicity
- Equine exfoliative eosinophilic dermatitis and stomatitis
- Squamous cell carcinoma
- Melanoma
- Grass seed awns

Swine
- FMD
- Swine vesicular disease
- Vesicular exanthema of swine
- Foot rot
- Thermal or chemical burns

TREATMENT

Treatment is seldom undertaken, but nonsteroidal antiinflammatories may contribute to the comfort of the animal and the rapidity of recovery.

CONTROL

Hygienic and quarantine precautions to contain the infection within a herd are sufficient control, and the disease usually dies out of its own accord. Animal movement off the farm should be prohibited until 30 days after all lesions have healed. There are usually restrictions of movement of animals from infected areas to different jurisdictional areas that are free of clinical disease, and VS is an **OIE List A disease**.

Immunity after an attack appears to be of very short duration, probably not more than 6 months, but serologic titers persist much longer. An **autogenous killed vaccine** was approved for use in dairy cattle in infected or at-risk areas during the 1995 outbreak in the United States, but vaccine efficacy could not be determined.

A DNA vaccine expressing the glycoprotein gene from VS-NJ virus elicits neutralizing antibody titers in mice, cattle, and horses. The level of protection of antibody required for protection is unknown.

A recombinant VSV-IND expressing NJ and IND glycoproteins has been generated and examined as vaccine candidate. When inoculated into pigs it induced neutralizing antibodies and the pigs were protected against homologous high-dose challenge.

Parasitic Diseases of the Alimentary Tract

CRYPTOSPORIDIOSIS

SYNOPSIS

Etiology Usually *Cryptosporidium parvum*, *C. andersoni*, and/or *C. bovis*

Epidemiology Infection common in ruminant neonates. May cause diarrhea, particularly if there is intercurrent infection with other enteropathogens and nutritional or environmental stress

Clinical findings Malabsorption-type diarrhea

Clinical pathology Oocysts in feces demonstrated by immunofluorescent or oocyst DNA detected by polymerase chain reaction

Lesions Villous atrophy

Diagnostic confirmation Demonstration of lesions and the organism

Treatment Supportive. Halofuginone in cattle, if approved

Control Hygiene and management to ensure passive transfer of colostral antibodies and minimization of infection pressure

ETIOLOGY

Cryptosporidium spp. are apicomplexan (coccidial) protozoans.[1-14] They have direct life cycles, and infections are transmitted via the fecal–oral route. Currently, based primarily on molecular data, more than 16 *Cryptosporidium* species and more than 44 genotypes have been reported to parasitize the epithelial cells (usually in the gastric or intestinal tract) of hosts representing all classes of vertebrates.[2-4] *C. parvum* is a **common infection** in young animals, including ruminants, and is found in many species of mammals, including humans. *C. parvum* is considered a significant cause of varying degrees of naturally occurring diarrhea in neonatal farm animals. This agent can act in concert with other enteropathogens to produce intestinal damage and diarrhea.

EPIDEMIOLOGY

Occurrence and Prevalence

Cryptosporidiosis has been recognized worldwide in numerous host animals, including cattle, lambs, goat kids, foals, and piglets.[4] Many studies report prevalence of infection, but this does not imply clinical disease.

Calves

Many studies have found limited association between infection and diarrhea, but there are many reports that associate infection in calves with diarrhea occurring between 5 and 15 days of age. A study of preweaned (5–60 days of age) and postweaned (3–11 months of age) calves has shown strong evidence of an age-related association between host and cryptosporidiosis. The prevalence of *Cryptosporidium* in preweaned calves has been shown to be ~50% (of 503) and can decrease to ~20% (of 468) calves following weaning. Interestingly, although most of the infections in preweaned calves relate to *C. parvum,* only a small percentage (e.g., <1%) of weaned calves have been found to be infected with this species; the dominant species in weaned calves, based on DNA studies, are *C. andersoni* and *C. bovis.* This information suggests that young calves represent a more significant zoonotic risk than older cattle. Infection of calves is often followed by the development of resistance to reinfection, and oocyst excretion is less common and intermittent in older and adult cattle, although high excretion rates can be found in adult cattle in some herds (which likely relate to species other than *C. parvum*).

Because calves are likely to be infected by *C. parvum* shortly after birth, and clinical signs of disease are typically limited to a period of intense, self-limiting diarrhea, and the high cost and limited effectiveness of chemotherapeutic and supportive treatment, there appears to have been little incentive for developing husbandry practices to limit bovine cryptosporidiosis. However, intensive farms (e.g., dairy and feedlots) can represent a significant source of human-infective oocyst contamination in the environment, which is presumably exacerbated by the presence of newborn calves.

Sheep and Goats

C. parvum is also a **common** enteric infection in **young lambs** and **goats**, and diarrhea can result from a monoinfection, but more commonly it is associated with mixed infections. The features of infection(s) and pattern of excretion of the cryptosporidial oocysts is similar to that in calves.[1] Infection can sometimes be associated with outbreaks of diarrhea, with high case fatality in lambs from 4 to 10 days of age and goat kids from 5 to 21 days of age.[1]

Pigs

Cryptosporidial infection in pigs occurs over a **wider age range** than in ruminants and has been observed in pigs from 1 week of age through to market age. Infection seems to be common between 6 and 12 weeks of age. Many cryptosporidial infections appear to be **asymptomatic**, although cryptosporidiosis might contribute to malabsorptive diarrhea after weaning.

Foals

Cryptosporidial infection in foals appears to be less prevalent. Diarrhea has been recorded in foals from 5 days to 6 weeks of age. Disease might occur in Arabian foals with inherited combined immunodeficiency.

Farmed Deer

Cryptosporidiosis is also recorded in young deer and can be a cause of diarrhea. Infection has also been recorded in red deer calves dying at 24 to 72 hours of age, following a syndrome of severe weakness and depression accompanied by a terminal uremia.[1]

Source of Infection and Transmission

Experiments have shown that a small number of oocysts are required for infection. The replicative cycle in the intestine amplifies a minor infective dose, and studies in gnotobiotic animals indicate a minimum **infectious dose** as low as one oocyst. The source of infection is **feces** that contain oocysts that are already sporulated and infective when excreted. Large numbers of oocysts are excreted during patency in calves, resulting in heavy environmental contamination. Transmission may occur directly from calf to calf, indirectly via fomite or human transmission, and from contamination in the environment or fecal contamination of the feed or water supplies. Infection in newborn animals and an increase in contamination of their immediate environment might occur as the result of a **periparturient rise** in fecal output oocysts by the dam.

Risk Factors

The factors that make animals susceptible to infection and that predispose infected animals to develop clinical disease are still not well understood.[4] Cryptosporidiosis in young agricultural animals is often associated with infection with *C. parvum*. Other enteric infections can occur concurrently with *Cryptosporidium*/cryptosporidiosis. The site of infection with *Cryptosporidium* is predominantly on the enterocyte where it results in cell damage, loss of brush border enzymes, and a reduction of villous surface area.

Pathogen Risk Factors

Oocysts are resistant to most **disinfectants** and can reportedly remain viable for ≥18 months in a cool, damp, or wet environment and can survive for several months in soil and slurry, but are susceptible to desiccation, temperatures of more than 60°C, and ultraviolet light. The infectivity of the oocysts can be destroyed by ammonia, formalin, freeze-drying, and exposure to temperatures below 0°C (32°F) and >65°C (149°F). Ammonium hydroxide, hydrogen peroxide, chlorine dioxide, 10% formol saline, and 5%

ammonia are effective in destroying the infectivity of the oocysts. The infectivity of oocysts in calf feces is reduced after 1 to 4 days of drying.

Concurrent Infections

Infections with other enteropathogens, particularly rotavirus and coronavirus, are common, and epidemiologic studies suggest that diarrhea is more severe with mixed infections with other pathogens. The rates of single and mixed infections vary among studies. Generally, mixed pathogen infections are most common, but cryptosporidial infection can be very significant in its own right. **Immunologically compromised** animals are more susceptible to cryptosporidiosis than immunocompetent animals, but the relationship between disease and failure of passive transfer of colostral immunoglobulins is not entirely clear. Disease can be reproduced in both colostrum-deprived and colostrum-fed calves and, in the field, clinical disease can occur, for example, in calves with adequate passive transfer of colostral immunoglobulins. However, the shedding of oocysts has been observed to be higher in calves with low absorptive efficiency of IgG from colostrum and low serum IgG concentrations.

Case–fatality rates in cryptosporidiosis are usually low and the disease self-limiting, unless there are other complicating factors. In addition to concurrent infections, these include deficits linked to an inadequate intake of colostrum and milk and chilling from adverse weather conditions. Age-related resistance, unrelated to prior exposure, has been observed in lambs but not calves. Infection may result in a serum antibody response, but both cell-mediated and humoral responses are important in immunity against cryptosporidia.

Zoonotic Implications

Infections in domestic animals may be a reservoir for infection to susceptible humans.[4-9] In humans, *Cryptosporidium* is recognized as a relatively common nonviral cause of self-limiting diarrhea in immunocompetent persons, particularly children. In symptomatic, immunocompetent patients, cryptosporidiosis most commonly presents with diarrhea that can lead to rapid weight loss and dehydration and require parenteral fluid therapy. The disease is usually self-limiting, with symptoms normally lasting between 3 and 12 days. In **immunologically compromised** persons, clinical disease may be severe. This is particularly serious in human patients with acquired immune deficiency syndrome or who are immunocompromised or immunosuppressed. The infection can be transmitted from person to person, but direct infection from animals and indirect water-borne infection from surface water and drinking water contaminated by domestic or wild animal feces can also be significant. Animal manures and slurry may contain *Cryptosporidium* oocysts, and there is potential for contamination of the food chain as a result of runoff into adjacent surface waters or from direct application of the untreated wastes to crops.

Direct animal contact can result in human infection where there is hand to mouth transmission and infection. Cryptosporidiosis has been recorded in veterinary students and is a concern for children at fairs, petting zoos, and sometimes during educational visits to farm settings. Cryptosporidiosis is one of a number of zoonotic infections that have recently emerged in these settings. The apparent increase in prevalence of these infections might be caused by the general movement of populations from rural to urban communities and the consequent removal from early exposure to farm animal–derived zoonotic agents. Similarly, it could result from better detection and reporting by public health authorities. Regardless, the risk of transmission of zoonotic agents associated with petting zoos, farm animal exhibits, fairs, etc., is real and veterinarians are increasingly asked for advice on this issue. This can be in association with an official capacity as a fair veterinarian or in consultation with farm owners, who desire to bridge the increasing estrangement of urban populations to farm activities. Animal handlers on cattle farms can be at high risk of diarrhea caused by cryptosporidiosis transmitted from calves infected with *Cryptosporidium,* and immunocompromised people might be restricted from access to young animals and possibly from access to farms.

PATHOGENESIS

Cryptosporidium is usually transmitted via the fecal–oral route and exhibits a monoxenous (single-host) life cyle.[4] Briefly, a sporulated oocyst (containing four infective sporozoites) is ingested by the host and excysts usually in either the intestine or the stomach (abomasum) (depending on the species of *Cryptosporidium*). Each motile sporozoite migrates, by gliding motility, along the exterior surface of the epithelial cells of the gut (e.g., microvilli in the small intestine) and penetrates the cell, eliciting an invagination in the cell membrane (of enterocytes in the small intestine) and forming a bilayered membranous vacuole (outer layer is host derived; inner layer is parasite derived, parasitophorous vacuolar membrane [PVM]). The host-derived outer layer of the vacuole disintegrates, and the inner PVM thickens and acts as the interface between the developing parasite and the host cytoplasm, which results in the parasite being located intracellularly but external to the cell cytoplasm (i.e., extracytoplasmic). Intracytoplasmic invasions are possible in rare instances, but appear to be limited to the invasion of macrophages within the Peyer's patches.

Within the cell, the sporozoite develops into a trophozoite, which subsequently undergoes asexual reproduction (schizogony or merogony; longitudinal binary fission) to produce type 1 meronts (schizonts). Each of these type 1 meronts contains 16 merozoites, which are released from the enterocyte. Each merozoite infects a new enterocyte, then replicates and develops into new type 1 meronts to repeat the cycle, or enters into the reproductive phase to replicate and develop into a type 2 meront, each of which contains four merozoites. After entering a host cell, each type 2 merozoite initiates the sexual cycle (gametogony) and eventually develops either into a microgamont (containing 12–16 microgametes) or a macrogamont (maturing into a macrogamete). Microgametes (male) are released and fertilize macrogametes (female) to form zygotes. The zygote then develops, within the PVM into an oocyst. In another asexual reproductive phase (sporogony), the oocyst sporulates to produce, internally, four naked sporozoites. Two types of oocyst are produced and slough off the epithelial layer. The thin-walled oocysts (~20% of the overall population of oocysts) remain in the alimentary tract and have the ability to sustain an autoinfection, whereas the thick-walled oocysts (~80%) are passed in the feces. The thin-walled oocysts are of particular relevance in immunocompromised, immunodeficient, or immunosuppressed individuals, as the likely cause of chronic cryptosporidiosis. In cattle, cryptosporidia are most numerous in the small intestine or abomasum (*C. andersoni*). The prepatent periods can range from 2 to 7 days in calves, and from 2 to 5 days in lambs. Oocysts are usually passed in the feces of calves for 3 to 12 days, but there is considerable variation in both prepatency and patency.

Cryptosporidium infection usually most directly and severely impacts the intestinal tract. Cryptosporidial infection in the intestine is best characterized and is initiated when zoites infect vicinal enterocytes and endogenous forms spread to the enterocytes of both the villi and crypts. Severe diarrhea occurs mainly as a result of proximal infection of the small intestine, whereas infections confined to the distal ileum and/or the large bowel tend to be associated with intermittent diarrhea or can be asymptomatic. Endogenous forms of *Cryptosporidium* disrupt the microvillous border, which leads to the loss of mature enterocytes, a shortening and fusion of villi, and a lengthening of crypts caused by increased cell division and edema. This leads to the loss of membrane-bound digestive enzymes; diminishes the absorptive capacity of the intestine; and reduces the uptake of fluids, electrolytes, and nutrients from the intestinal lumen.

CLINICAL FINDINGS

There are no clinical findings that are pathognomonic for cryptosporidiosis in calves.[4] Affected calves are usually 5 to 15 days old and have a mild to moderate diarrhea, which persists for several days, regardless of treatment. The duration of diarrhea tends to be a few days longer than that associated with rotavirus, coronavirus, or ETEC. Feces are yellow or pale and watery and can contain mucus. Persistent diarrhea can result in a marked loss of BW and emaciation. In most cases, the diarrhea is self-limiting after several days. Varying degrees of apathy, reduced feed intake, and dehydration are common. Only rarely does severe dehydration, weakness, and collapse occur, which is in contrast to other causes of acute diarrhea in neonatal calves. Case–fatality rates can be high in herds with cryptosporidiosis when the calf feeder withholds milk and feeds only electrolyte solutions during the episode of diarrhea. The persistent nature of the diarrhea leads to a marked energy deficit in these circumstances, and the calves can die of inanition at 3 to 4 weeks of life. This syndrome may be particularly common in the winter months when cold stress can affect energy requirements.

In the experimentally induced cryptosporidiosis in calves, depression and anorexia are the earliest and most consistent clinical findings. Feed intake is reduced and, combined with the persistent diarrhea over several days, may cause emaciation. Recovery can occur between 6 and 10 days after the onset of diarrhea. In the experimentally induced cryptosporidiosis in lambs and kids, depression, diarrhea, and reduced feed intake are common, and recovery can occur within a few days. Severe clinical manifestations have been observed in the field in lambs subject to environmental cold stress and those that are energy deficient because of an inadequate intake of colostrum.

CLINICAL PATHOLOGY

Traditionally, diagnosis of cryptosporidiosis has been based on the detection of *Cryptosporidium* oocysts or DNA in host feces. Oocysts can be detected in the feces by examination of fecal smears with particular stains, by fecal flotation, and by immunologically or DNA-based methods.[4] Diagnostic techniques include the immunofluorescent assay detection of fecal oocysts. It has been suggested that, if the diarrhea is associated with cryptosporidia, the feces might contain 10^5 to 10^7 oocysts per milliliter. The oocysts are small (5–6 μm in diameter), relatively nonrefractile, and difficult to detect by light microscopy. They can be detected by phase-contrast microscopy. Oocysts can be concentrated from fecal samples by centrifugal flotation in high specific gravity salt or sugar solutions. The modified Ziehl–Neelsen is a simple and rapid staining procedure suited for large-scale routine diagnosis.[4] Immunofluorescence and other immunologic techniques are relatively widely used, as are a range of PCR-coupled DNA methods for the specific detection and genetic characterization of *Cryptosporidium* stages present in fecal samples.[4]

NECROPSY FINDINGS

Varying degrees of dehydration, emaciation, and serous atrophy are present in calves that suffer from persistent diarrhea over many days. There is atrophy of villi in the small intestine. Histologically, large numbers of different stages of the parasite, including meronts or schizonts, are at the tips of the enterocysts (microvilli). In low-grade infections, only small numbers of parasite stages are detected, with no apparent or limited histopathological changes in the intestine. The villi are shorter than normal, and crypt hyperplasia and infiltration with a mixture of inflammatory cells are common.

Samples for Confirmation of Diagnosis

- **Parasitology:** Feces (microscopic examination, ELISA, IFAT)
- **Histology:** Formalin-fixed intestine (several sites) or abomasum (e.g., *C. andersoni*)

DIFFERENTIAL DIAGNOSIS

The disease must be differentiated from other common infectious diarrheas in calves, which are covered in the section Acute undifferentiated diarrhea of newborn farm animals.

PREVENTION AND CONTROL

In animals, the key **components for prevention and control** of cryptosporidiosis include the maintenance of a clean environment and the introduction of effective management strategies to minimize the potential for rapid spread from animal to animal, farm to farm, and from animal to human.[4] The prevention of *Cryptosporidium* infection is challenging in intensively farmed animals, because the infective dose can be very low; thus exclusion or elimination of the parasite from the farm environment is almost impossible. Although the maintenance of "closed" herds or flocks can control the introduction of cryptosporidiosis from animals purchased from external sources (e.g., saleyards), additional external factors, such as parasite transport via "mechanical" means and parasite introduction through contaminated water or feed, can introduce infection on to a farm and are difficult, if not impossible, to control. In addition, oocysts shed by wildlife and/or introduced into water supplies from wildlife may represent another potential source of infection for herds of domestic animals. The role of wildlife as a reservoir and its involvement in transmission to and disease in livestock and humans are not yet well understood, requiring further investigation using advanced molecular methods.

Because the prevention of infection in livestock herds is not always practical, control is a critical feature of a sound management strategy. However, limiting infection of neonatal animals and minimizing the risk of spread from infected to uninfected animals is a significant challenge. Numerous scientists have studied the factors linked to the prevalence of *Cryptosporidium* and the associated impact of cryptosporidiosis. Although useful for highlighting potentially important factors either contributing to or protecting against infection and disease, such studies are usually limited to showing a statistical association between any "factor" and increased or decreased "risk" caused by unavoidable limits of the experimental designs of such surveys. Specifically, because these surveys are conducted in herds, multiple factors (e.g., housing, frequency of pen cleaning, proximity to other livestock herds, food and water sources) can vary among herds, all of which can contribute to disease prevalence. None of these factors can be specifically isolated, making the determination of the actual impact of any single factor difficult. Acknowledging this, herd management practices, which appear to be associated with protection against infection by *Cryptosporidium* and/or affliction with cryptosporidiosis, include calving in winter rather than summer, removing neonates from the dam within 1 hour of birth, ensuring the neonate receives an adequate initial dosage of colostrum (either from the dam, from another animal, or via bottle feeding from a frozen supply), and ensuring optimal housing for calves.

Environmental factors considered important in decreasing the risk of cryptosporidiosis in neonates include low population density for calves; use of concrete flooring over straw, gravel, or sand; and the routine cleaning of pens (i.e., hygiene) and feeding utensils. The regular cleaning of pens and feeding apparatus is considered to be essential to a rigorous management strategy of cryptosporidiosis; however, because of the robust nature of *Cryptosporidium* oocysts, care must be taken to ensure that such cleaning regimens are effective. Oocysts remain viable for long periods of time and are resistant to various disinfectants suitable for use in agricultural settings (e.g., bleach-based disinfectants). Ammonia-based disinfectants can kill *Cryptosporidium* oocysts, but they release irritating fumes and can only be used after destocking. Disinfectants containing hydrogen peroxide plus either

peracetic acid or silver nitrate have also been shown to have a deleterious effect on the survival of *C. parvum* oocysts and are commercially available for application in a farm setting. Steam cleaning is another supportive measure, has been shown to be effective for killing *Cryptosporidium* oocysts on instrumentation in hospitals, and may be suitable for decontaminating instrumentation used in farming for feeding or milking.

Mechanical removal of oocysts daily from concrete surfaces using a high-pressure hose appears to be an effective means of reducing the spread of *Cryptosporidium* and is preferable to sweeping, which imposes an increased risk of cross-contamination among pens via the mechanical transfer of oocysts. Importantly, the desiccation of oocysts appears to be a highly effective means of parasite control and further highlights the benefit of using concrete floors in pens instead of porous or absorptive materials to facilitate drying.

Treatment Options

Compared with the previous management strategies, immunotherapeutic or chemotherapeutic options are limited.[4,10,11] The demonstrated host age stratification of *Cryptosporidium* in many animal species suggests that passive immunity is possible and likely results from prior exposure to disease, but the effective eliciting of passive immunity via colostrum is still unclear. Passive immunotherapy using colostrum from dams immunized with native or recombinant antigens of *Cryptosporidium* has been explored and shown to be a protective infection of young calves in some studies but not in others.[4]

"Risk-factor" surveys indicate that neonate calves have a reduced probability of infection by *Cryptosporidium* following the ingestion of colostrum; however, the prevalence of infection in neonates, even after colostrum ingestion, is high before weaning, indicating that the passive transfer of immunity is limited. Overall, evidence indicates that the passive transfer of immunity via colostrum is unlikely to be effective as a single means of defense against cryptosporidiosis in young calves.

Although various avenues have been explored for the development of a vaccine against cryptosporidiosis, none are yet commercially available. Recently the use of a whole oocyst-based vaccine from an attenuated line of *C. parvum* (gamma irradiated) has been revisited and shown to show a protective response in calves. Other efforts have focused on assessing immune responses against antigens derived from oocysts or the cell surface of sporozoites.[10] The proteins CP15 and P23, involved in zoite motility and/or host cell invasion, have been expressed using recombinant methods and appear to be promising immunogens. Although overall success has been limited, the availability of the complete nuclear genome sequences for some *Cryptosporidium* spp. and developments in molecular and computer technologies might provide opportunities for identifying novel proteins as vaccine targets.

In the absence of a vaccine, supportive and chemotherapeutic treatment options have been an area of significant research. The simplest, but at present one of the more effective, means of treating cryptosporidiosis cases in livestock is oral or intravenous rehydration of clinically affected, dehydrated animals. Chemotherapy has been explored with only limited success. Numerous organic-based antimicrobial compounds, including various quinones, aminoglycosides (e.g., paromomycin and streptomycin) and folate antagonists (e.g., sulfanitran and trimethoprim), have been evaluated with mixed success. **Halofuginone lactate** (HFL) has been used as a supportive measure to treatment of clinical cryptosporidiosis in calves. Studies have indicated that administering HFL to infected calves at a dosage of 60 to 125 µg/kg BW (e.g., for 7 days from 1 day of age) decreased the severity of clinical disease as well as oocyst numbers in feces shortly after treatment. Other studies have provided further support of these findings, indicating that HFL is an effective chemotherapy in calves for the purpose of reducing the severity of bovine cryptosporidiosis, and suggesting that HFL decreases the spread of *Cryptosporidium* from animal to animal because of decreased fecal oocyst output. However, although HFL may be useful in diminishing the severity of disease symptoms, this drug delays rather than eliminates the excretion of oocysts in feces. In spite of the use of HFL as a supportive measure, its recommended dosage must be strictly adhered to (given its limited safety index), and severely dehydrated calves should not be treated to prevent toxic effects. **Paromomycin sulfate** given orally at a dose of 100 mg/kg BW daily for 11 consecutive days from the second day of age seems to prevent disease in goat kids and to reduce, but not completely prevent, diarrhea in infected lambs.[1]

Supportive Treatment

Affected calves should be supported with **fluids and electrolytes**, both orally and parenterally, as necessary until spontaneous recovery occurs.[4,12] Cows' **whole milk** should be given in small quantities several times daily to optimize digestion and to minimize loss of BW. It is important to **continue to feed** milk to the full level of requirement despite the presence of diarrhea, because a reduction in intake may lead to death from inanition. Several days of intensive care and feeding may be required before recovery is apparent. **Parenteral nutrition** could be considered for valuable calves.

Management Strategies

In addition to treatment and control regimens to limit the impact of *Cryptosporidium* infection on herds, **management** strategies are critical to limit the spread of infective *Cryptosporidium* oocysts to other farms, and, for *C. parvum,* to the human population.[4] Cryptosporidiosis is difficult to control. The rational approach to prevention is to **minimize transmission** between the source of the organism and neonatal farm animals and between the animals. Reducing the number of oocysts ingested may reduce the severity of infection and allow immunity to develop. Calves should be born in a clean environment, and adequate amounts of colostrum should be fed at an early age. Calves should be kept separate without calf-to-calf contact for at least the first 2 weeks of life, with strict hygiene at feeding. Disinfectants detailed earlier should be used in hygiene.

Diarrheic calves should always be **isolated** from healthy calves during the course of the diarrhea and for several days after recovery. Sick calves are commonly treated by the same person who feeds the healthy calves, and great care must be taken to avoid mechanical transmission of infection. Calf-rearing houses should be vacated and cleaned out on a regular basis; an all-in/all-out management system, with thorough cleaning and several weeks of drying between batches of calves, should be used.

Manure from animals is a major contributor of *Cryptosporidium* oocysts in the environment on farms, and measures also need to be implemented to reduce the risks of pollution to drinking water.[4,13,14] Adequately controlled storage and handling of manures and slurry (e.g., from cattle yards or dairies) or leachate from bedding will assist to reduce the risk of contamination in waterways. Runoff into water catchments presents a significant risk, particularly during and after heavy rainfall; although the risk posed by oocysts in water runoff varies depending on the soil type and the density of vegetation in the surrounding area. Generally, grazing animals should be excluded from access to water catchments and water sources through the introduction of buffer zones.

COCCIDIOSIS

SYNOPSIS

Etiology Many different *Eimeria* spp., *Isospora* spp.

Epidemiology Mainly young calves, lambs, piglets, and kids. Infection rate can be high, clinical disease relatively common; high morbidity with low case–fatality rate. Occurs most often in crowded conditions both in barns and on pasture, particularly in calves and lambs moved from pasture to feedlot. Transmitted by fecal–oral route; oocysts shed from infected animals. Immunity develops after infection; clinical disease occurs rarely in adult cattle.

Signs Diarrhea, dysentery, tenesmus, appetite normal or inappetence, mild abdominal pain in lambs, nervous signs in calves with coccidiosis in cold climates, loss of body weight, and anemia in some cases but it is uncommon. Epidemics occur in calves and lambs, particularly in feedlot animals. Diarrhea without blood in feces of piglets

Clinical pathology Diagnostic number of oocysts in feces

Lesions Ileitis, cecitis, and colitis

Diagnostic confirmation Oocysts in feces; asexual stages (schizonts or merozoites) in intestinal tissues

Differential diagnosis
- **Calves:** Rotavirus and coronavirus diarrhea; *Clostridium perfringens* type C enterotoxemia; colibacillosis caused by attaching and effacing *Escherichia coli*
- **Lambs:** Salmonellosis; helminthiasis; *C. perfringens* type C enterotoxemia
- **Piglets:** Transmissible gastroenteritis; colibacillosis; *Strongyloides ransomi*; *C. perfringens* type C enterotoxemia

Treatment Supportive therapy. Coccidiostats

Control Control population density to minimize number of oocysts ingested while immunity develops. Use of coccidiostats in feed and water supplies. Sanitize the environment if possible.

ETIOLOGY

Coccidial species are as follows:

- **Cattle:** *Eimeria zuernii, E. bovis,* and *E. ellipsoidalis*; *E. alabamensis, E. auburnensis,* and *E. wyomingensis* may also cause disease in calves
- **Sheep:** *E. arloingi A* (ovina), *E. weybridgenis* (*E. arloingi* B), *E. crandallis, E. ahsata,* and *E. ovinoidalis* (previously known as *E. ninakohlyakimovae*), and *E. gilruthi*
- **Goats:** *E. arloingi, E. faurei,* and *E. gilruthi, E. caprovina, E. ninakohlyakimovae,*[1] and *E. christenseni*
- **Pigs:** *I. suis*; numerous species of *Eimeria* (no clinical importance), including *E. debliecki, E. neodebliecki, E. polita, E. perminuta, E. scabra,* and *E. suis*
- **Horses and donkeys:** *E. leuckarti* (ubiquitous, but of no clinical significance)

EPIDEMIOLOGY

Occurrence and Prevalence of Infection

Coccidiosis is most frequently seen in livestock animals housed or confined in small areas contaminated with oocysts.[2,3] Coccidia are usually host specific, and there is no cross-immunity between species of coccidia. Clinical disease is common in cattle and sheep. Coccidiosis causing diarrhea in newborn piglets is a major problem in some swine herds.

Coccidiosis is most common in young animals, with a seasonal incidence that may be associated with the time of year young calves and lambs are brought together for weaning or moved into feedlots or fed in small areas for the winter months. The prevalence of infection and the incidence of clinical disease are also age related. In housed dairy cattle, the prevalence of infection in calves and in yearlings can be high (40%–50%).

Calves

In North America, the disease is most common in beef calves after weaning in the fall and when confined and fed in small, overcrowded areas during the winter months. Infection occurs most often when weaned calves are fed on the ground, resulting in continuous fecal contamination of the feed. The prevalence of infection in calves in the northwestern and midwestern part of the United States is highest in summer, fall, and spring compared with midwinter (January) and early summer (June). In Canada, for example, winter coccidiosis occurs in beef calves 6 to 10 months of age, most commonly following a prolonged cold period or a sudden change from a moderate winter to severely cold temperature. Cold weather may act as a stressor to precipitate clinical disease in animals previously infected. Acute coccidiosis and a marked increase in the numbers of oocysts discharged will occur following the treatment of infected calves with a corticosteroid on the 20th day after infection, when clinical signs are apparent, or from the 12th to 15th day after infection.

Occasional outbreaks occur in nursing beef calves on pasture when they mingle near water supplies. Postweaning coccidiosis occurs in beef calves grazing on pastures in the subcoastal, dry tropics (e.g., northern Queensland, Australia). It may be more severe in dry years, suggesting that oocyst challenge is less important than immunosuppressive effect of weaning and dietary stress in precipitating clinical disease. Calves are usually weaned and yarded for 3 weeks and then turned out to graze. Severe *E. zuernii* coccidiosis causing diarrhea, dysentery, weight loss, and death occurs with up to 10% of calves clinically affected. The disease is most severe in hot, dry, and sunny conditions when, despite heavy fecal contamination, the yard conditions remain dry and dusty, and oocysts are difficult to find. Coccidiosis caused by *E. alabamensis* along with other species is a common cause of diarrhea and unthriftiness in calves 2 to 4 months of age within the first few weeks after being placed on permanent pasture in the spring.

In **dairy calves**, the disease occurs under overcrowded and dirty, wet conditions, and when feed is contaminated with feces. Some surveys of dairy farms reveal that coccidiosis is one of the most common health-related problems, particularly in crowded situations. Dairy farmers quite frequently elect to treat animals, or feeding a coccidiostat, for the control of coccidiosis.

Adult Cattle

Coccidiosis is uncommon in adult cattle, but occasional cases and even epidemics can occur, sometimes in dairy cows that have calved 6 to 8 weeks earlier. Older animals can serve as a source of infection for younger calves in the herd.

Sheep and Goats

Coccidiosis can be a major problem in housed lambs. In some countries, such as Germany, the cumulative incidences of *E. ovinoidalis* and *E. weybridgensis*/*E. crandallis* have been found to increase rapidly, resulting in an incidence of almost 100% in 8-week-old lambs. Acute coccidiosis in intensively grazed lambs occurs at about 6 to 8 weeks of age when the oocyst output is very high in healthy and in clinically affected lambs. There is no periparturient rise in oocyst output in ewes. The fecal oocyst excretion rates in grazing lambs are very high compared with those of ewes. Disease can occur commonly in lambs following introduction into a feedlot situation with problems of overcrowding and other stressors. Lambs with no previous exposure to coccidia are highly susceptible to infection.

Coccidiosis is one of the most important diseases of goats kept in large numbers under intensive management conditions. The prevalence of infection may be as high as 100% in some goat farms. Kids are the major source of pasture contamination, and newly weaned kids can have high oocyst counts. More than 13 different species of *Eimeria* have been described in different parts of the world.

Pigs

Observations suggesting neonatal porcine coccidiosis include repeated episodes of diarrhea in piglets 5 to 15 days of age, no response to therapy with antimicrobials, and a failure of vaccination of the pregnant sow with *E. coli* bacterins to control neonatal piglet diarrhea. Peak incidence occurs between 7 and 10 days of age, most commonly during the warm summer months when high temperatures favor the sporulation of the oocysts. *I. suis* is a common parasite on pig farms;[1,3] it can be found in 90% of herds and 25% to 50% of litters. The prevalence may be higher when piglets and their sows are kept on solid concrete floors compared with self-cleaning floors. The morbidity rates are variable, and case–fatality rates can be up to 20%. Rotavirus infection may occur concurrently with *I. suis* infection in piglets of 1 to 3 weeks of age, which may be important causes of steatorrhea or unspecified diarrhea, known as milk scour, white scour, or 3-week diarrhea. *I. suis* infection commonly occurs in large pig-producing farming systems; the highest rate of infection occurs in litters at 3 to 4 weeks of age.

Morbidity and Case Fatality

Generally, for **most species** of farm animals, the infection rate is high, and rate of clinical disease is usually low (5–10%), although epidemics affecting up to 80% can occur. The case–fatality rate is usually low, with the exception of the high case–fatality rate in calves with winter coccidiosis accompanied by nervous signs.[1] The case–fatality rate may be high in calves or lambs with no previous exposure to coccidia. In calves, BW gains and feed consumption are commonly reduced for many weeks after acute clinical coccidiosis, and affected calves do not regain losses in BW compared with uninfected controls.

In **lambs on pasture**, subclinical infections are common but there is no documented evidence that growth rate is affected, even with high levels of infection. Although medication with a coccidiostat may lower the infection rate, there is no apparent difference in performance between medicated and nonmedicated sheep. In lambs raised under crowded conditions indoors, the acquisition of infections with multiple species of *Eimeria* does not appear to affect growth rates, but artificial infection with *E. ninakohlyakimovae* has been shown to cause severe clinical disease and a case–fatality rate of up to 50%.

Piglets infected with *I. suis* have significantly reduced BW at 7, 14, and 21 days of age. The reduction in weight at 3 weeks is economically important, because this weight is factored into the "sow productivity index," which is used as a management aid to help producers assess the potential value of gilts as replacement animals.

Methods of Transmission

The **source of infection** is the feces of clinically affected or carrier animals, and infection is acquired by ingestion of feed and water contaminated with sporulated coccidial oocysts or by licking the hair coat contaminated with such oocysts. Unsporulated oocysts are passed in the feces and require suitable environmental conditions to sporulate. **Moist, temperate, or cool conditions favor sporulation, whereas high temperatures and dryness impede it.** Depending on the species of coccidium, oocysts sporulate at a range of 12°C to 32°C (53.5°F–89.5°F) and require oxygen. They can resist freezing down to approximately −7°C to −8°C (19.5°F–17.5°F) for 2 months, but −30°C (−22°F) is usually lethal.[1] It has been suggested that oocysts might sporulate in the winter months on the hair coats of animals contaminated with feces. This may explain the continual production of several different species of coccidia during the cold winter months, when sporulation on the ground is not possible.[1] Dry conditions and high temperatures also destroy sporulated oocysts within a few weeks, but the oocysts may survive for up to 2 years under favorable conditions. Temperatures of >35°C, humidity of <25%, and sunlight for at least 4 hours are fatal for *E. zuernii*.

Ingestion of the sporulated oocysts results in infection. **Large numbers of oocysts usually arise by continual reinfection and a buildup of the degree of environmental contamination.** This is most common when calves or lambs are crowded into small pens or confined in feedlots. Lambs can become infected within a few weeks after birth from lambing grounds heavily contaminated by the ewes. Overcrowding of animals on irrigated pastures, or around surface water holes in drought conditions, may also lead to heavy infections and disease. Feeder lambs and calves brought into feedlots from sparse grazing may carry a few oocysts, which build up into heavy infections in the lots, particularly if conditions are moist. In such situations, clinical signs of the disease usually appear several weeks to a month after the animals are confined. Young calves and lambs on pasture may shed large numbers of oocysts for long periods, which results in a buildup of coccidial populations. In cow–calf herds, the prevalence and intensity of oocyst excretion can vary with time, resulting in peak values around the time of parturition (periparturient rise).

Sows do not play a significant role in the transmission of *I. suis* infection from one generation of piglets to the next through contamination of the farrowing pen. Oocysts of *I. suis* cannot usually be found in the feces of sows on swine farms where neonatal coccidiosis occurs.

Risk Factors

Animal Risk Factors

Acute coccidiosis occurs primarily in **young animals**, but may occur at any age when resistance is affected by intercurrent disease or inclement weather. The prevalence of infection is usually higher in calves than yearlings or adults in the same herd, but there is also evidence of variation in resistance against *Eimeria* species. A concurrent experimental infection of calves with the viruses and *E. bovis* can result in clinical disease and lesions that are more severe than those caused by either infection alone.

Nutritional status of the animal as a risk factor for clinical coccidiosis is well known. Early weaning of lambs at 21 days of age, followed by experimental infection, results in a failure of growth. In addition, field observations have shown that lambs that are weaned early are more susceptible to coccidiosis than those weaned at a later date. This observation might be a reflection of a lack of immunity in the younger lambs, but dietary stress in early weaned lambs can contribute to disease. Lambs kept on a low plane of nutrition have been reported to be less affected by clinical coccidiosis than those

kept on a high plane of nutrition. The planes of nutrition can also be associated with differences in the prevalence of *Eimeria* spp. Considerable numbers of oocysts can be excreted into the environment, even by well-fed sheep 14 to 16 months of age.

In many countries in Europe, for example, coccidiosis is common in **housed lambs weaned at 6 to 8 weeks of age** and reared on straw with a high stocking density, which provides an ideal environment for oocyst survival and sporulation. Often the use of coccidiostats does not affect the oocyst excretion rate, which suggests either inconsistencies in the effect of in-feed medication, or the infection may be controllable in nonmedicated flocks without the use of coccidiostats.

Environmental and Management Risk Factors

Coccidiosis occurs in livestock when environmental and managemental conditions result in **oral exposure** of large numbers of sporulated oocysts to nonimmune animals. Overcrowding, overstocking, feeding animals on the ground, or situations in which the feed and water supplies are contaminated with feces and oocysts increase coccidial infection pressure and promote transmission. The disease is common in small beef cattle herds that raise their own replacements and finish their own feedlot cattle in small pens that are overcrowded; in these situations, feed and the environment become heavily contaminated with fecal matter. Grazing calves for the first time on permanent pastures can be associated with clinical coccidiosis caused by the ingestion of oocysts that have survived over the winter.

In parts of Europe, the rare occurrence of clinical coccidiosis in housed dairy cattle appears to be associated with management practices, in which calves are individually housed during the first few weeks and subsequently housed in small groups in relatively large pens. Hygiene standards are high, and manure is frequently removed. These measures reduce the intake of high numbers of oocysts and are favorable; the intensity of coccidial infections is usually associated with the number of oocysts in the environment and ingested by animals.

The production system can influence the development of subclinical and clinical coccidiosis. Two production systems are commonly used for the fattening of lambs. In the **extensive system**, lambs are not weaned until slaughter, with little or no concentrate feeding. In the **intensive system**, the lambs receive a high level of concentrates. Even if no clinical signs of coccidiosis are observed, lambs are likely to be subclinically affected in both systems. Straw and high stocking density predispose lambs to a heavy contamination of the environment, which supports oocyst survival and rapid sporulation.

Multiinfections

Natural infections commonly involve multiple species of coccidian. A single species of coccidia might be a major pathogen, but others likely contribute to disease. In some cases, clinical coccidiosis in cattle happens only when *E. bovis* and *E. zuernii* occur together. Although *E. bovis* and *E. zuernii* are the species most commonly associated with bovine coccidiosis,[2] many more species have been described. In sheep and goats, the prevalence of multiple species can be high (> 80%). *I. suis* is a major cause of neonatal or weanling diarrhea in pigs,[3] whereas *E. debliecki* is not pathogenic. Coccidia often have a widespread distribution in livestock animals.

Immune Mechanisms

Immunity against intestinal coccidia consists of both cellular and humoral components.[1] Cellular immunity appears to be more important in "resistance" against reinfection than humoral immunity. Field observations suggest that coccidiosis in cattle is immunosuppressive, which can increase their susceptibility to other common infections. In experimental coccidiosis, neutrophil function may be inhibited, and the feeding of decoquinate may prevent this inhibition.

The administration of dexamethasone to calves suppresses the immunologic response of the animal, and allows the life cycle of the coccidia to proceed uninterrupted. Estradiol and progesterone can enhance cell-mediated immunity and can provide some protection against the often severe wasting and debilitation in calves associated with *E. bovis* infection.

Coccidiosis is an important disease in young lambs on pasture after having been raised indoors, as is also the case in European countries, for example. In this situation, lambs spend the first few weeks of their life indoors and have little exposure to infective oocysts, and little or no immunity is acquired. When the lambs are turned out on to pastures grazed by sheep in the previous grazing season, they rapidly become infected with overwintered oocysts. Coccidiosis develops in such nonimmune lambs 2 to 3 weeks later. The immunity induced by the first infection seems to protect most lambs from reinfections later in the grazing season. If lambs are treated with sulfadimidine at 200 mg/kg BW on days 12, 13, and 14 after turnout, then a marked reduction in the severity of the coccidial infections is seen.

Specific immunity to each coccidial species develops after infection, so that young animals exposed for the first time are often more susceptible to a severe infection and clinical disease than other animals. A single initial infection with as few as 50 oocysts can induce strong immunity to reinfection with the same species, and oocyst production can cease after about 10 days. Under field conditions, animals (e.g., sheep) are probably continually ingesting oocysts from pastures that become increasingly contaminated as the season progresses. Thus immunity to a range of species of coccidia is boosted by frequent reinfection or reexposure.

Very young lambs are relatively resistant to infection with a mixture of pathogenic species of coccidia, but susceptibility increases progressively up to at least 4 weeks of age.[1] Lambs inoculated at 4 to 6 weeks of age develop severe diarrhea, whereas the same inoculum given at 1 day of age causes no clinical disease. Early subclinical infection improves the resistance of lambs to later challenge. When lambs receive a relatively large inoculum of oocysts during their first week of life, they are relatively resistant to the pathogenic effects of some coccidia, are able to respond immunologically, and seem to be protected from subsequent challenges. This information suggests that early exposure or infection of lambs with coccidia, before they are susceptible to the parasites' pathogenic effects, may assist in reducing the incidence, prevalence, and severity of subsequent coccidiosis. In calves, resistance to *E. zuernii* infection can occur after chemotherapy, or experimental infection, with monensin or amprolium. Both drugs suppress the development of disease, during which time immunity can develop. An effective immunity develops in piglets following natural or experimental infection with *I. suis,* which appears to be the most immunogenic coccidial parasite of pigs. Susceptible piglets are infected by this species from infected older pigs. Piglets develop a disease that is more severe when infected with *I. suis* at 1 to 3 days of age than when infected at 2 weeks of age.[3]

PATHOGENESIS

The coccidia of livestock pass through most stages of their life cycle in the gastrointestinal tract. Individual species of coccidia have their particular predilection sites. For instance, *E. zuernii* and *E. bovis* occur primarily in the cecum, colon, and the distal ileum, whereas *E. ellipsoidalis* and *E. arloingi* affect the small intestines. *E. gilruthi* localizes in the abomasum and occasionally the duodenum.

Life Cycle

The life cycles of *Eimeria* spp. are direct. Unsporulated oocysts are passed in the feces from an infected host and develop into the infective stage (sporulated oocysts) in the environment. The original single cell of *Eimeria* divides, forming four sporoblasts, each of which develops into one sporocyst, and within each sporocyst two sporozoites develop (1:4:2 configuration of the oocyst for *Eimeria*). When ingested, the wall of the oocyst breaks down, and sporocysts and sporozoites are released. The sporozoites then enter epithelial cells. Once within the cells,

the sporozoites transform to merozoites, which then undergo asexual replication (schizogony or merogony) and produce **first-generation schizonts,** which contain many merozoites. After the schizont matures, the merozoites are released by rupture of the epithelial cell. New epithelial cells are again invaded, and **second-generation and third-generation schizogony** occur. The second-generation and/or third-generation schizonts (depending on *Eimeria* species) are deeper in the mucosa than first-generation schizonts and usually lead to the sloughing of the epithelium, associated hemorrhage, and tissue destruction; therefore these schizonts cause pathogenic effects and lead to enteritis (bloody in severe infections) and clinical disease, but also induce immunity. Following schizogony, the final merozoites that are released invade epithelial cells and "switch" to produce sexual stages, **called the macrogametocyte** (female) **and the microgametocyte** (male) during the phase of **gametogony**. The microgametocyte eventually produces microgametes, which fertilize macrogametes (from microgametocyte; within the mucosa) to produce zygotes. These zygotes become oocysts, which slough from the epithelium and are excreted in the feces. The sloughing of the epithelial layer during gametogony can also lead to bleeding. The prepatent period varies depending on the species of coccidian.

In cattle, *E. zuernii* and *E. bovis* are pathogenic, and their life cycles are similar. In infected calves, first-generation schizogony occurs in the lower ileum, and second-generation schizogony and gametogony occur in the cecum and proximal colon. Both phases cause pathogenic effects for these two parasites and cause rupture of the cells they invade, with consequent exfoliation of the epithelial lining of the intestine. It is notable that the oocyst count is often low when the disease is at its peak, because the oocysts have not yet formed. Exfoliation of the mucosa causes diarrhea, and in severe cases, hemorrhage into the intestinal lumen, and the resultant hemorrhagic anemia may be fatal. If the animal survives this stage, the life cycle of the coccidia terminates without further damage, and the intestinal mucosa will regenerate and return to normal. The patent periods of *E. zuernii* and *E. bovis* are 15 to 17 and 18 to 21 days, respectively. Treatment of calves with a corticosteroid can convert subclinical infection in calves to acute disease, which suggests that environmental, nutritional, and managemental factors can also act as stressors in inducing disease.

Severely affected calves surviving the acute phase of the disease do not regain losses in BW unless they are fed for an additional 3 to 4 weeks, suggesting that bovine coccidia can have a marked effect on performance. A subclinical coccidial infection superimposed on an established, low-grade, subclinical nematode infection in the small intestine may have a marked effect on the mineralization of the skeletal matrix in young adult ruminants, predisposing them to osteodystrophy.

That infections with multiple species of *Eimeria* are so common in livestock may explain the variations in oocyst discharge from infected animals, but, more importantly, in groups of animals. New cases may develop every few days for some weeks, because of the variation in length of the prepatent periods among species of coccidia.

The **pathogenesis of the neurologic signs associated with coccidiosis** in calves is unknown. Examination of a series of cases excluded possible explanations such as alterations in serum electrolytes, vitamin A and thiamin deficiencies, lead poisoning, uremia, *H. somnus* meningoencephalitis, severity of disease, and gross alteration in intestinal bacterial flora and hepatopathy.

The **pathogenesis of bovine winter coccidiosis**, which occurs during or following very cold weather in Canada and the northern United States, is not understood. In January, February, and March, the outside temperatures may reach −40°C (−40°F) with daily mean temperatures of −10°C to −15°C (14°F–5°F) for several consecutive days. Such temperatures should be too cold for sporulation of oocysts in feces on the ground. There is speculation that sporulation could occur on the moist hair coats of cattle, or the endogenous stages of *E. zuernii* may be in a latent phase and reactivated by the stress of cold weather.

In **lambs**, most natural infections are composed of multiple different species of coccidia, and there is a wide range of values in the production of oocysts from individual lambs, either in the feces from the same lamb over a period of time or in the feces from a number of lambs on any one occasion. Under field conditions, constant reinfection occurs and waves of pathogenic stages succeed each other. The occurrence of villous atrophy in the intestinal mucosa of lambs affected by coccidiosis is probably related to recurrent diarrhea. However, in lambs, there is some doubt about the effects of coccidial infection on growth rate, feed consumption, and clinical signs. There may be no obvious relationship between infective dose, the fecal oocyst production, and disease. This information suggests that, in lambs, the mere presence of large numbers of fecal oocysts does not constitute a diagnosis of coccidiosis and that a range of factors may lead to disease. In many cases, it is possible that a large number of oocysts in sheep feces, in the absence of disease, may relate to nonpathogenic species of *Eimeria*.

I. suis has at least three asexual and one sexual intraintestinal replication cycles.[3] All stages are most prominent in the distal half of the small intestine, but also occur in the proximal small intestine, cecum, and colon. The prepatent period is 5 to 7 days; patency is usually 4 to 16 days. Disease relates to diarrhea, villous atrophy, and necrosis of intestinal epithelium, and is characterized by high morbidity and low mortality. In the temperature range of 32°C to 35°C (89.5°F–95°F), the oocysts of *I. suis* can sporulate and become infective within 12 to 16 hours. Pathogenic changes are most pronounced in the small intestine and consist of villous atrophy and focal ulceration from the destruction of villous epithelial cells, principally during the peak of asexual reproduction. A fibrinonecrotic pseudomembrane may develop in severe cases. Extraintestinal stages of *I. suis* have been detected in lymph nodes, liver, and spleen, and their significance is unclear. Piglets develop more severe clinical signs of coccidiosis when inoculated with *I. suis* at 3 days of age than at 19 days of age, and affected piglets that survive develop immunity to reinfection. Rotavirus and other infections can complicate disease.

CLINICAL FINDINGS

The prepatent period depends on the causative agent(s) and the host animal. It usually ranges from 1 to 3 weeks in cattle, from 2 to 3 weeks in sheep, and can be as short as 5 days in piglets. The clinical syndromes associated with the various coccidia are similar in all animals.

Cattle and Sheep

A mild fever may occur in the early stages, but in most clinical cases body temperature is normal or subnormal. The first sign of clinical coccidiosis is the sudden onset of diarrhea with foul-smelling, fluid feces containing mucus and/or blood. Blood may appear as a dark, tarry staining of the feces or as streaks or clots, or the evacuation may consist entirely of large clots of fresh, red blood. The perineum and tail are commonly smudged with bloodstained feces. Severe straining is characteristic, often accompanied by the passage of feces, and rectal prolapse may occur. The degree of hemorrhagic anemia is variable, depending on the amount of blood lost, and in most naturally acquired cases in calves anemia is not a feature. Nonetheless, in exceptional cases, anemia can occur with pale mucosa, weakness, staggering, and dyspnea. Dehydration is common, but is not usually severe if affected animals continue to drink water.

Inappetence is common and, in exceptional cases, there may be anorexia. The course of the disease is usually 5 to 6 days, but some animals undergo a long convalescent period in which feed consumption and BW gains are reduced. Severely affected calves do not rapidly regain BW losses that occurred during the clinical phase of the disease. In mild cases of coccidiosis, diarrhea and reduced growth rate may occur. Subclinical cases may show inferior growth rates and chronic anemia only.

Clinical coccidiosis occurs only rarely in adult cattle. Young dairy cows may be affected, commonly 6 to 8 weeks after calving. Diarrhea, dysentery, tenesmus, pale mucous membrane, thickening and corrugation of the rectal wall, and rapid recovery often without treatment are common signs.

Coccidiosis With Nervous Signs

Nervous signs consisting of muscular tremors, hyperesthesia, clonic–tonic convulsions with ventroflexion of the head and neck and nystagmus, and high mortality rate (80%–90%) can occur in calves with acute clinical coccidiosis. Outbreaks of this "nervous form" have occurred, in which 30% to 50% of all susceptible calves are affected. It is most common during, or following, severely cold weather in midwinter in the northern United States and in Canada. Affected calves may die within 24 hours of the onset of dysentery and the nervous signs, or they may live for several days, commonly in a laterally recumbent position with a mild degree of opisthotonus. In spite of intensive supportive therapy, mortality is high. Nervous signs have not been described in experimentally induced coccidiosis in calves, which suggests that the nervous signs may be unrelated to the dysentery or, indeed, even to coccidiosis.

Lambs

Coccidiosis in lambs is similar to that in calves, but with much less dysentery. In groups of lambs raised and fed under intensive conditions, inferior growth rate, diarrhea (with or without blood), low-grade abdominal pain, gradual onset of weakness, inappetence, fleece damage, mild fever, recumbency, emaciation, or death with a course of 1 to 3 weeks have been described. The diarrhea may escape cursory examination, but clinical examination of affected lambs reveals a perineum smudged with feces, and soft feces in the rectum. Lambs moved directly from range pasture to a feedlot and with little or no previous exposure to coccidia often develop acute disease with a high morbidity and case–fatality rate.

Piglets

In piglets, severe outbreaks of coccidiosis occur between 5 and 15 days of age, irrespective of time of the year. Anorexia and depression are common. There is profuse diarrhea; the feces are yellow, watery, and sometimes appear foamy. The diarrhea may persist for several days when dehydration and unthriftiness are obvious. Although affected piglets continue to suck, they become dehydrated and lose weight. Vomition may occur. Entire litters may be affected, and the case–fatality rate may reach 20%. The disease may persist in a herd for several weeks or months, particularly where a continuous farrowing program is used.

CLINICAL PATHOLOGY

Fecal Oocyst Counts

Animals with acute coccidiosis will be excreting oocysts in the feces only if the infection is patent (i.e., multiple generations of schizogony have occurred and gametogony has led to the production of oocysts). In ruminants with a patent infection and/or disease, a count of more than 5000 oocysts per gram of feces is considered "significant." Although counts of <5000 oocytes per gram of feces do not usually suggest clinical disease, they indicate a source of infection and spread, depending on management and environmental conditions. Oocyst counts of $>10^5$/g are common in severe coccidiosis outbreaks, although similar counts may also be encountered in asymptomatic animals (e.g., sheep). The output of oocysts following an acute infection or disease can fall sharply after a peak. If oocysts are not found and the disease is suspected, fecal smears can be examined for merozoites; these zoites can also be detected upon fecal flotation. Depending on the host animal, some species of coccidia can be identified and differentiated based on the size and characteristics of the oocysts (particularly following sporulation), although there can be some size overlap among species.

Calves

Affected animals exposed to oocysts may develop severe dysentery a few days before oocysts appear in the feces. However, when the feces from several affected animals are examined, and usually within 2 to 4 days after the onset of dysentery, oocysts can be detected in the feces. The period during which oocysts are discharged in significant numbers (patent period) varies among species of coccidia, the age of the animal, and the degree of immunity; therefore it is useful to examine a number of animals in a group or herd (preferably multiple times) rather than to rely only on the results from a single animal.

Lambs

In lambs at pasture, oocysts first appear in the feces at about 2 weeks of age. The oocyst count continues to rise in lambs until about 8 to 12 weeks when the counts can reach 10^5 to 10^6/g of feces. Thereafter, the counts will decline to approximately 500/g when lambs are 6 to 12 months of age. There is also considerable variation, both among individual lambs and from day to day, in the numbers and species of oocysts present in the feces. Hence, it is useful to examine several samples over a period of several days to assess oocyst output.

Piglets

In piglets, the prepatent period varies from 5 to 7 days, and oocysts are shed in the feces for 5 to 8 days after the onset of clinical signs. Piglets may develop coccidiosis at 5 days of age, and oocysts may not be present in the feces until 3 days later. The use of a saturated sodium chloride with glucose as a flotation solution is recommended when examining piglet feces for *I. suis* oocysts.

Necropsy examination of selected, untreated clinical cases is often useful to make a diagnosis. The disease should be suspected when piglets 5 to 8 days of age develop diarrhea that responds poorly to treatment. Outbreaks of diarrhea in piglets under 5 days of age are usually associated with *E. coli* or TGE. However, mixed infections are common, and extensive laboratory investigations are often necessary to isolate the causative agents. The diagnosis often requires a combination of consideration of the history of diarrhea in piglets of 5 to 15 days of age, gross and microscopic lesions, the presence of coccidial stages in mucosal scrapings and/or histologic sections, and the identification of oocysts in intestinal contents and feces. In heavy infections, piglets may die before the sexual stages of the parasite have developed, and the diagnosis is dependent on finding lesions and, in particular, schizonts and merozoites of *I. suis* in the jejunum and ileum. These developmental stages can also be detected on fecal smears or mucosal scrapings. A rapid field diagnostic procedure consists of staining glass slide impression smears of the mucosa of the ileum and jejunum. Autofluorescence microscopy and PCR-based methods can be used as complementary tools for the detection of *I. suis* and other coccidia.

NECROPSY FINDINGS

Carcasses often have generalized tissue pallor, and there is usually fecal staining of the hindquarters. **In cattle**, congestion, hemorrhage, and thickening of the mucosa of the cecum, colon, rectum, and ileum are the characteristic gross changes seen at necropsy. The thickening may be severe enough to produce ridges in the mucosa. Small, white cyst-like bodies, formed by large schizonts, may be visible on the tips of the villi of the terminal ileum. Ulceration or sloughing of the mucosa might occur in severe cases. Infections in the small and large intestines can be characterized by a fibrinous typhlitis and colitis. Clotted blood or bloodstained feces might be present in the lumen of the large intestine. Histologically, there is a denudation of the epithelium, and merozoites might be detected in some cells. Smears of the mucosa or intestinal contents should be examined for the various developmental stages.

The necropsy findings **in sheep** are marked by more severe involvement of the small intestine than in cattle. Characteristic intestinal changes seen in sheep are hemorrhagic typhlitis and colitis (*E. ovinoidalis*), focal epithelial desquamation (*E. crandallis*), focal mucosal lesions with the formation of

polyps (*E. bakuensis*), and catarrhal enteritis (*E. ahsata* and *E. faurei*), associated with the presence of one or more stages of the parasites (schizonts = meronts and/or gamonts). In sheep affected with *E. gilruthi,* the abomasum contains numerous nodules of 1 to 2 mm in diameter, similar (superficially) in gross appearance to nodules caused by *Ostertagia.* These nodules contain the large schizonts of *E. gilruthi.*

In piglets, the small intestines are usually flaccid, but occasionally a fibrinonecrotic enteritis may be observed. Clinical signs precede the production of oocysts, such that mucosal scrapings should be examined for the presence of earlier stages of the life cycle.

Samples for Confirmation of Diagnosis

- **Parasitology:** Feces (fecal flotation); segments of jejunum, ileum, and colon (direct smear)
- **Histology:** Formalin-fixed duodenum, jejunum, ileum, cecum, and colon (LM)

DIFFERENTIAL DIAGNOSIS

Calves Clinical coccidiosis is characterized by dysentery, tenesmus, mild systemic involvement, and dehydration. The presence of large numbers of oocysts supports the diagnosis, and necropsy findings are usually characteristic. When nervous signs occur in calves appearing to have coccidiosis, differentiation from other diseases causing brain dysfunction must be made.

Sheep The diagnosis is dependent on the clinical findings of diarrhea and/or dysentery, the presence of large numbers of oocysts in the feces, and the intestinal lesions at necropsy. Large numbers (10^5/g) of oocysts may occur in the feces of asymptomatic lambs; thus the observation of large numbers of oocysts in the feces of lambs affected with diarrhea and/or dysentery may not, in itself, constitute a diagnosis of coccidiosis. In lambs that have had previous exposure to coccidia, and that may be relatively immune, other causes of diarrhea, such as helminthiasis, salmonellosis, *Clostridium perfringens* type C enterotoxemia and helminthiasis, should be considered. See Table 7.7 for epidemiological and clinical features of the diseases causing diarrhea in small ruminants.

Piglets Diarrhea caused by coccidiosis must be differentiated from enteric colibacillosis, transmissible gastroenteritis, rotavirus infection, *Strongyloides ransomi,* and *C. perfringens* type C. See Table 7.6 for epidemiological and clinical features of the diseases causing diarrhea in pigs.

TREATMENT

Coccidiosis is usually a self-limiting disease, and spontaneous recovery without specific treatment is common when the schizogony (merogony) stages have passed. Many treatments have been recommended without taking this into account, and it is unlikely that any of the chemotherapeutic agents in common use for clinical coccidiosis has any effect on the late (gametogony) stages of the coccidia. Most of the coccidiostats have a depressant effect on the early, first-stage schizonts and are used for prevention or control.

In an outbreak, the clinically affected animals should be isolated and given supportive oral and parenteral fluid therapy, as necessary. The population density of animals in pens should be reduced. All feed and water supplies should be elevated from the ground to avoid fecal contamination. Mass medication of the feed and water supplies may be indicated, in an attempt to prevent new cases and to minimize the effects of an outbreak. Cattle with coccidiosis and nervous signs should be brought indoors, kept warm and on bedding, and given fluid therapy orally and parenterally. However, the case fatality of bovine coccidiosis can be high, in spite of intensive supportive therapy. Sulfonamide therapy parenterally may be indicated to control the development of secondary bacterial enteritis or pneumonia, which may occur in calves with coccidiosis during very cold weather. Corticosteroids are contraindicated.

Calves and Lambs

The chemotherapeutic agents recommended for treatment and control of coccidiosis in calves and lambs are summarized in Table 7-30. There is insufficient information available to make reliable recommendations for the specific treatment of acute clinical coccidiosis. Most of these chemotherapeutic agents have not been adequately tested in clinical trials. Sulfadimidine is used widely empirically for the treatment of acute coccidiosis in calves. **Amprolium** is also used for treatment, and there may be a beneficial effect in terms of increased BW gains and feed consumption compared with untreated controls recovering spontaneously.

Piglets

Symmetric triazinetriones are effective against the asexual and sexual stages of experimental *I. suis* infection in piglets and are most effective before the onset of clinical signs.[1]

Table 7-30 Chemotherapeutics recommended for treatment and control of coccidiosis in calves and lambs

Chemotherapeutic agent treatment prevention
Sulfadimidine (sulfamethazine) *Calves and lambs:* 140mg/kg BW orally daily for 3 days individually *Calves*: in feed 35mg/kg BW for 15 days
Lambs: daily dose 25mg/kg BW for 1 week
Amprolium *Calves*: individual dose at 10mg/kg BW daily for 5 days or 65mg/kg BW one dose *Calves*: in feed at 5mg/kg BW for 21 days
Lambs: in feed, 50mg/kg BW for 21 days
Monensin *Lambs*: 2mg/kg BW daily for 20 days beginning on 13th day following experimental inoculation Lambs: 20mg/kg feed fed continuously
Calves: 16.5 or 33g/tonne for 31 days
Lasalocid *Lambs*: 25–100mg/kg feed from weaning until market. Also, in ewe's diet from 2 weeks before and until 60 days after lambing.

CONTROL

The control of coccidiosis assumes greatest importance in calves, lambs, and pigs, and can sometimes be challenging to achieve.

Management of Environment

Successful control will depend on avoiding the overcrowding of animals while they develop a specific anticoccidial immunity. Only small numbers (50 per day) of oocysts are required for the development of solid immunity in lambs. Lambing and calving grounds should be well drained and kept as dry as possible. Lambing pens should be kept dry, cleaned out frequently, and bedding disposed of, such that oocysts do not have time to sporulate and become infective.[1] All measures that minimize the amount of fecal contamination of hair coats and fleece should be practiced. Feed and water troughs should be elevated to avoid fecal contamination. Feeding cattle on the ground should be avoided if possible, particularly when overcrowding is a problem.

Lambs at Pasture

In groups of lambs at pasture, the frequent rotation of pastures for parasite control will also assist in the control of coccidial infections. However, when lambs are exposed to infection early in life as a result of infections from ewes and a contaminated lambing ground, a solid immunity can usually develop; only when stocking density is extremely high will a problem arise.

Feedlot Cattle and Lambs

Control of coccidiosis in feeder calves and lambs brought into a crowded feedlot depends on the management of population density, or the preventative use of chemotherapeutics to suppress infections in animals while effective immunity develops. Management procedures include establishing a suitable stocking density, which can be assessed by visual inspection. When animals are overcrowded, they usually become dirty, there is excessive competition for feed supplies, and their growth rate can be affected.

Piglets

The control of coccidiosis in newborn piglets infected with *I. suis* has been unreliable. The use of coccidiostats in the feed of sows for several days or a few weeks before and following farrowing has been recommended and used in the field, but the results are variable. Amprolium and monensin have been evaluated for the prevention of experimental coccidiosis in piglets and are ineffective. An effective control program consisting of proper cleaning, disinfection, and steam cleaning of the farrowing housing to decrease oocysts in the environment has been recommended. Amprolium (25% feed grade) at the rate of 10 kg/tonne of sows' feed, beginning 1 week before farrowing and continuing until piglets are 3 weeks of age, has been recommended, but results are reported to be unsatisfactory. A single oral dose of 1.0 mL of toltrazuril, given to piglets of 3 to 6 days of age, reduces considerably the occurrence of coccidiosis and the patency period by approximately half.[1] A single treatment of toltrazuril at 20 mg/kg BW (oral) is highly effective against *I. suis* at an early stage of infection (e.g., 2 days) in suckling pigs.[1]

Coccidiostats

Coccidiostats are used for the control of naturally occurring coccidiosis, mainly in calves and lambs. The ideal coccidiostat suppresses the full development of the life cycle of the coccidia, allows immunity to develop, and does not interfere with production performance. Drugs that have been used for treatment are summarized in Table 7-30.

To be effective, coccidiostats must be given beginning early in infection. In any group of animals, there will be several different species of coccidia at different stages of the life cycle, some at the drug-susceptible stage (before 13–15 days in calves) and some beyond the drug-susceptible stage (after 16–17 days), which explains why coccidiostats appear to be effective in some epidemics and ineffective in others. In an epidemic in calves, new cases may develop for up to 12 to 15 days after the commencement of feeding of an effective coccidiostat to in-contact calves. However, precise commencement of infection is unknown and the prepatent period cannot be established; the most that can be done is to medicate the feed and water supplies with a coccidiostat of choice, treat new cases that develop, and avoid the stressors of overcrowding and nutritional disorders.

Some comments about some of the coccidiostats are made here. Routine prophylactic medication of the feed and water supplies of feeder calves and lambs with an effective coccidiostat will usually control the disease and allow the development of effective immunity, but drug resistance can develop.

Antimicrobials

Sulfonamides in the feed at a level of 25 to 35 mg/kg BW for at least 15 days are effective for the treatment of coccidiosis in calves and lambs. Sulfadimidine at 55 g/tonne is also effective in goats. A combination of chlortetracycline and a sulfonamide has provided protection in calves and lambs.

Ionophores

Monensin is an effective coccidiostat and growth promotant in cattle, sheep, and goats. The recommended doses are 16 to 33 g/tonne feed for calves and 20 g/tonne of feed for lambs. Levels of 11 g/tonne feed are not as reliable as the higher dose for calves. The recommended level for goats is 16 g/tonne of feed. A concentrated ration containing monensin at 15 g/tonne can be fed to ewes from 4 weeks before lambing until weaning, and to lambs from 4 to 20 weeks of age. Monensin can markedly reduce the oocyst output from ewes and lambs when fed before and after lambing. Withdrawal of monensin may be followed by the development of fatal coccidiosis in some animals, presumably because the drug suppressed infection and the development of immunity. Coccidiosis in beef calves after weaning has been treated with monensin from intraruminal continuous release devices. The toxic level of monensin for lambs is 4 mg/kg BW.

Lasalocid is related to monensin and is also an effective coccidiostat for use in ruminants. For maximum benefit, lasalocid should be used daily in the feed of coccidia-susceptible lambs for as long as possible. An effective method of control is to medicate the feed of the ewes beginning approximately 2 weeks before lambing and continuing the medication until the lambs are weaned. The lambs begin to receive lasalocid in their creep ration and subsequently in their rations from weaning until market. For the treatment of coccidiosis and improved feedlot performance, lasalocid should be given before and during the time that coccidia-naive lambs are first exposed to the natural occurrence of oocysts. A dose as low as 25 mg/kg of feed will control coccidiosis and improve performance when fed to lambs early in life. Improvements in feedlot performance do not usually occur in heavier lambs already passing oocysts and being fed lasalocid at 25 mg/kg feed.

Lasalocid fed at a dose rate of 40 mg/kg of starter to dairy calves beginning at 3 days of age, and up to 12 weeks of age, is effective in reducing fecal oocyst excretion rates and increasing mean daily BW gain, dry-matter intake, and improved feed efficiency. Mixing lasalocid in the milk replacer of calves beginning at 2 to 4 days of age is an effective method of preventing or controlling coccidiosis. It is also effective as a coccidiostat when fed free choice in salt at a level of 0.75% of the total salt mixture. Lasalocid at levels from 0.75 to 3 mg/kg BW are effective in preventing experimental coccidiosis in calves. The level of 1 mg/kg BW is the most effective and rapid and is recommended when outbreaks of coccidiosis are predicted or imminent in cattle. Lasalocid and decoquinate are effective in suppressing coccidial infections in young calves under conditions of apparent low exposure and good management. However, evidence shows that neither lasalocid nor decoquinate, or both, added to the feed of 16-week-old dairy calves naturally infected with subclinical coccidiosis for 56 days, have any significant effect on weight performance.[1]

Monensin, lasalocid, and decoquinate at the manufacturer's recommended levels are equally effective. A combination of monensin and lasalocid at 22 mg/kg and 100 mg/kg of diet, respectively, is an effective prophylactic against naturally occurring coccidiosis in lambs weaned early under feedlot conditions. Ionophores have been used in the feed continuously from weaning to market, and control coccidiosis and improve feedlot performance. The continuous feeding of lasalocid, decoquinate, or monensin will effectively control coccidiosis; cessation of medication might result in the appearance of oocysts in the feces and of diarrhea.

Decoquinate in the feed at a dose of 0.5 to 1.0 mg/kg BW can suppress oocyst production in experimentally induced coccidiosis of calves.[1] It is effective in preventing coccidial infections when fed continuously in dry feed at 0.5 mg/kg BW.[1] When fed to dairy calves from 9 weeks to 24 weeks of age, there appears to an improvement in growth rate. A level of 0.5 mg/kg BW is also effective in goats.

Toltrazuril is an efficacious compound.[4,5] Used at 20 mg/kg BW as a single oral dose, 10 days after being turned out to pasture, will prevent coccidiosis in cattle and sheep. In addition, medication of naturally infected lambs with toltrazuril on day 10 after turnout markedly reduces the excretion of oocysts for a prolonged period, and lessens the contamination of pasture with oocysts. A single treatment of toltrazuril can reduce the oocyst output in naturally infected lambs for a period of approximately 3 weeks after administration. Weekly oral treatment of suckling lambs with 20 mg/kg BW of toltrazuril can reduce oocyst output and increases weight gain over a 10-week period.[1]

Vaccines

Although subunit vaccines might offer theoretical advantages, limited detailed understanding of the immunobiology of coccidioses in livestock and the relatively large number of species remain obstacles to developing effective anticoccidial vaccines.

GIARDIASIS

SYNOPSIS

Etiology *Giardia duodenalis*. Zoonotic and livestock-specific assemblages

Epidemiology High prevalence of infection in young farm animals. Fecal–oral cycle of infection from excreting young animals, the dam, and fomite contamination in environment. Cross-species and water transmission possible

Clinical findings May result in intermittent pasty feces and growth suppression. Some infections are asymptomatic.

Clinical pathology Demonstration of cysts in feces by phase microscopy or fluorescent antibody

Necropsy findings Villous atrophy

Treatment and control Benzimidazoles, metronidazole, and hygiene

ETIOLOGY

Giardia duodenalis (synonym *G. lamblia, G. intestinalis*) is a flagellate (binucleated) protozoan that infects a variety of vertebrates, particularly mammals.[1-8] It is a major cause of diarrhea in humans and has been recognized to causing diarrhea in agricultural animals. Currently, there are numerous genetic variants within *G. duodenalis,* and the genotypic assignment of members of *G. duodenalis* is evolving. Genetic variants (genotypes) are called assemblages. Cattle are susceptible to infection with the zoonotic assemblage A, which infects several different animal species, and assemblage E, which appears to be restricted to hoofed animals.

The organism develops in the small intestine, where it multiplies by longitudinal binary fission on the surface of the intestinal mucosa at the trophozoite stage, and is excreted in feces as a cyst.[2,3]

EPIDEMIOLOGY

Occurrence

Giardia infection, as opposed to disease, has been reported from most continents and has been identified in **all of the common agricultural animals**.[4] There is a wide variation in reported prevalence among regions, which probably reflects sampling strategies and methods of detection. The excretion of *Giardia* cysts may be continual but is also usually intermittent in young animals. Most prevalence studies have been in calves, and reported point prevalence infection rates of 1% to 100% in different countries, with the majority of studies showing prevalences of between 20% and 80% in calves.[1] A similar range is evident for more limited studies in lambs, kids, foals, and piglets.[1] Longitudinal studies of excretion patterns in grazing beef cattle, feedlot cattle, dairy cattle, calves, and foals sometimes show high infection rates.[1]

Source of Infection

Young animals are the primary source of infection, and infection is transmitted through the fecal–oral route. High cyst excretion rates in young animals result in the contamination of the **environment** and infection via fomites.

The **dam** is also a source of infection for young animals. Linked to a decrease in immunity in terminal pregnancy, a **periparturient rise** in *Giardia* cyst shedding has been shown in ewes, where cyst excretion increased 2 weeks prepartum, peaked at 0 to 4 weeks postpartum, and declined to low levels at 6 to 8 weeks postpartum.[1] A periparturient rise is suspected to occur also in mares. Cross-infection from other animal species and infection from contaminated water and feed are other possible sources of infection.

Pathogen Risk Factors

The infectious dose of *Giardia* is thought to be very small. *Giardia* cysts are relatively resistant to environmental influences, can survive at 4°C for 11 weeks in water, 7 weeks in soil, and 1 week in cattle feces, but do not survive freezing. They are resistant to chlorination, and extensive disinfection of the environment does not prevent reinfection.

Animal and Management Risk Factors

Age is a determinant of infection; cyst excretion rates in feces are much higher in the young livestock than in adults. Cyst excretion rates in groups of calves are usually highest between 3 and 10 weeks of age, with the number of cysts in feces being highest at 1 to 6 weeks of age. Cyst excretion falls after weaning, but may persist intermittently into adulthood. Similar patterns are seen in lambs. The influence of age on infection in pigs may be confounded by prophylactic medicants routinely used in pig operations. No effect of housing, feeding water management, or season has been observed in cattle, but hygiene in management practices can influence exposure and infection dynamics. The high and early infection rates in calves and lambs compared with other livestock species are probably a reflection of this. Pigs reared on wire floors are infected later in life than pigs reared on porous concrete floors. The prevalence of infection is higher in calves left with their dams to nurse colostrum for 3 days than in calves removed from the dam at birth to individual housing and fed colostrum by a nipple bottle.

Experimental Studies

Based on experiments in calves, *Giardia* has a prepatent period of 7 to 8 days and a patency of 60 to 112 days without evidence of giardiasis.[1] Infection of 6-week-old SPF lambs with *Giardia* trophozoites resulted in the occurrence of episodes of diarrhea and soft feces that were temporally associated with the detection of *Giardia* cysts in feces.[1] Compared with controls, infected lambs had a reduced rate of weight gain without reduction in food intake and took longer to reach market weight.

Economic Importance

Evidence for a significant economic importance for the majority of *Giardia* infections in agricultural animals is not convincing.

Zoonotic Implications

The majority of giardial infections in cattle are with the livestock-associated assemblage E, with a small proportion of infections with the zoonotic assemblage A.[2-6] Contact with farm livestock is a risk factor for disease in humans. There is considerable concern in public health circles that infection of humans could also occur via water bodies receiving agricultural effluent and pasture runoff, leading to drinking water contamination. There is also concern for fecal dispersion of *Giardia* in back-country watersheds from pack animals.

PATHOGENESIS

Ingested cysts excyst and release trophozoites, which multiply and colonize the surface of small intestine. Trophozoites adhere to the villi of the small intestine by means of a sucking disk on their ventral surface. The parasite induces an inflammatory response, villous atrophy, a reduced **villus to crypt**

ratio, and a reduction in brush border disaccharidase enzymes.[1] Disease is believed to result from increased motility in the gut (as a consequence of inflammation) and consequent diarrhea and nutrient maldigestion and malabsorption.

CLINICAL FINDINGS

There are several reports that detail the demonstration of giardial infection in individual animals with a chronic, malabsorptive type of diarrhea, and most imply an association with diarrheal disease. Most of these reports relate to young animals at an age when both undifferentiated diarrhea and *Giardia* cyst excretion are common, but the evidence for a causal association is not always entirely convincing, because other possible causes of diarrhea are not excluded. There are also various studies in animals that describe that infection is sometimes not accompanied by evidence of clinical disease.[3-5] In calves and lambs, giardial infection has been associated with a semifluid, pasty, intermittent diarrhea containing mucus, lasting 2 to 3 days but up to 6 weeks in some animals, and growth depression despite a normal appetite. Controlled experimentation demonstrating loose feces and reduced weight gain in experimentally infected lambs has indicated that *Giardia* can be pathogenic in sheep.

CLINICAL PATHOLOGY

Giardia cysts can be demonstrated in feces by phase contrast microscopy or immunofluorescent microscopy following flotation. Saturated salt or sugar solutions may disfigure the cyst, and the demonstration of infection is best conducted by sucrose gradient or zinc sulfate solution flotation. Immunofluorescence might be more sensitive than microscopy for the detection of cysts, and PCR-coupled methods are commonly used for the detection and genetic characterization of *G. duodenalis.*[7]

NECROPSY FINDINGS

Findings are in the upper small intestine. Although there is often no macroscopic change, microscopically there may be an increase in intraepithelial lymphocytes in the jejunum, with moderate to severe diffuse inflammation, villous atrophy, crypt distortion, and a reduction in the villus to crypt ratio. Trophozoites can be detected histologically on the mucosa and in stained mucosal scrapings taken from the small intestine.

TREATMENT AND CONTROL

Giardial infections in agricultural animals have been successfully treated with dimetridazole at an oral dose of 50 mg/kg BW daily for 5 days[1] and are also susceptible to furazolidone, but both drugs are illegal for use in food animals in many countries.

Oral administration of the **benzimidazoles** albendazole (20 mg/kg BW daily for 3 days) and fenbendazole (10 mg/kg BW daily for 3 days) are effective for the treatment of *Giardia* infection or giardiasis in calves.[8] The 3-day course is required for effective treatment; some calves become reinfected following treatment. The principles for the control of giardiasis are similar to those used for cryptosporidiosis, but have not really been developed specifically for livestock. Recommended procedures described to achieve a reduction of exposure (in the section Acute undifferentiated diarrhea of newborn farm animals) are appropriate.

ASCARIASIS IN PIGS, HORSES, AND CATTLE

SYNOPSIS

Etiology Nematode worms from the ascarid family: *Ascaris suum* in pigs, *Parascaris equorum* in horses, and *Toxocara vitulorum* in buffalo and cattle

Epidemiology Transmission is by ingestion of highly resistant and long-lived larvated eggs; *T. vitulorum* is also transferred via colostrum.

Signs Heavy infestation leads to poor growth and afebrile diarrhea, sometimes with obstructive jaundice, intestinal obstruction, and respiratory signs.

Clinical pathology Characteristic eggs in feces and a marked eosinophilia

Lesions Petechial hemorrhages in lungs and fibrotic spots on the liver

Diagnostic confirmation Demonstration of characteristic eggs in feces

Treatment

Pigs: Ivermectin, abamectin, doramectin, flubendazole, febantel, oxibendazole, thiophanate, pyrantel tartrate, and levamisole

Horses: Febantel, fenbendazole, mebendazole, and oxibendazole

Control

Pigs and horses: Keep young stock away from sites in which eggs may accumulate.

Cattle/buffalo: Prophylactic anthelmintic treatment of 10- to 16-day-old calves

ETIOLOGY

Each species has its own ascarid: *Ascaris suum* in pigs and *Parascaris equorum* in horses are cosmopolitan, whereas *Toxocara vitulorum* is an important cause of mortality in buffalo calves in India and Southeast Asia.[1] Genetic studies show that although *A. suum* of the pig is very similar to *A. lumbricoides* of man, host-specific differences do exist,[2] and cross-infections occur only infrequently.[3] There is no ascarid specific for sheep, but they may rarely become infected with *A. suum.*

LIFE CYCLE

A. suum and *P. equorum* have similar life cycles. The adult worms are long (females are 20–40 cm and males are 15–25 cm in length), cylindrical, and pointed at both ends and have a thick, glistening, yellow-white cuticle. They live in the small intestine and lay very large numbers (0.5–2 million eggs per day) of thick-shelled eggs.[4] These are not infective until a larva has developed inside. This process needs suitable warmth and humidity and takes place over a period of several weeks. When swallowed, infective eggs hatch quickly in the intestine of the host and the larvae migrate through the intestinal wall, reach the portal vein, and are transported to the liver. They cross to the hepatic venous system and travel to the lungs, are passed up the bronchi and trachea to the pharynx, and are swallowed and come to rest in the intestine where they mature. The prepatent period (time from infestation to the appearance of eggs in the feces) is 6 to 8 weeks for *A. suum* and 11 to 15 weeks for *P. equorum.*

T. vitulorum has a more complex life cycle. When eggs are ingested by cattle or buffalo more than 4 to 5 months of age, the larvae settle in somatic tissues without developing or growing instead of traveling to the intestine. Subsequently they become activated around calving and migrate to the udder. They transfer to the calf in the colostrum and grow to the adult stage in the intestine over a period of 3 to 4 weeks and produce large numbers of eggs for about 4 weeks.[1] After 8 weeks of infection, the worm counts in the infected calf decline because of strengthened host immunity.[1]

EPIDEMIOLOGY

In pigs and horses the only route of infection is by ingestion of larvated eggs. Because the eggs have very thick walls the infective stage is protected from deleterious environmental influences. Few disinfectants will harm them, and they are very resistant to cold but survive most readily in cool, moist surroundings. Periods of survival of up to 5 years have been recorded. In the UK, *A. suum* eggs shed from September to May, become infective more or less synchronously in July, and the number of eggs becoming infective then falls away rapidly. This coincides with the prevalence of damaged livers recorded at bacon factories. Transmission is therefore seasonal but as ascarid eggs are very resistant and can overwinter, pigs and horses may in the absence of good hygiene become infected at all periods of the year. Clinical ascariasis is usually associated with conditions that allow infective eggs to accumulate. This may happen where, for example, the stocking rate is high and the same paddocks are used year after year, or when indoor pens are inadequately cleaned. Although the eggs in the environment are resistant to drying and freezing, exposure to sunlight will kill them within a few weeks.[4]

Protective immunity develops and consequently only the young are seriously affected. Ascarid worms are very immunogenic and induce strong Th2 immune responses characterized by eosinophilia and high levels of antiinflammatory cytokines, resulting in worm expulsion.[5] However, this strong Th2 induction may inhibit Th1 responses against bacterial and viral infections, reducing the efficacy of vaccinations.[6,7] Under field conditions, eggs are passed by foals from 12 to 13 weeks of age and spontaneous expulsion of worms occurs 6 to 9 weeks later. Eggs are seen occasionally in the feces of very young foals, but this is thought to be from the ingestion of uninfective eggs during coprophagia. In older animals no clinical signs are observed but infested animals, particularly adult sows and yearling horses, continue to contaminate their surroundings and are an important link in the chain of infection.

T. vitulorum larvae are present in greatest numbers in the colostrum 2 to 5 days after calving, and few are present after day 9. Mature worms are present in the intestine of the calf by 10 days of age, and eggs are passed by 3 weeks. Worms are expelled by 5 months of age; thus toxocariasis is a calfhood disease.

PATHOGENESIS

Migration of larvae through the liver results in hemorrhage and fibrosis, the latter appearing as white spots under the capsule. In heavy infection diffuse fibrosis may occur. The most serious damage occurs in the lungs where the larvae provoke alveolar injury with edema and consolidation. This damage can exacerbate preexisting lung infections or provide a portal of entry into the body for pyogenic organisms. Immunity to migrating larvae is acquired and can be transferred through colostrum or immune serum.

In animals other than pigs, *A. suum* larvae migrate and develop, but the worms do not normally reach the small intestine. During this process severe clinical signs of pulmonary involvement may appear. The disease has been produced experimentally in lambs and calves and has also been observed as a field occurrence in yearling cattle.

Foals with *P. equorum* have reduced gut motility, an increase in the ratio of body water to body solids, and a lowering of the body pool of albumin.

CLINICAL FINDINGS

In pigs up to 4 to 5 months old, clinical signs associated with heavy infestation are poor growth, an afebrile diarrhea, and lowered resistance to other disease. There is some evidence that exposure to parasites during the growing phase without anthelmintic treatment causes permanent damage to growth potential. Adult worms may be vomited up and occasional cases of obstructive jaundice and intestinal obstruction or rupture occur. There may be coughing while larvae are passing through the lungs, but this is not marked, and there is seldom sufficient damage to cause a noticeable increase in respiratory rate or depth. In rare cases the infestation may be so severe that pigs manifest severe dyspnea or die of acute hepatic insufficiency. Enzootic pneumonia of pigs and swine influenza are reported to be much more serious diseases when accompanied by heavy *A. suum* infections, and breaks in hog cholera vaccination with live virus have been attributed to this cause. *A. suum* in other host species produces fever, dyspnea, and anorexia about the 8th day after infestation.

Effects in foals and calves caused by heavy infestation with *P. equorum* and *T. vitulorum* are similar to those observed in young pigs and include poor coat, diarrhea, and occasionally colic. In addition, in foals, convulsions, intestinal obstruction, and perforation may occur. Lung damage may give rise to fever, coughing, and a mucopurulent nasal discharge.[8] In calves, anemia and steatorrhea are additional signs.

CLINICAL PATHOLOGY

Characteristic eggs are usually present in large numbers in the feces of clinically affected animals. A marked eosinophilia and systemic elevated expression of IL-4[7] often accompany the early stages of infestation in pigs and in other species, with the eosinophilia shown to persist in calves for at least 1 year.

NECROPSY FINDINGS

In the early stages of a massive infestation, there are subpleural hemorrhages and edema and congestion of the lungs. The pleural cavity may contain bloodstained fluid. The liver is enlarged and congested, and there may be hemorrhages under the capsule. Microscopically, necrotic tracts and sections of larvae are observed. In species other than the pig, infestation with *A. suum* is accompanied by emphysema, alveolar wall thickening with fibrin, eosinophils and hemorrhage in the lungs, and necrotic tracts in the liver.

In chronic cases the capsule of the liver is marked with small-diameter white spots which may, in severe cases, be confluent and constitute a network of connective tissue. Histologically, the necrotic tracts have been replaced by fibrous tissue. The carcass is usually in poor condition and may be jaundiced. Large numbers of mature worms may almost fill the lumen of the small intestine.

DIAGNOSTIC CONFIRMATION

Ascarid eggs are brown and have thick walls with a pitted surface. Fecal egg counts in excess of 1000 epg (eggs per gram) are considered to be indicative of significant infection. Migrating larvae are too small to be observed by the naked eye at postmortem examination. They can be recovered from macerated lung tissue by the Baermann technique or seen microscopically in scrapings of bronchial mucus. Experimentally, for *T. vitulorum,* species-specific and highly sensitive molecular diagnostic PCR and LAMP DNA-based tests have been developed for accurate identification and diagnosis of *Toxocara* spp., overcoming the inherent limitations of the traditional approaches.[8,9]

DIFFERENTIAL DIAGNOSIS

Early stages of massive infection:

- Enzootic pneumonia in pigs
- Chronic form of *Rhodococcus equi* pneumonia in young foals
- Other forms of pneumonia in calves

Chronic infection:

- Other causes of unthriftiness including malnutrition and chronic enteritis caused by infections with *Salmonella* and *Brachyspina* spp.

TREATMENT

TREATMENT AND PROPHYLAXIS

Treatment

Pigs

Ivermectin or doramectin (0.3 mg/kg by IM) (R1)[10,11]

Abamectin (0.1 mg/kg/day for 7 days in feed) (R1)[10]

Flubendazole (5 mg/kg as a single dose or 30 g/tonne finished feed given for 5–10 days) (R2)

Fenbendazole (5 mg/kg in feed as a single dose or divided over 7–14 days) (R3)

Febantel (5 mg/kg, orally) (R3)

Oxibendazole (15 mg/kg or 1.6 mg/kg/days orally for 10 days) (R3)

Horses

Febantel (6 mg/kg, orally) (R1)

Fenbendazole (7.5 mg/kg, orally) (R1)

Mebendazole (5–10 mg/kg, orally) (R1)

Oxibendazole (10 mg/kg, orally) (R1)

Buffalo

Pyrantel (12.5 mg/kg, orally) (R2)[17]

Pigs

In pigs, ivermectin, abamectin, or doramectin and flubendazole are effective against adult and fourth-stage (intestinal) larvae of *A. suum*, whereas fenbendazole, febantel, oxibendazole, thiophanate, pyrantel tartrate, and levamisole are effective against the adult worm. Ivermectin, fenbendazole, flubendazole, thiophanate, and pyrantel may be given in feed as divided doses over several days. Ivermectin may have some activity against migrating larvae.

Horses

In horses, febantel, fenbendazole, mebendazole, and oxibendazole are all effective against adult *P. equorum.* Fenbendazole is also active against immature forms in the intestine. *P. equorum* has been shown to be resistant to ivermectin and pyrantel.[11-15]

Buffalo Calves

In buffalo calves, the limited data available suggest that pyrantel has good efficacy against both immature and adult worms.[16] Other compounds such as levamisole, febantel, oxfendazole, and even piperazine can be used for treatment but may not expel all worms.

CONTROL

Important life cycle features that must be taken into account when devising a control program for ascarid infections include the following:

- Worms are prolific egg layers
- Infective eggs are very resistant and long lived
- Young animals are most susceptible

Emphasis must be placed on preventing the environment from becoming contaminated. This is achieved by periodic treatment of the animals likely to be shedding eggs, which are asymptomatic adult carriers and the more vulnerable young stock. Exposure of young pigs and foals to contaminated soil or bedding should be avoided.

Unnecessary treatments can be avoided by regular monitoring with fecal egg counts. In intensive pig-raising systems on concrete floors, the risk of ascarid infestation can be greatly reduced, but rarely eliminated, with good standards of hygiene. In the case of straw yards, epidemiologic studies in the UK suggest that all bedding should be removed at the end of June (to remove eggs shed in preceding months before they become infective) and again at the end of August (to remove eggs deposited in the summer). If pigs are allowed access to small earthen yards, these must be kept well drained and the manure removed frequently. Control is difficult in free-range systems because the eggs become infective in 4 to 6 weeks in summer and many persist over the winter. Deep plowing of contaminated soil after use will reduce risk of *A. suum* and *Trichuris suis* eggs infecting future batches of pigs.

If farrowing pens are regularly cleaned with high-pressure water and sows are treated immediately before entry, it may be possible to control infection in piglets without anthelmintic treatment. Breakdowns may occur as ascarid eggs are adhesive and not all will be washed away by hosing. For the same reason, eggs are easily introduced from outside on boots, etc. It may therefore be necessary to treat piglets at weaning. Ascarids may be controlled in growing pigs by periodic anthelmintic treatments, but this has to be combined with rigorous hygiene to eliminate liver damage caused by migrating larvae.

Young foals present more of a problem because they often run on permanent pasture used by foals in previous years. Such pastures may become heavily contaminated with eggs. Recommendations for control include:

- Thorough cleaning and disinfection of the maternity stall after each foaling
- Use of small exercise paddocks that should preferably have been rested from occupation by horses for a year
- Weekly removal of manure from the pasture. The foals should be routinely treated at about 10 to 12 weeks of age when the worms are first becoming mature and again at bimonthly intervals. In this way heavy egg contamination of the pasture can be avoided.

Anthelmintic resistance in *P. equorum* in recent years been widely reported.[11-14,]

In buffalo calves, a single anthelmintic treatment at 10 to 16 days of age using a compound with high activity against larval stages gives good control of *T. vitulorum.*[18]

STRONGYLOSIS (CYATHOSTOMINOSIS) IN HORSES

SYNOPSIS

Etiology Two nematode subfamilies: the Strongylinae (large strongyles) and Cyathostominae (known variously as small strongyles, small redworms, trichonemes, cyathostomes, or cyathostomins)

Epidemiology Eggs are shed by horses of all ages, the life cycle is direct, infective larvae develop seasonally on pasture, and hypobiotic cyathostomin larvae can cause severe disease when they resume development in late winter.

Signs

General strongylosis: Ill-thrift, weight loss, poor hair coat, and impaired performance

Verminous arteritis (associated with *Strongylus vulgaris*): Variable, including colic and diarrhea

Larval cyathostominosis: Rapid weight loss, often with sudden onset diarrhea

Clinical pathology Strongylid eggs in feces (except disease caused by larvae); reduced hemoglobin, erythrocyte counts, and packed cell volumes; leukocytosis; eosinophilia (with migrating larvae); hyperglobulinemia, particularly IgG(T); hypoalbuminemia

Lesions

General strongylosis: Large numbers of adult worms in cecum and colon; hemorrhagic inflammation of mucosa with multiple small ulcers, and large and small nodules

Larval cyathostominosis: Mucosa grossly inflamed with large numbers of larvae appearing as brown specks

Verminous arteritis: Wall of cranial mesenteric artery greatly thickened, organizing thrombi and larvae on internal surface; and ischemia or

Continued

necrosis of parts of the intestinal wall caused by emboli
Migratory larvae: Seen in various subserosal sites; some cause nodules in the liver

Diagnostic confirmation Few pathognomonic indicators; judgment made on overall appraisal of clinical history, presenting signs, and laboratory findings; arteritis of cranial mesenteric artery sometimes palpable per rectum; immature worms are sometimes in feces in larval cyathostominosis

Treatment
General strongylosis: Ivermectin, moxidectin; benzimidazoles, e.g., febantel, mebendazole, oxibendazole
Migrating strongyles: Ivermectin, moxidectin
Larval cyathostominosis: Ivermectin, moxidectin

Control Twice-weekly removal of feces from pastures, mixed or alternate grazing, and routine dosing to prevent contamination of pasture with eggs

ETIOLOGY

The redworms (strongyles) are nematodes commonly found in the large intestine of horses and other Equidae. They belong to two subfamilies: the Strongylidae (large strongyles) and Cyathostominae (known variously as small strongyles, small redworms, trichonemes, cyathostomes, or cyathostomins).[1] The large strongyles include *S. vulgaris, S. edentatus,* and *S. equinus,* which migrate extensively through the body, and *Triodontophorus* spp. and *Oesophagodontus robustus,* which do not. The cyathostomins consist of a complex of 50 species from 14 genera including *Cylicostephanus, Cyathostomum, Cylicocyclus, Cylicodontophorus, Poteriostomum, Gyalocephalus,* and *Cylindropharynx.*[1] Of these, about 10 species are common.

LIFE CYCLE

Eggs are passed in the feces, and under suitable climatic conditions produce infective third-stage larvae from 7 days onward. As in many other parasitic conditions, the survival of eggs and larvae is favored by shade, moisture, and moderate temperature. Desiccation, ultraviolet light, and repeated freezing and thawing are particularly detrimental to their development and survival.[2] Some eggs and larvae may withstand freezing temperatures, but development ceases below 7.5°C (46°F) to be resumed when temperatures increase. Optimum chances for infection of the host occur in the early morning or evening, when dew produces a moisture film on plants, or after rain, both of which give conditions that encourage larvae to migrate onto pasture.[3] The pasture's soil moisture content influenced by rainfall in the days before fecal deposition on pasture influences larval development and migration onto herbage.[4] The life cycle of all species is direct; horses become infected by ingestion of the infective larvae.

After ingestion, the larvae of nonmigratory strongyles, such as the cyathostomins, exsheath and enter the walls of the cecum and colon, where they remain in small subserous nodules for 7 to 18 weeks before breaking out into the lumen of the intestine. The time spent in the mucosa depends on the following:

- Species
- Season of the year
- Age and degree of immunity of the host

They can become arrested in their mucosal development, and their synchronous emergence some weeks later may provoke severe clinical signs. This may occur spontaneously, particularly in late winter, or may be induced by anthelmintic treatment. Expulsion of the adult worm population seems to remove an inhibitory feedback mechanism and may provoke clinical signs. Hypobiotic early third-stage larvae are present in the mucosa at all seasons of the year.

Larvae of *S. edentatus* penetrate the intestine and travel via the portal vessels to the liver, where larvae remain and produce hemorrhagic tracts for a month or so. They then migrate via the hepatorenal ligament to the connective tissue under the peritoneum and form hemorrhagic nodules. After about 3 months, they return via the root of the mesentery to the large bowel wall and again form hemorrhagic nodules, which finally rupture and release the worms into the lumen. Adult egg-laying females are present from 40 weeks. Larvae may be found in other organs, e.g., the testes, but these larvae do not return to the intestine. *S. equinus* migrates via the liver to the pancreas and peritoneal cavity but how they return to the intestine is uncertain.

Larvae of *S. vulgaris* penetrate the intestinal wall, molt to the fourth larval stage in the submucosa, and then pass into and up small arteries. By day 14, they have reached the cranial mesenteric artery, where they develop to late fourth-stage larvae. In 3 to 4 months they molt and the young adults then return to the intestine via the lumina of the arteries. Nodules are formed in the intestine wall and later rupture, releasing adults into the lumen of the intestine. The prepatent period is 6 months.

EPIDEMIOLOGY

Strongylosis is a common disease of horses throughout the world and causes death when control measures are neglected. In areas with cold winters and mild summers, egg deposition peaks in spring and remains high over summer. At this time, temperatures are suitable for larval development, and massive contamination of infective larvae may occur in late summer and early autumn, when young susceptible horses are present. *S. vulgaris* larvae can overwinter in considerable numbers in Europe. If the summers are hot and dry, only a small proportion of strongyle eggs develop to larvae and these may be short lived, but continual reinfestation keeps pasture contamination high.

In subtropical regions, eggs can hatch throughout the year, and larval availability is influenced more by rainfall than temperature. For example, in Florida fecal egg counts remain high throughout the year, and there is an autumn rise in infective larvae. Such associations between disease risk and local climate have important implications in the timing of treatments.

The onset of disease following ingestion of large numbers of larvae depends on the maturation period of the parasite in the host and whether it is the immature or adult stages that are pathogenic. Outbreaks of disease caused by the emergence of small strongyles after hypobiosis are commonly seen in Europe in late winter and early spring (winter or larval cyathostominosis), whereas arterial lesions caused by larval *S. vulgaris* are first seen in late summer and reach a maximum by midwinter.

Mares are the main source of infection for younger horses because many adults carry appreciable burdens of adult stages of strongyle worms and pass large numbers of eggs.[5] Nevertheless, horses do gain some acquired immunity to infection, so young stock are the most susceptible. Possibilities for vaccination are being investigated, but a commercial product seems an unlikely prospect in the short term.

The extensive use of anthelmintics with high efficacy at regular intervals has resulted in a marked decline in the prevalence of *S. vulgaris* in many regions. The cyathostomins, on the other hand, are becoming increasingly important. This may be caused by any of the following factors:

- Insusceptibility of mucosal cyathostomins to many drugs
- Selection for benzimidazole-resistant worms
- Selection for shorter egg reappearance periods

PATHOGENESIS

The disease processes associated with the strongyles can be divided into those produced by migrating larvae, those provoked by the mass emergence of mucosal larvae, and those associated with adult worms. Heavy intestinal infection can alter intestinal motility, permeability, and absorption.

The larvae of *S. vulgaris* are the most pathogenic, causing arteritis, thrombosis, and thickening of the wall of the cranial mesenteric artery. Emboli may break away and lodge in smaller blood vessels, leading to partial or complete ischemia in part of the intestine, thus producing colic. The result of this depends on the length of the segment of intestine affected and the ability of the collateral blood supply to become established

before necrosis and gangrene occur. It is not clear whether the ischemia is directly caused by the mechanical effects of embolism or by consequent pathophysiological events. Whatever the cause, greatly enhanced mobility proximal to the lesion follows and can cause volvulus or torsion. Intussusception is seen occasionally. Colic may also be caused by pressure of the thickened cranial mesenteric artery on the mesenteric plexus.

Other arterial lesions associated with migrating *S. vulgaris* larvae include aneurysm of the cranial mesenteric artery, but this is a relatively rare occurrence. More often, larvae aberrantly migrating beyond the cranial mesenteric artery cause migratory tracts and thrombi in other blood vessels. Multiple lesions may be seen in the cecal and colic arteries, which may completely occlude the lumen and cause gangrene in parts of the bowel. Smaller lesions are occasionally seen in iliac, renal, splenic, hepatic, and coronary arteries. Aortic and iliac thrombosis may result in hindlimb lameness. Field and experimental cases of cerebrospinal nematodosis caused by *S. vulgaris* invasion of the CNS have been reported.

***Strongylus* sp. larvae** returning to the intestine cause large nodules in the wall of the cecum and colon. Considerable hemorrhage may follow when these rupture to release the worm into the lumen of the intestine. In very heavy burdens, bleeding sufficient enough to cause death can occur.

Developing cyathostomin larvae provoke the formation of small nodules, which may be superficial or submucosal, depending on species. In heavy infections, the emergence of large numbers of larvae over a short period causes inflammation of the cecum or ventral colon, with small ulcers where larvae have emerged; hemorrhages of varying sizes; and excess mucous production. Typically, this leads to weight loss, diarrhea, and sometimes a variety of other clinical manifestations including colic and cecocecal intussusception. Affected animals may sometimes secrete *Salmonella*.

Adult strongyles can be divided into those that cause blood losses and those that are superficial tissue feeders. *Strongylus* spp. have large buccal cavities, which they use to draw in and digest plugs of mucosa, while secreting anticoagulants to aid the ingestion of blood. Hemorrhage continues from feeding points after worms detach to find new attachment sites. *Triodontophorus* spp. and *O. robustus* feed similarly but are less harmful because they have smaller buccal capsules. An exception is *T. tenuicollis,* because this species attaches in groups in the right dorsal colon and can cause large ulcers. The small strongyles (cyathostomins) have even smaller buccal cavities and produce only superficial damage, so that even relatively large numbers (tens or hundreds of thousands) of adults often cause little apparent harm.

CLINICAL FINDINGS

In natural infestations it is often impossible to quantify the effects of individual strongyle species because the clinical picture usually represents the combined effects of a mixed infestation. Ill-thrift, poor hair coat, impaired performance, weight loss, and anemia are signs associated with a "wormy" horse. The greatest losses are probably caused by the failure of young horses to grow optimally and the less efficient performance of moderately parasitized working horses and donkeys.

Clinical syndromes caused by arteritis in the cranial mesenteric artery, aorta, and iliac artery are described in other chapters. Experimentally, the migratory phase of *S. vulgaris* infection is associated with pyrexia, inappetence, depression, leukocytosis, and intermittent or continuous colic. In more chronic cases there is a

- Persistent low-grade fever
- Poor appetite
- Intermittent colic
- Poor weight gain

Diarrhea may be present. Adult mares exposed to heavy *S. vulgaris* in late pregnancy may become very weak to the point of recumbency. On clinical examination the mucosae are pale, the heart rapid and loud, and respiration moderately increased. Intestinal sounds are increased although the feces are normal. Abortion may occur and the mare usually dies.

The simultaneous maturation of large numbers of hypobiotic larvae induces the condition known as winter or larval cyathostominosis, which is potentially life-threatening and associated with development of large numbers of immature worm stages in the wall of the large intestines, typically in horses 1 to 3 years old. This is usually characterized by severe loss of weight, weakness, acute or chronic diarrhea, subcutaneous edema, pyrexia, and colic.[6] Numerous cyathostomin larvae may be passed with the feces or may be seen adhering to the glove after rectal examination. Larval cyathostominosis can occur in horses of all ages but are most common in adults under 5 years old. Unless treated early, prognosis is guarded.

CLINICAL PATHOLOGY

Examination of feces for strongylid eggs confirms the presence of adult strongyles but does not differentiate species. To do this it is necessary to hatch the eggs and examine the infective larvae. This has to be done by an expert parasitologist and delays results by at least 10 days. Experimentally, specific amplification of ribosomal DNA in feces can be used for the detection and identification of strongyle infections and may lead to diagnostic tests.

Hematological values, particularly reduced hemoglobin levels, erythrocyte counts, and PCVs are often taken as a nonspecific indication of the degree of infestation with strongyles. Leukocytosis is a feature of heavy infection, whereas eosinophilia may reflect the presence of migrating larvae. Serum analysis reveals a marked increase in β-globulins, particularly IgG(T), and a decrease in albumin.

NECROPSY FINDINGS

Adult strongyle worms may be seen attached or close to the mucosal surface. The three *Strongylus* spp. are red in color and 2 to 5 cm long. *Triodontophorus* and *Oesophagodontus* are smaller, up to 2 cm. Less easy to see are the small strongyles (cyathostomins), which are more slender and generally under 2 cm long with smaller buccal capsules. Because most cases of strongylosis are caused by mixed infestations with all genera, necropsy findings usually include most of the lesions characteristic of each worm.

In cases of general strongylosis, very large numbers of adult worms will be found in the cecum and colon. There may be so many that they appear to form a living cover to the contents of these organs. Catarrhal, hemorrhagic, or fibrinous inflammation of the cecum and ventral colon with multiple small ulcers is associated with the emergence of cyathostomin larvae. There may be edema with excessive mucous production or numerous punctate hemorrhages. Fewer adult worms may be present in winter cyathostominosis but large numbers of larvae (several per square centimeter) can be seen as brown specks in the mucosa, especially if this is illuminated from behind. Adult *T. tenuicollis* are often found in large numbers in the right dorsal colon in association with small circular hemorrhages, and they are sometimes attached in groups at the base of deep mucosal ulcers.

***Strongylus* larvae** occur in many subserous sites, especially in nodules in the intestinal wall, and the body cavities may contain an excess of bloodstained fluid. Verminous arteritis lesions of varying size associated with *S. vulgaris* are common at the root of the cranial mesenteric artery and occasionally in the iliac artery. The affected arterial wall is greatly thickened and contains loculi on its internal surface, many of which contain living larvae. Lamellated thrombi are also common at this site and these are sometimes infected. The thickening of the arterial wall often extends along the cecal and colic arteries and complete occlusion of these may be followed by gangrene of a segment of intestine. Similar lesions of arteritis may be present at the base of the aorta. Spontaneous rupture of the vessel occasionally occurs. A significant correlation has been reported between lesions in the proximal aorta and the presence of focal ischemic lesions in the myocardium. These are thought

to be caused by microembolization causing arteriosclerotic lesions in the myocardial arterioles.

Larvae of *S. edentatus* cause hemorrhagic tracts and nodules in the liver and adhesions and disruptions of omental architecture. Hemorrhagic nodules 1 to 3 cm in diameter are produced in the subperitoneal region, and these are reported to cause colic and anemia.

DIAGNOSTIC CONFIRMATION

A specific diagnosis is difficult to achieve in every case. Few clinical observations or laboratory results are pathognomonic for the disease syndromes associated with strongyle infection. Often a judgment has to be made on an overall appraisal of clinical history, presenting signs, and laboratory findings. For example, only 7 of 14 cases of larval cyathostominosis were diagnosed antemortem in a series of adult horses with chronic diarrhea investigated at university referral clinics.

A diagnosis of general strongylosis should be considered when poor growth, inappetence, diarrhea, and some degree of anemia are the presenting signs. It is generally accepted that strongylosis is an important cause of anemia in horses. Fecal egg counts are generally high (over 800 epg) but are difficult to interpret. They have little direct correlation with worm burden because they are influenced by immunity and species composition. Also, they do not differentiate between different strongyle genera or between these and *Trichostrongylus axei* infection of the stomach. In foals, eggs observed during the first few weeks of life are obtained by coprophagia and are not indicative of a patent infection.

The diagnosis of verminous arteritis also presents difficulty. The thickening of the cranial mesenteric artery may be palpable *per rectum;* the artery is situated below the aorta at the level of the posterior pole of the kidneys. Low serum albumin and increased β-globulins, particularly IgG(T), are the most useful laboratory tests, and arteriography may demonstrate lesions in a number of arteries. Transrectal ultrasonography may also be useful.

In larval cyathostominosis marked weight loss, diarrhea, leukocytosis, microcytosis, hyperglobulinemia, elevated serum fibrinogen, and hypoalbuminemia are usually seen.[6] Peripheral edema is present in a proportion of cases. Fecal egg counts may be low or zero because it is the immature stages that cause this disease, and owners have often wormed the animal before advice is sought. Consequently, species-specific serologic diagnostic tests using larval antigens are being investigated.[7,8] Additionally, experimental PCR assays targeting the intergenic spacer region of ribosomal DNA have been developed for the identification of cyathostomin larvae at species level.[9-11]

DIFFERENTIAL DIAGNOSIS

General strongylosis:

- Other causes of anemia in the horse, including:
  - Babesiosis
  - Equine infectious anemia
  - Dietary deficiency in stabled stock and the effect of racing for long periods
- Other causes of ill-thrift in horses, including:
  - Ascariosis in the foal
  - Gross nutritional deficiency or agalactia in the mare

Larval cyathostominosis:

- Other causes of chronic diarrhea including:
  - Other parasitic infections, particularly migratory strongyles
  - Granulomatous enteritis
  - Alimentary neoplasia
  - Salmonellosis
  - Chronic liver disease
  - Peritonitis
  - Sand enteropathy
  - Hyperlipidemia

TREATMENT

TREATMENT AND PROPHYLAXIS

Treatment and prophylaxis

Ivermectin (0.2 mg/kg, orally) (R1)

Moxidectin (0.4 mg/kg, orally) (R1)

Febantel (6 mg/kg, orally) (R3)

Mebendazole (10 mg/kg, orally) (R3)

Oxibendazole (10 mg/kg, orally) (R3)

Prophylaxis

Ivermectin (0.2 mg/kg orally every 8–10 weeks) (R3)

Moxidectin (0.4 mg/kg orally every 13–16 weeks) (R3)

Oxibendazole (10 mg/kg orally every 4–6 weeks) (R3)

Febantel (6 mg/kg orally every 4–6 weeks) (R-3)

Mebendazole (5–10 mg/kg orally every 4–6 weeks) (R3)

Treatment may be targeted against immature and adult large and small strongyle worms in the lumen of the intestine, against migrating *Strongylus* larvae, particularly *S. vulgaris,* or against cyathostomin larvae in the intestinal mucosa. The latter may be developing third- or fourth-stage, or hypobiotic early third-stage larvae. Anthelmintics vary in their efficacy against these larval stages. This influences the egg reappearance period (i.e., the time from treatment to the reappearance of eggs in the feces as new adult worm populations establish). This in turn determines the treatment interval in control programs.

For elimination of adult worms there is a wide choice of compounds and formulations for use in feed, as pastes, or by tubing. Most of these, however, belong to just three chemical groups that are administered orally:

1. *Avermectin/milbemycins,* also known as macrocyclic lactones (ivermectin 0.2 mg/kg, moxidectin 0.4 mg/kg)
2. *Benzimidazoles* (febantel 6 mg/kg, mebendazole 5–10 mg/kg, oxibendazole 10 mg/kg)
3. *Tetrahydropyrimidines* (pyrantel 19 mg pyrantel embonate [pamoate]/kg or 6.6 mg pyrantel base/kg)

In both Europe and North America, a high prevalence of cyathostomin populations resistant to the benzimidazoles and pyrantel has been reported.[12] Cyathostomin resistance to fenbendazole is ubiquitous in many regions, and this anthelmintic is now not recommended for use to control cyathostomins.[13-17] There are also reports of emerging resistance to macrocyclic lactones (both ivermectin and moxidectin).[18,19] Where resistance to any of the three groups is a problem, the choice of effective anthelmintics can be extended by use of products containing piperazine, which may be synergized with phenothiazine. An alternative is the cautious use of selected organophosphorus compounds such as dichlorvos or haloxon (which should not be given to foals).

Mucosal cyathostomin larvae are more problematic. Publications on this topic are difficult to interpret because results may be influenced by experimental design and methodology. Moxidectin 0.4 mg/kg orally has activity against hypobiotic and developing third-stage larvae as well as the fourth stage. Consequently, this compound has a prolonged egg reappearance period allowing a treatment interval of 13 weeks for prevention of egg output onto pasture. Ivermectin seems at best to be variable in its activity against mucosal stages, and a treatment interval of 8 to 10 weeks is generally recommended. Other anthelmintics at adulticidal doses have little or no effect on mucosal cyathostomin larvae, and treatment intervals of 4 to 6 weeks are necessary during periods of heavy pasture challenge.

Migrating *S. vulgaris* and *S. edentatus* can be controlled with ivermectin 0.2 mg/kg orally or fenbendazole at 60 mg/kg orally (single dose) or, more reliably, 7.5 mg/kg orally daily for 5 days. In cases of verminous arteritis, it may take some months after removal of the parasites for the lesion to resolve.

CONTROL

Eradication of all horse strongyles is not feasible, because infections are ubiquitous and no drug currently available can completely eliminate the mucosal larvae. Adult horses can pass substantial numbers of eggs throughout their lives; stocking densities are often high and foals usually graze with their dam. Infective larvae on grass can be long lived and there are usually few opportunities for the long-term resting or reseeding of

pastures on horse farms. Consequently, the primary objective of control programs is to minimize the numbers of infective larvae accumulating on pasture. There is no pasture treatment that is economically or environmentally acceptable. The possibility of using nematophagous fungi that will destroy larvae in the feces is an exciting prospect. Options for control by grazing management are limited. Alternate or mixed grazing with ruminants can reduce pasture infectivity, as horse strongyles will not establish in these hosts. The stomach worm *T. axei,* however, is a shared parasite. Removal of all horse feces from fields twice weekly is highly effective provided heavy rainfall does not disperse the material. This approach can be cost-effective where valuable animals are at risk or labor is relatively inexpensive. Tractor-mounted mechanical devices are available for this purpose. A further benefit of fecal removal is that the area within the field grazed by the horses is enlarged, i.e., the ratio of lawn to rough increases. Harrowing is effective in hot, dry conditions when eggs and larvae are quickly desiccated, but at other times is likely to have a deleterious effect by spreading infective larvae.

Prophylactic chemotherapy is used to a greater or lesser extent at most stables because land and labor constraints often limit the effectiveness of nonchemical approaches. The latter should, nevertheless, be used wherever possible to minimize the number of treatments needed during the year, which in turn reduces the risk of development of anthelmintic resistance. The purpose of prophylactic chemotherapy in the control of strongylosis is to prevent the output of strongylid eggs onto the pasture. Under conditions of heavy pasture challenge, regular dosing at 4 to 6 weeks with benzimidazoles (other than fenbendazole), 8 to 10 weeks with ivermectin, or 13 to 16 weeks with moxidectin is necessary throughout the period of risk. Once pasture larval counts have been reduced to insignificant levels, the time between doses can be extended. Routine fecal egg counts are an important component of any control strategy because they are a direct measure of the rate at which pasture contamination is taking place. They also confirm the continuing efficacy of the drugs used and can be used to determine optimum treatment intervals.

Parasitism is a herd problem and all horses on a property should be treated simultaneously, even if they have different owners. If routine fecal examinations are performed, dosing can be restricted to those horses with significant egg counts. Untreated animals then provide parasite refugia for conserving anthelmintic efficacy. As horses and ruminants generally harbor different worm parasites, disease risk can be reduced by grazing these species together or by alternating the use of paddocks between each species. As most eggs are deposited on the pasture in spring and summer in temperate regions, concentration of treatments at this time should reduce contamination and give much lower pasture larvae counts in the following autumn and winter. Intensive treatment programs are often adopted on stud farms, where maximum reduction of contamination is required. Less frequent dosing may be necessary on properties with lower stocking intensities or where horses are run with other stock. As the mare is the main source of contamination for the foal, she should be treated about 2 months before foaling, again at foaling, and regularly thereafter. Treatment of foals should commence at 10 weeks of age to remove small strongyles before they start to lay eggs and should be repeated at intervals, depending on the choice of drug.

Delaying the onset of resistance is an important consideration in the design of any control program. The major equine anthelmintics belong to just three chemical groups and worm populations resistant to one compound are usually insusceptible to, or more tolerant of, the effects of others in that chemical group. The level of resistance in a herd can be estimated by means of the **fecal egg count reduction technique**. At least six horses with high egg counts are weighed (e.g., with a weigh band) and treated with an accurately measured dose of anthelmintic. A reduction in mean egg count after 7 to 14 days of less than 90% is suggestive of resistance. More stringent tests are required for confirmation. Recommendations for extending the useful life of existing products similar to those listed earlier for ruminants have been published for horse anthelmintics.

OXYURIS EQUI (PINWORM)

Oxyuris equi is a nematode that provokes irritation of the perianal region of horses, causing them to rub and bite their tails. This can result in hair loss and sometimes physical damage to the tissues of the area. The parasite is ubiquitous but of greater prevalence in areas of high rainfall.

The life cycle is direct. The mature worms are gray in color and inhabit the cecum and colon. The male is 1 to 2 cm long, but the female is much longer, up to 15 cm, and has a long tapering tail. When full of eggs, the female migrates down the gut and crawls onto the perianal area, where she exudes her eggs onto the skin in yellow clusters and then shrivels up and dies. An embryo develops in about 3 days within the egg, which is then infective. Eggs may be licked off the skin and swallowed or they may eventually fall to the ground. They resist desiccation, may become airborne in dust, and remain viable in stables for long periods. Transmission then occurs via contaminated feedstuffs.

Diagnosis is by detection of operculated eggs, slightly flattened on one side, on transparent adhesive tape that has been pressed against the perianal skin and then placed on a microscope slide for examination or by the chance observation of an adult worm in the feces.

TREATMENT AND PROPHYLAXIS
Treatment
Ivermectin (0.2 mg/kg, orally) (R1)
Moxidectin (0.4 mg/kg, orally) (R1)
Pyrantel (13.2 mg/kg, orally) (R1)
Febantel (6 mg/kg, orally) (R1)
Mebendazole (10 mg/kg, orally) (R1)
Oxibendazole (10 mg/kg, orally) (R1)

Treatment comprises the application of a mild disinfectant ointment to the perianal region and the administration of ivermectin, moxidectin, pyrantel, and any of the newer broad-spectrum benzimidazoles at the standard dose rate for horses.[1] Piperazine salts are also effective. However, recent studies in Europe and the United States have found that *O. equi* resistance to ivermectin and moxidectin is emerging.[2,3]

STRONGYLOIDES (THREADWORM)

Farm animals in many countries are exposed to infection with the nematode genus *Strongyloides.* Disease outbreaks occur in young pigs, foals, calves, and lambs, but the overall economic importance of this parasite does not appear to be very great. Different species occur in each host: *S. ransomi* in pigs, *S. westeri* in horses, and *S. papillosus* in sheep and cattle. All are parasites of the small intestine. They are threadlike and less than 1 cm in length.

Only female worms are present in the intestine, so eggs are produced by parthenogenesis. The eggs are thin shelled and contain an embryo. The larvae that hatch out may develop into infective or nonparasitic forms. The latter become free-living males and females that live in decaying organic material and produce fertilized eggs that give rise to infective larvae. Transmission occurs when infective larvae enter the host either by ingestion or by skin penetration. In older animals they accumulate in subcutaneous tissues and migrate to the mammary gland when lactation starts. Thus neonates are infected via milk, and egg-laying females may be present in the intestine from about 1 week after birth. Infective larvae penetrating the skin of young animals travel via the blood to the lungs, where they break into alveoli, ascend the air passages to the pharynx, and are then swallowed.

Diarrhea in young animals is the most common clinical sign, but the passage of massive numbers of larvae through the skin may also provoke dermatitis. Experimental infections in calves cause pallor and coughing, but cases of sudden death without previous symptoms have been ascribed to heavy burdens with many migratory larvae. In bulls, balanoposthitis may be seen. In lambs, dermatitis, pulmonary hemorrhage, and enteritis occur. Sheep may also develop lameness or be more susceptible to foot rot when subject to heavy infestations. Experimental infection of young goats produced transient diarrhea, dehydration, cachexia, gnashing of teeth, foaming at mouth, anemia, and nervous signs. Pigs may show anorexia, listlessness, and anemia but diarrhea is the principal clinical sign. Infestation in pigs has been shown to reduce intestinal enzyme activity, to increase intestinal plasma and blood loss, and to reduce protein synthesis in the liver. In foals, high egg counts may be recorded in apparently healthy animals but may coincide with the onset of diarrhea (independent of the first heat of the mare) in other individuals. Episodes of frenzy in foals lasting approximately 30 minutes have been attributed to percutaneous larval invasion. Within 2 days skin lesions developed on the lower limbs that persisted for 2 to 3 weeks. Experimental PCR assays targeting the 18S ribosomal DNA sequence have been developed for species-specific identification of *Strongyloides* species.[1]

TREATMENT AND PROPHYLAXIS

Treatment

Pigs

Ivermectin (0.1 mg/kg, orally) (R1)[2]

Abamectin (0.1 mg/kg, orally) (R1)[2]

Moxidectin (0.4 mg/kg, orally) (R1)

Foals

Ivermectin (0.2 mg/kg, orally) (R1)

Moxidectin (0.4 mg/kg, orally) (R1)

Oxibendazole (15 mg/kg, orally) (R3)

Sheep

Combination of derquantel (2 mg/kg, orally) and abamectin (0.2 mg/kg, orally) (R1)[3]

Most broad-spectrum anthelmintics are effective in eliminating this parasite. In foals, ivermectin is used at the standard equine dose, but elevated doses of oxibendazole (15 mg/kg) are needed. The treatment of mares with ivermectin on the day of parturition did not prevent transmammary transmission but markedly reduced egg counts in the foals. Treatment of infected sows was effective in removing arrested larvae from the subventral fat. In sheep derquantel, which belongs to a new class of anthelmintics called spiroindoles, when used in combination with abamectin, has been shown to have consistently high efficacy against *Strongyloides* infections.[3]

Control depends on the elimination of warm, moist areas such as damp litter or bedding, which is suitable for parasite multiplication.

TRICHURIS (WHIPWORM)

Three species of whipworms are found in ruminants: *Trichuris ovis, T. discolor,* and *T. globulosa,* whereas *T. suis* occurs in pigs. Whipworms in farm livestock are usually considered to be relatively innocuous. Indeed, induced *T. suis* infections are being evaluated in human medicine for amelioration of chronic inflammatory bowel disease, because whipworm-induced Th2 immune responses dampen harmful Th1 activity in some patients.[1] Heavy infestations can, nevertheless, produce serious disease with diarrhea and dysentery, and the mortality rate can be high in recently weaned pigs. Severely affected animals are anorexic and rapidly lose weight. The feces may contain bloodstained mucus and strips of necrotic mucosa. The nematodes lie with their thin anterior end superficially embedded in the wall of the cecum, and in heavy infections the colon may also be involved. The activities of the worms produce little tissue reaction per se but enable microorganisms in the gut microflora to become invasive. This is the main cause of the severe inflammation and clinical signs associated with whipworm infestation. A synergy has also been demonstrated between *T. suis* and *C. jejuni.*

The life cycle of the whipworm is direct. The eggs are very resistant to external environmental conditions and can survive for up to 6 years in old pigsties, and for at least 2 years on pasture in the south of England. An infective larva develops inside the egg, but a relatively high temperature is required for rapid growth. In temperate climates, embryonation of *T. suis* eggs may take more than 1 year. When swallowed by a suitable host, the eggs hatch and develop to mature adults in about 12 to 20 weeks after infection in lambs and goats and 6 to 7 weeks in pigs.[2] The disease in sheep is most common after hot, dry weather, which effectively cleanses the pasture of other nematode larvae, but the resistant *Trichuris* spp. eggs survive and are ingested when the sheep eat close to the ground to obtain grain given as drought feed.

Diagnosis depends on detection in the feces of the yellow oval eggs, which have a transparent plug at each end. The eggs are heavier than many others and do not always float well in saturated salt (NaCl) solution. An alternative flotation fluid such as zinc sulfate or sugar is more reliable. At necropsy, the adult worms, which are 2 to 5 cm long, are easily recognized by their whiplike appearance—the anterior third is much thinner than the handle-like posterior end.

TREATMENT AND PROPHYLAXIS

Treatment

Ivermectin (0.1 mg/kg orally every 24 hours for 7 days) (R2)[3]

Abamectin (0.1 mg/kg orally every 24 hours for 7 days) (R2)[3]

Oxfendazole (30 mg/g orally) (R2)[4]

Chemotherapy

Low uptake of benzimidazoles by *Trichuris* worms is responsible for low pharmacologic efficacy of this class of anthelmintics against *Trichuris* infestations.[5] Therefore dosages that are five times higher than recommended are used to treat *Trichuris* infestations.[6] Similarly, high efficacy of ivermectin and

abamectin is achieved when they are administered repeatedly for seven consecutive days.[3]

PARASITIC GASTRITIS IN PIGS

SYNOPSIS

Etiology The nematodes *Hyostrongylus rubidus*, *Ascarops*, and *Physocephalus*

Epidemiology Infections occur in outdoor husbandry systems; *H. rubidus* has a direct life cycle, but *Ascarops* and *Physocephalus* use dung beetles as intermediate hosts.

Signs Generally asymptomatic but heavy infections can produce gastritis; sows with *H. rubidus* may become thin during lactation.

Clinical pathology Eggs of *Ascarops* and *Physocephalus* in feces are characteristic; those of *H. rubidus* are similar to *Oesophagostomum*.

Lesions Excess mucus; gastritis; often ulceration of glandular part of stomach; nodular hyperplasia in hyostrongylosis

Diagnostic confirmation Demonstration of eggs of *Ascarops* or *Physocephalus*; examination of larvae from fecal culture for *H. rubidus*

Treatment

H. rubidus: Doramectin, abamectin, ivermectin, fenbendazole, flubendazole, febantel, oxibendazole, thiophanate, levamisole, and dichlorvos

Ascarops: Ivermectin

Control Good husbandry practices, such as rotating pastures, normally suffice.

ETIOLOGY

Three categories of nematode inhabit the stomach of the pig. The first is a trichostrongylid, *Hyostrongylus rubidus.* This is closely related to the *Ostertagia* spp. of ruminants and occurs in most countries where pigs are kept. The next group comprises members of several related genera including *Ascarops strongylina, A. dentata,* and *Physocephalus sexalatus,* which occur in the United States, Southeast Asia, and Australia, and *Simondsia paradoxa,* found in parts of Europe and India. Finally, *Ollulanus tricuspis* is a very small nematode (0.7–1.0 mm) that causes gastritis on rare occasions in pigs, cats, foxes, and dogs.

LIFE CYCLES

H. rubidus is a small (0.5–1.25 cm) thin, red worm with a life cycle very similar to that of *O. ostertagi.* Eggs develop at temperatures between 10°C and 27°C (50°F and 80°F). In the UK, eggs deposited outdoors from May to October develop into infective larvae. These larvae survive on pasture for up to 10 months but are rapidly killed by desiccation and by freezing. Transmission occurs by ingestion of the infective larvae, which spend the next 13 to 14 days in the gastric glands. They then return to the lumen, and the first eggs are passed 20 to 25 days after infection. In some circumstances larvae become hypobiotic and remain in the gastric mucosa for several months.

Ascarops and *Physocephalus* are thick, white worms 1 to 2.5 cm long. They have indirect life cycles; eggs passed in the feces of the pig are eaten by dung beetles, in which hatching and development to infective larvae occur. Infestation of the final host occurs when pigs eat infested beetles. Little is known of the biology of *Simondsia paradoxa.*

EPIDEMIOLOGY

The stomach worms of pigs are almost exclusively confined to outdoor management systems. The reason for this is different in each group. With *Ascarops* and *Physocephalus,* it is a consequence of the essential role of the dung beetle in the life cycle. With *H. rubidus,* it is because the daily output of eggs by each female is so sparse that the life cycle is unlikely to persist in pig houses practicing a reasonable standard of hygiene. Young pigs are the most susceptible to hyostrongylosis but adult sows, especially when lactating, may also be affected. Hypobiosis is seasonal, but disease outbreaks analogous to type II ostertagiosis have not been reported.

PATHOGENESIS

Developing *H. rubidus* provokes hyperplastic nodular lesions in the glandular part of the stomach. These and consequent biochemical and physiologic sequelae are similar to those described for *O. ostertagi. Ascarops* and *Physocephalus* lie close to the gastric mucosa where they stimulate excessive mucous production. Heavy infections cause a catarrhal gastritis.

CLINICAL FINDINGS

The effect of *H. rubidus* on young pigs is not usually clinically apparent. Heavy infestations may be associated with anemia, unthriftiness, poor growth, and diarrhea. Signs in adult sows are usually seen during lactation. Affected animals lose more weight than normal and are slow to regain condition after weaning. In severe cases, sows may become emaciated. There may be pallor caused by anemia and often a depraved appetite, but no diarrhea. Adult sows often carry heavy infestations without clinical illness, but sudden death caused by hemorrhage from gastric ulcers or to peritonitis by ulcerative perforation has been observed on rare occasions.[1] Although *Ascarops* and *Physocephalus* are common in many areas, most infections are low grade and without clinical effect. Heavy infections can lead to inappetence and other signs of gastritis.

CLINICAL PATHOLOGY

Fecal examination is not very useful for the diagnosis of hyostrongylosis, because the eggs of *H. rubidus* are indistinguishable from those of the less pathogenic but more prolific *Oesophagostomum* spp. *Physocephalus* and *Ascarops* spp. eggs are small, thick shelled, and contain a larva when laid.

NECROPSY FINDINGS

The presence of *H. rubidus* is easily missed as the worms are slender and often lie beneath a thick layer of mucus. Adult worms are <10 mm in length and are bright red when first removed from the host. The gastric mucosa is hyperemic and nodular lesions are present. There may be one or more deep ulcers in the glandular region of the stomach. These may contain clusters of adult *H. rubidus.* In severe cases the mucosa is thickened and edematous and covered with a diphtheritic pseudomembrane.[1] In *Physocephalus* and *Ascarops* infections, adult worms are readily visible lying in mucus on the gastric mucosa. There is an obvious gastritis in heavy infections and ulceration may occur.

DIAGNOSTIC CONFIRMATION

Confirmation of infection with *H. rubidus* is made by examination of larvae from fecal cultures. Those of *H. rubidus* are longer and more vigorously motile than those of *Oesophagostomum* spp. As *H. rubidus* produces so few eggs, even small numbers of larvae may indicate a pathogenic worm burden. Elevated serum pepsinogen concentrations may also be indicative of infection.

DIFFERENTIAL DIAGNOSIS

Hyostrongylus rubidus must be differentiated from other causes of unthriftiness or emaciation such as:

- Swine dysentery
- Necrotic enteritis
- Coccidiosis
- Infestation with *Oesophagostomum* spp.
- Thin sow syndrome
- Malnutrition

TREATMENT

TREATMENT AND PROPHYLAXIS

Treatment

Doramectin (0.3 mg/kg, IM) (R1)

Abamectin (0.1 mg/kg of feed/day for 7 days) (R1)[2]

Continued

Ivermectin (0.3 mg/kg BW by SC or IM injection or 0.1 mg/kg of feed/day for 7 days) (R2)[3]

Fenbendazole (5 mg/kg BW in feed as a single dose or divided over 7–14 days) (R3)

Flubendazole (5 mg/kg BW as a single dose or 30 g/tonne finished feed given for 5–10 days) (R3)

Febantel (5 mg/kg BW) (R4)

Oxibendazole (15 mg/kg BW or 1.6 mg/kg BW/day for 10 days) (R4)

Doramectin, abamectin, ivermectin, fenbendazole, and flubendazole are active against fourth-stage and adult *H. rubidus*. Febantel, oxibendazole, and thiophanate have label claims only for the adult worms. Levamisole and dichlorvos have also been widely used in the treatment of pig nematodes. In-feed ivermectin is also effective against *A. strongylina*.

CONTROL

Standard hygienic precautions including frequent removal of manure, the provision of drainage in outside pens, and rotation of pastures will reduce environmental contamination. Control of the dung beetle intermediate hosts of *Physocephalus* and *Ascarops* is impracticable.

Hyostrongylosis is most likely to affect sows during lactation, so animals at risk should be dosed before farrowing. The behavior of *H. rubidus* larvae on pasture is similar to that described for *Oesophagostomum,* and control schemes should be effective for both parasites.

GASTEROPHILUS SPP. INFESTATION (BOTFLY)

Infestations with larvae of *Gasterophilus* spp. have a widespread distribution. They cause a chronic gastritis and a loss of condition in infested horses, donkeys, and mules. Reduced performance is often attributed to this infestation. On rare occasions they cause perforation of the stomach and death.

SYNOPSIS

Etiology Six species of *Gasterophilus* spp. that inhabit the gastrointestinal tract of horses

Epidemiology Eggs are laid on the hair of the body or around the lips; eggs hatch spontaneously or are stimulated to hatch by oral grooming, larvae penetrate oral mucosa or external epithelium of cheek and migrate to inner regions of mouth, and congregate at epithelial surface around teeth for 6–10 weeks before migration to the stomach and intestine. Larvae attach in stomach or intestine and remain there for a number of months before being passed in the feces. One species attaches near the rectum. Larvae pupate and adults emerge after 3–5 weeks. Adults only live a few days and are mainly active in the summer, and the larvae overwinter in the stomach.

Clinical signs Adult flies frighten horses and larvae cause nonspecific signs of unthriftiness.

Clinical pathology Eggs can be seen on hairs on legs or around the lips by direct inspection.

Lesions Area of larval attachment is pitted and the gastric wall may be thickened.

Diagnostic confirmation Eggs present on hairs, and there are characteristic lesions at autopsy.

Differential diagnosis Unthriftiness usually caused by helminth infection

Treatment Ivermectin, moxidectin

Control Treatment given when fly activity has ceased and when larvae are in stomach, usually two treatments in mid and late winter. Fringes and tassels protect against worry associated with one species of fly

ETIOLOGY

Six species of flies have larvae that are known to parasitize domestic equids: *Gasterophilus nasalis, G. intestinalis, G. haemorrhoidalis, G. pecorum, G. nigricornis,* and *G. inermis.* Their larvae are the "stomach bots" of horses, donkeys, and mules. Three species, *G. intestinalis, G. nasalis,* and *G. haemorrhoidalis,* are the most important and have a worldwide distribution, although *G. pecorum* is noted as becoming more important, particularly in parts of Asia and in the UK.[1,2] The later larval stages inhabit the stomach and duodenum. These creamy pink larvae are thick, segmented, and about 5 to 15 mm long. The adult flies are golden brown, hairy, and about the size of a bee, with two wings and vestigial mouth parts.

LIFE CYCLE AND EPIDEMIOLOGY

Flies do not feed and only live a few days. They are active during the summer months and there may be overlap among the species in their periods of activity. In areas with mild winters the flies may be active throughout the year. In colder regions fly activity ceases with the first frost, and there is usually only a single generation per year. In these regions the second and third instars remain in the stomach over the winter.

Eggs are attached to hairs while the fly hovers close to the horse. Fecundity is roughly correlated to the size of the fly. *G. haemorrhoidalis* matures about 50 to 200 eggs, *G. nasalis* 300 to 500 eggs, and *G. intestinalis* up to 1000. Eggs of the various species are laid in specific locations and are attached in a specific manner, allowing identification of eggs to species. The eggs are laid on the horse's coat except for *G. pecorum,* which lays up to 2000 eggs in batches of 100 to 200 on pasture plants. The eggs of *G. pecorum* and *G. haemorrhoidalis* are dark brown; the eggs of the others are yellow and are readily visible glued to the hairs, usually one to a hair. The eggs of *G. intestinalis,* the most common fly, are laid on the front legs, particularly the lower parts; those of *G. nasalis* in the intermandibular area; and the others species' eggs are laid on the cheeks and lips.

The eggs are ready to hatch in about 2 to 10 days, and the first instars enter the mouth either by host biting or licking or by subcutaneous migration from the cheeks into the oral cavity. The eggs of *G. intestinalis* and *G. pecorum* require a stimulus, provided by licking (moisture) or rubbing (friction), before they will hatch. The larvae penetrate oral mucosa, migrate to inner surfaces, and emerge in the interdental spaces. The larvae of *G. intestinalis* penetrate the anterior end of the tongue and burrow in the buccal mucosa for about 3 to 4 weeks before invading pockets between the teeth or between the gum and molars. *G. nasalis* may also accumulate in pockets alongside the molar teeth and cause mouth irritation. *G. haemorrhoidalis* can penetrate the skin of the cheek and after wandering in the tissues of the mouth may attach in the pharynx. The second instar of *G. intestinalis* may also attach for a few days to the pharynx and the sides of the epiglottis before passing to the stomach. The first instars of *G. pecorum* burrow into the mucous membranes of the hard palate, cheek, and tongue where they develop into second instars. They then move to the pharynx where they develop into the third instar. Occasional larvae migrate to abnormal sites including the brain, the cranial sinuses, the heart, and lungs.

Third instars of *G. intestinalis* larvae are found attached to the mucosa, usually in bunches, at the junction of the glandular and nonglandular portion of the stomach, where they become attached to the mucosa. *G. nasalis* larvae are found in the pyloric region of the stomach and the duodenum. *G. pecorum* larvae may be found in the pharynx and upper part of the esophagus and in the fundus of the stomach. *G. haemorrhoidalis* larvae are found in the tongue, the pharynx, and the gastric fundus.

In the host, two molts are made and the larvae pass out in the droppings 10 to 12 months after infestation, usually in the spring and early summer. Some larvae may attach temporarily to the rectal mucosa on their way through. The larvae migrate into the ground, pupate, and adult flies emerge after 3 to 5 weeks to recommence the late summer attacks on horses.

PATHOGENESIS

The adult fly causes considerable annoyance when ovipositing. The droning noise and the sudden attacks to lay eggs cause head tossing

and running in the host. *G. nasalis* is particularly troublesome because it darts at the lips and throat.

There is some doubt as to the importance of the lesions caused by the larvae. At the sites where they adhere there is an area of thickening and inflammation, and in rare cases gastric perforation occurs. It is probable that there is some chronic gastritis and interference with digestion in most infestations. *G. intestinalis,* the most common species, attaches to the squamous epithelium, and this has a relatively slight impact on the digestion in the horse. However, the ulceration, edema, and abscessation caused by this species cannot be overlooked, and one must expect some effect from such lesions, although it is difficult in practice to separate these findings from those caused by a concurrent worm burden. Occasional perforation of the gut has been documented The larvae do not remove sufficient blood to cause anemia, feeding mostly on tissue exudate. In rare cases pleurisy may occur following perforation of the esophagus close to the cardia. In very heavy infestations with *G. pecorum* the presence of large numbers of larvae (100–500) on the soft palate and base of the tongue can cause stomatitis and some deaths. Migration of first instars in the tongue and interdental gingiva and the aggregation of larvae in periodontal pockets may produce irritation or pain and may prevent foals from eating.

A recent proteomic analysis using two-dimensional (2D) gels and other techniques has described the influence of larvae on the development of immune responses.[3] Novel antigens that were identified could be developed as a vaccination for a control option.

CLINICAL FINDINGS

A nonspecific syndrome of unthriftiness, poor coat, occasional mild colic and lack of appetite, plus bad temper and unwillingness to work is usually ascribed to bot infestations. Adult flies frighten horses by their hovering, darting flight, especially around the head of the horse, and may be a cause of shying and balking.

CLINICAL PATHOLOGY

The eggs on the hairs can be seen by direct inspection, but the presence of larvae in the stomach and intestines can only be detected after treatment with a suitable insecticide.

NECROPSY FINDINGS

A few larvae are present in the stomach of most horses at necropsy, but clinical illness is usually associated with very large numbers. The areas of larval attachment are pitted and the gastric wall thickened. There may be an adhesive peritonitis and attachment and abscessation of the spleen over such areas.

DIAGNOSIS

The syndrome produced is not sufficiently characteristic to make antemortem diagnosis possible, and bot infestations are commonly associated with helminth infestations, which produce most of the signs observed. A tentative diagnosis of infestation of the gums can be made by signs of pain on mastication and the presence of botfly eggs on the horse at that time. A variety of serologic tests, including an ELISA, have been evaluated and found to be generally specific and sensitive. There has been no further development of a practical test. Endoscopy using an video gastroscope has been applied to the diagnosis of gasterophilosis, although its use has been confined to use in drug efficacy studies.

TREATMENT

Macrocyclic lactone-based compounds administered as a paste are the most effective products for treatment.

CONTROL

Treatment should be administered after fly activity has ceased and the larvae have reached the stomach but before gastric damage has occurred. Single treatments are usually all that is required for control. Recent combination therapies containing a macrocyclic lactone plus praziquantel are used for control of gastrointestinal worms, tapeworms, and bots in a single dose. In foals showing pain on mastication, treatment with ivermectin paste should be given as needed throughout the fly season.

Treatment Recommendations

Treatment with a macrocyclic lactone-based product is strongly advised to increase productivity and to maintain overall health of the animals.

THORNY-HEADED WORM IN PIGS (*MACRACANTHORHYNCUS HIRUDINACEUS*)

Macracanthorhynchus hirudinaceus is included with other nematodes for convenience, but it is not a nematode. It belongs to a different phylum, the acanthocephalans. These resemble roundworms in appearance but in some ways are more similar to tapeworms because they lack, for example, a digestive tract. The name "thorny-headed worm" denotes the hook-covered proboscis they all possess.

M. hirudinaceus infestations in pigs are not usually heavy and cause relatively little loss. The worms have thick bodies (0.5–1.25 cm), are long (up to 38 cm), and are transversely wrinkled. They inhabit the small intestine and pass eggs that are very resistant to environmental stress and survive for up to 2 years. The life cycle is indirect with a variety of beetles acting as intermediate hosts. Transmission occurs when a pig eats an infested grub or adult beetle, and eggs are passed about 2 to 3 months later. The female worm is a prolific egg layer and lives in the host for about 1 year.

Heavy infestations cause slow growth or loss of BW. The head of the worm pushes deeply into the intestinal mucosa and causes nodules that are clearly visible from the serous surface. Occasional deaths may occur because of intestinal perforation. Sedimentation techniques are better than flotation methods for detecting eggs in feces. Treatment is rarely given because the condition is usually only diagnosed at necropsy.

TREATMENT AND PROPHYLAXIS
Treatment Ivermectin (0.1 mg/kg orally every 24 hours for 5 days) (R3)

A single dose of doramectin is only partly effective. Control, if necessary, involves suitable disposal of pig manure and avoidance of contact with the intermediate hosts (beetles).

TAPEWORM INFESTATIONS

LARVAL TAPEWORM INFESTATION

Livestock may act as the intermediate hosts for the tapeworms of humans and other animals. The larval tapeworms (metacestodes) develop as fluid-filled cysts, each at a typical site in the body. They act as space-occupying lesions and cause condemnation at meat inspection. Cattle around the world may harbor the metacestode of *Taenia saginata* (the beef tapeworm of humans), also known as *Cysticercus bovis,* in their striated musculature. *T. solium* (the pork tapeworm of humans) occurs similarly in pigs (known as *C. cellulosae*), mainly in poorer regions.[1] The recently discovered *T. asiatica,* found only in East Asia, is closely related to *T. saginata* but uses pigs as its intermediate host. Cysts in the musculature of sheep (known as *C. ovis*) are the intermediate form of a dog cestode (*T. ovis*). Hydatid cysts (*Echinococcus granulosus*), which develop in the lungs and/or liver of sheep, cattle, and horses, are also acquired from tapeworm eggs excreted by infected dogs and wild canids. These metacestodes rarely cause clinical disease in veterinary species (although some are serious zoonoses), so the reader is referred to parasitology textbooks for detailed information.

Clinical disease is, however, associated with two other metacestodes. *T.* (*Multiceps*) *multiceps* metacestodes cause coenurosis ("gid") in sheep,[1] which is described later. *T. hydatigena* metacestodes are normally asymptomatic, but if a sheep or goat swallows a whole tapeworm segment, which may

contain 100,000 eggs, sudden death may occur as massive numbers of developing metacestodes (known as cysticerci) migrate through the liver parenchyma. This condition (hepatitis cysticercosis) resembles acute hepatic fasciolosis but is an individual rather than a flock problem.

ADULT TAPEWORM INFESTATION

SYNOPSIS

Etiology Cestodes belonging to the anoplocephalid family, including *Moniezia* spp. in ruminants and *Anoplocephala* spp. in horses

Epidemiology Transmission by ingestion of infected free-living pasture (oribatid) mites

Signs Little pathogenicity but heavy infestation may cause failure to thrive and, in horses, increased risk of ileocecal colic.

Clinical pathology Demonstration of tapeworm eggs in feces

Lesions
- **Horse:** Mild inflammation of intestinal mucosa with small ulcers

Diagnostic confirmation Tapeworm segments around tail base or on feces; eggs in feces

Treatment
- **Ruminants**: Albendazole, febantel, fenbendazole, mebendazole, netobimin, oxfendazole, and praziquantel
- **Horses**: Pyrantel, praziquantel

Control If necessary, periodic dosing is the only feasible option.

ETIOLOGY

The common anoplocephalid tapeworms of ruminants, *Moniezia expansa, M. benedeni,* and *Thysaniezia* (syn. *Helictometra giardi* also known as *T. ovilla*) are cosmopolitan, whereas *Avitellina* spp. occur mainly in Mediterranean countries and India, *Stilesia hepatica* in Africa, and *Thysanosoma actinioides* in North America.

In horses, *Anoplocephala magna, A. perfoliata,* and Anoplocephaloides (syn. *Paranoplocephala mamillana*) are cosmopolitan in their distribution.

LIFE CYCLE

The life cycles of all the anoplocephalid tapeworms are very similar. Eggs, which are immediately infective, pass in the feces of the host, either singly or protected within a tapeworm segment. These are ingested by free-living pasture (oribatid) mites and the intermediate stage (the metacestode) forms. Mature tapeworms develop when the primary host accidentally swallows infected mites while grazing. Most species establish in the small intestine, but *T. actinioides* also invades biliary and pancreatic ducts, whereas *A. perfoliata* is found around the ileocecal junction and *S. hepatica* lives in the bile ducts. Lengths vary with species: *A. perfoliata* grows to 4 to 8 cm and *Moniezia* may be over 2 m.

EPIDEMIOLOGY

Oribatid mites are ubiquitous but most numerous on permanent pastures in the summer months. All grazing animals are therefore potentially at risk.

PATHOGENESIS

In ruminants, anoplocephalid tapeworms have little apparent effect on health. In heavy infestations, it has been postulated that they may compete for nutrients, excrete toxic materials or, because of their length, interfere with the motility of the gut. Very heavy burdens of *M. expansa* in lambs have been associated with outbreaks of enterotoxemia. Pancreatic and biliary duct species cause little harm, but liver damage may cause rejection at meat inspection.

In horses, *A. perfoliata* causes a mild local inflammatory response around its site of attachment. Where 20 or more tapeworms are clustered, ulceration and other degenerative changes may occur. This may be accompanied by diphtheresis, granulomatosis, and occasionally polyp formation. The ileocecal valve may be thickened. Heavy infestations may interfere with gut motility and increase the risk of ileocecal colic. A recent matched case-control study indicated that 22% of a series of spasmodic colic cases were likely to have been tapeworm associated. Evidence is accumulating to implicate *A. perfoliata* as a significant risk factor in ileal impaction cases.

CLINICAL FINDINGS

In ruminants, there is disagreement over the importance of anoplocephalid tapeworms in causing disease; farmers usually overemphasize their importance and veterinarians underestimate it. Most infestations are asymptomatic but, on occasion, heavy burdens may result in unthriftiness; poor coat; vague digestive disturbances including constipation, mild diarrhea, and dysentery; and sometimes anemia. These signs are restricted chiefly to animals less than 6 months of age on an inadequate diet. With *T. actinioides,* signs may be delayed until the animal reaches a later age. Infested animals may be more susceptible to the effects of other internal parasites and to other diseases or adverse environmental conditions.

Infections in horses are usually asymptomatic[1] but, occasionally, heavy infestations may be associated with a range of abdominal conditions including colic[2]; perforation of the cecum; ileocecal, cecocolic, and ileoileal intussusception; colonic and cecal torsion; and ileal thickening and obstruction.

CLINICAL PATHOLOGY

Shed tapeworm segments may be visible macroscopically on the skin and hair around the tail base or in the feces. Eggs may be present in feces.

NECROPSY FINDINGS

The site of attachment on the intestinal mucosa may be indicated by the presence of a small ulcer and a mild inflammatory response. In the case of infestations with *T. actinioides* and *S. hepatica,* the presence of worms in the biliary and pancreatic ducts is accompanied by fibrosis and thickening of duct walls. In horses, *A. perfoliata* can cause inflammation of the lamina propria and mucosal damage at the region of the ileocecal junction, and there is an association between the number of worms present and the severity of the histologic changes.[3,4] Significant gross thickening and fibrosis of the ileocecal junction and several changes in neuronal cells in horses have been observed where more than 20 tapeworms were present.[4]

DIAGNOSTIC CONFIRMATION

Shed segments are much wider than they are long. They can be seen to be full of characteristic eggs if broken in a drop of water on a slide and examined microscopically. Anoplocephalid eggs are roughly D shaped, thick shelled, and contain an embryo within a chitinous ring. They are not easy to find in feces. Centrifugation/flotation using a saturated sugar solution is recommended for diagnosis in horses. At best the sensitivity of such techniques is only 60% for light infections rising to 90% for heavy burdens, so repeat samples may be needed to demonstrate the presence of the parasite. Methods have been devised for detection of specific antibodies in serum or antigen in feces[5] but are not as yet generally available. Experimentally, a species-specific and highly sensitive molecular diagnostic PCR has been developed for accurate identification and diagnosis of *Moniezia* species targeting the parasites' 18S regions of the ribosomal DNA.[6-8] In equines an experimental multiplex PCR assay for simultaneous detection of various *Anoplocephala* spp. targeting the hypervariable SSUrRNA gene regions has been developed.[9]

DIFFERENTIAL DIAGNOSIS

- Other causes of unthriftiness
- In horses, other causes of colic

TREATMENT

TREATMENT AND PROPHYLAXIS

Treatment
Cattle
Praziquantel (5 mg/kg BW, orally) (R2)

Horses
Pyrantel (38 mg/kg) (R2)
Praziquantel (2.5 mg/kg BW, orally) (R2)

For ruminants, praziquantel 3.75 mg/kg is highly effective against *Moniezia*, but higher doses are required for *Thysaniezia* spp. (5 mg/kg), *Avitellina* (7.5 mg/kg), and *S. hepatica* (15 mg/kg). Some benzimidazole and probenzimidazole drugs have cestocidal activity in ruminants, including albendazole, febantel, fenbendazole, mebendazole, netobimin, and oxfendazole. The efficacy of some of these compounds against *Moniezia* may be variable. Albendazole at 7.5 mg/kg orally is effective against cestodes in the bile ducts.

For horses, pyrantel embonate at 38 mg/kg orally (i.e., double the standard dose for roundworm control) is an established treatment for *A. perfoliata* but is ineffective against *A. mammillana*. Although toxic effects have not been fully evaluated at this high dose rate, pyrantel is generally regarded as having low toxicity in herbivores when administered orally. More recently praziquantel has been shown to provide high efficacy against *A. perfoliata* at doses of 1 to 2.5 mg/kg BW orally and *A. mammillana*. Such treatment may half the estimated risk of tapeworm-associated colic.

Control

Control of the mites that act as intermediate hosts is impractical. If a potential problem is perceived in, for example, valuable horses, consideration could be given to reducing the numbers of oribatid mites by plowing permanent pasture and reseeding. Otherwise stabling or tactical dosing, in early summer and autumn, are the only options.

Toxins Affecting the Alimentary Tract

PHOSPHORUS TOXICOSIS

Poisoning from phosphorous-containing products rarely occurs anymore. Rodenticides, once a common source of phosphorus intoxication for animals, are no longer used, and current exposure occurs primarily from ingestion of old products found in abandoned sheds and buildings. Animals may also be exposed either by grazing on pastures or drinking water contaminated with white phosphorous used for military ammunitions training.[1,2] Occasionally, animal feeds inadvertently contain an excess concentration of dietary phosphates disrupting the Ca:P balance and causing clinical signs. In ruminants, this may result in urinary or bladder calculi, and in horses, secondary hyperparathyroidism.[3]

Phosphorus has a local caustic action, and ingestion is associated with severe irritation of the gastrointestinal mucosa with signs of gastroenteritis appearing within an hour or two. Some phosphorus may be absorbed and is associated with acute hepatic necrosis, but signs do not appear for several days. Toxic effects are increased when the phosphorus is finely divided and mixed with oils or fats that facilitate absorption.

CLINICAL FINDINGS

Common signs include salivation, acute abdominal pain, intense thirst, and diarrhea. Pigs vomit violently and the vomitus is luminous with a garlic odor. The animal often dies of acute shock during this stage. Survivors show jaundice, weakness, anorexia, oliguria, and hematuria. Death may occur suddenly or be accompanied by convulsions. Phosphorus can be detected in the vomitus and feces of affected animals.

NECROPSY FINDINGS

Macroscopically there is congestion and hemorrhage of the gastrointestinal mucosa. The carcass is often jaundiced and the liver is swollen and pale. Histologically there is fatty degeneration of both the liver and kidney, sometimes accompanied by hepatic necrosis. The acute stages of phosphorus poisoning may appear similar to acute stages of inorganic arsenic, mercury, or selenium poisoning.

DIAGNOSTIC CONFIRMATION

Diagnostic confirmation requires evidence of access to the poison and the detection of large amounts of it in the gastrointestinal tract.

Samples for Analysis

- Toxicology: Use 50 g of liver, kidney, and a portion of gastrointestinal tract with content
- Histology: Formalin-fixed liver, kidney (LM)

TREATMENT

The use of emetics to remove the contents from the stomach is generally not recommended because phosphorous is caustic and can cause significant damage to the esophageal lining during emesis and because vomiting normally occurs. Gastric lavage followed by activated charcoal with a cathartic may be beneficial in solitary animals when used early after ingestion. Further treatment is supportive and includes analgesics and intravenous fluids for dehydration. Hypotension and shock as well as coagulopathy may occur and should be treated supportively as needed.

ARSENIC TOXICOSIS

SYNOPSIS

Etiology Insecticidal dips or sprays; herbicides; wood preservatives, pharmaceuticals, and feed additives. Inorganic compounds are the most toxic, and organic arsenicals are the least toxic.

Epidemiology Outbreaks caused by accidental access; use of excessive amounts in feed, spray, or dip. Most cases result from ingestion, but percutaneous absorption is also possible.

Clinical signs Enteric form a highly fatal gastroenteritis with diarrhea; dehydration. Neurological form with incoordination and blindness or a syndrome of incoordination, restlessness, squealing, and convulsions

Clinical pathology High levels of arsenic in feces, urine, and milk for 5 days (organic arsenicals) and 10 days (inorganic arsenic). Chronic cases best assayed in hair or skin

Necropsy lesions Gastroenteritis in enteric form, and no lesions in neurological form

Diagnostic confirmation Higher than normal levels of arsenic in body fluids or tissues

Treatment Decontamination, antidotes, and supportive care

Control Remove from environment and do not exceed label directions.

ETIOLOGY

Background Information

- Inorganic arsenicals most often have a valence of +3 (trivalent; arsenite) or +5 (pentavalent; arsenate) and arsenite is more toxic than arsenate.
- Organic arsenicals most often have valences of +3 (trivalent) or +5 (pentavalent) and by definition contain at least one carbon atom.

The toxicologic profile of arsenic is complicated. The absorption and toxicity of arsenic depend on many factors other than the valence and chemical form. Absorption is dependent on particle size, solubility, and species, with other factors such as animal

health playing a role. Large, less soluble particles of an inherently toxic arsenical compound may not be well absorbed, whereas a less toxic but more soluble substance may have greater absorption.[1,2] Animals in poor health with compromised gastrointestinal systems may have far greater absorption than those in good health. Species plays an important role with humans and dogs the most susceptible to arsenic toxicity and the development of clinical signs.

Arsenic compounds likely to be encountered by large animals are numerous and varied but include the following:

Inorganic compounds used as insecticidal dips or as herbicides
- Oxide, e.g., arsenic trioxide (+3)
- Trivalent, e.g., sodium arsenite (+3), copper acetoarsenite (Paris green)
- Pentavalent, e.g., sodium arsenate (+5)

Inorganic compounds used as wood preservatives
- Chromated copper arsenate (+5)

Inorganic compounds used as medicinals
- Inorganic lead arsenate (+5)
- Potassium arsenite (+3), e.g., Fowler's solution and others

Organic compounds used as herbicides
- Monosodium and disodium methanearsonates (+5), e.g., MSMA and DSMA

Organic compounds used as medicinals
- Trivalent phenylorganic arsenicals (+3), e.g., thiacetarsamide and melarsoprol
- Pentavalent phenylorganic arsenicals (5), e.g., arsanilic acid, roxarsone (4-hydroxy-3-nitrophenylarsonic acid), and nitarsone (4-nitrophenylarsonic acid)

Relative Toxicities

The organic pharmaceuticals are least toxic, the insoluble oxides are of medium toxicity, and the trivalent inorganic compounds are associated with the most severe syndrome.[1,2,4] Toxic oral doses may range from 1 to 25 mg/kg for the arsenites, 30 to 100 mg/kg for the arsenates, 25 mg/kg daily for 8 to 10 days for cacodylic acid, and 10 to 25 mg/kg for 5 to 6 days for the methanearsonates.

Aromatic organic arsenicals are toxic when the cumulative dose is exceeded by two to four times the recommended dose, delivered by either exceeding the recommended percentage in the feed, or feeding it for too long. Seven to 10 days' feeding of arsanilic acid at 500 mg/kg diet or 3-nitro, 4,hydroxyphenylarsonic acid at 250 mg/kg diet will be associated with toxicosis in swine; approximately twice these concentrations will result in poisoning of poultry.

EPIDEMIOLOGY

Occurrence

Arsenic toxicosis usually occurs after ingestion of the toxic substance, but dermal absorption can occur especially if the skin is abraded or hyperemic. Today, arsenic is less commonly associated with generalized livestock poisoning, but poisoning still occurs in some areas of the world because of its presence in groundwater.[3] In addition, arsenic can still be found in the following products.

Dips and Sprays

Fluids used for dipping and spraying of animals to control ectoparasites are a very common source of poisoning. Animals may swallow the solution while in the dip or in the draining yards after dipping. Animals that are not allowed to drain completely as well as faulty disposal of drainage from yards and dips may contaminate the pasture. Opened containers of dipping solutions or powders may accidentally contaminate feed or be mistakenly applied as a skin dressing. Appreciable amounts of arsenic are absorbed through the skin after dipping in sodium arsenite. The absorption is increased if the animals are dipped when hot, if the fleece is long, if they are crowded too tightly in draining yards, or driven too soon after dipping. However, in most outbreaks of poisoning some ingestion appears to occur and supplements the cutaneous absorption. There is some danger in dipping rams at mating time when erythema of the skin of the thighs and scrotum is present. Dipping immediately after shearing and jetting at too high pressure or with excessively strong solutions may also be associated with increased absorption.

Herbicides

These include sodium or potassium arsenite, arsenic pentoxide, and monosodium or disodium acid methanearsonate sprays used to kill weeds. Grass clippings taken from lawn areas treated 6 months earlier with arsenical herbicides may carry 15,000 mg/kg arsenic.

Insecticidal Sprays

These are often used in orchards and pasture applied to kill Colorado beetle grubs and other pests. In most instances poisoning occurs when animals accidentally gain access to recently sprayed areas, although drifting of windblown spray may result in accidental contamination of pasture.

Leaded Gasoline

The major effects are usually ascribed to the effects of the lead, but this does not always appear to be so.

Insect Baits

Paris green (copper acetoarsenite) has historically been mixed with bran and applied to large areas of land in an attempt to control grasshopper plagues.

Wood Preservatives

Wood products such as fence boards, posts, calf hutches, and old buildings treated with a chromated copper arsenate preservative remain a source of arsenic exposure. The compound has a salty taste and arsenic concentrates in the ashes when the wood is burned.

Metal-Bearing Ore Deposits

Several natural deposits, including iron arsenic pyrites in volcanic soils as well as gold and copper ores, contain large quantities of arsenic that may be licked in situ or carried off in the fumes from smelters and contaminate surrounding pastures and drinking water supplies.

Pharmaceuticals and Growth Stimulants

These include arsanilic acid and sodium arsanilate, as well as phenylarsonic acid preparations such as roxarsone and nitarsone, which are used as feed additives, growth promotants, antidotes for selenium toxicosis, and in the control and treatment of animal dysentery. Overdosing can occur by continuing the administration for too long or when there is an error in mixing a batch of feed. The toxicity of feed containing arsanilic acid depends to a certain extent on the intake of drinking water, but moderate water restriction does not make normal dose rates dangerous.

Animal Risk Factors

Soluble salts are highly poisonous; arsenic trioxide and sodium arsenate are much less soluble and thus less toxic than sodium arsenite. The LD_{50} of sodium arsenite varies between species with pigs, horses, cattle, and sheep requiring increasing doses to be affected. Organic chemicals used as herbicides are as poisonous as the arsenite, but organic arsenicals used as growth stimulants are less toxic, although they are absorbed rapidly.

In cases in which gastroenteritis is the predominant lesion, the case–fatality rate approximates 100%.[4] In cases characterized by nervous system involvement the illness is incidental and losses minimal if access to the poison denied, but residues become a problem.

Human Risk Factors

Meat and milk residues reduce the safety of the products for human consumption.[1,5] Arsenic is excreted rapidly after absorption, chiefly in the urine, and after the ingestion of nontoxic amounts by the cow there is no detectable secretion into the milk.[6] When much larger doses are consumed arsenic may be excreted in the milk, as well as in urine and feces, but the concentration is still low. The biological half-life of arsenic taken orally in the form of arsanilate is 4.2 days in liver, 5.7 days in kidney, and 15 days in muscle. In pigs receiving arsanilic acid at 200 mg/kg in the feed the level of arsenic in muscle is still more than the admissible level of 0.1 mg/kg 18 days after withdrawal. The usual recommendation is to withdraw arsanilic acid 5 to

7 days before slaughter. This is adequate at normal dose levels.

Environmental Risk Factors

The presence of arsenic in groundwater is well documented in various parts of the world, especially in some parts of Asia.[7,8] This is associated with suboptimal milk production in cows as well as the potential for further soil and water contamination from arsenic excreted in the urine.[8]

PATHOGENESIS

Mechanism of Action

Inorganic trivalent salts and trivalent organic compounds exert their toxic effects by combining with sulfhydryl groups on proteins and inhibiting tissue enzymes such as α-keto oxidase, pyruvic acid oxidase, and α-oxyglutaricacidoxidase.[2,4,9]Trivalentarsenicals are most toxic because of their greater affinity for these sulfhydryl groups. The efficiency of sulfur-containing compounds such as dimercaptopropanol (British antilewisite or BAL) as antidotes depends on the ability of these compounds to compete with sulfur-containing compounds of enzyme systems for the available arsenic.[2,4] Pentavalent inorganic arsenates work by uncoupling oxidative phosphorylation, perhaps by substituting phosphate into the reaction. The mechanism of action for pentavalent organic compounds is unknown, but interference with the actions of pyridoxine and thiamine may be involved.[2] In ruminants, pentavalent arsenicals can be converted to trivalent arsenicals.

Tissue Susceptibility

Once absorbed into the bloodstream, arsenic is well distributed to all body organs, accumulating in the liver before distribution. Others organs such as the kidneys, lungs, and spleen also accumulate arsenic.[2,4,9] The body areas affected are primarily those with tissues rich in oxidative enzyme systems. Thus the alimentary tract wall, liver, kidney, spleen, and lung are most susceptible to the general depression of metabolic activity and development of clinical signs. Gastrointestinal tract lesions produce the most obvious clinical signs because of the extensive damage to capillaries causing increased permeability and exudation of serum into tissue spaces. The mucosa lifts from the underlying muscle coat and is shed with a resultant loss of large quantities of body fluids. Arsenic does not precipitate protein, and there is no direct local effect on alimentary tract mucosa; this is indicated by the fact that the parenteral injection of arsenic produces lesions in the gut wall, which are identical with those associated with ingestion.

Time Lag

Because arsenic does not precipitate protein it does not limit its own absorption, and there is a considerable time lag after ingestion before clinical signs appear; corrosive substances produce lesions and signs immediately.

Percutaneous Absorption

Arsenic absorbed from the skin may be associated with local necrosis without systemic signs if the peripheral circulation is poor or the concentration of arsenic is excessively high, but if the cutaneous circulation is good, the arsenic is quickly carried away and is associated with a systemic disease without skin necrosis.

Chronic Poisoning

The chronic toxicity of arsenic at low levels of intake is caused by its accumulation in particular organs, especially the skin, bone, hooves, and hair.[1,4,10]

Nervous Tissue Lesions

Pentavalent organic arsenicals cause degenerative changes in peripheral nerves. These appear as demyelination and axonal degeneration in prolonged cases.[2] Animals recumbent longer than 7 days are unlikely to recover and will remain paralyzed until death from other associated conditions. In poisoning with arsanilic acid compounds the lesions occur primarily in the optic nerves, causing blindness. In poisoning with the phenylarsonic acid group the nerves to the limbs appear to be most affected.

CLINICAL FINDINGS

The occurrence of clinical signs depends on the specific form of arsenic to which animals are exposed. As a general rule, all inorganic arsenicals and trivalent organic arsenicals affect the capillaries and gastrointestinal tract, and pentavalent organic arsenicals affect the neurologic system.

GASTROINTESTINAL SYNDROME

Peracute Cases

These animals show little except depression and prostration and generally die before signs of enteritis develop.[4,11] Death occurs minutes to a few hours after exposure and may be preceded by clonic convulsions and diarrhea.

Acute and Subacute Cases

In ruminants, the onset of signs of illness is often delayed 20 to 50 hours from ingestion of the poison, with the length of time depending on the fullness of the forestomachs.[4,11] Distress develops suddenly, beginning with severe abdominal pain, restlessness, groaning, an increased respiratory rate, salivation, grinding of the teeth, complete rumen stasis, and vomiting (even in cattle), followed by a fluid and fetid diarrhea that may be hemorrhagic. Tachycardia, rapid and weak pulse, dehydration, and oliguria are marked.

Horses show similar signs with a marked congestion of the mucous membranes and a very sudden onset of severe colic. Severe diarrhea (± blood) may be followed by a period of complete stasis of the alimentary tract with diarrhea recurring just before death.

Subacute cases give the same signs as acute cases, but the course may extend over 2 to 7 days. Nervous signs of muscle tremor, incoordination, and clonic convulsions are followed by terminal coma.

Chronic Cases

Commonly observed signs include low BW; a dry, rough coat that is easily shed; fatigue; bouts of indigestion; conjunctival and mucosal erythema; eyelid edema; and conjunctivitis. Buccal mucosal ulceration may extend to the muzzle. Milk yield is seriously reduced and abortions and stillbirths may occur. Local skin lesions include initial hyperemia followed by necrosis and sloughing, leaving indolent lesions that are extremely slow to heal.

NEUROLOGICAL SYNDROME

Chronic poisoning resulting from arsanilic acid overdose occurs primarily in pigs and lambs. It is manifested by incoordination 3 to 7 days after ingestion; blindness may or may not occur. Consciousness, body temperature, and appetite are unaffected. If feeding is continued the signs gradually worsen; if feed is changed the signs disappear within a few days. Some pigs remain permanently blind or paralyzed. In chronic poisoning with roxarsone and nitarsone the emphasis is on restlessness, frequent urination and defecation, incoordination caused by loss of balance, frequent shrill "screaming," tremor, and convulsions, all of which are stimulated by rousing the pig. If left alone in a recumbent position it may appear normal. Almost all animals have some form of gastrointestinal irritation.

CLINICAL PATHOLOGY

Arsenic can be detected in the urine, feces, and milk for periods of up to about 10 days, beginning shortly after the toxic material is ingested. The rate of excretion is faster with organic compounds than with inorganic arsenic, and urine levels may be back to normal in 5 days. The most satisfactory material for laboratory examination from a living animal is a large volume (about 1 L) of urine in which arsenic levels may be as high as 16 mg/kg. Levels in milk are low.[6] Normal levels of up to 0.25 mg/kg in cows' milk may be elevated to 0.34 to 0.47 mg/kg in cases of acute poisoning and to 0.8 to 1.5 mg/kg in the milk of normal cows that graze arsenic-contaminated pasture for long periods. Deposition in the hair occurs and arsenic persists there until the hair is shed, making possible the detection of prior arsenic ingestion in the absence of arsenic from the blood and feces. The hair of animals not exposed to arsenic should contain less than 0.5 mg/kg, and that of exposed animals may contain as much as 5 to 10 mg/kg.

NECROPSY FINDINGS

In acute and subacute cases of **inorganic arsenic poisoning** there are pronounced

hyperemic and patchy submucosal hemorrhages in the stomach, duodenum, and cecum. Hemorrhage and multifocal ulceration of the cecum and large colon have been observed in horses. In ruminants, the mucosa of the forestomachs is unaffected, but typical lesions are present in the abomasum and intestines. Renal tubular necrosis, suppurative pyelonephritis, and petechiation of bladder mucosa are found in cattle.[4] The gut contents are very fluid and contain mucus and shreds of mucosa. Profuse subendocardial hemorrhages are common, and ulceration of the gallbladder mucosa is often observed in sheep. Macroscopic lesions may be minimal in cases that die after a very short course. Histologically, most of the hemorrhages can be attributed to the necrosis of capillaries, although damage to the walls of larger vessels may sometimes be found. Severe intravascular hemolysis has been observed in sheep. Degenerative changes are common in the liver and kidney of animals suffering from arsenic toxicosis, and these changes become more pronounced if the disease course is prolonged. In some cases of chronic poisoning, loss of myelin may be observed in the peripheral nerves, with secondary neural degeneration in the CNS.

The liver is the best organ for assay of acute arsenic poisoning, whereas the kidney may contain high levels in subacute or chronic poisoning. Levels of over 10 to 15 mg/kg wet matter of arsenic trioxide in the kidney or liver are considered to be diagnostic of arsenic poisoning. However, it is probable that many animals die of arsenic poisoning when their hepatic levels are much lower than this. Maximum concentrations of arsenic in tissues occur about 8 hours after ingestion, and animals that survive for 2 to 3 days may have levels as low as 3 mg/kg. Diagnostic levels in the urine and feces are between 10 and 20 mg/kg. Conversely, normal animals that are dipped routinely in arsenical dips may have hepatic levels of the element as high as 8 mg/kg. Levels of 1 to 3 mg/kg are obtained in cattle dying from arsenic poisoning after percutaneous exposure, and levels of over 10 mg/kg are found in cattle that ingest arsenical dip. Assay of the arsenic level in hair may be useful in chronically poisoned animals.

Animals poisoned with **organic arsenicals** show no significant gross pathologic changes. Histologically, degeneration and demyelination of the optic nerves, optic tracts, and peripheral nerves are apparent. The animals maintain tissue levels of arsenic for as long as exposure continues, although the levels fall rapidly during the first 7 days after feeding of the arsenic ceases, and normal levels are not reached for another 7 days. The liver and kidney obtained from pigs dying of roxarsone toxicosis contained an average arsenic content of 2.9 and 1.8 mg/kg (wet weight), respectively.

Samples for Confirmation of Diagnosis

TOXICOLOGY:

- Liver and kidney, segment of stomach/intestine including content, sample of suspected poison, and hair (chronic)

HISTOLOGY:

- Inorganic arsenic: Formalin-fixed stomach, intestine, cecum, large colon, liver, kidney, and peripheral nerve
- Organic arsenic: Formalin-fixed optic nerve and tract and peripheral nerve

DIFFERENTIAL DIAGNOSIS

Diagnostic confirmation in all arsenic poisoning is by detection of toxic levels of arsenic in animal tissues and fluids.

Differential diagnosis list:

- **Acute inorganic arsenic toxicosis**
  - Bovine malignant catarrhal fever (peracute, gastrointestinal form)
  - Lead toxicosis
  - Mushroom toxicosis (amatoxins)
  - Poisonous plants (bracken, mustards, etc.)
  - Salmonellosis
- **Chronic inorganic arsenic toxicosis**
  - Parasitism (ostertagiasis, trichostrongylosis, and oesophagostomiasis)
  - Starvation
- **Organic arsenical toxicosis**
  - Encephalitis
  - Mercury (organic) toxicosis
  - Salt toxicosis
  - Selenium toxicosis
  - Tri-ortho-cresyl phosphate or other industrial chemical toxicosis

TREATMENT

TREATMENT AND PROPHYLAXIS

Treatment and prophylaxis[2,4]

Sodium thiosulfate (20–40 mg/kg intravenously every 8 h; 80 mg/kg orally every 24 h or 30–60 mg/kg orally every 6 h for 3–4 days) (R2)

2,3-Dimercaptopropanol (1.5–5 mg/kg intramuscularly every 4–6 h for 10 days) (R2)

Thioctic acid (50 mg/kg intravenously every 8 h) (R2)

In acute cases, treatment is of little value because of the large amount ingested and the delay between ingestion and the onset of clinical signs. Affected animals are unsuitable for human consumption, so treatment is not usually undertaken. Although BAL has a general beneficial effect and is recommended as a treatment, the drug is quite toxic itself and in the doses required may be associated with death in sheep. It also is associated with a reaction at the injection site that is sometimes serious enough to warrant the animal's destruction.

The most commonly used antidotes are sodium thiosulfate, dimercaptopropanol (BAL), and thioctic acid.[2,4] There is a wide variation in results as well as recommended dose and dosage. A comparison of these antidotes used in experimentally poisoned cattle showed little benefit from sodium thiosulfate administration, and most benefit with a combination of BAL and thioctic acid. Dimercaptosuccinate, a water-soluble analog of dimercaprol, is less toxic than BAL, may be available in the United States, and should be more effective than BAL. The antioxidants zinc, methionine, and cysteine, used with chelation therapy, have been reported to enhance excretion of arsenic in experimental poisoning. Their use may be helpful as adjuncts to recommended chelation therapy.

Further therapy is supportive. Attempts should be made to adsorb the residual arsenic in the gut by administering charcoal (1–4 g/kg orally), and moved through the gastrointestinal tract with the administration of an oil demulcent or osmotic agent like magnesium sulfate. Drastic purgatives should be avoided. Severe dehydration occurs, and outcome improves when supportive treatment includes the provision of ample fluids, preferably by parenteral injection.[4] An adequate supply of drinking water containing electrolytes should be provided, and the animals should be disturbed as little as possible and provided shelter from the sun and elements. Recovering animals should receive a bland diet and high-quality protein.

CONTROL

Arsenical preparations must be handled and stored with care and contamination of feed and pasture avoided. Old products should not be left in abandoned sheds or buildings. Wood treated with chromated copper arsenate should not be used for fences, posts, or buildings inhabited by animals. When treated wood is destroyed, animals should not be allowed access to the ashes, and the ashes should not be spread on the pasture or drylots. Therapeutic preparations containing arsenic should be labeled "Poison" and strict instructions given on dosage, particularly the length of time for which administration should continue. Animals to be dipped in arsenical solutions should be allowed to cool off before dipping, drain properly afterward, and dry before being driven. They should be watered before dipping to prevent them from drinking the dip. Much mortality has occurred when instructions for mixing dip solutions were not closely followed. Dipping solutions containing more arsenic than is safe usually occur when tanks, which have lost water by evaporation, are reconstituted by guesswork. The maximum safe concentration of arsenic trioxide in a dip for cattle is 0.20%.

MOLYBDENUM TOXICOSIS (MOLYBDENOSIS)

SYNOPSIS

Etiology Ingestion of toxic amounts of molybdenum

Clinical pathology High serum levels of molybdenum, low serum levels of copper

Necropsy lesions No significant lesions

Diagnostic confirmation High levels of molybdenum in feed and blood

Treatment
Primary: Copper salts orally
Supportive: None necessary

Control Dietary supplementation with copper

ETIOLOGY

Molybdenum is an essential element needed by humans and animals for activity of the biological enzymes xanthine oxidase, aldehyde oxidase, and sulfite oxidase.[1] It is involved in a variety of metabolic processes including protein and sulfur metabolism and iron transport. Signs of molybdenum toxicosis may be associated with inhibition of these processes and other enzymes, such as glutaminase and cytochrome oxidase, but many are linked to specific deficiencies in copper-containing enzymes.[1,2] Species variation occurs, with cattle the most susceptible to poisoning, followed by sheep and goats, pigs, and finally horses.[3] The toxic dose varies widely with the intake of sulfate, copper, and other factors.[2,3]

EPIDEMIOLOGY

Occurrence

The major occurrence of molybdenum poisoning is associated with ruminants grazing on pasture growing on molybdenum-rich soils, usually derived from particular geological formations, e.g., the "teart" pastures of Somerset (UK), the United States, and Canada; marine black shales in the UK; pastures containing excess molybdenum intake with or without a marginal deficiency of copper in New Zealand, Canada, Ireland, and Australia.[4] Soil in areas of mining operations, metallurgical industries, paint manufacturers, and refineries may be heavily contaminated with molybdenum, and animals grazing there or ingesting water or plants grown there may develop molybdenum toxicosis.[4-6]

Acute poisoning has occurred in cattle ingesting 7400 mg molybdenum/kg of diet ingested or approximately 30 mg molybdenum/kg BW per day.[2,7] Acute toxicosis occurred in sheep receiving 132 to 137 mg molybdenum/kg for 2 to 3 days.

Chronic toxicosis occurs in cattle receiving only 3 mg molybdenum/kg BW per day.[7] Diets providing less than 3 mg/kg BW are usually considered to be safe, but signs of toxicosis may occur when the diet contains as little as 1 mg/kg BW if the sulfate intake is high and the copper status low; the level of molybdenum at which the interference with the metabolism of copper may occur is 2.4 mg/kg dry matter in the diet.

Forage containing 10 mg/kg must be considered dangerous at all times and, on pasture, affected by aerial contamination levels of 10 to 200 mg/kg may be encountered. Such intakes can be provided by the following:

- The use of molybdenum in fertilizer mixtures to increase nitrogen fixation by legumes may lead to excessive amounts of molybdenum in soils.
- Contamination of pasture by motor oil containing molybdenum as an additive
- Industrial fallouts of 5 to 40 ng/m^3 of air or 2 mg/m^2 per month on pasture

Aerial contamination by fumes from aluminum and steel alloy factories and oil refineries using molybdenum is associated with secondary copper deficiency.

Drinking water may not be as toxic as the same amount in fresh forages. For calves, the minimum toxic concentration in drinking water is between 10 and 50 mg/kg when dietary copper and sulfur intake in the diet is normal.

Risk Factors

Animal Risk Factors

Cattle, sheep, and goats are clinically affected in field outbreaks of the disease and signs are most marked in young growing animals. Cattle are much more susceptible than sheep.[3] Horses and pigs are susceptible to a lesser extent, presumably because of a decreased absorption and lack of a rumen.[3]

Environmental Risk Factors

The concentration of molybdenum in forage varies with the season; it is highest in the spring and autumn and with the plant species, legumes, and particularly alsike clover taking up molybdenum in much greater quantities than grasses. Soil and plants in pastures and other grazing areas near mining industries or using molybdenum may be contaminated.[4-6]

Transmission

Animals are primarily poisoned by ingesting plants or soil high in molybdenum, but the amount of dietary sulfur/sulfates and copper in the diet plays an integral role.

PATHOGENESIS

Molybdenum, sulfur, and copper are all intimately involved in the development of poisoning. The mechanism of action differs for ruminants and monogastrics. Sulfur or sulfate in the rumen is converted to sulfide, which combines with molybdenum to form four thiomolybdates (mono-, di-, tri-, and tetra-).[2,3,8] In the digestive tract, these thiomolybdates bind to copper forming a cupric–thiomolybdate complex that prevents copper absorption; once systemic, they bind to copper preventing further copper utilization and increasing copper excretion.[2,3,9] In addition, some free molybdenum is absorbed throughout the intestinal tract.[2] Monogastric animals, who lack a rumen, do not form thiomolybdates; instead molybdenum is absorbed beginning with the stomach and continuing throughout the intestinal tract.[9]

Once absorbed molybdenum is rapidly distributed to many body tissues, with the highest concentrations in the liver, kidney, spleen, and bone.[3,10] Excretion is rapid and occurs primarily in the urine and bile (ruminants), with milk a concentration-dependent route in lactating animals.[9,11]

Most signs of molybdenum poisoning result from some form of copper deficiency, either real or functional. The situation is exacerbated by a high intake of sulfur or a low intake of copper. The syndrome of molybdenum intoxication resembles that of copper deficiency, and treatment and prevention by the administration of copper is effective.

Not all signs of molybdenum poisoning, particularly diarrhea, are characteristic of copper deficiency and may represent a specific toxic effect of molybdenum. An identified toxic effect specific to molybdenum occurred in sheep experimentally fed molybdenum. Exostoses and hemorrhages about the long bones developed, as well as separation of the great trochanters of the femur. The lesions appear to be caused by defects in connective tissue at muscle insertion points and by defects in the epiphyseal growth plates.

CLINICAL FINDINGS

Acute Intoxication

Cattle and sheep show anorexia and inappetence, profuse salivation, weakness and progressive ataxia beginning with the hindlimbs, recumbency, and death.[9]

Chronic Intoxication

Cattle, sheep, and goats show the following signs[1,8,9,11]:

- Persistent diarrhea within 8 to 10 days of the animals having access to affected pasture
- Emaciation and a dry coat
- Profound decrease in milk production
- Depigmentation of black hair with the appearance of a red or gray tinge to hair. This may be particularly noticeable around the eyes, giving a bespectacled appearance.
- Intense craving for copper supplement has been noted.
- Young cattle (3 months to 2.5 years) show abnormalities of locomotion, including marked stiffness of the legs and back, difficulty in rising, and great reluctance to move. The gait is suggestive of laminitis but the feet appear normal. The lameness may be caused by the periosteal lesions described earlier. The appetite remains good.

Horses, although rarely affected, show diarrhea and impaction colic. The mortality rate is high.

CLINICAL PATHOLOGY

Blood copper levels are reduced from the normal of 1.0 µg/mL to 0.25 µg/mL. Seasonal variations occur depending on the intake of molybdenum.

Blood molybdenum levels in normal animals are of the order of 0.05 mg/kg and rise to about 0.10 mg/kg when excess molybdenum is ingested. Levels as high as 0.70 and 1.4 mg/kg have been recorded in cattle and horses grazing on pasture contaminated by smelter fumes. On very large intakes of molybdenum cattle, which are clinically normal, may have molybdenum levels of 1000 mg/kg in feces, 45 mg/kg in urine, 10 mg/kg in blood, and 1 mg/kg in milk.

Goats treated with ammonium molybdate orally at 20 mg/kg BW per day for 30 days developed significant declines in the mean values of hemoglobin, PCV, total leukocyte count, total erythrocyte count, and mean corpuscular hemoglobin concentration, with significant increases in neutrophil count and mean corpuscular volume.[1] These did not occur in a similar group treated with molybdenum and copper sulfate (II) pentahydrate.

NECROPSY FINDINGS

There are no gross or histologic findings that characterize the disease, and enteritis is conspicuously absent. The carcass is emaciated and dehydrated and there may be anemia if there is an accompanying copper deficiency. Tissue copper levels will be below normal.

DIFFERENTIAL DIAGNOSIS

Diagnostic diagnosis list:

- Copper toxicosis
- Internal parasitism, e.g., trichostrongylosis, ostertagiasis
- Paratuberculosis
- Acute enteritides including salmonellosis, winter dysentery, and virus diarrhea

TREATMENT

Effective treatment depends on removing the source of molybdenum and providing copper to the affected animals. The most effective method is to treat affected animals orally with copper sulfate (2 g daily or 5 g weekly for adult cattle and 1.5 g for adult sheep). The diarrhea should stop in 2 to 3 days, and improvement in the other signs is rapid. Care should be used in sheep not to overdose and cause copper toxicoses. In monogastric animals, sulfate may enhance elimination.[9]

TREATMENT AND PROPHYLAXIS

Treatment

Copper sulfate (2 g/day orally for adult cattle; 1.5 g orally for adult sheep × 2–3 days) (R1)

Prophylaxis

Keep Cu : Mo ratio at 4 : 1 and S : Mo ratio < 100 : 1. (R2)

CONTROL

If animals cannot be removed from the source (i.e., grazing on contaminated lands), then copper sulfate should be added to their diet.[6] For long-term control, the recommended ratio of Cu : Mo is 4 : 1 to 10 : 1, and a S : Mo ratio of <100 : 1 is considered safe as opposed to copper accumulation.

AMITRAZ TOXICOSIS

ETIOLOGY

Amitraz is a topical acaricide and insecticide widely used in most large-animal species including cattle, sheep, goats, and ostriches.[1] It is not labeled for use in horses because they are easily poisoned when amitraz is applied to their skin or accidentally ingested.[1] Most commercial products on the market contain 12.5 to 50% amitraz in a solvent such as xylene and must be diluted before use.[1,2]

PATHOGENESIS

Amitraz is a centrally acting α-2 adrenergic agonist that also inhibits monoamine oxidase and prostaglandin synthesis. It is highly soluble and rapidly absorbed through skin and mucous membranes.[3] Concentration of the dipping fluid, solvent carrier, environmental temperature, and the condition of the skin may influence absorption of the compound, clinical signs, and susceptibility of the animal.

CLINICAL FINDINGS

Clinical signs occur in horses within 12 to 48 hours and include anorexia, depression, sedation, ataxia, incoordination, and large intestine impaction. Resolution of signs may take 7 to 8 days.[1] Equine susceptibility to amitraz is likely caused by prolonged persistence in the body. Salivation, depression, anorexia, ataxia, tremors, and coma are signs attributed to amitraz in other species.

TREATMENT

Decontamination with activated charcoal and a cathartic may be used in an ingestion if clinical signs have not yet occurred. Residual topical amitraz should be removed from affected animals by bathing with soap and tepid water. Further therapy is supportive and includes oral or intravenous fluids, analgesics, and treatment of the impaction colic. The use of α-2 adrenergic antagonists such as yohimbine and atipamezole has been suggested.[1]

PROPYLENE GLYCOL TOXICOSIS

Propylene glycol is an unlikely poison, but it is used extensively as an oral treatment for acetonemia in cattle and can be associated with poisoning if it is accidentally administered to horses, when mistaken for mineral oil. Dose rates of 3 L to horses of 500 kg BW by stomach tube is associated with an immediate but short duration episode of abdominal pain, sweating, salivation, severe ataxia and depression, and a fetid odor of the feces. Much larger doses (8 L) can be fatal. Moderate-to-severe inflammation of the lining of the gut and edema of the brain are noticeable at necropsy examination.

PLANT MATERIALS CAUSING PHYSICAL DAMAGE

COLIC IN HORSES FROM INGESTION OF INDIGESTIBLE FIBER IS ASSOCIATED WITH

- Gastric impaction (*Senecio jacobaea*)
- Impaction of the ileocecal valve (*Sorghum* spp.)

RUMINAL IMPACTION IN CATTLE IS ASSOCIATED WITH INGESTION OF CUTTINGS FROM

- *Fraxinus excelsior* (ash tree)
- *Chrysocoma tenuifolia* (bitter weed)
- *Eriocephalus* spp.
- *Pinus taeda* (loblolly pine)
- *Prosopis juliflora* (mesquite)
- *Eremocarpus setigerus* (turkey mullein)

Gastric impaction in pigs is associated with ingestion of *Nicotiana* spp. stalks.

The tough fiber in *Romulea rosea* (onion grass, rosy sandcrocus) is associated with an enzootic problem of bovine intestinal and abomasal impaction by phytobezoar in parts of Australia.[1] Phytobezoars can be a problem wherever indigestible fiber is available to ruminants. Cocoon silk of *Gonometa* spp. (Molopo moth) can be associated with ruminal impaction in cattle that eat foliage of *Acacia erioloba* or *A. mellifera* trees, the preferred habitat for the moth larvae.

Other physical injuries associated with plant material include persistent corneal ulcers from the bristles of *Arctium lappa* (burdock seeds) and ulcers in the mouth from the spines of *Setaria lutescens* (yellow bristle grass) and the awns of *S. geniculata* (prairie foxtail) and *Triticosecale* (triticale varieties).[2] *S. lutescens* carries heavy bristles that are associated with mechanical stomatitis in cattle and horses. *S. geniculata* awns are associated with ulcerative stomatitis and glossitis and gingivitis in horses.[2] Triticale is a hybrid between wheat and rice used mainly for grain production. If it is harvested green as a crop and made into hay the dried awns are irritating to the pharynx and mouth of cattle and horses. Affected horses are slow eaters, refuse hay, and show excess salivation. Clinical signs result in about a week and include cough, mucoid nasal discharge, foul breath, hypersalivation, quidding, and loss of BW. Some horses develop submandibular edema and there are severe ulcerations at the gum–tooth margins, with many awns embedded in the ulcers. The ulcers are very painful and up to 5 cm in diameter at the labial–gingival junction, the lingual frenulum, the base of the lingual dorsum, soft palate, and the sides of the tongue. After careful cleaning, the lesions heal slowly over about 3 weeks.

Grass seed abscesses are frequent when there is a large population of *Stipa* and *Stipagrostis* spp. (spear grass), *Tagetes* spp., *Aristida arenaria* (silver or kerosene grasses), *Opuntia* spp. (prickly pear), and *Hordeum jubatum* (barley grass) in the pasture. The hairs on the plant *Dittrichia graveolens* (stinkwort) are thought to be associated with the fatal enteritis that occurs in sheep eating the plant.

PLANT TOXINS AFFECTING THE ALIMENTARY TRACT

ANDROMEDOTOXIN

Andromedotoxin (syn. acetylandromedol, grayanotoxin, rhodotoxin) is a resinoid substance, a member of the diterpenoid group of substances, and found in plants of the Ericaceae family including:

Agarista spp.
Agauria salifolia
Clethra arborea
Kalmia spp. (laurels, lambkill)
Ledum spp. (labrador tea)
Leucothoe spp. (sierra laurel, hanahiri)
Lyonia ligustrina (staggerbush)
Menziesia ferruginea (mock azalea)
Pieris (Andromeda) spp.
Rhododendron spp. (rhododendrons and azaleas)

Andromedotoxins, or more commonly grayanotoxins, are found in the flowers, leaves, twigs, and stems of plants in the Ericaceae family.[1-4] More than 25 different grayanotoxin isoforms (e.g., grayanotoxin I, grayanotoxin II, etc.) exist depending on the species of plant.[1] Plants in this family are very poisonous to animals and humans. Cattle, horses, sheep, and goats have all become symptomatic or died shortly after exposure.[1,2] Death occurs most often when livestock or horses have access to clippings thrown into their pastures or drylots. Different grayanotoxin isoforms do not degrade in a similar manner during composting but are not expected to be a risk to animals coming into contact with the waste.[5] Humans are exposed by ingesting honey produced by bees obtaining nectar from rhododendrons (mad honey disease), herbal teas, and other natural products.[1]

The toxins interfere with the function of voltage-gated sodium channels resulting in a continuous state of cell membrane depolarization.[1,2] Clinical signs are related to the gastrointestinal, cardiovascular, nervous, and respiratory systems. Signs generally begin within 3 to 14 hours after the plant or clippings are eaten and include dullness, salivation, projectile vomiting, bloat, repeated swallowing or belching, tenesmus, abdominal pain, a staggering gait, recumbency, convulsions with opisthotonus, tremor, dyspnea, and groaning and bleating. Tachycardia, hypotension, and cardiac arrhythmias occur in some cases. Aspiration pneumonia is a common sequel and is the only common gross necropsy finding. Histopathological changes are limited to minor lesions in the gray matter of the spinal cord.

ANTHRAQUINONE

Anthraquinones are extracted commercially from plants for use as irritant cathartics. Plants growing wild that contain these compounds include:

Cassia occidentalis (syn Senna occidentalis) (coffee senna)
Senna obtusifolia (sicklepod)
C. roemierana
C. italica
Frangula alnus (alder buckthorn)
Rhamnus spp. (buckthorn)

Horses, pigs, and cattle may be poisoned by *S. occidentalis* seeds that contaminate prepared rations.[6] All of these plants are associated with severe gastroenteritis manifested by diarrhea, often with transitory signs of abdominal pain if the dose is large. Liver damage is a common lesion in experimental and field cases and may dominate the necropsy findings.[6,7] Smaller doses of *Senna* spp. over a period of a week are associated with necrosis of striated muscle fibers characterized by limb weakness, incoordination, dragging the hind toe tips, and eventually paralysis in sternal or lateral recumbency. Necropsy lesions are cardiac and skeletal muscle necrosis, but these have not been shown to be direct effects of anthraquinones.

COLCHICINE

The alkaloid colchicine, found in *Colchicum autumnale* (autumn crocus, meadow saffron) and *Gloriosa superba* (flame or glory lily), is associated with acute fetid diarrhea ± blood), abdominal pain, tenesmus, vomiting, and salivation in sheep, cattle, and pigs.[2,8] Colchicine interferes with mitotic spindle formation, and the rapidly dividing, sensitive cells of the gastrointestinal tract are most frequently affected.[8] Consumption of 8 to 10 g of fresh leaves/kg BW has been associated with severe diarrhea. Mortalities are likely when cattle graze dense patches of *C. autumnale* in pasture or are fed hay containing the plant. Excretion is primarily through the bile with extensive enterohepatic recirculation; a small percentage (10%–30% in humans) is excreted unchanged in the urine. The toxin is excreted in the milk for an unspecified time period.[8] Confirmation of colchicine in the serum, urine, or milk can be made with several laboratory methods; liquid chromatography/mass spectrometry is the most current.[2,8] Treatment is limited as sudden death is the normal result, but would include multiple doses of activated charcoal and intravenous fluid and electrolyte therapy. In human cases, colchicine-specific antibodies (colchicine-specific Fab fragments) have been used successfully.[8] At necropsy, subserosal hemorrhages and gastroenteritis are evident.

IRRITANT DITERPENOIDS

The two important irritant diterpenoids are 12-deoxyphorbol found in *Euphorbia* spp. (spurges) and simplexin, an irritant diterpenoid daphnane ester found in *Pimelia simplex, P. trichostachya,* and others.

Poisoning by **12-deoxyphorbol** is associated with a syndrome of stomatitis and enteritis presumably related to the irritant nature of the latex sap.[9] Cattle generally avoid leafy spurge (*E. esula*), apparently because they develop a conditioned aversion to it, but sheep and goats will graze it.

Simplexin is primarily associated with a syndrome of congestive heart failure with diarrhea and anemia in cattle in eastern Australia called St. George disease or Marree disease.[10,11] The syndrome is only rarely reported in horses.[12] St. George or Marree disease is associated with ingestion of *P. trichostachya, P. simplex, P. contunua,* and *P. elongata* (desert rice flower, flaxweed, wild flax, mustard weed, broom bush) and is characterized clinically by massive edema under the jaw and down the brisket, distended jugular veins, persistent diarrhea, anemia, loss of condition, and death. Ingested simplexin is associated with constriction of pulmonary venules, pulmonary venous hypertension, and right heart failure.[12] Diarrhea is caused by direct irritation of the intestinal lining. Inhalation of the powdered plant is associated with the pulmonary–cardiac lesion only. A severe anemia caused by a significant hemodilution of unknown pathogenesis occurs. The usual field picture is that of cattle looking for feed between old, dry flaxweed plants and inhaling it, so the pulmonary–cardiac form is most common in summer. Experimentally, it has been possible to produce two forms of the disease: the subacute with diarrhea, weakness, and anemia as the predominant signs, and the chronic form characterized by circulatory failure as evidenced by anasarca, hydrothorax, and cardiac dilatation.

Severe diarrhea and colic without other cardiac effects have occurred in cattle, sheep, and horses consuming *Pimelea* plant material.[11,12] The difference between the signs present in St. George disease and acute diarrhea/colic, among other things, is likely related to lower concentrations of simplexin in various species of *Pimelea*.[10,11]

IRRITANT OILS

Irritant oils in plants are associated with gastroenteritis, salivation, oral mucosal lesions, abdominal pain, diarrhea, and sometimes dysentery. Plants known to contain these oils include:

Actaea spicata (baneberry)
Artemisia filifolia
Barbarea vulgaris (yellow rocket)
Bryonia dioica (white bryony)
Croton spp. (croton)
Cryptocarya pleurosperma (poison walnut; contains cryptopleurine and pleurospermine)
D. graveolens (stinkwort)
Inula conyza (ploughman's spikenard)
Sambucus spp. (elders, elderberry)

Bryonin is an irritant oil found in the roots and seeds of *B. dioica* (white bryony or British mandrake) and is associated with a syndrome of depression, dyspnea, diarrhea, polyuria, stumbling gait, tremor, recumbency, and convulsions. Sweating, agalactia, and sudden death are also recorded.

LYCORINE

Lycorine, an alkaloid found in the bulbs or roots of many garden plants, e.g., *Amaryllis, Clivia, Daffodil, Lycoris, Narcissus,* and *Nerine* spp., is associated with salivation, vomiting, and diarrhea when eaten by animals.

PODOPHYLLIN POISONING

Podophyllin, a resin found in *Podophyllum peltatum,* is associated with enteritis with excessive salivation and severe, acute diarrhea.

PROTOANEMONIN POISONING

Protoanemonin exists in the plant as a glucoside ranunculin, which releases protoanemonin when the leaves are macerated. Plants containing ranunculin include:

Anemone spp.
Caltha palustris
Clematis spp.
Pulsatilla spp.
Ranunculus spp. (buttercups)
Thalictrum spp.
Trollius spp.

Ingestion of these plants may be associated with salivation, stomatitis, abdominal pain, diarrhea, dysentery, hematuria, blindness, ataxia, and convulsions.

TOXALBUMINS (LECTINS)

Plants known to be associated with toxalbumin poisoning are:

Abrus precatorius (abrin is toxin; jequirity, rosary pea, Crab's eye)[15]
Adenia spp.
Jatropha curcas (purging nut, Barbados nut)
Phaseolus vulgaris containing phytohemagglutinin (*Phaseolus* hemolytic agent)
Robinia pseudoacacia (robinin is toxin; black locust, false acacia)[2,16]
Ricinus communis (ricin is toxin; castor bean, wonder tree)[2,13,14]
Wisteria sinensis (wisteria, Chinese wisteria)

Lectins are important glycoproteins in human nutrition because of their common occurrence in foods. Many of the toxalbumins, however, are poisonous to animals. Horses appear to be the most susceptible to toxicosis followed by sheep, cattle, and pigs.[2,13,14] Toxalbumins are associated with inhibition of protein synthesis and damage to the gut epithelium, leading to defective digestion and absorption and increased permeability of the intestinal mucosa.[13,15] The toxins are present in foliage and seeds but are concentrated in the latter.[14] The clinical syndrome includes inappetence, vomiting, severe diarrhea, dehydration, dyspnea, rapid weight loss, recumbency, and death in most cases. Neurologic signs including depression, weakness, and encephalopathy may occur.[2,15,16] PCV, serum liver enzymes, and blood urea nitrogen (BUN) and creatinine levels are elevated.[14] Necropsy lesions include abomasal and intestinal hemorrhage and erosions, hepatocyte and renal tubular injury, pulmonary hemorrhage, edema, and emphysema.

PLANTS (UNIDENTIFIED TOXINS) AFFECTING THE GASTROINTESTINAL TRACT

The following plants affect the gastrointestinal tract in some manner. Toxins are believed to be involved but have not yet been identified.

DIARRHEA: WITHOUT GASTROENTERITIS AS A LESION

Anredera cordifolia (lamb's tail)
Blechnum spp. (bungwall fern)
Bulbine bulbosa (native leek)
Cadaba rotundifolia
Centaurium spp.
Chaerophyllum sylvestre
Cichorium intybus (chicory)
Chlorozophora spp.
Datisca glomerata (Durango root)
Dichrocephalia chrysanthemifolia
Juncus inflexus (blue rush)
Linum catharticum (purging flax)
Mentha australis (native mint)
Pipturus argenteus
Philydrum languinosum (woolly water lily)
Polygala klotzchii
Salvia coccinea (red salvia)
Synadenium arborescens (African milk bush)

DIARRHEA: WITH GASTROENTERITIS AS A LESION, OFTEN WITH ABDOMINAL PAIN AND INCOORDINATION, SOMETIMES WITH DYSENTERY AND VOMITING

Azadirachta indica (neem)
Brunfelsia australis (*B. bonodora*; yesterday, today, and tomorrow)
Buxus sempervirens (common box bush)
Centaurium beyrichii (rock centaury)
Chrysocoma tenuifolia (bitter bush)
Cissus quadrangularis
Cuscuta spp. (dodder)
Datisca glomerata (Durango root)
Dichrocephalia chrysanthemifolia
Dipcadi glaucum (poison onion)
Diplocyclos palmatus
Diplolophium africanum
Drymaria spp.
Ephedra viridis
Fagus sylvatica (European beech tree)
Galanthus nivalis (snowdrop)
Gymnocladus dioica (Kentucky coffee tree)
Ligustrum vulgare (privet hedge)
Ludwigia peploides (water primrose)
Ornithogalum longibracteatum (chincherinchee)
Robinia pseudoacacia (black locust, locust tree)
Rudbeckia spp.
Sapium sebiferum (Chinese tallow wood)
Scrophularia aquatica (water betony)
Sisyrinchium spp. (scour weed)
Sium angustifolium
Tulipa spp. (tulips)
Turraea robusta

DYSPHAGIA

Buxus sempervirens (box tree)
Descurainia pinnata (tansy mustard); difficulty in swallowing caused by paralysis of the tongue and the masseter and pharyngeal muscles is accompanied by spasmodic contractions of neck muscles, causing head bobbing in sheep, and may occur after sheep ingest *D. pinnata*; there is doubt about the relationship.[3]
Prosopis juliflora

ESOPHAGEAL ULCERATION

Crotalaria aridicola (horses only)
C. medicaginea (horses only)

SALIVATION WITH OR WITHOUT STOMATITIS

Arenaris serpyllifolia (thyme-leaved sandwort)
Puccinia graminis
Scabiosa succisa (devil's bit)

VOMITING

Cephaelis ipecacuanha
Tamus communis (black bryony; plus colic, paralysis, and death)

SLAFRAMINE TOXICOSIS (SLOBBERS, BLACK PATCH DISEASE)

SYNOPSIS

Etiology Contamination of leguminous pasture plants with slaframine, a mycotoxin produced by the fungus *Rhizoctonia leguminicola*

Epidemiology Ingestion of slaframine from contaminated hay or pasture is associated with a syndrome identified as "slobbers"; the term *black patch disease* refers to the discoloration of pasture or stored hay.

Clinical pathology Nothing in particular

Lesions The primary clinical sign in horses and ruminants is profuse salivation occurring within 4–6 h of ingestion.

Diagnostic confirmation The diagnosis is made based on the clinical sign of profuse salivation after ingestion of contaminated hay or pasture. The toxin can be identified in legumes by gas chromatography/mass spectrometry.

Treatment Treatment is generally not needed. Signs resolve 24–48 h after removal from contaminated pasture or hay.

Control Remove animals from contaminated food source, dispose of hay, and plant chemically treated seeds.

ETIOLOGY

Slaframine is an indolizidine alkaloid produced by the fungus *Rhizoctonia leguminicola* that contaminates leguminous pasture plants, in particular red clover (*Trifolium pretense*) and *Medicago sativa* (alfalfa or lucerne). Swainsonine, the phytotoxin found in *Swainsona* and *Astragalus* spp., is very similar to slaframine and has also been isolated from this fungus. Infested plants carry bronze to black spots or rings, and the hay is usually discolored by black patches on the stems and leaves.

EPIDEMIOLOGY

Occurrence

Ingestion of slaframine is associated with a syndrome, identified colloquially as "slobbers." Horses and cattle are primarily affected, although sheep, goats, llamas, and swine have also developed signs of toxicosis after ingestion.[1-3] Slaframine poisoning has been reported most often in the United States, but domestic animals in South America (Uruguay, Argentina, and Brazil), Japan, France, and the Netherlands have been affected.[2,4] The fungus *R. leguminicola* grows well in hot, humid weather and remains active in stored hay for at least 10 months and perhaps as long as 2 years.[2,4]

Risk Factors

Animal Risk Factors

There are no animal risk factors.

Environmental Risk Factors

The fungus grows well in hot, humid weather and survives growth cycles once the pasture or field is contaminated.[2]

Farm or Premise Risk Factors

Intoxication is primarily associated with ingestion of contaminated red clover or alfalfa, either in the field or stored hay, but other legumes such as white clover, alsike clover, soy beans, kudzu, cowpea, blue lupine, and black medic can become infected under the right weather conditions.[4] The fungus appears as black patches or rings in the pasture or black to brownish discolored areas on the plant stems or leaves.[1,5]

Transmission

Animals are intoxicated by grazing on pastures or eating hay infected with *R. leguminicola*. The fungus is seedborne and contaminates hay and pasture in this manner.[1]

PATHOGENESIS

Slaframine, a mycotoxin, undergoes metabolism in the liver into 6-ketoimine.[2,5] Structurally, ketoimine is very similar to acetylcholine, a parasympathetic neurotransmitter. Pharmacologically, ketoimine is a cholinergic agonist with action at the muscarinic receptors. Stimulation of muscarinic receptors by slaframine results in stimulation of exocrine glands, in particular the salivary glands and pancreas.[1,2] Swainsonine, another alkaloid produced by *R. leguminicola*, may also be involved with the production of some of the clinical signs.[1,5]

CLINICAL FINDINGS

Horses

Hypersalivation (and thus the term *slobbers*) is most frequent and often the only sign observed.[1,2,4] Other signs such as anorexia, diarrhea, polyuria, epiphora, and abortion have been reported but are uncommon.[2,4] Salivation occurs 4 to 6 hours after ingestion and lasts for 24 to 48 hours after the horses have been removed from contaminated pastures or hay.[1]

Ruminants

Hypersalivation occurs in ruminants as well but is often accompanied by decreased milk production, epiphora, and piloerection.[1,2] Other less common signs are polyuria, bloat, dyspnea, and stiffness. Occurrence and regressions of signs is similar to horses.

Swine

Vomiting, dyspnea, and stiffness have been reported.

NECROPSY FINDINGS

No necropsy lesions are recorded.

DIFFERENTIAL DIAGNOSIS

The diagnosis is generally made based on the clinical sign of hypersalivation and consumption of contaminated hay or pasture. The toxin can be identified in hay by gas chromatography/mass spectrometry.[4]

Differential diagnosis list:

Horses

Cholinesterase toxicosis (e.g., carbamates [imidocarb], organophosphorus insecticides)

Dental abnormalities

Esophageal choke

Foreign body (oral cavity, plant awns in hay)

Glossitis

Other infectious diseases (rabies, botulism, etc.)

Trauma

Vesicular stomatitis virus

Ruminants

Bluetongue virus

Caterpillar hairs (*Thaumetopoea processionea*, oak processionary caterpillar)

Cholinesterase toxicosis (e.g., carbamates [imidocarb], organophosphorus insecticides)

Food-and-mouth disease

Foreign body (oral cavity, plant awns in hay)

Vesicular stomatitis

TREATMENT

No treatment other than removing animals from the contaminated source is generally needed.[2,4] Atropine may be used to reverse hypersalivation but must be used with caution in horses and ruminants.[2]

CONTROL

The presence of the fungus *R. leguminicola* cannot be controlled once the pastures and/or hay are contaminated. Grazing animals should be removed from contaminated pasture, contaminated hay disposed, and seeds chemically treated before planting.[4]

CANTHARIDIN TOXICOSIS (BLISTER BEETLE POISONING, CANTHARIASIS)

SYNOPSIS

Etiology Blister beetle (*Epicauta occidentalis*, *E. temexa*, etc.)

Epidemiology Cantharidin, the toxin present in blister beetles, is incorporated into alfalfa hay and ingested by animals

Clinical pathology Hemoconcentration, azotemia, profound hypomagnesaemia and hypocalcaemia, hematuria, hyposthenuria

Lesions Oral and gastrointestinal ulcers and erosions

Diagnostic confirmation History, presence of beetles in hay, GCMS or LCMS using urine, blood, gastrointestinal contents, and feed

Treatment Activated charcoal, intravenous fluids, electrolyte replacement as needed, analgesics, gastrointestinal protectants

Control Know beetles in area, examine hay, do not harvest infested fields.

GCMS, gas chromatography-mass spectrometry; LCMS, liquid chromatography-mass spectrometry.

ETIOLOGY

Cantharidin toxicosis has been reported in horses as well as a number of other species including emu, sheep, goats, and cattle.[1,2] Horses are more susceptible and generally poisoned by the consumption of blister beetles (*Epicauta* spp.) present in hay. Cantharidin, a potent vesicant, is found in the hemolymph and leg joints of blister beetles.[3] There are over 200 named species of the beetle, and the most common association with toxicosis in horses are the three striped blister beetles *E. occidentalis* and *E. temexa.*

EPIDEMIOLOGY

Occurrence

Blister beetles feed on flowering foliage, primarily alfalfa, and are incorporated into hay when it is harvested. Cantharidin is stable in the environment and persists for extended time periods. Toxicosis was originally confined to the Southern states, but outbreaks now occur elsewhere because of the widespread shipment of alfalfa hay, and occasionally weedy meadow hay, infested with the beetles.

Risk Factors

The greatest risk factor for horses is the ingestion of blister beetle–contaminated hay. The beetles contain cantharidin, and administration of 1 g of ground beetles by nasogastric tube is fatal to a pony. The ingested lethal amount in adult horses is 0.5 to 1 mg/kg or about 4 to 6 g of dried beetles.[2,3] The cantharidin content of the beetles varies widely (0.77%–3.31% dry weight) between species, and male beetles contain more toxin than females.

Transmission

Whole or crushed blister beetles can be incorporated into hay and fed to horses and other livestock. It is possible that cantharidin released from crushed beetles may contaminate hay without any evidence of their presence.

PATHOGENESIS

The mechanism of action of cantharidin is not well established but may include inhibition of phosphatase 2A and protein mitochondrial damage from inhibition of enzymes responsible for active transport.[1,3]

Cantharidin is rapidly absorbed across all mucous membranes and to some extent the skin. It produces a strong irritant effect on the esophagus, stomach, and intestines. Once absorbed it is transferred to several body organs in which it produces systemic effects. It is not metabolized but is excreted unchanged in the urine where the irritant effect continues in the bladder, ureters, and urethra.[3]

CLINICAL FINDINGS

Clinical signs are dose dependent. Horses ingesting large amounts may die within 4

hours of ingestion. The ingestion of smaller doses may result in gastroenteritis (anorexia, diarrhea ± blood and/or mucus, severe colic), myocarditis (tachycardia, decreased capillary refill), nephritis (polyuria, oliguria), cystitis, or urethritis.[1,3,4] Generalized systemic signs include hyperthermia, depression, dehydration, sweating, synchronous diaphragmatic flutter, dyspnea, and rales. Death occurs in approximately 50% of cases. Prognosis is good for those horses surviving 7 days or more.[3]

CLINICAL PATHOLOGY

Serum protein and PCV will be elevated, indicating hemoconcentration, dehydration, and shock. Other laboratory abnormalities include an elevation in BUN, profound hypocalcemia and hypomagnesemia, hyposthenuria, and hematuria.[1,3]

NECROPSY FINDINGS

Vesiculating gastropathy of the gastric squamous mucosa is highly diagnostic, but no necropsy findings occur in many cases. Mass spectrometric and gas or liquid chromatographic methods facilitate detection of cantharidin in field specimens of blood, urine, stomach and intestinal contents, and feed. Cantharidin is rapidly excreted and may not be present in samples taken more than 4 to 5 days after ingestion.[3]

DIFFERENTIAL DIAGNOSIS

Differential diagnosis list:

- Arsenic toxicosis
- Cyanobacteria toxicosis
- Ionophore (monensin) toxicosis
- Colic (impaction and tympanic)
- Gastrointestinal enteriditis (colitis, proximal enteritis, peritonitis)

TREATMENT

There is no antidote and treatment is symptomatic. In early cases, activated charcoal or smectite may be used to decrease absorption of cantharidin.[1,5] The use of mineral oil is not recommended because it may actually increase cantharidin absorption and worsen morbidity.[1,2] Intravenous fluid therapy should be used to correct fluid and electrolyte deficits, with specific attention to calcium and magnesium supplementation.[1,5] Analgesics and gastrointestinal protectants should be used as needed. Broad-spectrum antibiotics may be used in animals with gastrointestinal erosions; the use of nephrotoxic antibiotics is contraindicated.

TREATMENT AND PROPHYLAXIS

Activated charcoal (1–3 g/kg per nasogastric × 1) (R2)

Mineral oil (4–6 L per nasogastric tube × 1) (R4)

Furosemide (1 mg/kg intramuscularly or intravenously every 6 h) (R3)

Sucralfate (20 mg/kg orally every 6–8 h) (R1)

CONTROL

Veterinarians should be aware of the presence of blister beetles in their area, and infested fields should not be harvested. Hay purchased from unknown sources should be inspected for the beetles, although cantharidin may still be present in the absence of beetles.

Neoplasms of the Alimentary Tract

MOUTH

Oral neoplasms in ruminants, other than viral papillomas, may be associated with heavy bracken intake. The tumors are usually squamous cell carcinomas arising from the gums and cause interference with mastication. They are most common in aged animals and probably arise from alveolar epithelium after periodontitis has caused chronic hyperplasia. Sporadic occurrences of other tumors, e.g., adenocarcinoma, cause obvious local swelling and dysphagia.

PHARYNX AND ESOPHAGUS

Papillomas sometimes involve the pharynx, esophagus, esophageal groove, and reticulum and cause chronic ruminal tympany in cattle. A high incidence of malignant neoplasia affecting the pharynx, esophagus, and rumen has been recorded in one area in South Africa. The tumors were multicentric in origin and showed evidence of malignancy on histologic examination. The clinical disease was chronic and confined to adult animals, with persistent, moderate tympany of the rumen and progressive emaciation as typical signs. A similar occurrence has been recorded in cattle in western Scotland and related to the long-term consumption of bracken. The tumors were squamous cell carcinoma in the pharynx and dorsal esophagus. The principal clinical abnormality was difficulty in eating and swallowing. Many of the carcinomas arise in preexisting papillomas, which are associated with a virus infection. The carcinomas occur only in cattle more than 6 years of age.

STOMACH AND RUMEN

Squamous cell carcinomas occasionally develop in the mouth and stomach of horses and the rumen of cattle. In the stomach of the horse, they occur in the cardiac portion and may cause obscure indigestion syndromes, lack of appetite, weight loss, anemia, obstruction of the lower esophagus, dysphagia, colic, and occasionally chronic diarrhea. Also, a tumor may ulcerate to terminate with perforation of the stomach wall and the development of peritonitis. Metastases may spread to abdominal and thoracic cavities with an accumulation of fluid. Subcutaneous edema is a common accompanying sign. There may also be pleural effusion caused by metastases in the pleura. Metastases in the female genital tract have also been noted. Most affected animals are euthanized because of anorexia and chronic weight loss. Large masses of metastatic tumor tissue may be palpable on rectal examination. In such cases an examination of paracentesis fluid sample cells should be valuable.

Lymphoma in horses is classified into multicentric, alimentary, mediastinal, cutaneous, and solitary tumors of extranodal sites. The alimentary form accounts for approximately 19% of the equine lymphoma cases and is often manifested by chronic diarrhea caused by massive infiltration of the intestinal wall.[1] There is severe weight loss, even in the absence of diarrhea in some cases, usually a large appetite and often severe ascites, and anasarca and sometimes colic. The same signs are recorded in a case of mesothelioma in a horse. The oral glucose absorption test is abnormal with a poor absorption response. Rectal examination may reveal large masses of hard nodular tissue, and hematological examination may be of assistance in diagnosis. Pseudodiverticula or intestinal obstruction may develop in the small intestine associated with tumor tissue.[2,3] Paracentesis and examination of cells in the fluid for the presence of mitotic figures is an essential part of an examination in suspected cases of neoplasia in the abdominal cavity. Nasal fibrogastroscopy is an obvious technique for visualizing proximally located tumors but is limited because standard instruments are usually not long enough. The course of this disease in horses is quite variable, with the period of illness lasting from 3 weeks to 3 months.

In a large case series from Brazil, the alimentary tract was the most common

location for tumor development (comprising 24% of 586 tumors), with squamous cell carcinoma of the upper gastrointestinal tract predominating.[4] Lesion locations were preferentially located at the base of the tongue, in the esophagus, and adjacent to the cardia in the ruminal wall. Lesion location was typically associated with clinical signs, including dysphagia and coughing for proximal tumors and bloating for tumors in the dital esophagus or ruminal wall.[5] Almost all affected cattle had access to bracken fern (*Pteridium aquilinum*), and it was speculated that chronic bracken fern ingestion was the cause for the tumors. Small numbers of lingual fibroma, abomasal adenoma, small-intestinal adenocarcinoma, ruminal fibrosarcoma, peritoneal mesothelioma, peritoneal fibroma, and anal squamous cell carcinoma were also reported. Ruminal tumors in cattle include papilloma/fibropapilloma, and bovine papillomavirus-1, -2, and -5 were associated with some of these lesions.[6] Squamous cell carcinoma of the reticulum with metastasis to the liver has been reported in a Simmental cow.[7] Although most ruminal tumors are small, if large enough they may obstruct the cardia and cause chronic tympany.

Small omasal and abomasal papillomas have been reported in 1-week-old calves and were associated with papillomavirus infection.[8] In lymphomatosis of cattle, there is frequently gross involvement in the abomasal wall causing persistent diarrhea. Ulceration, hemorrhage, and pyloric obstruction may also occur.

INTESTINES

A higher than normal rate of occurrence of carcinoma of the small intestine has been recorded in sheep in Iceland, Norway, and New Zealand and in cows only in New Zealand. A series of intestinal carcinomas is also recorded in Europe and another series in Australia. The tumors in the Australian series were located at abattoirs and were causing intestinal stenosis. Metastasis to regional lymph nodes occurred readily. In New Zealand there appeared to be a much higher prevalence in British-breed ewes (0.9%–0.15%) compared with Merino and Corriedale ewes (0.2%–0.4%), and a report of intestinal adenocarcinomas in three generations of sheep is suggestive of a genetic predisposition.[9] Significantly higher tumor rates were observed in sheep that had been pastured on foodstuffs sprayed recently with phenoxy or picolinic acid herbicides. The use of the herbicides 2,4-D, 2,4,5-T, MCPA, piclorum, and clopyralid has been associated with an increased incidence of these tumors. A higher prevalence in sheep kept at higher stocking rates was also suggested.

Occasional tumors of the intestine are recorded in abattoir findings, but they can cause clinical signs such as chronic bloat and intermittent diarrhea in cattle, persistent colic caused by partial intestinal obstruction in horses, and anorexia and a distended abdomen in sheep. A series of cases of lymphoma in horses was characterized by malabsorption without diarrhea but with some cases of anemia.

Occasional tumors recorded as causing colic in horses include an intramural ganglioneuroma occluding the jejunum, a jejunal myxoma that resulted in jejunoileocecal intussusception,[10] a stromal tumor in the cecum[11] or colon,[12] an intraluminal leiomyoma causing an intussusception of the small colon, a granulosa cell tumor of an ovary causing external pressure and occlusion of a small colon, and a ganglioneuroma in the small colon.[13] A juvenile granulosa cell tumor in a weanling filly caused a fatal volvulus and severe continuous colic. Anorexia, weight loss, abdominal distension, and constant chewing and swallowing movements are the prominent signs in gastric leiomyoma and squamous cell carcinoma. Leiomyoma may also be confined totally to the omentum and cause colic because of its size or excessive tension on the omentum.[14] Metastases in the peritoneal cavity are palpable in some cases. Leiomyosarcomas have caused chronic intermittent colic caused by constriction of the duodenum and partial intestinal obstruction. A colonic adenocarcinoma has caused weight loss, intermittent colic, poor appetite and scant feces, and a mass palpable in the abdomen.

Carcinoma of the stomach, small intestine, and colon are occasionally encountered in pot-bellied pigs.[15,16]

Tumors of the anus are rare; a mucoepidermoid carcinoma is recorded in a goat, but most tumors of the perineal area are anogenital papillomata. A rectal carcinoma has been reported in an aged Holstein cow.[17]

TUMORS OF THE PERITONEUM

Primary tumors of the peritoneum are rare. Most tumors of the peritoneum occur by metastasis from adjacent organs, such as with gastric squamous cell carcinoma, or disseminated disease such as lymphosarcoma. Primary tumors include leiomyomatosis and mesothelioma.

Disseminated peritoneal leiomyomatosis has been reported to occur in a mature Quarter Horse. Clinical findings included inappetence, weight loss, intermittent fever, chronic abdominal pain, and enlargement of the abdomen. Rectal examination revealed a prominent, firm, smooth-walled mass in the ventral aspect of the abdomen. Transabdominal ultrasonography was used to detect the mass, which was a friable, polycystic structure occupying a large portion of the abdominal cavity and weighing 34 kg. The mass was removed and recovery was complete.

Mesothelioma has been reported in cattle and goats,[1] predominantly in the peritoneal cavity, but mesothelioma can also occur in the pleural cavity and the vagina of adult cattle. The cause of mesothelioma in cattle is unknown, but pleural mesothelioma in humans is associated with asbestos exposure. One report suggested that the frequency of diagnosis in cattle is increasing. All ages of cattle can be affected with peritoneal mesothelioma, but affected animals are typically young, with fetal and neonatal cases also being reported. Calves and adult cattle most frequently present with moderate abdominal distension. Other presenting signs include scrotal edema in intact males and ventral pitting edema. Occasionally, small 2- to 20-mm, well-demarcated "bumps" can be felt on all serosal surfaces during palpation per rectum in adult cattle. Peritoneal fluid is easily obtained by ventral abdominal paracentesis and has the characteristics of a modified transudate with a moderate to marked increase in phagocytically active mesothelial cells. Definitive diagnosis is made during a right-sided exploratory laparotomy, in which numerous raised, white, and well-demarcated masses are palpated on all serosal surfaces, with copious abdominal fluid present. Biopsy of these masses and microscopic examination confirms the presumptive diagnosis of mesothelioma. Extensive peritoneal mesothelioma is fatal and there is no known treatment. All cases reported have been sporadic, and there is no apparent association with asbestos or other toxic agent in cattle.

Congenital Defects of the Alimentary Tract

HARELIP AND CLEFT PALATE

Harelip may be unilateral or bilateral and may involve only the lip or extend to the

nostril. It may be associated with cleft palate and cause dysphagia and nasal regurgitation of milk and food, and a risk of inhalation pneumonia. It may be inherited or a result from poisoning of lambs with *Veratrum californicum*. Cleft palate is difficult to correct surgically, especially in foals, in which it is a common congenital defect. Cleft palate (palatoschisis) is a common inherited defect in calves and is described later.

ATRESIA OF THE SALIVARY DUCTS

Congenital atresia of salivary ducts usually results in distension of the gland followed by atrophy. Rarely the gland may continue secreting, resulting in a gross distension of the duct.

AGNATHIA, MICROGNATHIA, AND BRACHYGNATHIA

These are variations of a developmental deficiency of the mandible, which is relatively common in sheep. The mandible and its associated structures are partially or completely absent. Single cases of a similar defect, combined with cleft palate, are recorded in calves.

Brachygnathia is an abnormal shortening of the mandible, resulting in malocclusion of the maxillary and mandibular dental arcades and creating the appearance of a maxillary overbite. It is considered to be a congenital abnormality but may be acquired within the first few months of life. The incisive malocclusion is of little consequence to the nursing foal but can affect the ability to prehend and masticate as the animal matures. It is not known to spontaneously regress, and surgical intervention is necessary to correct the malocclusion.

The cause may be genetic or environmental. Some reports indicate a genetic influence but the mode of inheritance is controversial. One report suggests that brachygnathia in Angus calves was transmitted by a single autosomal recessive gene, but such mode of inheritance has not been supported in other studies. In a series of 20 horses with brachygnathia the amount of disparity between the mandible and premaxilla varied between 0.75 and 3.0 cm. Surgical correction of the abnormality resulted in improved incisive occlusion. Complete correction of the malocclusion was more likely to occur if foals were treated before 6 months of age.

PERSISTENCE OF THE RIGHT AORTIC ARCH

Persistence of the right aortic arch as a fibrous band may occlude the esophagus and cause signs of obstruction, particularly chronic bloat in young calves.

CHOANAL ATRESIA

Failure of the bucconasal membrane to rupture during fetal life prevents the animal breathing through the nostrils. The membrane separates the alimentary tract and the nasal cavities in the pharynx. It is incompatible with life in foals, lambs, and llama and alpaca crias, the species in which it is identified. The defect is usually bilateral; a unilateral lesion is tolerable. Surgical correction is likely to be only partially effective.

CONGENITAL ATRESIA OF THE INTESTINE AND ANUS

Congenital intestinal atresia is characterized by the complete closure of some segment of the intestinal tract. Intestinal atresia has been reported in calves, lambs, foals, and piglets, and the affected newborn usually dies of autointoxication within a few days of birth. The incidence of intestinal atresia in 31 Irish dairy herds monitored over 1 year was 0.3% of all calves born.

INTESTINAL ATRESIAS

Congenital atresia of the intestine can be differentiated from retention of meconium in foals, and rarely calves, by the passage of some fecal color in the latter. Animals with intestinal atresia die at about 7 to 19 days of age unless the defect is corrected surgically. The intestine is grossly distended by then, and the abdomen is obviously swollen as a result. There is marked absence of feces.

Intestinal atresias have been classified into type I (membrane atresia caused by a diaphragm or membrane), type II (cord atresia caused by blind ends joined by a small cord of fibrous or muscular tissue or both, with or without mesentery), and type III (blind-end atresia, caused by absence of a segment of the intestine, with disconnected blind ends and a gap in the mesentery, and often a short small intestine).

Atresia of the ileum and colon is probably conditioned by inheritance in Swedish Highland cattle.

ATRESIA OF THE TERMINAL COLON

Atresia of the terminal colon occurs in foals, especially those of the Overo breed; the ileum and colon are affected in calves and the small intestine in lambs. Atresia coli has been reported in Holstein, Ayrshire, Shorthorn, Simmental, Hereford, Angus, and Maine Anjou breeds and in crossbred cattle. In one dairy herd over a 10-year period the overall incidence of atresia coli in calves was 0.76%. All the affected calves were related to one another, some were inbred, and the frequency was higher in males than females. Some affected calves were aborted or born dead at term. More calves were born with atresia coli from dams in which pregnancy was diagnosed before 41 days of gestation than from dams diagnosed as pregnant at a later date.

It is suggested that atresia coli in calves has an inherited basis and that affected calves are homozygous recessives for the defective allele for atresia coli. This is supported by planned matings between putative carrier sires and putative carrier dams. The estimated minimum gene frequency of atresia coli in cattle is 0.026, and it is thought that the defective allele for atresia coli is at high frequency in Holstein cattle in the United States. It is also plausible that early pregnancy diagnosis by palpating the amniotic sac before 40 days of gestation may be a contributing factor, but it is not essential for all cases. Intestinal atresia can be produced experimentally by terminating the mesenteric blood supply to some parts of the intestine during development.

In atresia coli, the abdomen may be grossly distended before birth when the defect is in the small intestine, and the distension may interfere with normal parturition. In defects of the large intestine, distension usually occurs after birth. In these the anus is normal, and the part of the intestine caudal to the obstructed section may be normal or absent. The principal clinical findings are depression, anorexia, and abdominal distension. Frequently the owner has not seen the calf pass meconium or feces. Thick mucus may be passed through the anus if it is patent or through the vagina in heifers with concomitant rectovaginal fistula. In many cases the animal has not sucked since the first day, and 5- to 6-day-old animals are very weak and recumbent. The intestine may rupture and acute diffuse peritonitis develop. Intestinal segmental atresia has been produced experimentally by occluding the blood supply to the intestine in fetal lambs. In one large series of congenital defects in calves the most common site of atresia was the midportion of the spiral loop of colon. The passage of a rectal tube or the infusion of barium and radiography may assist in the detection of atresia of the intestine, but care must be exercised during this procedure or the rectum and descending colon may be perforated. There are usually large quantities of thick tenacious mucus in the rectum with no evidence of meconium or feces. In the latter case only exploratory laparotomy can reveal the extent and nature of the defect. The differential diagnosis of atresia coli in calves includes acute intestinal obstructions such as volvulus and intussusception, diffuse peritonitis, and septicemia. **The presence of feces in the rectum rules out the presence of atresia coli.**

Surgical repair appears to be a satisfactory outcome in 30% to 50% of cases, and may be better with placement of a colostomy or cecostomy rather than a colocolic anastamosis.[1-3] In a series of intestinal atresia in calves admitted to a veterinary teaching hospital over a period of 10 years, the

survival rate was influenced by the atretic segments affected. In a series of 58 cases of intestinal atresia in calves, 7 of 18 cases corrected surgically made a satisfactory recovery; the remaining 40 calves were euthanized for different reasons.

The incidence of **atresia coli in foals** has been reported at 0.44% of foals under 2 weeks of age admitted to veterinary teaching hospitals over a period of 27 years. Clinical findings included progressive abdominal distension, colic, lack of feces, and lack of response to enemas. A neutropenia may reflect the presence of toxemia. The large transverse or small colon is commonly involved. Agenesis of the mesocolon in a 1-month-old foal with colic has been described. The prognosis for most cases is grave and surgical correction is usually unsuccessful. Atresia coli has also been reported in an alpaca cria.[4]

The common causes of colic in newborn foals include ileus with or without gas distension, intussusception, diaphragmatic hernia, gastroduodenal ulcers, necrotizing enterocolitis, small and large-intestinal strangulation, large intestine displacement, intraluminal obstruction other than meconium, ruptured bladder, and congenital abnormalities of the gastrointestinal tract.

ATRESIA OF THE ANUS

This is recorded as a congenital defect in pigs, sheep, and calves. Its occurrence is usually sporadic and no genetic or management factors can be indicated as causes. When the rectal lumen is quite close to the perineum, surgical intervention is easy and the results, in terms of salvaging the animals for meat production, are good. These animals can usually be identified by the way in which the rectal distension bulges in the perineum where the anus should be; pressure on the abdomen provokes a tensing or further distension of this bulge.[1]

MULTIPLE ORGAN DEFECTS

In many animals the congenital defects of the intestine are accompanied by defects in other organs, especially the lower urinary tract, so that reparative surgery is not possible. For example, multiple gut and urogenital defects are recorded in one calf and gut defects plus defects of the pancreas and gallbladder in another.

Congenital constriction of the anus and vagina is an inherited defect of Jersey cattle and discussed later. The defect may be combined with rectovaginal fistula manifested by the passage of feces via the vulva or penile urethra.

Inherited Defects of the Alimentary Tract

INHERITED DEFECTS OF THE MOUTH AND JAW

Harelip in cattle often has a distinct familial tendency but little work appears to have been done on the mode of inheritance. An apparently inherited harelip combined with poor growth and accompanying cryptorchidism is recorded in Holstein-Friesian cattle. Bilateral cleavage of the lip, which also involves the maxilla, is recorded in Texel sheep as being conditioned by a single recessive autosomal gene.

Cleft Palate

Cleft palate is inherited as a simple recessive character in Hereford and Charolais cattle, concurrent with arthrogryposis in the latter, and is commonly thought to be inherited in sheep and pigs. The progeny of a commercial swine herd (Landrace × Duroc) and Large White Boar contained a number of piglets with cleft palates. Chromosomal analysis of affected piglets found all had identical unbalanced karyotype with partial monosomy of chromosomes 16 and partial trisomy of chromosome 3, compared with normal piglets in the litters with balanced karyotypes.

Jaw Deformity

Shortness of the maxilla is thought to be inherited in Jersey cattle and Large White pigs, sometimes in association with chondrodysplasia. Shortness of the mandible is also inherited in cattle, and in Angus in combination with cerebellar hypoplasia and osteopetrosis.

Smooth Tongue (Epitheliogenesis Imperfecta Linguae Bovis)

Smooth tongue is a defect of Holstein-Friesian and Brown Swiss cattle, and it is inherited as an autosomal recessive factor. The filiform papillae on the tongue are small, there is hypersalivation and poor hair coat, and the calves do not fare well. The heterozygote is normal.

Tongue Aplasia

Congenital absence of the median part of the tip of the tongue occurs rarely in piglets, often in association with cleft palate and/or harelip.

Rectal Prolapse

Rectal prolapse may be inherited in piglets as a result of agenesis of the anal sphincter (see Inherited atresia of alimentary tract segments).

INHERITED RECTOVAGINAL CONSTRICTION

The rectovaginal constriction defect is inherited in Jersey cattle and is manifested as stenosis of the rectum in either sex and stenosis of the vaginal vestibule in females. The tone of both rectal and vaginal sphincters is increased, but attempts to detect heterozygotes by electromyographic measurement of these tones have been unsuccessful. The defect is regulated by an autosomal recessive gene. Affected cows are difficult to inseminate and have difficulty in calving. Their udders are small and hard and productivity is low. The condition is caused by the presence of bands of nonelastic fibrous tissue. Edema of the udder is also a common complication. Some assistance in the identification of affected animals is available by the detection of collagen type II in muscle biopsies. Fifty percent of heterozygotes also test positively as well as a small percentage of normals.

INHERITED ATRESIA OF ALIMENTARY TRACT SEGMENTS

Anal sphincter atresia occurs rarely in piglets and causes rectal prolapse. **Atresia ani** is quite common in pigs, sheep, and, to a less extent, cattle. Affected animals may survive for up to 10 days, and are identified by their depression, anorexia, colic, marked abdominal distension and lack of feces, and feces being replaced by thick white mucus. Abdominal distension in utero occasionally causes dystocia. Surgical repair is possible in some cases, but in others a large segment of rectum is missing, and creation of a colonic fistula in the inguinal region is necessary. The condition is thought to be inherited in pigs and calves, but supporting evidence is slim, and the evidence is less clear still in sheep. A suggestion that the defect may be also associated with the manipulation of the fetus during pregnancy examination has not been supported. A calf with atresia ani and diphallus and separate scrota has been described.

Inherited **atresia coli**, with complete closure of the ascending colon at the pelvic flexure, has been recorded in Percheron horses. A clinically similar defect in overo horses, described in the section on pseudoalbinism, is in fact an aganglionosis. Death occurs during the first few days of life. The defect appears to be inherited as a simple recessive character.

Inherited **atresia ilei** has been recorded in Swedish Highland cattle. Affected calves manifest marked abdominal distension causing fetal dystocia. The distension is caused by accumulation of intestinal contents. Inheritance of a single recessive gene conditions the occurrence of the defect in some species and breeds, but the prevalence may be higher than would be expected with

that form of inheritance, especially in Jersey cattle with atresia coli.

LETHAL WHITE SYNDROME IN FOALS AND LAMBS (INTESTINAL AGANGLIONOSIS)

White foals and white lambs of certain breeds or matings are affected by this syndrome, which is attributable to a mutation in the endothelin type B receptor gene (EDNRB).[1,2] Lethal white foal syndrome (OMIA #000629-9796) is an autosomal-recessively inherited condition of newborn foals born to American Paint Horse parents of the overo coat-pattern lineage.[3] In addition to foals of American Paint Horses, Quarter Horses and, rarely, Thoroughbreds are affected.[1] The overo coat-color pattern is characterized by pigment spreading down both sides from the dorsal midline, giving way to lack of pigment (i.e., white) primarily on the ventral surfaces.[3]

A mutation in the EDNRB of two nucleotides (TC > AG) in the coding EDNRB sequence results in the substitution of a single amino acid (Ile118Lys) and interference with migration of neural crest cells to the intestine causing intestinal aganglionosis, leading to a functional obstruction (megacolon) and death. Both melanocytes and myenteric ganglia cells are of neural crest origin, and their failure to migrate from the neural crest results in the absence of melanocytes in the skin and aganglionosis of the intestine.[1]

Over 94% of frame overo, highly white calico overo, and frame blend overo horse are heterozygotes, whereas fewer than 20% of tobiano, sabino, minimally blend overo, and breeding-stock solid are carriers.[1] Many solid (nonwhite coat-color pattern) horses with Paint horse bloodlines are heterozygous; therefore the genotype cannot necessarily be inferred from coat-color patterns.[1] White coat color can result from other genetic conformations and is not invariably associated with lethal white syndrome. Some affected foals may have flecks of black hair in the mane and tail or a small black body spot.[1]

Affected foals and lambs die within hours to several days of birth. Affected foals are all white or nearly all white and die of colic shortly after birth because of functional intestinal obstruction. Rectal examination reveals a lack of meconium. Radiographic examination of the abdomen reveals a distended large colon. Diagnosis is based on characteristic coat color and confirmation of megacolon. Diagnostic testing for the causative mutation is available commercially. Control is by testing and detection of heterozygotes and implementation of appropriate breeding programs.

A similar hypopigmentation syndrome occurs in Cameroon sheep and is associated with a homozygous 110-kb interstitial deletion on chromosome 10, including the entire EDNRB gene. The disease is inherited as an autosomal recessive trait.

8 Diseases of the Alimentary Tract–Ruminant

Diseases of the Forestomach of Ruminants

Forestomach motility of ruminants, especially cattle, is of major concern to the veterinarian. Evaluation of forestomach motility is an integral part of the clinical examination and differentiation of forestomach abnormalities into primary and secondary causes and is essential for diagnosis and accurate therapy. Application of the knowledge of the physiology of normal reticulorumen motility can improve the diagnosis, prognosis, and therapy for diseases of the forestomach. A brief review of the clinical aspects of the motility of the reticulorumen is presented here.

ANATOMY AND PHYSIOLOGY

The ruminant forestomach compartments, consisting of the reticulum, rumen, and

omasum, are like a fermentation vat. The animal exerts some control over the fermentation process by selecting the feed, adding a buffer-like saliva, and providing continual agitation and mixing with specialized contractions of the forestomach. Reticulorumen motility ensures a consistent flow of partially digested material into the abomasum for further digestion.

The forestomach can be divided into primary structures such as the **reticulorumen and the omasum**, and they are functionally separated by a sphincter called the **reticuloomasal orifice**. The reticulorumen of an adult cow occupies almost the entire left half of the abdominal cavity and has a capacity of up to 90 kg of digesta. Because of its large size and ease of clinical examination, rumen motility is considered to represent digestive functions in the ruminant.

Both parasympathetic and sympathetic nerves supply the reticulorumen, but only the former nerves stimulate motility. Parasympathetic innervation occurs through the vagus nerve, which is predominantly sensory from the forestomach. Sympathetic innervation to the forestomach consists of numerous fibers from the thoracolumbar segment; these fibers join at the celiac plexus to form the splanchnic nerve. The splanchnic nerve can inhibit motility, but normally there is little or no tonic sympathetic drive to the forestomach.

RETICULORUMEN MOTILITY

Four different specialized contraction patterns can be identified in the forestomach:

1. Primary or mixing cycle
2. Secondary or eructation cycle
3. Rumination (associated with cud chewing and associated with the primary cycle)
4. Esophageal groove closure (associated with sucking of milk)

It is important for the clinician to understand the motility pattern of each cycle. Specific diseases of the forestomach have characteristic alterations in motility, which aid in the diagnosis and prognosis.

Primary Contraction Cycle

The primary cyclic activity results in the mixing and circulation of digesta in an organized manner. The primary contraction in cattle begins with a **biphasic contraction of the reticulum**. The first reticular contraction forces ingesta dorsal and caudad into the rumen, as does the much stronger second reticular contraction. The dorsal ruminal sac then begins to contract as the ventral sac relaxes, causing digesta to move from the dorsal to the ventral sac. Sequential contractions of the caudoventral, caudodorsal, and ventral ruminal sacs force digesta back into the reticulum and cranial sac. After a brief pause the contraction sequence is repeated. During each reticular contraction fluid and food particles, particularly heavy grain, pass into the reticuloomasal orifice and into the omasum and abomasum.

Reticulorumen motility results in stratification of ruminal contents, with firmer fibrous material floating on top of a more fluid layer. Solid matter remains in the rumen until the particle size is sufficiently small (1–2 mm in sheep, 2–4 mm in cattle) to pass through the reticuloomasal orifice. The size of digested plant fragments in ruminant feces can therefore be considered an indirect measurement of forestomach function.

Identification of ruminal contractions requires both auscultation and observation of the left paralumbar fossa. Sound is produced when fibrous material rubs against the rumen during contraction. Only slight sound is produced when the rumen contains small quantities of fibrous material.

External palpation of the rumen is valuable in determining the nature of ruminal contents. The normal rumen feels doughy in the dorsal sac and more fluid ventrally; the difference in consistency is attributable to stratification of ruminal contents. Very liquid ruminal contents that splash and fluctuate on ballottement (fluid-splashing sounds) are suggestive of lactic acidosis, vagal indigestion, ileus, or prolonged anorexia.

Rumen hypomotility or hypermotility is usually associated with a change in the type of sounds heard during auscultation, with gurgling, bubbling or distant rustling sounds replacing the normal crescendo–decrescendo crackling sounds. The rumen can be examined and evaluated using a combination of auscultation and simultaneous ballottement or percussion, by palpation through the left flank, and by rectal examination. Inspection and laboratory analysis of rumen contents is also possible.

Control of Primary Contractions

The primary contraction cycle of the reticulorumen is a complex and organized contraction that is initiated, monitored, and controlled by the gastric center in the medulla oblongata. These cycles are mediated by the vagus nerve. The reticulorumen is under extrinsic nervous control compared with the remainder of the gastrointestinal tract. It is also affected by hormones and smooth muscle tone.

The gastric center is bilaterally paired and located in the dorsal vagal nucleus in the medulla. It has no spontaneous rhythm of its own but acts as a processor and integrator of afferent information. Various excitatory and inhibitory inputs are brought together to determine both the rate and strength of contraction.

Ruminal Atony

Ruminal atony, seen in lactic acidosis and endotoxemia, can be attributed to one or more of the following factors:

- Direct depression of the gastric center, usually associated with generalized depression and severe illness (toxemia)
- Absence of excitatory inputs to the gastric center
- Increase in excitatory inhibitory inputs to the gastric center
- Failure of vagal motor pathway (Table 8-1).

Hypomotility

Hypomotility is a reduction in the frequency or strength of extrinsic contractions, or both, and usually is caused by either a reduction in the excitatory drive to the gastric center or an increase in inhibitory inputs.

Properties of Contractions

The **frequency** of primary contractions is determined from information accumulated during the quiescent phase of motility. Frequency provides a rough estimate of the overall health of a ruminant. In cows, the frequency of primary contractions averages 60 cycles per hour but decreases to 50 cycles per hour during rumination and even lower when the cow is recumbent. Feeding increases the rate to up to 105 cycles per hour. Because of this variability, the clinician should auscultate the rumen for at least 2 minutes when determining the frequency of contractions.

The **strength** and **duration** of each contraction are determined by information obtained just before and during the contraction and are therefore more dependent on the nature of the forestomach contents than is frequency of contraction. The strength of contraction is subjectively determined by observing the movement of the left paralumbar fossa and assessing the loudness of any sounds associated with ruminal contraction.

The distinction between frequency and strength is important clinically, particularly in reference to therapy of reticulorumen hypomotility. When feed is withheld from sheep for 4 days, the rate of forestomach contractions remains unchanged, but the strength of contractions progressively decreases because of changes in ruminal contents.

Extrinsic Control of Primary Contractions

Excitatory Inputs to the Gastric Center

Tension and chewing movements are two major excitatory inputs to the gastric center. Low-threshold tension receptors deep in the circular smooth muscle layer detect reticulorumen distension. The greatest density of receptors is found in the medial wall of the reticulum and dorsal ruminal sac. These low-threshold tension receptors send afferent impulses along the dorsal or ventral vagus nerve to the gastric center in which they excite extrinsic reticulorumen contractions. Prolonged anorexia, leading to a smaller reticulorumen volume, decreases this excitatory input. Feeding increases reticulorumen

Table 8-1 Effects of some common clinical excitatory and inhibitory influences on primary cycle movements of the reticulorumen

Clinical afferent input	Clinical findings and responses to treatment
Excitatory inputs: low threshold reticular tension receptors	
Increased reticular tension After feeding Mild ruminal tympany	Increases frequency, duration, and amplitude of primary cycle contractions and mixing promotes fermentation
Decreased reticular tension Starvation Anorexia	Decreases frequency, duration, and amplitude of primary cycle contractions and decreases fermentation
Lesions of medial wall of reticulum Chronic induration and fibrosis caused by traumatic reticuloperitonitis	Cause hypomotility of rumen contractions and may be an explanation for atony in some cases of vagus indigestion; some cases are characterized by erratic hypermotility
Acid receptors in abomasum Increases in abomasal acidity following emptying of organ	Increase primary cycle movements, which increases flow of ruminal contents into abomasum to maintain optimum volume and to decrease acidity
Buccal cavity receptors Following eating Inhibitory inputs	Increased reticulorumen activity
High-threshold reticular tension receptors	
Peak of reticular contraction Severe ruminal tympany Ruminal impaction with forage, hay, straw (not necessarily grain overload)	Depression of primary cycle movements, ruminal hypomotility, depression of fermentation because of failure of mixing
Abomasal tension receptors	
Impaction, distension or displacement of abomasum	Abomasal impaction, dilatation and volvulus may result in complete ruminal stasis; left-side displacement of abomasum usually does not cause clinically significant hypomotility
Pain	
Visceral pain caused by distension of abomasum or intestines; severe pain from anywhere in body	Moderate to total inhibition of reticulorumen movements possible with visceral pain. The degree of inhibition from pain elsewhere will vary
Depressant drugs	
Anesthetics, central nervous system depressants Prostaglandin E	Inhibition of primary and secondary cycle movements and of eructation, resulting in ruminal tympany
Changes in rumen content	
Marked decrease (<5) or increase (>8) in pH of ruminal fluid; engorgement with carbohydrates or protein-rich feeds	Inhibition of primary and secondary cycle movement and lack of fermentation; transfer ruminal fluid from a healthy animal promotes return to normal activity
Absence of protozoa in ruminal acidosis and in lead and other chemical poisoning	
Changes in body water, electrolytes and acid-base balance	
Hypocalcemia Dehydration and electrolyte losses, acidosis, and alkalosis	Inhibition of primary and secondary cycle movements and of eructation, resulting in ruminal tympany which responds to treatment with calcium
Peritonitis	
Traumatic reticuloperitonitis	Inhibition of primary and secondary cycle movements and of eructation, resulting in ruminal tympany; return of primary movements is good prognostic sign; lesions must heal without involvement of nerve receptors or adhesions that will interfere with normal motility
Toxemia/fever	
Peracute coliform mastitis Acute bacterial pneumonia	Inhibition of primary and secondary cycle movements, which return to normal with treatment of endotoxemia
Ruminal distension	
Early ruminal tympany	Increased frequency of secondary cycle movements and of eructation
Covering of cardia (fluid or form)	
Ruminal tympany Recumbent animal	Cardia does not open; failure of eructation, resulting in ruminal tympany; clearance of cardia results in eructation

Most of the sensory inputs are transmitted to gastric centers in the dorsal vagal nerve nuclei from which the efferent outputs originate and pass down the vagal motor nerve fibers.
Source: modified from Leek BF. Vet Rec 1969; 84:238.

volume, leading to a prolonged increase in forestomach motility.

Buccal receptors, which are stimulated during feeding, are also excitatory to the gastric center. These are mechanoreceptors, and their effect is mediated by the trigeminal nerve. This reflex increases the rate of primary contractions only but is short-lived and wanes with time. The stimulatory response of feeding also has a higher brain center component: the sight of feed can increase the frequency of primary contractions by 50% during a period of 4 to 5 minutes. Rumination, in comparison with feeding, is accompanied by a lower than normal primary contraction rate.

Other relatively minor excitatory inputs to the gastric center include milking, environmental cold, and a decrease in abomasal pH. Milking or udder massage of dairy goats markedly increases the frequency and strength of primary contractions. In a cold environment, the ruminant increases the frequency of forestomach contractions, maximizing the fermentation rate and helping to maintain body temperature.

Inhibitory Inputs to the Gastric Center

The four most important inhibitory inputs to the gastric center are fever, pain, moderate to severe rumen distension, and increased ruminal volatile fatty acid concentrations.

Fever

Fever has been associated with decreased rumen motility. Endogenous pyrogens may cause prolonged forestomach hypomotility or atony often seen in cattle with endotoxemia caused by bacterial infections. Pyrogens directly affect the gastric center in the hypothalamus, and opioid receptors mediate their action.

Endotoxemia

Endotoxemia is common in cattle and often associated with fever, anorexia, and rumen atony. Inhibition of forestomach motility during endotoxemia is thought to be a combination of two different pathways: a prostaglandin-associated mechanism and a temperature-independent mechanism. The former can be attenuated by administration of nonsteroidal antiinflammatory drugs (NSAIDs). Therapy for endotoxin-induced hypomotility or atony includes the use of antimicrobials for the underlying cause of the inflammation and NSAIDs for the effects of the endotoxemia.

Pain

Pain may be associated with rumen hypomotility or atony. Painful stimuli act directly on the gastric center, although modification of reticulorumen motility in response to painful stretching of viscera can be partially attributed to catecholamine release. The sympathetic nervous system response to pain can also stimulate splanchnic motor nerves, directly inhibiting reticulorumen motility.

Because of their stoic nature, the only clinical evidence of pain in ruminants may be anorexia and depressed forestomach motility. Prostaglandins have been implicated in increasing the sensitivity to pain both locally and centrally, and NSAIDs are indicated for alleviation of pain associated with inflammation. Other analgesics are of limited usefulness in the treatment of pain-induced forestomach hypomotility. Xylazine, an excellent sedative-analgesic for ruminants, causes a dose-dependent inhibition of reticulum contractions.

Distension of Forestomach

Moderate to severe forestomach distension exerts an inhibitory influence on reticulorumen motility. Epithelial receptors located in the ruminal pillars and papillae of the reticulum and cranial rumen sac respond to mechanical stimulation (stretch) as well as changes in ruminal volatile fatty acid concentration. These receptors, also known as high-threshold tension receptors, are stimulated continuously during severe rumen distension. The opposing actions of low- and high-threshold tension receptors help to control the fermentation process and maintain an optimum reticuloruminal volume. A good example of their activities is the motility changes evident with some forms of vagus indigestion.

Ruminal Volatile Fatty Acids

The ruminal volatile fatty acid concentration also influences forestomach motility. Epithelial receptors detect the concentration of nondissolved volatile fatty acids in ruminal fluid, which is normally high enough to produce a tonic inhibitor input to the gastric center. Volatile fatty acids in the reticulorumen exist in both the dissociated and nondissociated forms, with the degree of ionization governed by the rumen pH and the logarithm to the base 10 of the equilibrium acid dissociation constant (pKa) of each particular acid. Ruminal atony in animals with lactic acidosis results from elevated levels of nondissociated volatile fatty acids in ruminal fluid, with the decrease in rumen pH changing more of the volatile fatty acids into a nondissociated form. Systemic acidosis does not appear to contribute to ruminal atony, although increased volatile fatty acid concentrations in the abomasum may reduce forestomach motility.

Abomasal Disease

Diseases of the abomasum influence forestomach motility. Abomasal distension may contribute to the decreased forestomach motility often observed with abomasal volvulus (AV), impaction, or right-side dilatation. Abomasal tension receptors detect overfilling and reflexively decrease reticuloruminal movements, reducing the rate of flow of ingesta into the abomasum. Ruminal hypomotility is not always observed in left-side displacement of the abomasum even though appetite may be decreased.

Effect of Depressant Drugs

General anesthetics and other depressant drugs acting on the central nervous system also inhibit reticulorumen motility by a direct effect on the gastric center.

Acid-Base Imbalance and Blood Glucose

Reticulorumen activity can be inhibited by alterations in blood pH, electrolyte imbalances, deprivation of water, and hyperglycemia.

Hormonal Control of Primary Contractions

Forestomach motility can be influenced by the action of hormones. Both cholecystokinin and gastrin can reduce feed intake and forestomach motility observed in sheep with certain intestinal nematodes.

Intrinsic Control of Primary Contractions

The contribution of intrinsic smooth muscle tone to forestomach motility is not well understood. Intrinsic contractions are involved in maintaining normal reticulorumen tone, directly influencing the discharge of low-threshold tension receptors to the gastric center. Calcium is required for smooth muscle contraction, and hypocalcemia will usually cause ruminal atony. The administration of calcium borogluconate to cattle, sheep, and goats with hypocalcemia will restore rumen motility, and eructation commonly occurs after the intravenous administration of the calcium.

Treatment of Forestomach Hypomotility

Anorexia and forestomach hypomotility usually exist together. Reduced feed intake reduces the two primary drives for reticulorumen activity: moderate forestomach distension and chewing activity. A wide variety of drugs have been used for many years to induce forestomach motility with the aim of stimulating anorexic cattle with forestomach hypomotility to begin eating. Most if not all of these drugs have been unsuccessful. Ruminatorics such as nux vomica, gentian, and tartar given orally have not been effective, but ginger shows potential promise as a prokinetic in cattle (see section on simple indigestion elsewhere in this chapter). Parasympathomimetics, such as neostigmine or carbamylcholine, should not be used to treat forestomach atony. Neostigmine requires vagal activity to be effective and therefore cannot incite normal primary contractions in atonic animals. Neostigmine may increase the strength

of a primary contraction without altering rhythm or coordination. Carbamylcholine causes hypermotility in sheep, but the contractions are uncoordinated, spastic, and functionless.

Any effective drug must be able to induce forestomach motility in a coordinated sequence so that the ingesta move through the reticuloomasal orifice, into the omasum, out of the omasum, and into the abomasum, and out of the abomasum into the small intestine. This means that there must be a coordinated sequence of contractions and relaxations of sphincters.

Secondary Cycle Contraction and Eructation

Secondary cycles are contractions that involve only the rumen and are associated with the **eructation of gas**. They occur independently of the primary cycle contractions and usually less frequently (about once every 2 minutes). The contraction rate depends on the gas or fluid pressure in the dorsal sac of the rumen. Secondary cycles can be inhibited by severe distension of the rumen.

Normally, the dorsal sac of the rumen contains a pocket of gas composed of CO_2, N_2, and CH_4. Gas is produced at a maximum rate of 1 L/min in cattle, with the rate depending on the speed of microbial degradation of ingesta. Eructation occurs during both primary and secondary contraction cycles, but most gas is removed during the latter. Eructation is capable of removing much larger quantities of gas than is produced at the maximum rates of fermentation; therefore free gas bloat does not occur because of excessive gas production but rather from insufficient gas elimination.

Ruminal contractions are essential for eructation. Tension receptors in the medial wall of the dorsal ruminal sac initiate the reflex by means of the dorsal vagus nerve. Contractions begin in the dorsal and caudodorsal ruminal sacs and spread forward to move the gas cap ventrally to the cardia region. Contraction of the reticuloruminal fold is necessary to stop fluid from moving forward to the reticulum and covering the cardia. Receptors in the cardia region detect the presence of gas; the cardia remains firmly closed if fluid or foam (as in frothy bloat) contacts it. Injury to the dorsal vagal nerve decreases the efficiency of eructation but either the ventral or dorsal vagus nerve alone can initiate enough eructation activity to prevent bloat.

Despite the presence of normal secondary contractions, eructation may not occur in recumbent animals when the cardia is covered with fluid. Bloat is often observed in ruminants in lateral recumbency. Eructation occurs after the animal stands or attains sternal recumbency as fluid moves away from the cardia. Bloat can also result from peritonitis, abscesses or masses that distort the normal forestomach anatomy, and preventing active removal of fluid from the cardia region. Esophageal obstructions associated with intraluminal, intramural, or extraluminal masses are a common cause of free gas bloat. Passage of a stomach tube usually identifies these abnormalities, and forestomach motility is unimpaired unless the vagal nerve is damaged.

Bloat is often observed in cattle with tetanus. Distension of the rumen is usually not severe and can be accompanied by strong and regular ruminal contractions. Because the ruminant esophagus is composed of striated muscle throughout its length, tetanus-associated bloat may be caused by spasm of the esophageal musculature.

Persistent mild bloat is often observed in ruminants that have rumen atony or hypomotility secondary to systemic disease. Although the fermentation rate is lower than normal in these cases, ruminal contractions are not strong enough to remove all the gas produced. The bloat usually requires no treatment and resolves with return of normal forestomach motility.

Secondary contractions cannot be distinguished from primary contractions by auscultation of the left paralumbar fossa only, unless a synchronous belch of gas is heard. However, primary contractions can be identified by simultaneous palpation of the left paralumbar fossa and auscultation with the stethoscope over the left costochondral junction between the seventh and eighth ribs. Reticular contractions indicating the beginning of a primary contraction can be heard followed by contraction of the dorsal sac and lifting of the paralumbar fossa.

Secondary contractions are relatively autonomous and are not subject to the same central excitatory and/or inhibitory influences as are primary contractions. Agents that inhibit reticulorumen motility by a central action have a lesser effect on eructation than on primary contraction cycles. However, high doses of xylazine can inhibit secondary contractions, and the duration of inhibition is dose dependent.

No drugs are yet available to improve secondary contractions as a means of treating bloat. Severe bloat usually arises from mechanical or diet-related causes, and therapy should be directed specifically to those causes.

Rumination

Rumination is a complex process and consists of the following:

- **Regurgitation**
- **Remastication**
- **Insalivation**
- **Deglutition**

Rumination is initiated by the rumination center close to the gastric center in the medulla oblongata. Rumination allows further physical breakdown of feed with the addition of large quantities of saliva and is an integral part of ruminal activity. The time devoted to rumination is determined by the coarseness of ruminal contents and the nature of the diet. Rumination usually commences 30 to 90 minutes after feeding and proceeds for 10 to 60 minutes at a time, resulting in up to 7 hours per day spent on this activity.

The epithelial receptors located in the reticulum, esophageal groove area, reticulorumen fold, and ruminal pillars detect coarse ingesta and initiate rumination. The receptors can be activated by increases in volatile fatty acid concentration, stretching, and mechanical rubbing.

An intact dorsal or ventral vagus nerve is necessary for regurgitation to proceed. Regurgitation is associated with an extra contraction of the reticulum immediately preceding the normal reticular biphasic contraction of the primary cycle. The glottis is closed, and an inspiratory movement lowers the intrathoracic pressure. The cardia then relaxes, and the distal esophagus fills with ingesta. Reverse peristalsis moves the bolus up to the mouth in which it undergoes further mastication. Abnormal rumination can occasionally result in "dropped cuds," during which the regurgitated bolus is dropped on the ground (Fig. 8-1).

The usual causes for a reduction or absence of rumination are the following:

- Reticulorumen hypomotility or atony
- Central nervous system depression
- Excitement, pain, or both
- Liquid ruminal contents such as a high-concentrate diet with no coarse fiber
- Mechanical injury to the reticulum (peritonitis)

Other less common causes include chronic emphysema (difficulty in creating a negative thoracic pressure) and extensive damage to the epithelial receptors that incite the reflex, as occurs in rumenitis.

Reticulorumen motility is required for rumination to proceed. The extra reticular contraction is not essential for regurgitation because fixation or removal of the reticulum does not prevent rumination from occurring. Rumination can be easily inhibited by higher brain centers, as disturbance of a ruminating cow often stops the process and is absent when animals are stressed or in pain. Milking commonly elicits rumination in cows and goats.

Pharmacologic stimulation of regurgitation is not attempted.

Esophageal Groove Closure

The esophageal groove reflex allows milk in the sucking preruminant to bypass the forestomach and directs milk from the esophagus along the reticular groove and omasal canal into the abomasum. Milk initiates the reflex by chemical stimulation of receptors in the oral cavity, pharynx, and cranial esophagus. Once the reflex is established in neonatal

Fig. 8-1 **A and B,** Two-year-old Holstein Friesian heifer demonstrating dropped cuds while being retained in a head-gate. The heifer had a tooth root abscess.

ruminants, sensory stimuli (visual, auditory, and olfactory) can cause esophageal groove closure without milk contacting the chemoreceptors. This occurs in calves teased with milk or given water in an identical manner to which the calf previously received milk. The esophageal groove reflex continues to operate during and after the development of a functional rumen, provided the animal continues to receive milk.

Liquid administered to calves with an esophageal feeder (tube) does not cause groove closure. In calves younger than 3 weeks of age, overflow of liquid from the rumen into the abomasum begins when 400 mL of liquid are given. Thus if the goal of oral feeding is to ensure that fluid administration by esophageal tube rapidly enters the abomasum, more than 400 mL of liquid must be given.

Closure of the esophageal groove in cattle younger than 2 years of age can be induced by solutions of sodium chloride, sodium bicarbonate, or sugar. From 100 to 250 mL of 10% solution of sodium bicarbonate induces esophageal groove closure in 93% of cattle immediately and it lasts for 1 to 2 minutes. Any other oral solution administered during this time is directed into the abomasum to avoid dilution in the rumen. Closure of the groove may be used to treat abomasal ulcers if magnesium hydroxide or kaolin–pectin solutions are given orally immediately after a sodium bicarbonate solution.

RUMINANT GASTROINTESTINAL DYSFUNCTION

Clinical findings that suggest primary ruminant gastrointestinal dysfunction include the following:

- Inappetence to anorexia, failure to ruminate.
- Dropping regurgitated cuds (see Fig. 8-1) occurs occasionally and is associated with teeth abnormalities including tooth root abscess, straw impaction of the rumen, vagus indigestion, esophageal dilatation, and rumenitis.
- Visible distension of the abdomen, which may be asymmetric or symmetric, dorsal or ventral. or both. Distension of the left dorsal abdomen because of ruminal tympany is most common.
- The abdomen may appear gaunt or empty.
- The rumen may feel abnormal on palpation through the left paralumbar fossa. It may feel more doughy than normal, distended with gas, fluid filled, or it may not be palpable.
- Ruminal atony or hypermotility observed visually and detectable on auscultation and palpation.
- Abdominal pain is usually subacute and characterized by humping of the back, reluctance to move. or acute colicky signs of kicking at the abdomen and stretching. Pain may also be detectable on deep palpation of the abdomen if there is peritonitis, either local or diffuse.
- Abnormal feces: they may be absent, reduced in amount or voluminous, and the composition may be abnormal. In carbohydrate engorgement the feces are usually increased in amount and are sweet–sour smelling. In most other diseases of the ruminant stomachs the feces are reduced in amount (scant), are pasty and foul-smelling, and appear overdigested because of the increased transit time in the alimentary tract. A complete absence of feces for 24 to

48 hours is not uncommon with diseases of the ruminant stomach and may be confused with an intestinal obstruction or the earliest stages of hypocalcemia in a recently calved mature cow,

- The temperature, heart rate, and respirations are variable and may be within normal ranges. With an inflammatory lesion such as acute peritonitis, a fever is usually present. In acute diffuse peritonitis with toxemia, the temperature may be normal or subnormal; in subacute and chronic peritonitis the temperature is usually normal. In most other diseases of the ruminant stomachs except carbohydrate engorgement and abomasal volvulus, in which dehydration, acidosis and gastric infarction occur, vital signs may be within the normal range.

The differential diagnosis of the diseases associated with gastrointestinal dysfunction in cattle is summarized in Table 8-2.

In contrast with most other parts of the ruminant alimentary tract, and with the stomach of nonruminants, specific lesions of the mucosa of the forestomachs are uncommon. Penetration of the reticular wall by metallic foreign bodies is a common disease and is dealt with under the heading of traumatic reticuloperitonitis, but it is peritonitis that causes interference with ruminal motility. Rarely, there are actinomycotic or neoplastic lesions at the fundus of the reticulum that interfere with the proper functioning of the esophageal groove and lead to a syndrome of vagus indigestion described later. Rumenitis is common but only as a secondary change in acute carbohydrate engorgement and it is this that has such damaging effects on gut motility and fluid and electrolyte status and eventually kills most cows. The rumenitis may have a long-term effect

Table 8-2 Differential diagnosis of causes of gastrointestinal dysfunction of cattle

Disease	Epidemiology and history	Clinical findings	Clinical pathology	Response to treatment
Simple indigestion	Dietary indiscretion, too much of a palatable, or indigestible, or change of, or damaged, or frozen food; can be outbreak. Consumption of excessive quantities of finely chopped straw	Simple gastrointestinal atony Voluminous feces during recovery Gross distension of the rumen and abdomen in straw impaction	All values normal Slight changes in ruminal acidity, should be self-buffered	Simple indigestion Excellent just with time Usually a mild purgative Rumenotomy necessary in case of straw impaction
Carbohydrate engorgement	Access to a large amount of readily fermentable carbohydrate when not accustomed; enzootic in high-grain rations in feedlots	Severe gastrointestinal atony with complete cessation of ruminal activity Fluid splashing sounds in rumen Severe dehydration, circulatory failure Apparent blindness, then recumbency and too weak to rise Soft odoriferous feces	Hemoconcentration with severe acidosis, pH of rumen juice <5, serum phosphorus concentration up to 3–5 mmol/L, serum calcium levels depressed No living protozoa in rumen	Intensive intravenous fluid and electrolyte therapy necessary for survival Rumenotomy or rumen lavage may be necessary Alkalinizing agents
Ruminal tympany	Frothy bloat on lush legume pasture or low-roughage feedlot ration, especially lucerne hay Free gas bloat secondary, occasionally primary on preserved feed	Gross distension of abdomen, especially high up on left. Sudden onset Severe pain and respiratory distress. Rumen hypermotility initially Liquid feces Resonance on percussion over rumen	None	Excellent if in time; stomach tube for free gas Froth-dispersing agent in frothy bloat Severe cases may require trocarization or emergency rumenotomy
Acute traumatic reticuloperitonitis	Exposure to pieces of metal. Sporadic; usually adult cattle	Sudden-onset reticulorumen atony, mild fever Pain on movement and deep palpation of ventral abdomen caudal to xiphoid Reduced amount of feces Lasts 3 days, then improvement begins	Neutrophilia and shift to left If no recovery after 3 days consider rumenotomy	Good response to antimicrobials for 3 days, magnet, immobilize in stall
Chronic traumatic reticuloperitonitis	Previous history of acute local peritonitis	Inappetence to anorexia; loss of weight; temperature, heart rate and respirations normal; rumen small and atonic, chronic moderate bloat common, feces scant, grunt may be detectable on deep palpation over xiphoid, reticular adhesions on laparotomy	Hemogram depends on stage and extent of inflammation	Antimicrobials for several days Consider rumenotomy Small percentage will respond
Vagus indigestion	May or may not have history of acute local peritonitis. Inappetence and progressive distension of abdomen during late pregnancy and no response to treatment with laxatives	Progressive distension of abdomen, scant soft sticky feces containing undigested feed, anorexia, rumen distended with well-macerated and frothy contents, persistent moderate bloat, hypermotile initially and atonic later, temperature normal, heart rate variable, large L-shaped rumen rectally, abomasal impaction in some, marked loss of weight, eventual recumbency, dehydration and weakness	Varying degree of dehydration, alkalosis, hypochloremia, and hypokalemia; increase in rumen chloride	Inadequate response to treatment medically or surgically Mild cases near term may respond spontaneously following parturition

Table 8-2 Differential diagnosis of causes of gastrointestinal dysfunction of cattle—cont'd

Disease	Epidemiology and history	Clinical findings	Clinical pathology	Response to treatment
Jejunal hemorrhage syndrome	Sporadic cases, sometimes several in one herd over a few months. History of sudden death or decreased milk production, anorexia, dark tarry feces, abdominal distension High-producing lactating dairy cattle, and beef cows. *Clostridium* sp. may be factor	Anorexia, abdominal discomfort, depression, abdominal distension, ping or fluid splashing sounds on ballottement over right abdomen, melena and distended loops of intestines on rectal examination. Black tarry feces	Dehydration, hypochloremia, hypokalemia fluid and electrolyte therapy, and surgery to remove damaged jejunum and obstructive luminal blood clot	Surgical treatment is occasionally successful if very early in disease course, but generally prognosis of affected cows is very poor
Rumen collapse syndrome	Diseases causing complete anorexia, fever, and toxemia for several days	Rectangular-shaped "pong" (low-pitched tympanitic sound) in left paralumbar fossa; rumen pack not easily palpable through abdominal wall; on rectal examination can feel collapsed dorsal sac of rumen	None	Treat primary disease causing anorexia and ruminal stasis Rumen transfaunation often beneficial if primary cause identified and treated
Early hypocalcemia	Usually within 48 h following parturition in mature dairy cow	Anorexia, rumen hypotonic or atonic, scant or absence of feces for 12–24 h, temperature normal, heart rate increased and possibly arrhythmia, still milking and may appear normal in all other aspects	Total serum calcium <1.5 mmol/L	Good response to calcium administered intravenously or subcutaneously May require several hours to return to normal
Abomasal impaction (dietary)	Excessive intake of poor-quality roughage during cold weather outbreaks; cattle eating crops contaminated with sand or small stones	Anorexia, moderate abdominal distension, weight loss, scant feces, weak, recumbent Abomasum palpable through abdominal wall or rectally	Alkalosis, hypochloremia, hypokalemia, and dehydration	Excellent response to surgical treatment if impaction confined to pyloric antrum High case–fatality rate in advanced cases Fluids, laxatives Slaughter for salvage may be indicated
Left displaced abomasum	High-level grain diets, immediately postpartum, dairy cows, inactivity	Acetonemia in cow within days after parturition, inappetence, feces soft and amount variable (usually reduced) Ketonuria Rumen sounds present but faint Ping on percussion and auscultation of left upper abdomen between the 9th and 12th ribs and paralumbar fossa	Ketonuria	Excellent response following surgical correction unless concurrent hepatic lipidosis
Right displaced abomasum	Usually 2–4 weeks postpartum	Anorexia, scant feces, reduced milk production, moderate dehydration, rumen sluggish, fluid-filled viscus under right costal arch, ping over large area; tense viscus palpable per rectum in right lower quadrant, progressive and commonly results in volvulus	Alkalosis, hypochloremia, hypokalemia Calcium borogluconate intravenously and hay diet Surgery is immediately indicated. Prognosis good if treated early. Fluid therapy	Some recover spontaneously with medical therapy, but cannot definitively differentiate from abomasal volvulus without abdominal surgery.
Abomasal volvulus	Sequel to RDA	History of right displaced abomasum followed by sudden onset of acute abdominal pain, distension of right abdomen, loud ping Distended tense abomasum palpable per rectum in right lower quadrant, marked circulatory failure, weakness, bloodstained feces, death in 48–60 h if not treated surgically	Dehydration alkalosis, hypochloremia	Laparotomy and omentopexy, abomasotomy and drainage only if abomasum cannot be safely returned to its normal anatomic location Survival rate at least 75% if treated early Fluid therapy required
Primary acetonemia (wasting form)	Insufficient intake of energy in early lactation	Dullness, anorexia, reduced feces, lose body condition, milk yield down Rumen activity depressed	Ketonuria and hypoglycemia	Dextrose intravenously and propylene glycol orally, or intramuscular corticosteroids Usually excellent response

Continued

Table 8-2 Differential diagnosis of causes of gastrointestinal dysfunction of cattle—cont'd

Disease	Epidemiology and history	Clinical findings	Clinical pathology	Response to treatment
Acute intestinal obstruction	Often no particular history	Sudden onset, short period acute abdominal pain Kicking at belly, rolling Complete anorexia, failure to drink, and alimentary tract stasis. Progressive dehydration Distended loops of intestine may be palpable Gray to red foul-smelling rectal contents	Progressive dehydration and hemoconcentration over 3–4 days	Surgery is necessary
Idiopathic paralytic ileus	Few days postpartum, may be change in diet	Anorexia, complete absence of feces for 24–48 h; may detect ping over right flank	None	Usually recover spontaneously
Obstruction of small intestine by phytobezoar	Single animal usually Area prevalence may be high some years Depends on frequency of fibrous plants, e.g., *Romulea* spp.	Sudden onset acute abdominal pain Attack brief, often missed; then anorexia, ruminal stasis, heart rate increases to 120 beats/min over 3–4 days Abdomen distends moderately, splashing sounds and tympany right flank Rectal examination shows distended loops of intestine if obstruction in distal small intestine, may feel 5- to 6-cm diameter fiber ball; feces pasty, gray-yellow, foul-smelling, small amount only Untreated and fatal cases have course of 4–8 days	Hypochloremia, hypokalemia, severity depends on location	Depends on nature of phytobezoar: dense fiber balls require surgery, crumbly masses may pass after mineral oil for several days
Abomasal ulcer	Soon after (2 weeks) parturition High producers on heavy grain feed In intensive feeding systems disease is becoming enzootic in some areas	Gastrointestinal atony with melena and pallor May be sufficient blood loss to cause death; prompt recovery after 4 days more likely Perforation and rupture of ulcer leads to death in a few hours	Melena or occult blood in feces On perforation with local peritonitis may be leukocytosis and left shift Anemia caused by hemorrhage	Alkalinizing agents orally Surgery if medical treatment unsuccessful
Pregnancy toxemia of beef cattle	Fat beef cattle deprived of feed in last month of pregnancy Commonly have twin pregnancy	Complete anorexia, rumen stasis, scant feces, ketonuria, weak and commonly recumbent	Ketonia, increase in nonesterified fatty acids, ketonuria, increase in liver enzymes	Poor response to therapy Fluids, anabolic steroids, insulin
Fatty liver (fat cow) syndrome	Fat dairy cow, a few days following parturition or may have had LDA for several days	Complete anorexia, rumen stasis, almost no milk yield, ketonuria initially but may have more later	Ketonemia, increase in liver enzymes	Poor response to therapy in cattle that are not eating Oral propylene glycol, intravenous glucose, intramuscular corticosteroids
Cecal dilatation or cecocolic volvulus	Single case Dairy cow, early lactation, inappetence, feces may be scant Severe cases have history of mild abdominal pain	Systemically normal Rumen only slightly hypotonic, high-pitched ping on percussion over right upper flank, which may be distended Rectally enlarged cylindrical movable cecum with blind end can be felt	Nothing diagnostic, but has hemoconcentration, compensated hypochloremia, hypokalemia, and alkalosis	Good response to surgical correction Unfavorable prognosis with severe volvulus and gangrene of apex
Acute diffuse peritonitis	Following acute traumatic reticuloperitonitis, uterine rupture at parturition, rupture of rectum, postsurgical	Acute toxemia, fever followed by hypothermia, weakness, tachycardia, recumbency, groaning, moderate distension, scant feces; palpate fibrinous adhesions rectally	Leukopenia, neutropenia, degenerative left shift Hemoconcentration Paracentesis positive	Usually die
Chronic ruminal tympany in feeder calves	Beef calves 6–8 months of age following weaning; feeder cattle after arrival in feedlot	Chronic free-gas bloat, relapses after treatment, no other clinical findings	None	Good response to surgical ruminal fistula or insertion of corkscrew-type trocar and cannula left in place for a few weeks
Omasal impaction	Uncommon Single cases in pregnant cows with vagus indigestion Feedlot cattle with abomasal impaction dietary in origin	Inappetence to anorexia Scant feces, abdominal distension Rectally, large distended round hard viscus below kidney can be felt	None	Effectively impossible to confirm diagnosis without exploratory laparotomy Slaughter for salvage Treat for abomasal impaction

on ruminal motility, but its main significance is as a portal for infection leading to the development of hepatic abscesses. Ingested animal hairs, plant spicules, and fibers are also credited with causing rumenitis, but no clinical signs have been associated with the lesions. Because of the high prevalence of rumenitis lesions in cattle on heavy concentrated feed, especially when the feed is awned barley, the awns have been incriminated as traumatic agents. In acute arsenic poisoning there is an early postmortem dehiscence of the ruminal mucosa but no apparent lesions during life.

Other lesions of the forestomachs are parakeratosis, discussed later in this chapter, and villous atrophy, sometimes encountered in weanling ruminants on special diets low in fiber, even succulent young pasture, but these are not known to influence stomach function or motility. The factors that principally affect ruminal motility are those chemical and physical characteristics of its contents that are dealt with in simple indigestion and acute carbohydrate engorgement. Lesions in, and malfunctioning of, the abomasum are much more akin to abnormalities of the stomach in monogastric animals.

Some of the physiologic factors that affect reticulorumen function and the clinical factors, which cause reticulorumen dysfunction, are summarized in Table 8-1. When reticulorumen hypomotility is present, the problem is to decide if the cause is directly associated with the forestomach and abomasum, or both, or other parts of the alimentary tract, or if the cause is from an abnormality of another system. Differentiation requires a careful clinical examination, including simple laboratory evaluation of the rumen contents.

The factors that affect the motility of the rumen are presented in the section on simple indigestion, as are the principles of treatment in cases of ruminal atony.

Special Examination of the Alimentary Tract and Abdomen of Cattle

When gastrointestinal dysfunction is suspected, a complete special clinical and laboratory examination may be necessary to determine the location and nature of the lesion. A systematic method of examination is presented here.

HISTORY

A complete history with as much detail as is available should be obtained. The stage of the pregnancy–lactation cycle, days since parturition, the nature of the diet, the speed of onset, and the duration of illness may suggest diagnostic possibilities. An accurate description of the appetite will suggest if the disease is acute or chronic. The previous treatments used and the response obtained as well as any evidence of abdominal pain and its characteristics should be determined. The nature and volume of the feces may suggest enteritis or alimentary tract stasis.

SYSTEMIC STATE, HABITUS, AND APPETITE

The vital signs indicate the severity of the disease and suggest whether it is acute, subacute, or chronic. In acute intestinal obstruction, AV, acute diffuse peritonitis, and acute carbohydrate engorgement, the heart rate may be 100 to 120 beats/min and dehydration is usually obvious. **Pallor of the mucous membranes** is an indicator of alimentary tract hemorrhage, especially if there is concurrent **melena**. If cattle with any of these diseases are recumbent and unable to stand, the prognosis is usually unfavorable. A marked increase in the rate and depth of respirations associated with alimentary tract disease usually indicates the presence of fluid or electrolyte disturbances and possible subacute pain. **Grunting or moaning** suggests abdominal pain associated with distension of a viscus or acute diffuse peritonitis.

The **appetite** and the **presence or absence of rumination** is very reliable indicators of the state of the alimentary tract, including the liver. Complete anorexia persisting for more than 3 to 5 days is unfavorable. The return of appetite and rumination with chewing of the cud following medical or surgical treatment for alimentary tract disease is a favorable prognostic sign. Persistent inappetence suggests a chronic lesion, which usually has an unfavorable prognosis.

ORAL CAVITY AND ESOPHAGUS

The oral cavity is easily examined by inspection and manual palpation with the aid of a suitable mouth speculum. The patency of the esophagus is determined by passage of a stomach tube into the rumen through the oral cavity, with the aid of a cylindrical metal speculum, or through the nasal cavity. The cylindrical metal speculum should always have a rope or chain handle on one end so that the veterinarian can maintain hold of the speculum while passing a stomach tube into the rumen. Adult cattle can swallow a 45-cm (18-inch) long metal speculum, and then a rumenotomy is required to remove the speculum from the thoracic portion of the esophagus.

INSPECTION OF THE ABDOMEN

The **contour** or **silhouette of the abdomen** should be examined from the rear and each lateral region viewed from an oblique angle. Examination of the contour can assist in determining the cause of abdominal distension, which may be **unilateral, bilaterally symmetric,** or **asymmetric** or more prominent in the dorsal or ventral half. Recognition of the anatomic region of maximum distension suggests diagnostic possibilities, which are shown in Fig. 8-2. The differential diagnosis of abdominal distension of cattle is summarized in Table 8-3.

DISTENSION OF THE ABDOMEN

The cause of distension of the abdomen of cattle is determined by a combination of the following examinations:

- Inspection of the contour or silhouette of the abdomen to determine the region of maximum distension.
- If necessary, relief of rumen contents with a stomach tube to determine whether the distension is caused by an enlarged rumen. The ruminal contents can also be examined grossly at the same time.
- Percussion or ballottement and simultaneous auscultation to detect fluid-splashing sounds indicating the presence and location of gas-filled and fluid-filled viscera.
- Palpation per rectum to feel any obvious enlargements or abnormalities.
- Abdominocentesis to determine the nature and amount of peritoneal fluid, which may indicate the presence of ischemic necrosis of intestines or peritonitis.
- Trocarization of severely gas-filled distended regions that are impeding respiration, such as an AV in a calf.

LAVAGE OF DISTENDED RUMEN

In adult cattle presented with severe abdominal distension caused by gross distension of the rumen it is difficult, if not impossible, to assess the status of the abdomen. To determine whether the rumen is distended and/or to relieve the pressure, a large-bore stomach tube should be passed into the rumen. In vagus indigestion, the rumen may be grossly distended with fluid contents that will gush out through a large-bore tube. In some cases 100 to 150 L of rumen contents may be released. If no contents are released, the contents may be frothy or mushy and the rumen end of the tube will plug almost instantly. Rumen lavage may then be attempted using a water hose to deliver 20 to 40 L of water at

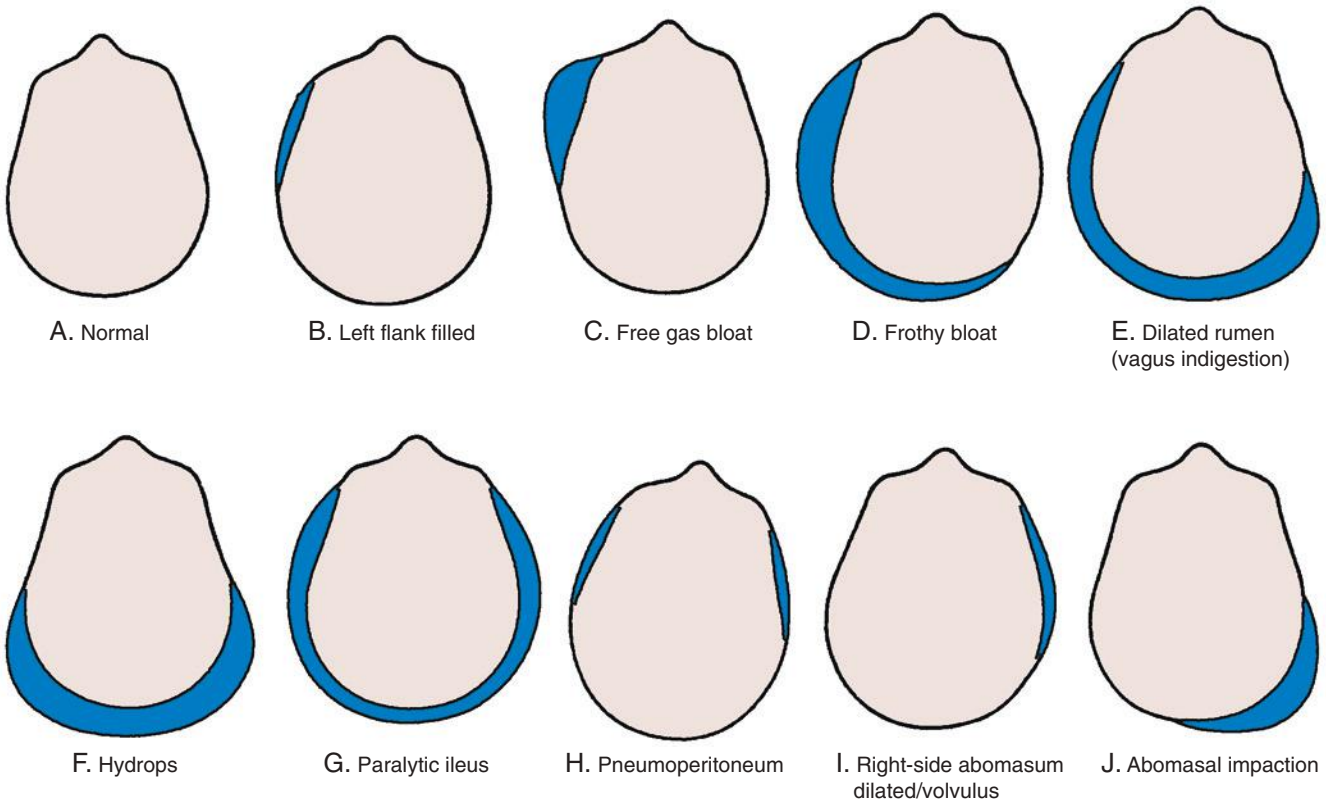

Fig. 8-2 Silhouettes of the contour of the abdomen of cattle, viewed from the rear, with different diseases of the abdominal viscera. *a,* normal; *b,* left flank filled; *c,* free-gas bloat; *d,* frothy bloat; *e,* dilated rumen (vagus indigestion); *f,* hydrops; *g,* paralytic ileus; *h,* pneumoperitoneum; *i,* right-side abomasal dilation/volvulus; *j,* abomasal impaction. (From Stober M, Dirksen G. *Bovine Pract* 1977; 12:35-38.)

a time, followed by back drainage by gravity flow. After the rumen is partially emptied, it is usually possible to more accurately assess the rumen and the abdomen.

LEFT SIDE OF ABDOMEN AND RUMEN

Inspection and Palpation

The **primary and secondary cycle contractions** of the reticulorumen are identified by simultaneous auscultation, palpation, and observation of the left paralumbar fossa and the left lateral abdominal region. During contractions of the rumen there is an alternate rising and sinking of the left paralumbar fossa in conjunction with **abdominal surface ripples**. The ripples reflect reticulorumen contractions and occur during both the **primary** (or mixing) cycle contraction and the **secondary** (or **eructation**) cycle contractions. As the left paralumbar fossa rises during the first part of the primary cycle contraction, there are two horizontal ripples that move from the lower left abdominal region up to the paralumbar fossa. When the paralumbar fossa sinks, during the second part of the primary cycle, the ripple moves ventrally and fades out at the lower part of the left abdominal region. Similar ripples follow up and down after the rising and sinking of the paralumbar fossa associated with the secondary cycle movements.

In early **vagus indigestion**, there may be three to five vigorous incomplete contractions of the reticulorumen per minute. These contractions may not be audible because the rumen contents are porridge-like and do not cause the normal crackling and rustling sounds of a rumen containing coarse fibrous ingesta. **However, the contractions are visible and palpable as waves of undulations of the left flank. If reticulorumen motility is assessed *only* on the basis of inspection and palpation, the results will be misleading.**

Nature of Rumen Contents

The nature of the rumen contents can be assessed by palpation of the rumen through the left paralumbar fossa. In the roughage-fed animal, the rumen contents are doughy and pit on pressure. In cattle that have consumed large quantities of unchopped cereal grain straw, the rumen is large and the contents feel very firm but not hard, and they always pit on pressure. In the dehydrated animal the contents may feel almost firm. In the grain-fed animal the contents may be soft and porridge-like. When the rumen contains excessive quantities of fluid, the left flank fluctuates on deep palpation. In the atonic rumen distended with excess gas, the left flank will be tense, resilient, and tympanitic on percussion.

In mature cattle that have been anorexic for several days, the rumen may be smaller than normal and the dorsal sac will be collapsed (**rumen collapse**). There will be a **"pong"** (low-pitched ping) in the left upper abdomen extending dorsally to the transverse processes of the lumbar vertebrae, lack of abdominal distension, absence of fluid on succession of the area of the ping, and on rectal palpation the dorsal sac of the rumen will feel collapsed.

Auscultation of the Rumen and Left Flank

In the normal animal on a roughage diet there are two independent contraction sequences of the reticulorumen. The **primary cycle** recurs approximately every minute and consists of a **diphasic contraction of the reticulum** followed by a **monophasic contraction of the dorsal ruminal sac** and then by a **monophasic contraction of the ventral ruminal sac.** These movements are concerned primarily with "mixing" the rumen contents and with assisting the passage of rumen contents into the omasum.

Table 8-3 Differential diagnosis of abdominal distension in cattle

Cause	Major clinical findings and methods of diagnosis
Distension of rumen	
Acute ruminal tympany	Marked distension of left abdomen, less of right; very tense distended left paralumbar fossa, dull resonance on percussion; pass stomach tube and attempt to relieve gas or froth
Vagal indigestion	Marked distension of left abdomen, less of right "papple-shaped" abdomen; fluctuating rumen on palpation; excessive rumen activity or complete atony; large L-shaped rumen on rectal examination; pass large-bore stomach tube to remove contents to aid in diagnosis
Acute ruminal acidosis	Moderate distension of left flank, less of right; rumen contents are doughy or fluctuate; fluid-splashing sounds may be audible on ballottement; rumen static and systemic acidosis; rumen pH below 5
Simple indigestion	Moderate distension of left flank; rumen pack easily palpable and doughy; contractions may be present or absent depending on severity; systemically normal
Distension of abomasum	
Right displaced abomasum and abomasal volvulus	Right flank and paralumbar fossa normal to severely distended; ping; rectal palpation of fluctuating or tense viscus in right lower quadrant
Abomasal impaction	Right lower flank normal to moderately distended; doughy viscus palpable caudal to costal arch; rectal palpation feel doughy viscus in right lower quadrant
Left displaced abomasum	Abdomen usually gaunt; occasionally distended left paralumbar fossa because of displaced abomasum; ping on percussion over upper aspects of ribs 9–12
Abomasal trichobezoars	Older calves (2–4 months); right lower flank distended; fluid-splashing sounds; painful grunt on deep palpation Confirm by laparotomy and abomasotomy
Distension of intestines	
Enteritis	Slight to moderate distension of right abdomen; fluid-rushing and splashing sounds on auscultation and ballottement Diarrhea and dehydration
Intestinal obstruction	Slight to moderate distension of right abdomen; fluid tinkling, percolating, and splashing sounds on auscultation and ballottement; may palpate distended loops of intestine or intussusception rectally; scant dark feces; paracentesis abdominis
Paralytic ileus	Slight to moderate distension of right abdomen; tinkling sounds on auscultation; tympanitic ping on percussion Loops of distended intestine palpable per rectum; scant feces but recover if no physical obstruction
Cecal dilatation and cecocolic volvulus	Right flank may be normal or moderately distended; ping present in right paralumbar fossa; palpate movable blind end cecum on rectal examination (cecal dilatation) or multiple loops of distended large intestine (cecocolic volvulus); confirm by laparotomy
Enlargement of uterus **physiologic**	Gross distension of both flanks, especially right; normal pregnancy with more than one fetus; may palpate rectally
Pathologic	
Hydrops amnion	Gradual enlargement of lower half of abdomen in late gestation; flaccid uterus; fetus and placentomes are easily palpable per rectum
Hydrops allantosis	Gradual distension of lower half of abdomen in late gestation; palpable uterus rectally, cannot palpate placentomes or fetus
Fetal emphysema	History of dystocia or recent birth of one calf, twin in uterus and emphysematous; diagnosis obvious on vaginal and rectal examination
Fluid accumulation in peritoneal cavity	
Ascites	
Congestive heart failure, ruptured bladder	Bilateral distension of lower abdomen; positive fluid waves; paracentesis abdominis; may feel enlarged liver behind right costal arch
Pneumoperitoneum	
Perforated abomasal ulcer, postsurgical laparotomy	Not common; bilateral distension of dorsal half of abdomen; ping both sides

The **secondary cycle** movements occur at intervals of about 2 minutes and are confined to the rumen and consist of a **contraction of the dorsal sac** followed by a **contraction of the ventral sac**. The former causes the fluid contents of the dorsal sac to be forced ventrally and the gas layer to be forced cranially to the region of the cardia in which eructation takes place. Contractions of the dorsal and ventral sacs cause undulations of the left paralumbar fossa and lower flanks that are readily visible and palpable.

The clinical recognition of the presence or absence of either the primary cycle or secondary cycle contractions or both may aid in determining the cause and severity of the disease and the prognosis. These are outlined in Table 8-1.

Auscultation of Rumen

To auscultate the rumen, the stethoscope is placed in the middle of the left paralumbar fossa. After two complete contractions have occurred, the stethoscope is moved cranially in the fossa and cranial to the fossa over the dorsal third of the 10th to 13th ribs to determine whether rumen contractions are audible in the region, which commonly becomes occupied with a left-side displacement of the abomasum. In the normal animal, ruminal contractions *are* audible in this region.

The **type, strength, and frequency of rumen movements should be noted.** The rumen sounds of the normal animal consuming roughage are rasping, rustling, exploding, and booming-crackling sounds.

When the rumen contains less coarse roughage or primarily grain, the sounds may be much less distinct but still possess a crackling characteristic.

Fluid-Tinkling or Fluid-Splashing Sounds

The presence of fluid-tinkling or fluid-splashing sounds over the left paralumbar fossa, usually along with an atonic rumen, suggests the presence of an excessive quantity of liquid contents in the rumen and that the coarse ingesta is not floating on the fluid layer of the rumen contents as in the normal animal. Fluid-splashing sounds suggest diseases such as grain overload or an atonic rumen associated with prolonged anorexia (chronic diffuse peritonitis and abomasal or omasal impaction). Fluid-splashing and fluid-tinkling sounds can also be elicited by ballottement and simultaneous auscultation of the left lower flank in left-side displacement of the abomasum, because of its liquid contents. To assist in the differential diagnosis, the outline of the rumen can be auscultated and percussed to observe a much wider area of metallic sound than is normally expected in left-side displacement of the abomasum.

In early **vagus indigestion** with an enlarged hypermotile rumen, the contractions of the rumen occur more frequently than normal, at 3 to 6 contractions per minute, and are easily visible as prominent abdominal ripples over the left flank. Characteristically, the **ruminal sounds are usually not audible** or barely so because the rumen contents are homogeneous and porridge-like as a result of prolonged maceration in the rumen. The absence of coarse fiber in the ingesta and the lack of coordinated reticulorumen primary and secondary contractions minimize the intensity of the ruminal sounds. The lack of effective secondary cycle contractions and eructation results in frothy bloat. Complete atony and gross distension of the rumen is characteristic of advanced vagus indigestion.

Percussion and simultaneous auscultation of the left paralumbar fossa over an area extending from the midpoint of the 9th rib to the 13th rib is used to detect the presence of a **"ping"** or high-pitched metallic tympanic sound associated with left-side displacement of the abomasum. Percussion is performed with a flick of the flexed finger or most reliably with a percussion hammer. The **causes of pings on percussion of the left abdomen in mature cattle** include **left-side displacement of the abomasum, atonic rumen** and, rarely, **pneumoperitoneum**. The tympanic sound associated with an atonic rumen is lower-pitched than that associated with a left-side displacement of the abomasum and may be called a **pong**.

For special investigations of reticulorumen motility radiotelemetry capsules that measure motility, ruminal pH, and temperature can be placed in the rumen.

RIGHT SIDE OF ABDOMEN

The contour of the right side of the abdomen should be examined by **inspection** for evidence of distension, which may be caused by a **viscus filled with fluid, gas, or ingesta; ascites;** or a **gravid uterus**. In severe distension of the rumen, the ventral sac may also distend the lower half of the right flank.

A combination of deep palpation, ballottement and simultaneous percussion and auscultation, and succussion (slightly rocking the animal from side to side) is used to detect the presence of viscera that are distended with gas and/or fluid, or ingesta.

The causes of **pings** audible on auscultation and percussion over the right abdomen include the following:

- Right-side dilatation and volvulus of the abomasum
- Cecal dilatation and cecocolic volvulus
- Obstruction of the spiral colon
- Gas-filled descending colon and rectum in a cow with persistent tenesmus
- Intestinal tympany of unknown etiology
- Volvulus of the root of the mesentery in young calves
- Intussusception causing intestinal tympany
- Pneumoperitoneum
- Postpartum intestinal tympany, which occurs in the postparturient cow (for the first few days following parturition)

The causes of fluid-splashing sounds on ballottement and auscultation of the right flank include the following:

- **Fluid-filled intestines in acute intestinal obstruction and enteritis**
- **Fluid-filled abomasum in right-side dilatation, but more prominently in AV.**

Palpation of a firm viscus in the right flank caudal or ventral to the right costal arch may be caused by the following:

- **Enlarged ventral sac of the rumen, which extends over to the right abdominal wall**
- **Abomasal impaction**
- **Omasal impaction**
- **Enlargement of the liver; the liver must be grossly enlarged before it is palpable caudal to the right costal arch**

A **rectal examination** is necessary to identify the distended viscus associated with these abnormal sounds, and often a laparotomy is required.

EXAMINATION OF RUMEN FLUID

Examination of the rumen fluid is often essential to establish an accurate diagnosis of diseases of the forestomach. Rumen fluid can be obtained with a stomach tube passed into the rumen, with the fluid being withdrawn with the vacuum of a stomach pump. The major difficulty is avoiding contamination of the sample with saliva, which can be avoided if a free flow of fluid is obtained. Specialized stomach tubes are available that are weighted and can be directed into the ventral sac to collect up to 500 mL of fluid. Rumen fluid samples can also be obtained by **rumenocentesis**, which is percutaneous aspiration of the ventral sac of the rumen on the lower left ventrolateral abdominal quadrant, horizontal with the patella, and 20 cm caudal to the last rib. The site is prepared, xylazine sedation given, and a 12- to 15-cm 14- or 16-gauge needle is thrust firmly and quickly perpendicular to the skin into the rumen. Rumen fluid is quickly withdrawn with a syringe and pH is measured immediately with a portable pH meter or wide-range pH paper (pH values of 2–12).

ANALYSIS OF RUMEN FLUID

The **color**, depending on the feed to a limited extent, will be a green, olive green, or brown green. At pasture, the color is very green, with root crops the color tends to be gray, and with silage or straw the color is mostly yellow-brown. The color of the rumen contents is milky-gray in grain overload and greenish-black in cases in which rumen stasis is of long duration and in which putrefaction is occurring within the rumen.

The **consistency** of the rumen fluid is normally slightly viscid, and watery rumen contents are indicative of inactive bacteria and protozoa. **Excess froth** is associated with frothy bloat as in primary ruminal tympany or vagus indigestion. The odor is normally aromatic and, although somewhat pungent, not objectionable to the nose. A **moldy, rotting odor** usually indicates protein putrefaction, and an intensely sour odor indicates an excess of lactic acid formation, which is caused by grain or carbohydrate engorgement.

The **pH of the rumen fluid** varies according to the type of feed and the time interval between the last feeding and taking a sample for pH examination. The **normal range, however, is between 6.2 and 7.2. High pH values** (>8.0) will be observed when putrefaction of protein is occurring in the rumen or if the sample is mixed with saliva. **Low pH values** (**4–5**) are found after the feeding of carbohydrates. Generally, a value below 5 indicates carbohydrate engorgement, and this pH level will be maintained for 6 to 24 hours after the animal has actually consumed the carbohydrate diet.

For experimental purposes, continuous monitoring of the pH of the rumen contents is possible with a pH probe containing a commercial microelectrode and a reference-electrode with a pressure-equalizing system placed in the reticulum. By feeding diets with changing composition it is possible to provoke marked changes in rumen pH. The probes are programmed to sample pH and temperature every 30 seconds.

Microscopic examination of a few drops of rumen fluid on a glass slide with a low-power field will reveal the level of protozoon activity. Normally five to seven protozoans are active per low-power field. In lactic

acidosis the protozoa are usually absent, or a few dead ones are visible. The rumen fluid can be stained with Gram stain to determine the predominant bacterial flora, which are normally gram-negative but in grain overload become gram-positive.

Chloride concentration can be determined by centrifuging the fluid and analyzing the supernatant for chloride levels. These are normally 10 to 25 mEq/L in cattle and <15 mEq/L in sheep. Elevated rumen chloride concentrations result from abomasal reflux, ileus, or high salt intake. Current laboratory analyzers that use ion-selective potentiometry to measure chloride concentration are not accurate when measuring rumen chloride concentration. This is because the electrode is also sensitive to acetate and bicarbonate concentration; typical concentrations of these anions in rumen fluid often result in erroneously high rumen chloride values when measured using ion-selective potentiometry.

PALPATION PER RECTUM OF THE ABDOMEN

Some of the specific abnormalities of the digestive tract, which are commonly detected on palpation per rectum, include the following, which relates to Fig. 8-3, *a–l*, illustrating the abnormalities through a transverse section of the abdomen.

(a) Normal.
(b) L-shaped rumen: occurs commonly in vagus indigestion and other diseases of the rumen characterized by gradual distension of the rumen.
(c) Cecocolic volvulus: commonly palpable as long distended organ, usually movable, may feel the blind end.
(d) Abomasal volvulus: commonly palpable as tense viscus in lower right half of abdomen.
(e) Abomasal impaction: not usually palpable per rectum except in extreme cases in which it needs to be differentiated from an enlarged ventral sac of the rumen. This is most easily accomplished by monitoring the location of the viscus over a 2-minute period; typically during this time interval the ventral ruminal sac will contract at least once and move away from the hand.
(f) Left-side displacement of the abomasum: usually cannot palpate the displaced abomasum but can often feel rumen, which is usually smaller than normal and may be displaced a little to the right side of the midline.
(g) Intussusception: only palpable per rectum in approximately 25% of cases; the ability to detect is dependent on the location of intussusception and the size of the animal.
(h) Mesenteric volvulus: usually tight bands of mesentery are palpable, along with distended loops of small intestine.
(i) Intestinal incarceration: rarely palpable.
(j) Peritonitis: only palpable if peritoneum of posterior aspect of abdomen is affected.
(k) Lipomatosis: commonly palpable as "bricks" in the abdomen and pelvic cavity.
(l) Omental bursitis: not common and usually not palpable per rectum.

In Fig. 8-3, *m–p* is included for the differential diagnosis of the diseases each represents.

As part of the differential diagnosis of digestive tract disease in the postparturient cow, the uterus should be examined carefully for evidence of retained placenta and metritis. Both vaginal and rectal examinations should be performed. The toxemia caused by retained fetal membranes and postpartum metritis may cause anorexia, rumen stasis, paralytic ileus, scant feces, and sometimes an **idiopathic postpartum ping in the right flank,** all of which may be misinterpreted as a primary digestive tract disease.

GROSS EXAMINATION OF FECES

The gross appearance of the feces of cattle is not only an indicator of disease of the digestive tract but can provide valuable clues for the differential diagnosis of disease elsewhere.

AMOUNT

In adult cattle, the passage of ingesta through the digestive tract takes 1.5 to 4 days. Mature cattle generally pass some feces every 1.5 to 2 hours, amounting to a total of 30 to 50 kg/day in 10 to 24 portions.

A **reduction in the bulk of feces** can be caused by a decrease in feed or water intake or a retardation of the passage through the alimentary tract. In diarrhea, the feces are passed more frequently and in greater amounts than normal and contain a higher water content (>90%) than normal.

ABSENCE OF OR SCANT FECES

Failure to pass any feces for 24 hours or more is abnormal, and the continued absence of feces may be caused by a physical intestinal obstruction. However, in many cases the intestine is not physically obstructed; instead, there is a functional obstruction. Diseases causing disturbances of motility of the rumen and abomasum often result in a relative absence of feces. Paralytic ileus of the intestines caused by peritonitis or idiopathic intestinal tympany also results in a marked reduction in feces, sometimes a complete absence, for up to 3 days. The marked reduction of feces that occurs in functional obstruction is a major source of diagnostic confusion because it resembles physical obstructions of the intestines. The causes of physical and functional obstruction of the alimentary tract of cattle are summarized in Fig. 8-4.

COLOR

The color of the feces is influenced by the nature of the feed, the concentration of bile in the feces, and the passage rate through the digestive tract. Calves reared on cows' milk normally produce gold-yellow feces, which become pale brown when hay or straw is eaten. The feeding of milk substitutes adds a gray component to a varying degree.

The feces of adult cattle on green forage are dark olive-green, on a hay ration more brown-olive, and the ingestion of large amounts of grain produces gray-olive feces. A retardation of the ingesta causes the color to darken. The feces become ball-shaped and dark brown with a shining surface caused by a mucous coating. Diarrheic feces tend to be paler than normal because of their higher water content and lower concentration of bile.

The presence of large amounts of bile produces a dark olive-green to black-green color such as in cattle with hemolytic anemia. In cattle with obstruction of the common bile duct, the feces are pale olive-green because of the absence of bile pigments.

Blood in the feces may originate from the following locations:

- Hemorrhage into the abomasum: acute hemorrhage usually appears as black, tarry feces (**melena**); chronic hemorrhage as occult blood.
- Hemorrhagic enteritis of small intestines: the feces are uniformly dark red.
- Hemorrhagic enteritis of the large intestines: in the cecum or colon, blood appears evenly distributed throughout the feces (**dysentery**); in the rectum, blood appears as streaks or chunks of frank blood unevenly distributed throughout the feces (**hematochezia**).
- **"Occult blood"** is not visible grossly; the color of the feces may be normal or dark. A variety of commercially available fecal occult blood tests have been developed for humans and adapted for use in ruminants. The most widely used occult blood tests in ruminants have been the **o-tolidine (orthotolidine) tablet test** (such as Hematest) and the **guaiac paper test,** which are performed following the manufacturers' instructions. A positive o-tolidine test is a blue color change that develops on the paper at the periphery of the test tablet within 2 minutes. This test is based on hemoglobin's peroxidase-like ability to catalyze the oxidation of a chromogen, tetramethylbenzidine, and the test is reported to detect 6 mg of hemoglobin per gram of feces. A positive guaiac test is the development of a blue color on

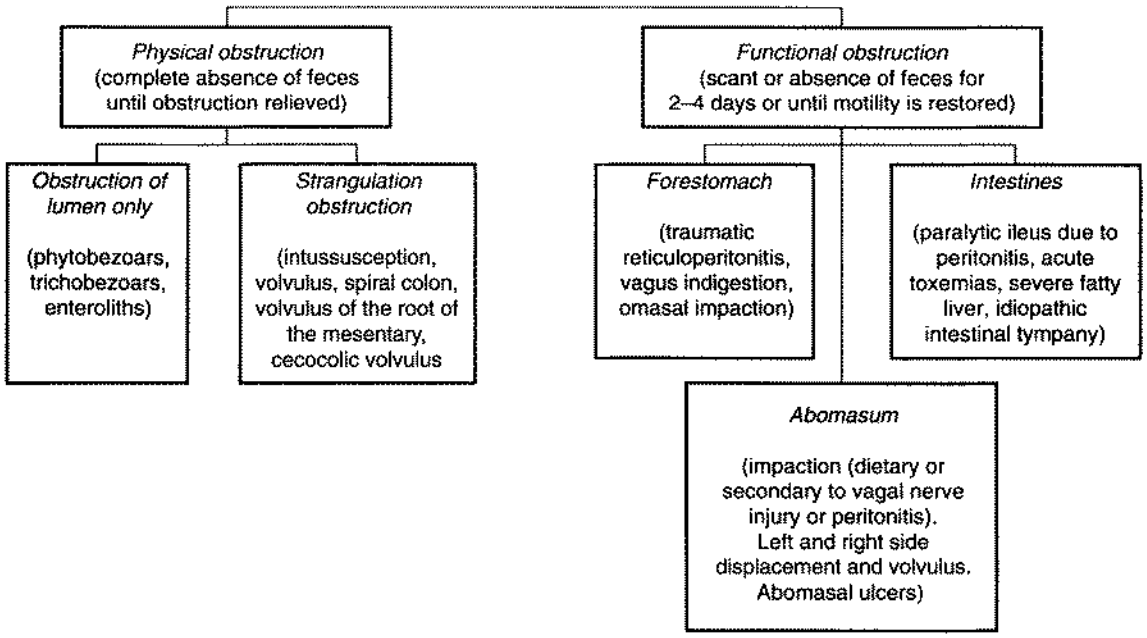

Fig. 8-4 Some common causes of physical and functional obstruction of the alimentary tract of cattle.

the test paper following the addition of hydrogen peroxide. This test is also based on hemoglobin's peroxidase-like ability to oxidize a phenolic compound in guaiac (α-guaiaconic acid) to a quinone, and the test is reported to detect 10 mg of hemoglobin per gram of feces. One report in cattle indicated that a dilute alcoholic solution of guaiac was the most sensitive and reproducible method, but this test is no longer commercially available. Occult blood occurs most commonly when there are only small quantities of blood in the alimentary tract, as with minimal hemorrhage insufficient to result in melena. It also may be caused by swallowing blood coughed up from a pulmonary hemorrhage such as in caudal vena cava thrombosis. The minimum transit time of blood from abomasum to rectum was 7 to 19 hours in adult cattle.

ODOR

Fresh bovine feces are not normally malodorous. Objectionable odors are usually caused by putrefaction or fermentation of ingesta, usually associated with inflammation. For example, the feces in cattle with salmonellosis may be fetid, whereas in advanced pericarditis with visceral edema caused by passive congestion the feces are profuse but not odoriferous.

CONSISTENCY

The consistency of the feces is dependent on the water content, the type of feed, and the length of time the ingesta has remained in the digestive tract. Normally, milk-fed calves excrete feces of a medium to firm porridge-like consistency. After transition to a plant diet, the first solid particles begin to appear. Normal bovine feces are of a medium porridge-like consistency. A moderate thickening leads to the passage of fecal disks of a more solid consistency, and severe dehydration causes the formation of firm balls of feces arranged in facets inside the rectum, the surfaces of which are dark and coated with mucus. The feces of cows with left-side displacement of the abomasum are commonly pasty in appearance. Sticky and tenacious feces are commonly seen in obstruction of the forestomachs (vagus indigestion and chronic peritonitis).

DEGREE OF DIGESTION

The proportion of poorly digested plant particles in the feces is dependent on the duration and adequacy of rumination and the rate of passage of ingesta through the forestomach and abomasum. The length of time the ingesta is in the postruminal digestive tract seems to have no appreciable influence on its digestion. Inadequate digestion indicates failure in rumination or accelerated passage of ingesta through the forestomach. Thus in some cattle with acute traumatic reticuloperitonitis, the feces may contain small walnut-sized chunks of undigested plant fibers that have escaped the cellulose digestive processes of the forestomachs. The presence of large numbers of kernels of grain in the feces is associated with the ingestion of large quantities of unprocessed grain such as whole wheat or barley.

OTHER SUBSTANCES IN THE FECES

Mucus

The presence of excessive mucus on the surface of feces suggests increased transit time of the ingesta in the large intestine. The presence of a plug of mucus in the rectum is suggestive of a functional obstruction (paralytic ileus). In enteritis, large quantities of clear, watery mucus may be passed, which sometimes clot to form gelatinous masses.

Fibrin

In fibrinous enteritis, fibrin may be excreted in the form of long strands, which may mold into a print of the intestinal lumen (**intestinal fibrinous casts**).

DETECTION OF ABDOMINAL PAIN

Cattle with acute local or diffuse peritonitis may grunt spontaneously with almost every expiration; this is usually exaggerated in the recumbent position. However, **grunting** may also be caused by **severe pneumonia, pleurisy,** and **severe pulmonary emphysema**. Careful auscultation and percussion of the lungs is therefore necessary to exclude the presence of pulmonary disease.

Not all grunts occur spontaneously. **Deep palpation of the cranial part of the abdomen using the closed hand or knee is often necessary to elicit a grunt in cattle**. Auscultation over the trachea is often necessary to hear the grunt, which is best elicited if pressure is applied to the abdomen at the end of inspiration and the beginning of

expiration. The inspiratory and expiratory sounds are noted for six to eight respirations by auscultation over the trachea and then, without warning to the animal, firm palpation is applied to the abdomen. A grunt indicates the presence of a peritoneal lesion (stretching or inflammation of the peritoneum regardless of cause). The absence of a grunt does not preclude the presence of a peritoneal lesion. In acute traumatic reticuloperitonitis the grunt may be present for only 3 to 5 days after the initial penetration of the reticulum.

A rigid bar or wooden pole may be necessary to apply pressure in large cattle (large cows and bulls). The bar is held by two people in a horizontal position just behind the xiphoid sternum while a third person auscultates over the trachea when the bar is lifted firmly up into the abdomen. Simultaneous auscultation over the trachea ensures that the grunt is heard. Several attempts should be made to elicit a grunt before concluding the absence of one. The ventral aspect and both sides of the abdomen should be examined beginning at the level of the xiphoid sternum and moving caudally to appr oximately the umbilicus. This will ensure that the cranial and caudal aspects of the abdomen are examined for the presence of **points of abdominal pain.**

Pinching of the withers is also used to elicit a grunt. In the average-sized cow, pinching of the withers causes the animal to depress its back. In an animal with a painful lesion of the peritoneum, depression of its back will commonly result in a grunt, which is clearly audible by auscultation over the trachea and is often audible without the use of the stethoscope.

The term **anterior abdominal pain** is used to characterize the pain associated with several diseases of the anterior abdomen of cattle, which would include **traumatic reticuloperitonitis**, **hepatic abscesses**, **abomasal ulcers,** and **intestinal obstruction.** The differential diagnosis of the anterior abdominal pain would include diseases that cause thoracic pain such as pleuritis, pericarditis, and severe pulmonary disease.

ULTRASONOGRAPHY

Ultrasonography has become a routine diagnostic method in ruminants suspected of having gastrointestinal tract disease. This is because of the widespread availability of reasonably priced portable battery powered units and the many advantages of "on-farm" diagnostic tests.

Ultrasonography provides an excellent method for investigating the presence and nature of reticular contractions in healthy ruminants and for the diagnosis of traumatic reticuloperitonitis in cattle.[1,2] In contrast to radiography, ultrasonography provides more precise information about the contour of the reticulum and the frequency of reticular contractions. Ultrasonography also provides information on the stratification of rumen contents (dorsal gas dome, fiber mat, and ventral fluid layer; Fig. 8-5).[3-5] The gas dome in the cow rumen can be identified ultrasonographically by reverberation lines that run parallel to the line identifying the rumen mucosa. The fiber mat presents a patter indicating gaseous inclusions, whereas the fluid layer appears darker without reverberation lines.

Ultrasonography provides an ideal diagnostic aid for the examination of the omasum,[6,7] and abomasum of adult cattle,[8,9] the reticulum, rumen, omasum and abomasum of calves up to 3 months of age,[10,11] the reticulum, rumen, omasum, abomasum, liver, spleen, and greater omentum of adult goats,[12-15] and the diaphragm and abdominal wall of adult cattle,[16,17] as well as left and right displacement of the abomasum, abnormal motility of the small and large intestines, and cecal dilatation.

Ultrasonography is performed on the standing nonsedated animal using a 3.5-MHz linear transducer. The techniques used are presented under the specific headings for each disease.

RADIOGRAPHY

Radiography of the cranial abdomen and reticulum of mature cattle with the animal in a standing position can only be performed at referral centers because of the need for high-powered radiographic units. Radiologic

examination of the reticulum with the animal in dorsal recumbency (dorsal reticulography) should not be performed in cattle with suspected traumatic reticuloperitonitis because of the potential for the breaking down of adhesions and dissemination of infection throughout the abdomen. Specific techniques for radiography of standing animals suspected to have traumatic reticuloperitonitis are presented under that heading.

ENDOSCOPY OF THE RUMEN

Endoscopic examination in ruminants has been most commonly used to examine the upper respiratory tract, pharyngeal area, and esophagus. Nasoruminal endoscopy is very challenging in calves, sheep, and goats because endoscopes that are sufficiently small to pass through the nasal passages are usually not long enough to reach the rumen. Ororuminal endoscopy using a mouth gag has been infrequently performed because of the risk of damage to the instrument as well as poor visualization of the rumen and reticulum. Visualization through a rumen fistula in 1- to 2-month-old calves was superior to visualization though the oral cavity;[18] however, removal of rumen contents using a siphon and lavage method improved visualization ability.

COMPUTED TOMOGRAPHY

Increased insight into normal anatomy has been obtained in calves, sheep, goats, alpacas, and llamas using computed tomography (CT) with the animal placed in sternal recumbency. In contrast to cattle, CT has demonstrated that the rumen in goats extends to the right of the midline, and metal objects causing traumatic reticulitis are very visible on CT.[19,20]

RUMINATION MONITORS

The time spent ruminating provides an excellent indicator of health in cattle, sheep, and goats. Moreover, the return of rumination is a positive clinical sign in a ruminant that has been inappetent, leading to the adage "never give up on a ruminating animal." At least two technologies have been developed to monitor the time spent chewing each day. These use a microphone placed in the cranial cervical region in a neck band, with rumination having a different acoustic signal than eating,[21] or a noseband pressure sensor that is incorporated in a halter.[22] The microphone system appears to work better for dairy cattle than beef cattle. Typical values for confinement-fed dairy cattle are 16 daily eating phases, each with a mean duration of 28 minutes, and 13 rumination phases, each with a mean duration of 30 minutes. The total time spent ruminating per day was 6 to 7 hours, with 410 cuds per day and 60 chewing cycles per cud.[22] It is likely that as confinement operations adopt more precision agriculture methods that rumination monitors become a routine monitoring tool for periparturient dairy cattle or dairy cattle in the sick pen.

SERUM BIOMARKERS OF GASTROINTESTINAL FUNCTION

Pepsinogen, a proenzyme that is the inactive form of pepsin, is the most important proteolytic enzyme in abomasal fluid. A small amount of pepsinogen is present in the serum of healthy ruminants. Abomasal injury, particularly caused by abomasal parasitism, causes a marked increase in serum pepsinogen concentration,[23,24] providing a useful clinical test for gastrointestinal parasitism and the magnitude of the injury that can guide treatment. Serum pepsinogen concentration is increased in ruminants with abomasal ulcers and cattle with ostertagiasis.

Gastrin is a hormone secreted from G (gastrin) cells of the pyloric region of the abomasum into the blood from where it reaches the parietal cells and subsequently stimulates acid and pepsinogen secretion.[23] Serum gastrin concentration is increased in ruminants with abomasal ulcers, cattle with left displaced abomasum (LDA) or right displaced abomasum (RDA),[25] and sheep with hemonchosis.

Serum **motilin** and **ghrelin** concentrations are increased in cattle with LDA and RDA.[25] Motilin is increased by cells in the proximal gastrointestinal tract and promotes abomasal emptying rate. Ghrelin is also a gastrointestinal regulating hormone.

INTERPRETATION OF CLINICAL FINDINGS

A guide to the interpretation of the clinical findings associated with diseases of the digestive tract and abdomen of cattle is summarized in Table 8-4. In conjunction with the history and the laboratory findings, a differential diagnosis list can be generated.

EXPLORATORY LAPAROTOMY

An exploratory laparotomy can usually assist in the diagnosis of diseases of the digestive tract or abdomen. Identification and evaluation of the abnormality allows for a more accurate diagnosis, prognosis, and rational treatment. However, because a properly done laparotomy is time-consuming and expensive, the veterinarian would like to minimize the number of laparotomies in which no significant lesions are present. Therefore the challenge is to improve the accuracy of diagnosis and to evaluate the prognosis as much as possible before doing a laparotomy unnecessarily.

There are some well-recognized diseases in which, if a clinical diagnosis can be made, a laparotomy is indicated (Table 8-5). (In some cases slaughter for salvage may be more economical.)

Other than the rumenotomy for the treatment of grain overload and the cesarean section, the most common indication for a laparotomy in cattle is for the surgical correction of displacement or obstruction of parts of the digestive tract (i.e., abomasal displacement, abomasal dilatation and volvulus, intussusception and volvulus, volvulus of the root of the mesentery, luminal obstruction of the spiral colon, cecal dilatation and cecocolic volvulus). If any of these diagnoses can be made, a laparotomy is indicated.

In other cases, the diagnosis may be suspected, but is not obvious and the indications for a laparotomy, slaughter, euthanasia, or conservative medical treatment are not clear. The major question is under what conditions is a laparotomy indicated if the history and clinical and laboratory findings *suggest* an obstruction (strangulation obstruction or functional) but the obstruction cannot be located on clinical examination?

Some examples of diseases that may elude diagnosis before laparotomy and that are or may be amenable to surgical correction are included in the following sections.

INTUSSUSCEPTION AND OTHER STRANGULATION OBSTRUCTIONS OF THE SMALL INTESTINES

An intussusception may be located in the anterior part of the abdomen and not palpable per rectum. A clinical history of acute onset of colic, absence of feces, and serosanguineous exudate on peritoneal tap are indications for a laparotomy. However, phytobezoars and trichobezoars can cause acute intestinal obstruction that may not be palpable rectally and which becomes progressively more severe with time, and only minimal, if any, changes may occur in the peritoneal fluid. A progressively worsening systemic state warrants a laparotomy.

"ATYPICAL" LEFT-SIDE DISPLACEMENT OF THE ABOMASUM

A small percentage of cases are difficult to detect on auscultation and percussion. When the typical left-side displacement of the abomasum ping cannot be detected after several examinations over a period of a few days, a presumptive diagnosis may be made on the basis of ketosis in a recently calved cow (within the last week); the presence of rumen contractions, but reduced intensity; normal vital signs (unless fatty liver is present); and spontaneous fluid-gurgling sounds audible over the left flank or fluid-splashing sounds on ballottement and auscultation of the lower left flank. Ultrasonographic examination of the left ventral abdomen using a 3-MHz transducer will identify the abomasal position within the abdomen (see section on left displaced abomasum in this chapter).

Table 8-4 Pathogenesis and interpretation of clinical findings associated with diseases of the digestive tract and abdomen of cattle

Clinical findings	Pathogenesis, interpretation
Anorexia, inappetence	Toxemia, distension of intestines and stomachs, enteritis, peritonitis
Scant feces, includes small-volume diarrhea	Reduced feed intake, functional obstruction of forestomachs and abomasum, paralytic ileus, strangulation obstruction or obstruction of lumen of intestine with phytobezoar or trichobezoar
Large-volume diarrhea	Profuse, watery diarrhea usually associated with enteritis, simple indigestion or carbohydrate engorgement
Dehydration	Failure to drink adequate amounts of water (caused by toxemia or lesions of oral cavity), malabsorption caused by enteritis, diseases of the forestomachs interfering with absorption of water, e.g., vagus indigestion
Tachycardia	Toxemia, acid-base imbalance, abdominal pain, distension of intestines
Polypnea	Acid-base imbalance (abomasal volvulus, severe enteritis, and vagus indigestion), distension of the abdomen caused by gas-filled or fluid-filled intestines
Weakness and recumbency	Toxemia, severe dehydration, severe distension of abdomen, peritonitis
Colic (abdominal pain)	Sudden onset of distension of forestomachs, abomasum, or intestines Stretching of mesenteric bands, strangulation of intestine in mesenteric tear or scrotal hernia
Grunting with every respiration	Diffuse peritonitis (also pleuritis, pulmonary emphysema, and advanced pneumonia), distension of stomachs or intestines
Presence of grunt on deep palpation of ventral abdominal wall	Presence of peritoneal lesion (stretching of the peritoneum, inflammation, edema, and recent adhesions)
Abdominal distension	Most commonly caused by gas-filled or fluid-filled intestines and/or forestomachs and abomasum; rarely caused by pneumoperitoneum Also caused by ascites and hydrops allantois/amnion
Rumen distension	May be distended with gas, fluid, or ingesta; primary dietary ruminal tympany and grain overload; secondary ruminal tympany caused by peritonitis, vagus indigestion
Rumen stasis	Toxemia, metabolic (hypocalcemia), fever, ruminal acidosis, distension of omasum or abomasum, peritonitis, vagal nerve injury
Hypermotile rumen	Early stages of primary dietary ruminal tympany; vagal nerve injury
Acidic rumen pH	Ruminal acidosis associated with carbohydrate engorgement; almost no other cause known
Alkaline rumen pH	Ruminal alkalosis associated with accidental consumption of high-protein diet, urea poisoning
Reduced or absent rumen protozoon activity	Ruminal acidosis (lactic acid inactivates protozoa); primary starvation lasting more than 2–3 days; ingestion of lead, arsenic, and other poisonous substances
Abnormal foul-smelling	Putrefaction of rumen contents in static and defaunated rumen contents
Presence of ping or pong over left flank	Left displacement of abomasum (ping), atonic rumen with a gas cap (pong), pneumoperitoneum (rarely)
Ping over right flank	Right-side dilatation displacement and volvulus of the abomasum, cecal dilatation and cecocolic volvulus, obstruction of the spiral colon, gas in distended colon and rectum
Presence of low-pitched pings not clearly distinct over right flank	Tympany of right paralumbar fossa in recently calved cows (2–3 days); gas in distended colon and rectum; fluid- and gas-filled intestines with enteritis
Distended upper right flank	Dilatation and volvulus of abomasum; cecal dilatation and cecocolic volvulus; obstruction to the spiral colon
Distended lower right flank	Impaction of the abomasum; enlarged L-shaped rumen and distension of ventral sac to the right flank; advanced pregnancy
Fluid-splashing sounds on ballottement of abdomen or succussion	Fluid-filled intestines or forestomachs or abomasum; usually associated with enteritis, paralytic ileus, or obstruction; fluid-splashing sounds are *rarely* caused by fluid in the peritoneal cavity; percolating fluid sounds audible over right flank are common in cattle with acute intestinal obstruction
Dropping cuds	Cattle rarely regurgitate uncontrollably (dropping cuds); it is usually associated with chronic inflammatory lesions of the reticulum and cardia resulting in lack of control of regurgitation and a larger than normal bolus of rumen contents being regurgitated that cannot be controlled by the animal; also occurs in certain heavy-metal poisonings such as arsenic poisoning; cattle affected with straw impaction of the rumen will also drop large, dry, fibrous cuds

TRAUMATIC RETICULOPERITONITIS

In traumatic reticuloperitonitis with a persistently penetrating foreign body, conservative medical treatment of immobilization in a stanchion, antimicrobials, and a magnet may be unsuccessful even after several days of antimicrobial therapy. Diagnosis depends on continued anorexia, mild fever, grunt, rumen stasis, a hemogram indicating infection, and peritoneal fluid containing predominant neutrophils (typically >90% in traumatic reticuloperitonitis). Recent reports of reference ranges for peritoneal fluid constituents in healthy cattle are available,[26] as well as changes in peritoneal fluid constituents in cattle with peritonitis.[27] More information on peritonitis is available in Chapter 7.

The guidelines for the indications of an exploratory laparotomy when a tentative diagnosis is not made are listed in Table 8-6.

LAPAROSCOPY

Endoscopy of the abdomen through the right paralumbar fossa, left paralumbar fossa, and cranioventral midline provides a safe alternative to exploratory celiotomy in cattle. Feed and water are withheld for 24 hours, and the animals are sedated with acepromazine for both right and left paralumbar fossa laparoscopies and xylazine for the

Table 8-5 Diseases of the digestive tract and abdomen of cattle in which a laparotomy is indicated if the diagnosis can be made

Disease	Major clinical findings
Left displaced abomasum	Ping over ribs 9–12 and other well-recognized findings
Right displaced abomasum and volvulus of the abomasum	Distension of upper right flank, ping on percussion over ribs 9–12, viscus palpable per rectum
Cecal dilatation and cecocolic volvulus	Distension of upper right flank, ping in right paralumbar fossa, long cylindrical mass palpable per rectum
Obstruction of the spiral colon	Distension of upper right flank, ping, distended loops of intestine easily palpable
Intussusception	Abdominal pain, absence of feces, distended loops of intestine, palpable intussusception
Phytobezoars or trichobezoars	Scant feces, subacute abdominal pain, distended loops of intestine and hard lumps palpable rectally
Severe life-threatening ruminal tympany	Severe distension of rumen, skin over rumen cannot be picked up, animal grunting, is lying down, mouth breathing, cannot relieve with stomach tube or trocar
Unidentifiable lumps palpable on rectal examination, i.e., fat necrosis	Chronic gastrointestinal atony, scant feces, large hard lumps palpable per rectum
Peracute grain overload	Weakness, recumbency, dehydration, tachycardia, rumen pH 5 (see Table 8-8 for guidelines in the treatment of grain overload)

Table 8-6 Clinical and laboratory indications for an exploratory laparotomy in cattle when the diagnosis is not obvious

Parameter/criterion	Significance and interpretation of criteria
History	Does the history suggest an acute surgically correctable condition?
Abdominal distension	Laparotomy indicated if distension of abdomen caused by distension of abomasum, cecum, or intestines with fluid and gas
Volume and nature of feces	Scant or absence of feces for more than 36–48 h indicates a *physical* or *functional* obstruction. In *functional obstruction* (i.e., peritonitis) some dark feces are usually present; in *physical obstruction* (intussusception) feces are very scant and dark red because of leakage of blood into intussusceptum Laparotomy indicated unless can determine that cause of absence of feces is not surgically correctable (diffuse peritonitis or impaction of abomasum or omasum)
Rectal findings	Distended viscera other than rumen (abomasum, cecum, and small and large intestines) warrant laparotomy Palpable "bread and butter" fibrinous inflammation in caudal part of abdomen suggests acute diffuse peritonitis and laparotomy would not be rewarding
Peritoneal fluid and hemogram	Bloodstained peritoneal exudate and a degenerative left shift in the leukocyte count suggest leakage of the intestinal wall and warrants laparotomy if history and clinical findings suggest a strangulation obstruction
Abdominal pain (colic) and grunting	Behavioral and postural signs of acute abdominal pain (colic), such as kicking at the belly and stretching the body, suggest acute distension of the stomachs or intestines with fluid and gas Spontaneous grunting with each respiration, which usually becomes pronounced in sternal recumbency, or the presence of a grunt on deep palpation of the abdomen suggests inflammation or stretching of the peritoneum

cranioventral approach. For laparoscopy through the fossae, the sites are prepared aseptically and a 2-cm incision is made through the skin and abdominal musculature after infiltration with 2% lidocaine. Each incision is made 8 cm ventral to the tip of the transverse process of the third lumbar vertebra and 5 cm caudal to the caudal aspect of the last rib. The laparoscope is introduced by standard technique and carbon dioxide gas is used to insufflate the abdominal cavity, after introduction of the trocar and cannula and before introduction of the laparoscope. The abdominal cavity is insufflated to a pressure of 20 to 24 mm Hg. Each examination is completed by directing the laparoscope cranially then moving counterclockwise to examine the caudal portion of the abdomen. After the laparoscopy, the abdomen is passively deflated through the cannula and the skin is closed with sutures.

Cranioventral laparoscopy is performed with the animal positioned in dorsal recumbency. The incision for entry is made on the midline, through the linea alba, 10 cm caudal to the xiphoid process. Examination of the cranioventral portion of the abdomen is begun at the central aspect of the diaphragm then circularly moving the laparoscope counterclockwise.

Right paralumbar fossa laparoscopy provides excellent viewing of the caudal and right cranial portions of the abdomen for evaluation of diseases involving the right kidney, liver, diaphragm, small intestine, cecum, colon, reproductive tract, and cranial part of the pelvic canal. Inadvertent penetration of the greater omentum or mesoduodenum may be avoided by careful placement of the trocar and periodic examination with the laparoscope to assess proper positioning of the cannula. Left paralumbar fossa laparoscopy provides excellent viewing of the left cranial portion of the abdomen and is appropriate for evaluation of diseases involving the left kidney, rumen, spleen, and diaphragm.

The cranioventral midline laparoscopy provides excellent visibility of the cranioventral portion of the abdomen. It allows evaluation of diseases involving the abomasum, liver, reticulum, spleen, and diaphragm.

CLINICAL EXAMINATION OF THE DIGESTIVE TRACT AND ABDOMEN OF THE CALF

Clinical examination of the digestive tract and abdomen of the calf may be more difficult than in the adult animal. The rumen in the preruminant calf is not yet functional and thus cannot be used as an indicator of the state of the alimentary tract as in adult cattle. Also, rectal examination is not usually possible until the animal is about 10 to 12 months of age, depending on the breed. A digital examination of the rectum of young calves is useful for determining the nature and amount of feces. This may provide an indication of the presence of impending diarrhea.

A complete absence of feces suggests the presence of an acute intestinal obstruction, acute diffuse peritonitis, or atresia coli.

The oral cavity of the calf is easily examined and should be part of the clinical examination of every sick calf.

ABDOMINAL DISTENSION IN CALVES

Abdominal distension is common in calves under 2 months of age. If the distension is symmetric, it may be difficult to determine whether it originates in the rumen, abomasum, intestines, or peritoneal cavity.

Examination of the abdomen of the young calf includes inspection of the contour of the abdomen to determine the maximum area of any distension, deep palpation and ballottement of each flank to determine the presence of fluid-splashing sounds that indicate a fluid-filled viscus, and percussion and auscultation to determine the presence of a gas-filled viscus. Placing the calf's hindquarters on the ground and allowing the viscera to move to the caudal part of the abdomen may allow visual inspection and palpation of a distended abomasum below the xiphoid sternum. With the calf in lateral recumbency, careful palpation and simultaneous auscultation may reveal the location of the distended viscus. However, it is often necessary to do an exploratory laparotomy to determine the cause. A stomach tube should always be passed into the rumen to relieve any pressure caused by the accumulation of gas or fluid. In the case of severe distension of the abdomen accompanied by severe abdominal pain (kicking, bellowing, rolling, and getting up and lying down) it may be necessary to relieve intraabdominal pressure with a large-gauge needle (12- to 14-gauge, 75–100 mm; 3–4 inches). The most common cause of severe abdominal distension in a young calf that can be relieved by trocarization is AV.

Abdominocentesis is easily done in the calf and at least three punctures should be attempted before concluding the absence of fluid. To avoid puncture of the abomasum, sites that are caudal to the umbilicus are used (see Chapter 7).

The differential diagnosis of the common causes of abdominal distension in the calf is summarized in Table 8-7.

Table 8-7 Differential diagnosis of diseases of the digestive tract and abdomen of young calves presented with distension of the abdomen

Disease	History, clinical and laboratory findings, treatment
Abomasal volvulus	Always acute to peracute, 1 week to 6 months of age, acute abdominal pain, bellowing, up and down, severe tight distension of abdomen, loud ping and fluid-splashing right side, emergency surgery necessary; recovery about 50% if recognized and corrected early
Abomasal dilatation (fluid, milk, hairballs, and often abomasal ulcers)	Chronic or acute onset, calves 1–6 months of age, history of abnormal feces, may be unthrifty, mild to moderate abdominal distension and pain, fluid-splashing sounds over right flank, dehydration, negative peritoneal fluid, laparotomy and abomasotomy required
Perforated abomasal ulcers	Acute onset, sudden collapse, calves 2 weeks to 3 months, hand-fed or nursing calves, weakness, recumbency, tachycardia, mild to moderate abdominal distension, mild or no abdominal pain, abdominal splinting occasionally, *positive paracentesis,* feces variable Laparotomy required; survival about 25%
Volvulus of root of mesentery	Sudden onset, found in state of collapse, abdominal pain common, moderate abdominal distension, distended loops of intestine visible and palpable over right flank, bloodstained peritoneal tap, fluid-splashing sounds on palpation and auscultation, scant feces, emergency surgery
Acute diffuse peritonitis (not caused by perforated abomasal ulcer)	Usually in calves under 3 weeks of age, toxemia, temperature variable, weak, may be grunting, splinting of abdominal wall, mild abdominal distension, scant feces, fluid-splashing sounds over right flank (caused by paralytic ileus), *abnormal peritoneal fluid,* commonly associated with enteric colibacillosis, polyarthritis and umbilical and urachal abscess Exploratory laparotomy, prognosis poor
Atresia coli	Calf usually under 10 days of age, progressive distension of abdomen, bright and alert for first few days then becomes depressed, no feces only thick mucus from rectum, surgery indicated but only a minority have a successful lactation as a first-calf heifer, potential genetic component in Holstein Friesian cattle
Intussusception	May have history of diarrhea, now scant bloodstained feces, depressed, will not suck or drink, dehydrated, contour of abdomen may appear normal or slightly distended, fluid-splashing sounds and small ping may be audible, bloodstained peritoneal fluid, presurgical diagnosis often difficult, surgery necessary Recovery rate moderate if diagnosis early
Peracute to acute enteritis	Usually in calves under 3 weeks of age, acute onset of abdominal pain (kicking and stretching), will not suck or drink, may not yet appear dehydrated, temperature variable, mild to moderate abdominal distension, fluid-splashing sounds on auscultation and succussion of abdomen, continuous loud peristaltic sounds on auscultation, diarrheic feces may not be present on first examination, digital examination of rectum may stimulate defecation of foul-smelling, soft, watery feces, peritoneal tap negative
Omphalitis, omphalophlebitis, umbilical abscess	Single calf, usually 2–6 weeks of age. May be unthrifty, chronic toxemia. Large, painful swelling of umbilicus that may be obvious externally or deep palpation dorsal to umbilicus reveals firm swellings directed toward liver or bladder. Surgical excision required, usually with excellent outcome
Gastrointestinal tympany of dietary origin	Calves under 10 days of age, nursing calves sucking good cows. May be caused by ingestion of excessive quantities of milk and excessive gas formation in abomasum and large intestine Abdominal pain (kicking at abdomen), and pain on palpation of abdomen Marked to severe abdominal distension At laparotomy there is gaseous distension of the abomasum and cecum Recovery is usually good
Intestinal hairball	Calves 3–8 weeks of age, sudden onset of failure to suck, normal vital signs, total absence of feces, slight to moderate distension of the abdomen, fluid-splashing sounds over right abdomen, and normal peritoneal fluid; will remain anorexic, and fail to pass any feces for up to several days; hemogram normal; metabolic alkalosis with hypokalemia, and hypochloremia may occur Laparotomy and surgical removal of hairball required

Diseases of the Rumen, Reticulum and Omasum

SIMPLE INDIGESTION

SYNOPSIS

Etiology Excessive feed intake (grain and silage); indigestible roughage; sudden change in diet.

Epidemiology Usually in hand-fed dairy cattle and stall-fed beef cattle.

Signs Inappetence, drop in milk production, lack of rumination, rumen usually full and reticulorumen contractions decreased or absent, vital signs are normal. Spontaneous recovery in 12–24 h.

Clinical pathology None needed except to rule out differential diagnoses. Lesions not fatal.

Diagnostic confirmation A diagnosis of exclusion associated with spontaneous recovery.

Differential diagnosis list Early parturient hypocalcemia, acetonemia, traumatic reticuloperitonitis, carbohydrate engorgement, left-side displacement of the abomasum, right-side dilatation of abomasum, abomasal volvulus, vagus indigestion, phytobezoars, and secondary ruminal atony in toxemia.

Treatment None required except consider need for rumen transfaunation.

Control Feeding management and provision of digestible feeds.

ETIOLOGY

Indigestion is common in dairy cattle and stall-fed beef cattle because of the variability in quality and the large amounts of feed consumed. It is not common in pastured beef cattle or sheep because they are less heavily fed. The common causes are minor dietary abnormalities including indigestible roughage, particularly when the protein intake is low, moldy, overheated, and frosted feeds, and moderate excesses of grain and concentrate intake.

Cases occur under excellent feeding regimens and are usually attributed to overfeeding with grain or a sudden change in feed. Although the difference between simple indigestion and carbohydrate engorgement (grain overload) is one of degree, their separation can be justified by the marked clinical difference between the two syndromes. Gross overfeeding usually occurs when cattle or sheep gain accidental access to large quantities of grain or are suddenly introduced to high-grain diets in feedlots. Indigestion is more common when heavily fed cows are fed a little more concentrate than they can digest adequately. A sudden change to a new source of grain, especially from oats to wheat or barley, may have the same effect.

Indigestible roughage may include straw, bedding, or scrub fed during drought periods. It is probable that limitation of the available drinking water may contribute to the occurrence of the disease during dry seasons. Depraved appetite may also contribute to the ingestion of coarse indigestible material. Although good-quality ensilage cannot be considered an indigestible roughage, cases of indigestion can occur in cattle that are allowed unlimited access to good-quality ensilage. This is most likely to happen in heavy-producing cows running outside in cold weather whose hay and grain rations are limited. It is not uncommon for large Holstein cows to eat 45 to 50 kg of ensilage daily in such circumstances, and the high intake of acetate and acetic acid may be sufficient to depress their appetite. Prolonged or heavy oral dosing with antimicrobials may cause indigestion from inhibition of the normal ruminal flora. An unusual circumstance is the feeding of a special diet to produce milk, and dairy products, with a high content of polyunsaturated fats for special diets in humans. Fats in the diet are protected against hydrogenation in the rumen by a coating of formalin. The efficiency and safety of the diet depends on a thorough mixing of the formalin with the concentrates. If this is not done, the free formalin causes severe rumenitis.

PATHOGENESIS

Primary atony caused by dietary abnormality is difficult to explain. Changes in the pH of its contents markedly affect the motility of the rumen, and in cases caused by overeating on grain an increase in acidity is probably of importance. High-protein diets, including the feeding of excessively large quantities of legumes or urea, also depress motility because of the sharp increase in alkalinity that results. Atony that occurs after feeding on damaged feeds may have the same basis or be caused by other unidentified agents in the food. The simple accumulation of indigestible food may physically impede ruminal activity. Putrefaction of protein may also play a part in the production of atony. The toxic amides and amines produced may include histamine, which is known to cause ruminal atony when given intravenously and to be reversed by the administration of antihistamine drugs. Histamine may contribute to the ruminal atony that occurs in allergy, or after heavy grain feeding, but the absorption of histamine from the forestomachs in any circumstances is probably very limited.

A marked fall in milk yield occurs, caused probably by the sharp decrease in volatile fatty acid production in a hypotonic reticulorumen. Rumen contractions appear to play the same role as hunger contractions in simple stomachs and the decreased food intake is probably caused by the ruminal hypomotility or atony.

CLINICAL FINDINGS

A reduction in appetite is the first clinical finding, followed closely in milking cows by a slight drop in milk production. Both occur suddenly; the anorexia may be partial or complete but the fall in milk yield is relatively slight. The animal's posture is unaffected but there is mild depression and dullness. Rumination ceases and the ruminal movements are depressed in frequency and amplitude and sometimes are almost absent. The rumen may be larger than normal if the cause is

sudden access to an unlimited supply of palatable feed. There may be moderate tympany, especially with frozen or damaged feeds or in allergy, but the usual finding is a firm, doughy rumen without obvious distension. The feces are usually reduced in quantity and are drier than normal on the first day. However, 24 to 48 hours later the animal is commonly diarrheic; the feces are softer than normal, voluminous, and commonly malodorous.

There is no systemic reaction and the heart rate, temperature, and respirations are usually within normal ranges. Pain cannot be elicited by deep palpation of the ventral abdominal wall, although cows that have consumed an excessive quantity of a highly palatable feed such as silage, after not having had any for a long period of time, will have a grossly distended rumen, and mild abdominal discomfort may be present for several hours. The discomfort usually resolves when the rumen movements return to normal and the rumen returns to its normal size. Most cases recover spontaneously or with simple treatments in about 48 hours.

CLINICAL PATHOLOGY

Examination of the urine for ketone bodies is usually necessary to differentiate indigestion from acetonemia. Two simple laboratory tests have been introduced to assess the activity of the ruminal microflora. The sediment activity test is performed on aspirated ruminal fluid strained to remove coarse particles. The strained fluid is allowed to stand in a glass vessel at body temperature, and the time required for flotation of the particulate material is recorded. The time in normal animals varies between 3 minutes, if the animal has just been fed, and 9 minutes, if the last feeding has occurred sometime previously. Settling of the particulate material indicates gross inactivity, and less severe degrees are manifested by prolongation of the time required for flotation. The cellulose digestion test is also performed on aspirated rumen fluid and depends on the time required to digest a thread of cotton. A bead is tied to the end of the thread to indicate when separation occurs. Digestion times in excess of 30 hours indicate abnormality; the time required to obtain the test results has meant that the test is rarely performed.

The rumen fluid can be examined for pH using wide-range indicator paper. Values between 6.5 and 7.0 are considered normal. In cattle on grain diets, the pH may range from 5.5 to 6.0 normally but in cattle that have been on roughage diets such low values should arouse suspicion of lactic acidosis and careful monitoring is necessary.

NECROPSY FINDINGS

Simple indigestion is not fatal.

DIFFERENTIAL DIAGNOSIS

Simple indigestion is a **diagnosis of exclusion** and as such must be differentiated from all the diseases of the forestomachs and abomasum in which ruminal atony is a common clinical finding, and from diseases of other body systems that cause secondary ruminal atony:

- **Acetonemia**: the appetite and milk production decrease over a few days, there is ketonuria and the rumen contractions are present but weaker than normal.
- **Traumatic reticuloperitonitis**: there is a sudden onset of anorexia and agalactia, a mild fever, a painful grunt on deep palpation of the xiphoid sternum, and the rumen is static with an increase in the size of the gas cap.
- **Carbohydrate engorgement**: characterized by depression, dehydration, tachycardia, staggering, recumbency, diarrhea, and ruminal stasis with the presence of fluid-splashing sounds, and the pH of the ruminal fluid is usually below 6 and commonly down to 5.
- **Left displaced abomasum (LDA):** usually occurs within a few days after parturition and the rumen is usually smaller than normal, the contractions are usually reduced in amplitude, there is a ping on percussion over the lower left flank, and ketonuria.
- **Right displaced abomasum**: is most common in dairy cows 2–4 weeks postpartum, there is inappetence, reduced feces, ruminal atony, reduced milk production and a ping over the right flank, and a distended viscus is palpable per rectum in the lower right quadrant.
- **Abomasal volvulus**: anorexia, depression, reduced feces, dehydration, tachycardia, a ping over the right flank, and a distended viscus in the lower right quadrant are common.
- **Vagal indigestion**: characterized by gradual distension of the abdomen caused by distension of the rumen over a period of several days, progressive dehydration, and scant feces. Initially there is hypermotility of the rumen and the development of secondary frothy bloat. This is commonly followed by ruminal atony.
- **Phytobezoars**: cause inappetence to anorexia and scant feces, and on rectal examination distended loops of intestine and the firm masses may be palpable.
- **Secondary ruminal atony**: occurs in many diseases in which septicemia or toxemia (coliform mastitis) are present, but there are usually additional clinical findings to indicate their presence.
- Ruminal atony with mild bloat is common in the early stages of hypocalcemia, which may last for 6–18 hours, and is usually accompanied by anorexia and a decreased amount of feces. The ruminal motility and appetite return to normal following treatment with calcium borogluconate.
- The rumen is also atonic in allergic and anaphylactic states and returns to normal following treatment.

TREATMENT

Spontaneous Recovery

Most cases of simple indigestion recover spontaneously. Small quantities of fresh, good-quality, palatable hay should be provided several times daily to encourage eating and to stimulate reticulorumen motility. Because anorexia and forestomach hypomotility usually exist together, the objective is to stimulate both appetite and motility. Reduced feed intake reduces the two primary drives for reticulorumen activity: moderate forestomach distension and chewing activity.

Rumenatorics

A wide variety of oral preparations containing rumenatorics were available for many years and it was conventional to administer these to "stimulate" reticulorumen motility and to stimulate appetite. These preparations contained nux vomica, ginger, and tartar emetic in powder form to be added to water and pumped into the rumen. However, there is no evidence that nux vomica and tartar emetic are effective and they are not recommended. Ginger may be an effective prokinetic agent in ruminants, based on the results of a preliminary study demonstrating that the daily oral administration of ginger extract (40 mg/kg body weight [BW]) increased the frequency of reticular and ruminal contractions in healthy sheep within 24 hours.[1]

Parasympathomimetics

These agents have also been used to stimulate reticulorumen activity but have the disadvantage of inducing undesirable side effects and being uncoordinated and transitory in effect. Large doses depress reticulorumen activity, and there is no data indicating they increase ruminal activity in normal animals. The normal flow of rumen contents from the reticulorumen to the abomasum is the result of a complex of synchronized contractions and relaxations of various parts of the forestomachs, orifices, and abomasum occurring simultaneously. One of the major limitations of injectable parasympathomimetics used as rumenatorics is that they do not provide these synchronized movements; therefore minimal effective movement of ingesta can occur. Carbamylcholine chloride, physostigmine, and neostigmine have been most commonly administered to ruminants. Carbamylcholine acts on the musculature only and causes uncoordinated and functionless movements. Neostigmine at 0.02 to 0.04mg/kg subcutaneously has no effect on the rate and strength of reticular contractions in healthy cattle.[2] These drugs are not without danger, especially in very sick animals or those with peritonitis, and are specifically

contraindicated during late pregnancy. Their use is no longer recommended.

Experimentally, metoclopramide increases the rate of ruminal contractions and therefore might be beneficial in rumen hypomotility or motility disturbances associated with vagal nerve damage. However, a positive prokinetic effect of metoclopromide was transient and only seen when administered at 0.3mg/kg intramuscularly, at which dose rate mild neurologic signs were evident and manifested as restlessness followed by depression.[2] Similarly, Epsom salts (0.5–1.0 kg per adult cow) and other magnesium salts have not been demonstrated to be effective and are not recommended.

Alkalinizing and Acidifying Agents

If an excessive quantity of grain is the cause of the simple indigestion, the use of alkalinizers, such as magnesium hydroxide, at the rate of 400 g per adult cow (450 kg BW), is recommended when the rumen contents are excessively acid. Magnesium hydroxide should be used only if ruminal acidosis is present. A sample of rumen fluid can be readily obtained and the pH determined. If the rumen contents are dry, 15 to 30 L of water should be administered by stomach tube. The oral administration of boluses of magnesium hydroxide (162 g) or a powdered form (450 g) dissolved in 3.5 L of water daily for 3 days resulted in a significant increase in rumen pH after 48 and 24 hours, respectively. Both the boluses and the powder forms of magnesium hydroxide decreased rumen protozoal numbers and increased methylene blue reduction times compared with baseline values. There was no change in blood pH, bicarbonate, or base excess values.

Acetic acid or vinegar, 5 to 10 L, is used when the rumen contents are alkaline as a result of the ingestion of high-protein concentrates. This is a very uncommon occurrence.

Reconstitution of Ruminal Microflora (Rumen Transfaunation)

In cases of indigestion that have run a course of more than a few days, and in animals that have been anorexic for prolonged periods, there will be significant loss of ruminal microflora, especially if there have been marked changes in pH. Reconstitution of the flora by the use of rumen fluid transfers from healthy cows is highly effective. An abattoir is the best source of rumen contents (especially rumen fluid). Sufficient quantities of rumen fluid cannot be obtained from live animals by reaching into their mouth during rumination when the bolus is regurgitated, and "stealing the cud." Rumen fluid may also be removed from healthy animals by siphoning from the rumen with a stomach tube or by vacuum withdrawal with a special pump. The best results are obtained if 20 to 30 L of water is pumped into the rumen and then allowed to siphon by gravity flow (rumen lavage). The rumen fluid to be transferred should be strained and administered as an oral drench or preferably by stomach tube. At least 5 L of rumen fluid should be transferred to be effective, although a dose–response study verifying this volume has not been completed.[3] Repeated daily dosing is advisable, and rumen fluid will keep for several days at room temperature. Commercial products comprising dried rumen solids are available and provide some bacteria and substrate for their activity when reconstituted with warm water at 37°C.

When affected animals resume eating, they are best tempted by good, stalky meadow or cereal hay. Good-quality alfalfa (lucerne) or clover hay, green feed, and concentrate may be added to the diet as the appetite improves.

TREATMENT AND CONTROL

Treatment

Feed palatable grass hay and discontinue grain feeding (R-2)

Rumen transfaunation, 5 L daily for at least 3 days (R7-2)

Metoclopramide IM, neostigmine SC, carbamylcholine (R-3)

Oral magnesium hydroxide without determining rumen pH (R-3)

Control

Change rations gradually over 7–14 days (R-1)

IM, intramuscularly; SC, subcutaneously.

RUMEN IMPACTION DUE TO INDIGESTIBLE FOREIGN BODIES

Foreign body ingestion is common in ruminants because of a general lack of alimentary finesse, particularly in cattle. Ingestion of metallic foreign bodies can lead directly to penetration of the reticular or ruminal wall, and this common disease is covered elsewhere in this chapter in the section on traumatic reticuloperitonitis. Ingestion of nonmetallic foreign bodies is addressed in this section, and if extensive or located in the reticulum, such ingestion can result in decreased feed intake, weight loss, and electrolyte and acid-base abnormalities. Nonmetallic foreign bodies are most frequently found in the rumen.

Foreign bodies were detected in 42% of 400 cattle, 21% of 320 sheep, and 12% of 320 goats at slaughter in northern Ethiopia.[1] In a related study, foreign bodies were detected in 43% of 332 cattle, 57% of 193 sheep, and 59% of 169 goats at slaughter in eastern Ethiopia.[2] The foreign bodies were predominantly located in the rumen and consisted of plastic bags, cloth, rope, and leather (Fig. 8-6); consequently, increased use of paper bags is recommended wherever possible. Foreign bodies were detected in 17% of 1261 cattle at slaughter in Rwanda.[3] The foreign bodies were primarily plastic bags, despite a ban on the use of plastic bags in supermarkets. Cattle with foreign bodies present in the rumen were much thinner than cattle without foreign bodies. In a study in Jordan, cattle with nonmetallic foreign bodies in the rumen were more likely to exhibit signs of ruminal tympany than unaffected cattle.[4] Cattle with foreign body ruminal impaction have serum biochemical changes consistent with low BW and decreased feed intake.[5]

Rumen impaction in sheep with indigestible foreign bodies has been described in a semiarid region of Nigeria. The sheep had visited refuse dumps around a town. Only certain breeds of sheep, the Yankasa, Uda, and their crossbreeds, were found feeding on refuse dumps. Rumen-indigestible foreign bodies were present in 19% of the sheep slaughtered in the local abattoir. The foreign bodies were plastic materials, ropes, dry seeds, caked sand, metallic objects, paper, fiber, and hairballs. The plastic materials were present in 82% of the sheep. Clinically, the rumen impaction was characterized by emaciation, abdominal distension and symmetry, lack of feces in the rectum, foamy salivation, recumbency, and inappetence. At necropsy, the foreign bodies were usually loosely matted together and impacted with rumen ingesta. Hyperglycemia, metabolic alkalosis, hyponatremia, hypochloremia, hypocalcemia, hypoproteinemia, and hypoalbuminemia occurred in some cases. The impaction was related to the sheep scavenging on refuse dumps and the blood biochemical changes, along with the clinical signs, might be of some diagnostic significance.

Ultrasound of the rumen using a 3.5-MHz transducer at the left 11th-12th intercostal space after intraruminal placement of 1.5 to 2.0 L of water was helpful in identifying the presence of intraruminal foreign bodies in goats.[6] Foreign bodies appeared as a hyperechoic band with acoustic shadowing. Esophageal and ruminal endoscopy was helpful in resolving esophageal obstruction and removing foreign bodies in calves, with a low rate of complication.[7] The use of

Fig. 8-6 Rope rumen foreign body removed during a rumenotomy on a dairy cow with chronic weight loss, weakness, and clinical signs of vagal indigestion.

duck-billed loop snares or Dormi baskets facilitated capture of foreign objects located in the esophagus.

Foreign bodies are more common in sheep and goats that graze at the outskirts of urban areas. The lower prevalence of foreign bodies in goats in some studies is consistent with decreased exposure because they feed mainly on bushes and shrubs.

INDIGESTION IN CALVES FED MILK REPLACERS (RUMINAL DRINKERS)

A form of indigestion known as ruminal drinking occurs in veal calves and is characterized clinically by recurrent ruminal tympany, inappetence, unthriftiness, and the production of clay-like feces. The disease is most common in calves 5 to 6 weeks after being placed on a milk diet and being fed with a bucket.

The cause is insufficient closure of the reticular groove while drinking milk. The ingested milk enters the rumen in large quantities instead of flowing directly into the abomasum. The experimental intraruminal administration of milk to calves at 6 weeks of age induces changes in the rumen similar to those seen in spontaneous cases of the disease. The pH of the rumen decreases and L-lactate and D-lactate concentrations increase rapidly. The daily oral administration of untreated whole milk via stomach tube into calves 5 to 23 days of age results in a D-lactic metabolic acidosis within a few days. The onset of ruminal acidosis occurred quickly, and mean ruminal pH values fell from 6.7 to 4.9 after the first feeding. In the following days the rumen pH values varied between 4 and 5, and rumen fluid usually has a milky appearance and a sour smell. During ruminal acidosis, both L-lactic acid and D-lactic acid are produced abundantly by bacterial fermentative activity. Both isomers of lactic acid are absorbed from the rumen, or from the intestines, in which they exert an acidemic effect by inducing a strong ion (metabolic) acidosis.[1] The L-lactate can be metabolized quickly by the body and does accumulate despite the continuous influx into the blood. However, D-lactate cannot be metabolized at the same rate because of a lack of specific metabolic pathway, and it accumulates with the consequence of the risk of hyper–D-lactatemia. This will result in acidemia caused by strong ion acidosis, depression, and reluctance to move, with impaired palpebral reflex being the best clinical indicator of hyper–D-lactatemia in calves with ruminal drinking or diarrhea.[2]

There is marked ruminal hyperkeratosis. Villous atrophy occurs in the proximal jejunum accompanied by a reduction in brush border enzyme activities. Clinical recovery occurs within several days after returning to normal feeding practices, with restoration of villous length and brush border enzyme activities in 3 to 4 weeks.

On clinical examination the temperature, heart rate, and respiratory rates are within normal range. The abdominal contour is increased in size, especially over the ventral half of the abdomen. Distension is more obvious on the left side. Ballottement of the left abdominal wall commonly reveals fluid-splashing sounds. Auscultation of the left paralumbar fossa while the calf is drinking reveals loud fluid-splashing sounds. Large volumes of foul-smelling or acid-smelling, grayish-white fluid can be siphoned off from the rumen. Examination of the rumen contents after calves have consumed milk reveals the presence of a casein clot. Radiologic examination reveals that ingested milk enters the rumen and reticulum and is only slowly moved on to the abomasum. An acetaminophen absorption test can be performed in equivocal cases, in which acetaminophen (paracetamol) is added to a 2-L test solution of milk or milk replacer at 20 to 50 mg/kg and the calf allowed to ingest the test solution.[3,4] Calves that are ruminal drinkers have a very flat acetaminophen absorption curve and delayed time to maximal plasma acetaminophen concentration, indicating failure of the esophageal groove closure and ruminal drinking syndrome. Alternatively, the dimensions of the abomasum can be measured on the ventral midline before and after the calf suckles a 2-L volume of milk or milk replacer. From the abomasal dimensions and assuming the abomasum can be modeled as an ellipse, abomasal volume can be calculated as length × width × depth × $\pi/6$;[5,6] in healthy calves the calculated abomasal volume should have increased by 2 L. Alternatively, an ultrasound can be performed on the ventral abdomen and the reticulum examined for the presence of milk. Immediately after suckling, the reticulum is displaced dorsally by the enlarged abomasum, which lies on the ventral abdominal floor. In calves with ruminal drinking syndrome, the reticular content could be visualized and consisted of a heterogeneous echoic liquid content.[7] Milk can also be visualized in the ventral aspects of the rumen after milk ingestion by calves with ruminal drinking syndrome.[7]

Affected calves remain unthrifty while they continue to drink milk. Esophageal groove reflex dysfunction may be a complication in some milk-fed calves affected with diarrhea. Treatment should initially start with draining of the rumen contents by passing an ororuminal tube. Drainage may require the addition of 1 to 2 L of warm tap water to create a siphon and facilitate emptying of the rumen. Calves should not be bucket fed, but should be fed milk with a small nipple hole to ensure slower ingestion. This is done because the disease is rarely diagnosed in calves that are left suckling their dam. Retraining the calf to suckle on a nipple by allowing the calf to suck on a finger before offering the nipple can be important.

In older calves that can be weaned, weaning on to hay and concentrates returns the calf to normal very quickly. Rumen movements, via eructation reflex, and ruminations become normal within 1 to 2 weeks.

The administration of colostrum and other fluids to calves using an esophageal feeder does not induce the esophageal groove reflex. However, colostrum and other fluids administered directly into the rumen with a feeder does move from the forestomach into the abomasum within minutes. Feeding colostrum to newborn calves by means of an esophageal feeder is a labor-saving and effective method of obtaining optimum levels of serum immunoglobulins. This is particularly useful in large dairy herds because colostrum can be given to calves immediately after birth.

At necropsy the rumen of calves with ruminal drinking syndrome is enlarged and there are varying degrees of hyperkeratosis and parakeratosis. Villous atrophy is prominent in the small intestine, which is partially restored to normal when the reticular groove reflex is restored.

Affected calves can be treated by inducing them to suck on the herdsman's fingers while they are being fed a small quantity of cows' whole milk or milk replacer. Ideally, calves recovering from ruminal drinking syndrome should be fed multiple small meals of milk or milk replacer frequently.

ACUTE CARBOHYDRATE ENGORGEMENT OF RUMINANTS (RUMINAL LACTIC ACIDOSIS, RUMEN OVERLOAD) AND SUBACUTE RUMINAL ACIDOSIS

ETIOLOGY

Acute ruminal acidosis is most commonly caused by the sudden ingestion of toxic doses of carbohydrate-rich feed, such as grain. Less common causes include engorgement with apples, grapes, bread, baker's dough, sugar beet, mangels, sour wet brewers' grain that was incompletely fermented in the brewery, and concentrated sucrose solutions used in apiculture. **Subacute ruminal acidosis** (**SARA**) in dairy cattle is a disorder of ruminal fermentation in dairy cattle caused by the ingestion of large amounts of concentrates and inadequate amounts of fiber administered to increase milk production in early lactation.

SYNOPSIS

Etiology Sudden ingestion of large amounts of highly fermentable carbohydrates.

Epidemiology Accidental consumption by ruminating cattle of excessive quantities of highly digestible feeds such as cereal grains, corn, baker's bread, grapes, apples, and the like. In beef and lamb feedlots the rapid introduction of high-level grain diets is a major risk factor. Outbreaks occur when animals gain access to a large quantity of grain. High mortality rate when large quantity of grain ingested. Subacute ruminal acidosis is considered an important problem in dairy herds.

Signs Anorexia, depression, dehydration, ruminal stasis, profuse diarrhea with sweet–sour odor of feces that may contain undigested kernels, weakness, and ataxia leading to recumbency. Rumen may or may not feel full, but atonic and fluid-splashing sounds are audible on ballottement. Laminitis and mycotic rumenitis are complications.

Clinical pathology Ruminal fluid pH below 5, rumen protozoa absent or inactive in rumen fluid; hemoconcentration, blood L-late and D-lactate concentration increased, hypocalcemia.

Lesions Acute congested and inflamed rumenitis, sloughing ruminal mucosa; mycotic inflammation and necrosis of forestomach and fungal hepatitis if disease lasts several days.

Diagnostic confirmation Ruminal fluid pH below 5.

Differential diagnosis list Simple indigestion, parturient hypocalcemia, peracute coliform mastitis, acute diffuse peritonitis.

Treatment Triage to determine which animals need medical treatment, rumen lavage, or rumenotomy. Correct ruminal and systemic acidosis with alkalinizing agents parenterally or orally depending on severity. Fluid and electrolyte therapy as necessary. Restore forestomach and intestinal motility by providing palatable hay.

Control Prevent accidental access to grain. Gradual introduction to high-level grain diets in feedlots. Total mixed rations containing chopped roughage and grain to ensure controlled intake of carbohydrates. Careful feeding management of dairy cattle during late pregnancy and early lactation. Use of ionophores in feed alter rumen metabolism and potentially can control ruminal acidosis.

EPIDEMIOLOGY

Occurrence

All types of **ruminant** cattle and sheep are susceptible to acute ruminal acidosis, but the disease is most common in feedlot cattle. It also occurs in lamb feedlots and has been recorded in goats, wild deer, and farmed ungulates. SARA is most common in dairy cattle fed high-level grain diets.

Previous Diet and Change of Ration

Because the type and level of ration consumed by a ruminant affects the numbers and species of bacteria and protozoa in the rumen, a change from one ration to another requires a period of microbial adaptation, which is a variable interval of time before stabilization occurs. Animals being fed a low-energy ration are most susceptible to a rapid change to a high-energy ration because satisfactory adaptation cannot occur quickly enough. This results in the rapid onset of abnormal fermentation.

Accidental Consumption of Excess Carbohydrates

The disease occurs is common following accidental consumption of toxic amounts of grain by cattle gaining sudden access to large quantities of grain. A single animal or a group of hungry cows may break into a grain storage bin or find a large supply of unprotected grain, which is not uncommon on a mixed cattle–grain farm. Another common occurrence is when cattle are left under the care of an assistant who, being unaware of the feeding schedule, gives the cattle an unaccustomed quantity of grain. Outbreaks have occurred in dairy herds following malfunction of automatic feeders, which delivered many times more than the usual amount of grain. In a similar outbreak, recently calved cows consumed an excessive amount of feed delivered by an automatic feeder but not eaten by other cows because of hot weather.

Outbreaks have occurred when cattle have been turned into unripe, green corn standing in the field, when cattle or sheep have been placed on stubble fields in which considerable grain lost by the harvester was available on the ground, and following the irregular feeding of large quantities of other less common animal feeds and by-products, such as bread, baker's dough, and wet brewers' grain. Problems usually arise with these feeds when a larger than usual amount is fed to cattle either for the first time or because the usual supplementary feed is in short supply.

Feedlot Cattle

The occurrence of grain overload in feedlot cattle, however, has gained the most attention, presumably because of its economic impact. Digestive disorders account for approximately 25% to 35% of deaths in feedlot cattle and may contribute to decreased performance and efficiency of production. The economics of feedlot beef production dictate that cattle should gain weight at their maximum potential rate, and this usually involves getting them on to a full feed of a high concentration of grain quickly. Economics also favor the processing of grain by

one of several methods available that will increase the availability of starch, increase the rate of degradation in the rumen. All these factors set the stage for a high incidence of grain overload in feedlot cattle.

There are some critical periods during which grain overload occurs in feedlot cattle. When starting cattle on feed, animals with previous experience of eating grain will commonly consume a toxic dose if offered a ration with a high percentage of grain. The disease is common in feedlot cattle in which the total daily feed intake has been brought up to what is considered the same feed on an ad libitum basis, and they gorge themselves. When increasing the concentration of grain in the ration from one level to another, if the increment is too high the total amount of grain consumed by some cattle will be excessive. Rapid changes in barometric pressures may affect the voluntary intake of cattle. A rapid change to cold weather may result in a moderate increase in feed intake in animals that are fed ad libitum and outbreaks of grain overload may occur. When rain is involved and feed becomes wet and possibly even moldy, feed intake will drop, but when fresh dry feed is offered again there may be a marked increase in feed intake that results in grain overload.

The disease also occurs when cattle that have been on a high-level grain ration (full feed) have become hungry because they have been out of feed for 12 to 24 hours as a result of a breakdown in the feed mill or handling facilities. Offering an unlimited supply of feed to these cattle will often result in severe cases of grain overload. In large feedlots, in which communications can be a problem, the accidental feeding of a high-level grain ration to cattle that are on a high-level roughage ration is a common cause of the disease.

The ruminal lesions of rumenitis and ruminal parakeratosis, which are common in feedlot cattle at slaughter, are thought to be associated with the continuous feeding of grain. These lesions are often remarkable at slaughter in well-nourished cattle, and their effect on live weight gain and feed conversion is not known.

Beef Breeding Herds

Cows in beef cow–calf herds may develop acute ruminal acidosis if offered a high-energy grain ration during the winter feeding period without a period of adjustment.

Lamb Feedlots and Liquid-Fed Calves

Outbreaks of the disease occur in lamb feedlots in which lambs are started on a high-level grain ration without a period of adjustment. The disease is not as common in lambs as in cattle, perhaps because lambs are usually fed on oats.

Rumenitis and metabolic acidosis have also been reported when newborn calves were force-fed liquid feeds or nutrient–electrolyte solutions containing easily digestible carbohydrates.

Dairy Cattle Herds

SARA occurs in dairy cattle herds fed high-grain, low-fiber rations in early lactation. It is considered of major economic importance because of the possible association with laminitis in dairy herds.

The transition from the pregnant, nonlactating state to the nonpregnant, lactating state is the period during which the majority of metabolic diseases occur in the dairy cow. During this period, which ranges from 3 weeks before until 3 weeks after calving, the cow is changed from a high-fiber, low-concentrate diet to a diet that is higher in concentrate feeds and lower in fiber. Cows that have not adapted to these high-grain diets are particularly susceptible to ruminal acidosis. SARA is characterized by repeated bouts of depressed rumen pH between 5.2 and 5.6. The abnormality often results from a large intake of rapidly fermentable carbohydrates that leads to the accumulation of organic acids in the rumen. Up to 20% of cows on commercial dairy farms in early to midlactation have a rumen pH of less than 5.5, indicative of SARA. The economic losses associated with SARA have been estimated at $1.12 per cow per day.

Field observations suggest that periparturient cows are at risk of SARA because of the time required for the rumen microflora and papillae to adapt to increased intakes of concentrates immediately before parturition and during early lactation when feed intake increases rapidly to meet the energy needs of high-producing dairy cows. The adaptation of the ruminal microflora and papillae from a system appropriate for forage to a system capable of using high-energy lactation rations requires a gradual change during a period of 3 to 5 weeks.

The need for individual cows to adapt to high-energy rations and the common practice of feeding dairy cows as groups results in periparturient cows being at risk of developing SARA. For practical reasons, as total mixed rations have become more common, many dairy herds limit the number of rations to a single dry-cow ration and a single lactating-cow ration, because of the time and labor required to mix each ration. This system has made it difficult to introduce concentrates to individual cows in the first few weeks after calving. If the dry-cow ration has not resulted in adaptation of the ruminal microflora required for high-energy rations, acidosis may occur when the cow is fed the lactating-group ration. The net energy of a ration can be safely increased in 10% increments. For example, a change from an energy density of 0.70 Mcal/lb NE_l (net energy, lactation) to 0.77 Mcal/lb NE_l would be considered safe. The National Research Council recommends that dry-cow total mixed rations have 0.57 Mcal/lb NE_l and that a high-production lactation cow ration have 0.78 Mcal/lb NE_l. Using the 10% guideline for gradual energy change would require at least two intermediate rations.

Dairy producers attempt to minimize the **negative energy balance** of lactating cows in early lactation by maximizing concentrate intake early in the period after parturition. The early lactation period is a high-risk period for lactating dairy cows if they are fed rations as separate components, for three reasons:

1. Concentrates are consumed by the cow in preference to forage.
2. Forage consumption is not usually measured on an individual cow basis and is commonly assumed to approximate the herd average.
3. Dry matter intake of periparturient cows is lower than commonly thought and is very dynamic through this period.

Thus high-producing lactating dairy cows consuming large quantities of high-energy grains are susceptible to SARA during early lactation.

Field recommendations for feeding component-fed concentrates during the first 3 weeks of lactation are usually excessive. Feeding excessive quantities of concentrate and insufficient forage results in a fiber-deficient ration likely to cause subacute acidosis. The same situation may occur during the last few days before parturition if the ration is fed in separate components; as dry matter intake drops before calving, dry cows will preferentially consume too much concentrate and insufficient fiber, and develop acidosis.

SARA may also be caused by formulation of rations that contain excessive amounts of rapidly fermentable carbohydrates, a deficiency of fiber, or errors in delivery of the rations. Recommendations for the fiber content of dairy rations are available in the National Research Council (Nutrient Requirements of Dairy Cattle). Dry matter content errors in total mixed rations are commonly related to a failure to adjust for changes in moisture content of forages.

Morbidity and Case–Fatality Rates

Outbreaks of the disease occur in cattle herds kept on grain farms and in feedlots. Depending on the species of grain, the total amount eaten and the previous experience of the animals, the morbidity will vary from 10% to 50%. The case–fatality rate may be up to 90% in untreated cases, whereas in treated cases it still may be up to 30% to 40%.

Types and Toxic Amounts of Feeds

Wheat, barley, and corn grains are the most toxic when ingested in large quantities. Oats and grain sorghum are least toxic. All grains are more toxic when ground finely or even crushed or just cracked, which are processes

that expose the starch component of the grain to the ruminal microflora. The experimental feeding of unprocessed barley to cattle did not result in rumenitis, whereas feeding rolled barley was associated with ruminal lesions. An unrestricted supply of stale bread can cause outbreaks.

The amount of a feed required to cause acute illness depends on the species of grain, previous experience of the animal with the grain, its nutritional status and body condition score, and the nature of the ruminal microflora. Dairy cattle accustomed to high-level grain diets may consume 15 to 20 kg of grain and develop only moderate illness, whereas beef cows or feedlot cattle may become acutely ill and die after eating 10 kg of grain to which they are unaccustomed. Amounts of feed that are lethal range from 50 to 60 g of crushed wheat per kilogram BW in undernourished sheep to 75 to 80 g/kg BW in well-nourished sheep, and in cattle doses ranging from 25 to 62 g/kg BW of ground cereal grain or corn produced severe acidosis.

PATHOGENESIS

A summary of the events that occur in the rumen and the systemic effects on the animal with acute ruminal acidosis is presented here. The disease provides an excellent example of strong ion (metabolic) acidosis in ruminants.

Changes in Rumen Microflora

The ingestion of excessive quantities of highly fermentable feeds by a ruminant is followed within 2 to 6 hours by a marked change in the microbial population in the rumen. There is an increase in the number of *Streptococcus bovis,* which use the carbohydrate to produce large quantities of lactic acid. In the presence of a sufficient amount of carbohydrate (a toxic or a lethal amount) the organism will continue to produce lactic acid, which decreases the rumen pH to 5 or less, which results in the destruction of the cellulolytic bacteria and protozoa. When large amounts of starch are added to the diet, growth of *S. bovis* is no longer restricted by energy source and it multiplies faster than any other species of bacteria.

Volatile Fatty Acids and Lactic Acid in the Rumen

The concentration of volatile fatty acids increases initially, contributing to the fall in ruminal pH. The low pH allows lactobacilli to use the large quantities of carbohydrate in the rumen to produce excessive quantities of lactic acid, resulting in **ruminal lactic acidosis**. Both D and L forms of the acid are produced, which markedly increases ruminal osmolality, and water is drawn in from the systemic circulation, causing hemoconcentration and dehydration. Ruminal osmolality increases from a normal of 280 mOsm/kg to almost 400 mOsm/kg, and this increase in rumen osmolality plays an important role in decreasing appetite and increasing dehydration, because extracellular fluid volume is translocated into the rumen.

Some of the lactic acid is buffered by ruminal buffers, but large amounts are absorbed by the rumen and some moves into and is absorbed further down the intestinal tract. Lactate is a 10 times stronger acid than the volatile fatty acids, and accumulation of lactate eventually exceeds the buffering capacity of rumen fluid. As the ruminal pH declines, the amplitude and frequency of the rumen contractions are decreased, and at about a pH of 5 there is ruminal atony. The increased concentration of undissociated volatile fatty acids in the rumen is thought to be more important than increased lactic acid concentration or decreasing ruminal pH in causing ruminal atony. Experimentally, ruminal atony occurs in sheep within 8 to 12 hours after grain engorgement, but the precise pathophysiological mechanism for loss of forestomach motility is uncertain. The diarrhea is thought to be osmotic because of the large increase in rumen osmolality and, consequently, small and large intestinal osmolality, which is similar to the cathartic effects of orally administered magnesium sulfate.

In experimental lactic acidosis using sucrose in sheep, feed intake does not resume until rumen pH has returned to 6.0 or higher and lactic acid is no longer detectable in the rumen. Renal blood flow and glomerular filtration rate are also decreased, resulting in anuria. Eventually there is shock and death. All these events can occur within 24 hours after engorgement of a lethal dose of carbohydrate; with toxic doses the course of events may take 24 to 48 hours.

Systemic Lactic Acidosis

The absorbed lactic acid acts as a strong anion, and when absorbed in sufficiently large enough amounts results in a decreased strong ion difference (the net difference in charge between strong cations and strong anions) and a strong ion acidosis and acidemia. The L-lactate is rapidly metabolized to bicarbonate, increasing the plasma strong in difference and increasing blood pH toward the normal range. D-lactate is very slowly metabolized and plasma concentrations decrease primarily by renal excretion, which is low in advanced cases of ruminal acidosis because of marked dehydration. In animals with mild or moderate dehydration that survive the acute form of the disease, the rapid clearance of L-lactate and D-lactate and other compensatory mechanisms may overcompensate, resulting in alkalosis. In severe cases of lactic acidosis the reserves of plasma bicarbonate are reduced, the blood pH declines steadily, and the blood pressure and renal blood flow decline, causing a decrease in perfusion pressure and oxygen supply to peripheral tissues. This results in a further increase in lactic acid from cellular respiration and decreased elimination of D-lactate in the urine.

Both D- and L-lactic acids are produced. The L-lactic acid is used much more rapidly than the D-isomer, which accumulates and causes a severe D-lactic acidosis. If the rate of entry of lactic acid into body fluids is not too rapid, compensatory mechanisms are able to maintain the blood pH at a compatible level until the crisis is over, and recovery is usually rapid. This may explain the common observation that feedlot cattle may be ill for a few days after being introduced to a grain ration but quickly recover, whereas in other cases when the rate of entry is rapid the compensatory mechanisms are overcome and urgent treatment is necessary.

Chemical and Mycotic Rumenitis

The high concentration of lactic acid in the rumen causes chemical rumenitis, which is the precursor for mycotic rumenitis in those that survive; this occurs about 4 to 6 days later. The low pH of the rumen favors the growth of *Mucor, Rhizopus,* and *Absidia* spp., which invade the ruminal vessels, causing thrombosis and infarction. Inoculation of *A. corymbifera* orally into sheep with experimental ruminal acidosis produced with barley causes desquamation of the superficial layers of the mucosae and focal necrosis from lamina propria to muscular layers. Severe bacterial rumenitis also occurs. Widespread necrosis and gangrene may affect the entire ventral half of the ruminal walls and lead to the development of an acute peritonitis. The damage to the viscus causes complete atony and this, together with the toxemia resulting from the gangrene, is usually sufficient to cause death. Mycotic omasitis and rumenitis may also occur without a history of grain engorgement in cattle. Anorexia and forestomach atonicity associated with a primary illness in other body systems may predispose the mucosae to fungal infection because of abomasal reflux of acid and the prolonged use of antimicrobials.

Chronic rumenitis and ruminal parakeratosis are common in cattle fed for long periods on grain rations, and the lesions are attributed to the chronic acidosis, but it is possible that barley awns and ingested hair may contribute to the severity of the lesions.

Hepatic Abscesses

In uncomplicated chemical rumenitis, the ruminal mucosa sloughs and heals with scar tissue and some mucosal regeneration. Hepatic abscesses commonly occur as a complication as a result of a combination of rumenitis caused by lactic acidosis and allowing *Fusobacterium necrophorum* and *Trueperella* (formerly *Arcanobacterium* or *Corynebacterium*) *pyogenes* to enter directly into ruminal vessels and spread to the liver, which may have also undergone injury from the lactic acidosis. Severe diffuse coagulation

necrosis and hyperplasia of the bile duct epithelium and degeneration of renal tubules may also be present histologically. A small proportion of cattle with hepatic abscesses proceed to develop **caudal vena caval syndrome**, which is addressed in Chapter 12.

In cattle being placed on a grain ration, even with control of the daily intake, hepatic cell damage and liver dysfunction occur even though dietary adaptation may have occurred in 2 to 3 weeks. The biochemical profile indicates that complete metabolic adaptation requires at least 40 days following the start of grain feeding.

Laminitis

Laminitis occurs in acute, subclinical, and chronic forms associated with varying degrees of severity of ruminal acidosis. The association between acidosis and laminitis appears to be associated with altered hemodynamics of the peripheral microvasculature. Vasoactive substances are released during the decline of rumen pH and the bacteriolysis and tissue degradation. These substances cause vasoconstriction and dilatation, which injure the microvasculature of the corium. Ischemia results, which causes a reduction in oxygen and nutrients reaching the extremities of the corium and cell swelling. Ischemia causes physical degradation of junctures between tissues that are structurally critical for locomotion, and cell swelling within an enclosed noncompliant structure such as the hoof can result in further decrease in blood flow within the digit. The insidious rotation of the distal phalanx (pedal bone) can result in permanent anatomic change. Manifestations of subclinical laminitis are sole hemorrhages and yellowish discoloration. Other clinical manifestations include double soles, heel erosion, dorsal wall concavity, and ridging of the dorsal wall.

Other Toxic Substances Produced

Several toxic substances other than lactic acid have been suggested as contributory to the disease. Increased concentrations of histamine have been found in the rumen of experimentally engorged cattle, but its possible role in the disease remains unknown. Histamine is not absorbed from the rumen except at abnormally high pH values, but is absorbed from the small intestine. Laminitis occurs in some cases of rumen overload, but the pathogenesis is unknown.

Other substances that have been recovered from the rumen in grain overload include a suspected endotoxin, ethanol, and methanol. In experimental lactic acidosis induced in cattle with 70 g of barley per kilogram BW, endotoxin and arachidonic acid metabolites are produced and may be important. However, the role of the endotoxin is uncertain but appears to be minor because of effective hepatic clearance. Endotoxin administered into the intestine of lactic acidotic sheep is not absorbed. *Clostridium perfringens* and coliform bacteria have also been found in increased numbers, but their significance is uncertain. The electrolyte changes that occur include a mild hypocalcemia caused by temporary malabsorption, loss of serum chloride caused by sequestration in the abomasum as a result of gastrointestinal hypomotility, and an increase in serum phosphate concentration caused by renal failure.

Experimental Lactic Acidosis

The disease can be reproduced in cattle and sheep with a variety of grains, fruits, sugars, and pure solutions of lactic acid. The oral administration of sucrose at 18 g/kg BW to goats can cause lactic acidosis. In cattle the sucrose is used to induce rumen lactic acidosis experimentally. The severity of the experimental disease and the magnitude of the pathophysiological changes vary depending on the substance used, but changes similar to the natural disease occur.

Lesions in the brain have been recorded in the experimental disease in sheep and naturally occurring cases in cattle, but their pathogenesis and significance are uncertain. There are detectable changes in the cellular and biochemical composition of the cerebrospinal fluid, which suggests that the blood-brain barrier may be affected. Experimentally, sublethal doses of volatile fatty acids, lactate, and succinate have an effect on liver function. Toxic and lethal doses of butyrate can cause sudden flaccid paralysis and death from asphyxia.

Subacute Ruminal Acidosis (Dairy Cattle)

There continues to be disagreement as to the consensus definition of SARA, although there is agreement that the definition should focus on rumen pH. Part of the disagreement is caused by differences in mean rumen pH measured by stomach tube or rumenocentesis in which it appears that stomach tube pH values are approximately 0.3 units higher than those obtained by rumenocentesis. This difference may reflect handling differences in the sample, because the pH of free-catch urine samples are often 0.2 to 0.3 pH units higher than those obtained with an anaerobically collected sample from a bladder catheter; loss of carbon dioxide is thought to account for the difference in pH values. Part of the disagreement is caused by **SARA being the result of repetitive transient and moderate decreases in rumen pH**, compared with acute ruminal acidosis, which is the result of a **sustained and marked decreased in rumen pH**. There is a growing consensus that a **definition of SARA is a rumen pH (measured by rumenocentesis) ≤5.5**;[1,2] preferably this low pH should be sustained for at least 3 hours of each day.[3,4] However, it should be noted that in vitro fiber digestibility is decreased when pH is below 6.2.[5]

The pathogenesis of SARA in lactating dairy cows is not as well understood as acute ruminal acidosis associated with the sudden ingestion of large amounts of readily fermentable carbohydrates, for example, it is most common in beef cattle that gain accidental access to large quantities of grain. In early-lactating dairy cows, SARA is usually caused by the consumption of diets with high levels of rapidly fermentable carbohydrates or marginal, often deficient, levels of physically active fiber. SARA has been documented most frequently in confinement herds fed a total mixed ration or component feeds; however, it can also occur in pasture-fed cattle in Ireland and New Zealand in which there are lush pastures with high concentrations of rapidly fermentable carbohydrates and low levels of effective fiber.[5,6]

The biochemical changes that occur in lactating dairy cows in early lactation that are affected with SARA have not been examined in detail. In SARA, fermentation of nonstructural carbohydrates leads to the production of large quantities of volatile fatty acids and lactate, which accumulate in the rumen and subsequently decrease rumen pH. It has been difficult to reproduce SARA in early-lactation dairy cows even with diets such as high-moisture corn, cracked dried corn grain, and rolled barley. These feeds did not induce SARA, either because of an inability of the feeds to depress the rumen pH rapidly enough or because of the cow's refusal to consume them.

Wheat/barley pellets were readily consumed by lactating dairy cows and did result in a sustained reduction in rumen pH. When cows with experimental SARA are given a choice between alfalfa hay and alfalfa pellets, cows will choose the alfalfa hay more often, which implies that dairy cows would increase their dietary preference for a feed of longer particle size when given the appropriate choice during a bout of SARA. As intake of long hay will result in more saliva production and rumen buffering than intake of pelleted alfalfa, this indicates that cows select feeds with high rumen-buffering capacity in an attempt to prevent SARA. When cows with SARA were offered sodium bicarbonate ad libitum, they did not select the compound to attenuate the ruminal acidosis. When cows with SARA were offered a choice between two test pellets, one containing 4% sodium bicarbonate and the other 4.5% sodium chloride, the intake of the sodium bicarbonate pellets increased over time, but the intake of sodium chloride pellets remained unaltered.

There is some evidence that lactic acid is not the causal reason for the prolonged reduction in pH of the ruminal contents. Studies have shown only low lactate levels between 0.45 and 0.74 mmol/L in cows with suspected SARA. Excessive volatile fatty acid production may be a more important contributor to SARA in lactating dairy cows.

The induction of SARA by excess feeding of wheat/barley pellets reduces the rumen digestion of neutral detergent fiber from grass hay, legume hay, and corn silage. It is thought that SARA affects the productivity of dairy cows by reducing the fiber digestion, because low pH negatively affects cellulolytic bacteria. The induction of SARA in lactating dairy cows by replacing 25% of the total mixed ration intake with pellets consisting of 50% wheat and 50% barley reduced the in situ dry matter and neutral detergent fiber digestion of mixed hay. Disappearance of neutral detergent fiber was reduced from 39.5% to 30.9%.

Rumen pH drops considerably in dairy cows after calving when the diet is changed. Monitoring rumen pH throughout the transition period of dairy cows in which the concentrate to forage ration was changed from 70:30 to 55:45 at calving found that 1 week before calving the average daily pH was 6.83, the average daily time with rumen pH below 6 was 26 minutes, and the average daily time with rumen pH below 5.6 was 6 minutes. During the first week after calving, the average daily pH was 6.51, and the average daily time with rumen pH below 6 and 5.6 were 312 and 60 minutes, respectively. The drop in rumen pH is associated with an increase in the rate of production of volatile fatty acids, which temporarily increases the concentration of volatile fatty acids in the rumen, until the absorptive capacity of the rumen mucosa for volatile fatty acids has been increased.

The pathogenesis of rumenitis, hepatic abnormalities, and laminitis associated with SARA is considered to be similar to those described earlier for acute ruminal acidosis.

CLINICAL FINDINGS

Speed of Onset and Severity

The speed of onset of the illness varies with the nature of the feed; it is more rapid with ground feed than with whole grain. The severity increases with the amount of feed eaten. If cattle are examined clinically within a few hours after engorgement, the only abnormalities that may be detectable are a **distended rumen** and **abdomen**, and occasionally some abdominal discomfort, evidenced by kicking at the belly. In the **mild form**, affected cattle are anorexic and still fairly bright and alert, and the feces may be softer than normal. Rumen movements are reduced but not entirely absent. Affected cattle do not ruminate for a few days but usually begin to eat on the third or fourth day without any specific treatment.

In **outbreaks of the severe form**, within 24 to 48 hours some animals will be recumbent, some staggering, and others standing quietly alone. Most affected cattle are anorexic, apathetic, and depressed. Teeth grinding may occur in about 25% of affected sheep and goats. Once they are ill they usually do not drink water, but cattle may engorge themselves on water if it is readily available immediately after consuming large quantities of dry grain. In an outbreak, inspection of the feces on the ground will usually reveal many spots of soft to watery feces.

Individual Animals

Depression, **dehydration**, **inactivity**, **weakness**, **abdominal distension**, **diarrhea,** and **anorexia** are typical. The temperature is usually below normal, 36.5°C to 38.5°C (98°F–101°F), but animals exposed to the sun may have temperatures up to 41°C (106°F). In sheep and goats, the rectal temperatures may be slightly higher than normal. The heart rate in cattle is usually increased and continues to increase with the severity of the acidosis and circulatory failure. Generally, the prognosis is better in those with heart rates below 100 beats/min than those with rates up to 120 to 140 beats/min. In sheep and goats, the heart rate may be higher than 100 beats/min. The respirations are usually shallow and increased up to 60 to 90 beats/min. A mucopurulent discharge is common because animals fail to lick their nares.

Diarrhea is almost always present and usually profuse, and the feces are light-colored with an obvious sweet–sour odor. The feces commonly contain an excessive quantity of kernels of grain in grain overload and have pips and skins when grapes or apples have been eaten. An absence of feces is considered by some veterinarians as a grave prognostic sign, but diarrhea is much more common. The **dehydration is severe and progressive.** In mild cases, the dehydration is about 4% to 6% BW with severe involvement up to 10% to 12% BW. Anuria is a common finding in acute cases, and diuresis following fluid therapy is a good prognostic sign.

Careful examination of the rumen is important. The rumen contents palpated through the left paralumbar fossa may feel firm and doughy in cattle that were previously on a roughage diet and have consumed a large amount of grain. In cattle that have become ill on smaller amounts of grain, the rumen will not necessarily feel full but rather resilient because the excessive fluid contents are being palpated. Therefore the findings on palpation of the rumen may be deceptive and a source of error. The primary contractions of the reticulorumen are usually totally absent, although **low-pitched tinkling and gurgling sounds** associated with the excessive quantity of fluid in the rumen are commonly audible on auscultation of the rumen. The ruminal fluid is a milky green to olive brown color and has a pungent acid smell. Collection of a sample of ruminal fluid in a glass beaker will reveal an absence of foam. The **pH of the rumen fluid is usually below 5.**

Severely affected animals have a staggery, drunken gait and their eyesight is impaired. They bump into objects and their palpebral eye preservation reflex is sluggish or absent. Recent investigations in calves with diarrhea have associated high plasma D-lactate concentrations with depressed palpebral reflex,[7] and presumably the same is true in adult ruminants. The pupillary light reflex is usually present but slower than normal. Acute laminitis may be present and is most common in cases that are not severely affected and appear to be good treatment risks. Affected animals are lame in all four feet, shuffle while they walk slowly, and may be reluctant to stand. The lameness commonly resolves if the animal recovers from the acute acidosis. Evidence of chronic laminitis may develop several weeks later.

Recumbency usually follows after about 48 hours but may occur earlier. Affected animals lie quietly, often with their heads turned into the flank, and their response to any stimulus is much decreased so that they resemble **parturient paresis**. A rapid onset of recumbency suggests an unfavorable prognosis and the necessity for urgent treatment, because death may occur in 24 to 72 hours after the ingestion of the feed. Evidence of improvement during this time includes a fall in heart rate, rise in temperature, return of ruminal movement, and passage of large amounts of soft feces.

The clinical findings described previously are the most common, but when a group of animals has been exposed to overfeeding there are all degrees of severity from simple indigestion, cases of which recover spontaneously, to the severe cases that need intensive therapy. The prognosis varies with the severity, and the clinical variables that are useful when deciding on a course of treatment or action are summarized in Table 8-8.

Ultrasonography

Transabdominal ultrasonography of the rumen mucosa has the potential to be a useful noninvasive diagnostic tool for identifying SARA in cattle.[8] The thickness of the rumen mucosa is inversely associated with rumen pH caused by pH-induced epithelial changes, particularly in the upper portion of the ventral rumen sac. The optimal site for ultrasonographic imaging can be obtained by identifying the intersection of a horizontal line going through the costochondral junction and a vertical line centered on the third lumbar vertebrae. In a preliminary study using an 8-MHz linear transducer, a ruminal mucosal thickness >7.3 mm at this location was associated with a ruminal fluid pH <5.5 approximately 4 hours postfeeding.[8]

Mycotic Rumenitis

Some animals appear to recover following treatment but become severely ill again on the third or fourth day. Mycotic rumenitis is common in these animals and is characterized by a fluid-filled atonic rumen, dehydration in spite of fluid therapy, diarrhea, anorexia, weakness leading to recumbency, and death in 2 to 3 days caused by acute diffuse peritonitis.

Table 8-8 Guidelines for the use of clinical findings in assessing the severity of grain overload in cattle for the selection of the treatment of choice

	CLINICAL PARAMETERS						
Degree of illness	*Mental state and muscular strength*	*Degree of dehydration (% of BW)*	*Abdominal distension*	*Heart rate (/min)*	*Body temp. (°C)*	*State of rumen; fullness, consistency of contents, movements and pH*	*Treatment*
Peracute	Severely depressed, weak, in lateral recumbency, unable to stand, apparent blindness, pupils dilated and slow response	8–12	Prominent	110–130	35.5–38.0	Distended with fluid and soft rumen contents, complete stasis, sweet–sour smelling fluid contents Rumen juice pH below 5 and usually about 4 No protozoa	Rumenotomy Sodium bicarbonate 5 L (5%) IV in 30 min (for 450 kg BW) followed by isotonic balanced fluids and electrolytes at 150 mL/kg BW for 6–12 h
Acute	Depressed, still able to walk but ataxic, complete anorexia, may want to drink water, pupils slightly dilated and slow response	8–10	Moderate	90–100	38.5–39.5	Distended with fluid, complete stasis, sweet–sour smelling fluid contents Rumen pH between 5 and 6 No protozoa	Consider immediate slaughter Rumen lavage or rumenotomy Sodium bicarbonate and fluids IV as in peracute case Feed hay
Subacute	Fairly bright and alert, able to walk, no ataxia, may eat, usually wants to drink, pupils normal	4–6 (Just barely detectable clinically)	Mild or none	72–84	38.5–39.0	Moderate distension with fluid, some doughy ruminal ingesta palpable, some weak ruminal contractions, rumen pH between 5.5 and 6.5 Some protozoa alive	Magnesium hydroxide 500 g/450 kg BW into rumen Fluids if indicated Feed hay Should begin eating in 24–36 h
Mild	Bright and alert, able to walk, no ataxia, eats and drinks normally	Not detectable clinically	Not significant	Normal	Normal 38.5–39.0	No detectable distension, ruminal contents palpable, ruminal contractions still present but not as strong as normal, rumen pH 6.5–7 Almost normal protozoal activity	Feed hay and observe for 48 h Watch for anorexia

BW, body weight; IV, intravenously.

Complications

Chronic laminitis may occur several weeks or months later. This is particularly important in dairy cattle herds affected with SARA. The mechanism remains undetermined and does not appear to be related to systemic endotoxemia, because endotoxin is rarely detected in cattle with acute ruminal acidosis. However, it is hypothesized that endotoxin absorbed into the portal circulation creates a proinflammatory response, but that the endotoxin is subsequently cleared by resident macrophages (Kupffer cells) in the liver.

Abortions may occur 10 days to 2 weeks later in pregnant cattle that survive the severe form of the disease.

Subacute Ruminal Acidosis in Dairy Cattle

SARA is being recognized with increased frequency in dairy herds. However, the case definition is not yet well described. Clinical findings include laminitis, intermittent diarrhea, suboptimal appetite or cyclic feed intake, a high herd culling rate, loss of body condition in spite of adequate energy intake, liver abscesses, and hemoptysis and epistaxis associated with venal caval thrombosis and pulmonary hemorrhage. Milk-fat depression and suboptimal milk production in the second-lactation and subsequent-lactation cows compared with the first-lactation cows may occur.

A decrease in dry matter intake is commonly reported in herds with SARA. The causes of a lowered dry matter intake are uncertain but may be related to weaker rumen motility during low pH phases, bacterial endotoxins, and changes in the osmolality of the rumen contents.

The laminitis is characterized by ridges in the dorsal hoof wall, sole ulceration, white line lesions, sole hemorrhages, and misshapen hooves. It is suggested that when the incidence of laminitis exceeds 10% of the herd, it should be considered a herd problem related to the feeding program.

CLINICAL PATHOLOGY

The severity of the disease can usually be determined by clinical examination, but field and laboratory tests are of some additional value, particularly in diagnosing SARA in lactating dairy cattle.

Ruminal Fluid pH

The pH of the ruminal fluid obtained by specially designed stomach tubes or by rumenocentesis through the left ventral abdominal region can be measured in the field using wide-range pH (2–12) indicator paper. The ruminal fluid must be examined immediately because the pH will increase on exposure to air. Cattle that have been fed a roughage diet will have a ruminal pH of 6 to 7; for those on a grain diet it will be 5.5 to 6. A ruminal pH of 5 to 6 in roughage-fed cattle suggests a moderate degree of abnormality, but a pH of less than 5 suggests severe grain overload and the need for aggressive treatment. Feedlot cattle that have been on grain for several days or weeks and are

affected with grain overload usually have a pH below 5.

Rumen fluid pH measurement has not been widely adopted because of producer concern regarding the safety of the rumenocentesis procedure and the time taken and facilities required to obtain a suitable rumen fluid sample using a stomach tube.[8] Whether rumen fluid obtained by a specially designed stomach tube provides an accurate reflection of rumen pH remains controversial. Challenges with sampling rumen fluid using a tube are to ensure that the tube opening is ventral to the rumen mat and in the fluid layer, and that the sample is not contaminated with saliva. Use of specialized designed tubes and rapid collection of a large rumen fluid volume increase the likelihood that the sample accurately reflects intraruminal pH.[9] There is no doubt that the agreement between rumen pH values collected by rumenocentesis and a standard stomach tube is poor in some studies, most likely because of excessive saliva contamination and sustained exposure of a large surface are of the sample to air. What remains in dispute is the level of agreement between pH values for rumen fluid collected by rumenocentesis or by specially designed stomach tubes.[9] The consensus is that rumenocentesis of the ventral ruminal sac provides the most accurate method for measuring ruminal pH.

Rumenocentesis has become a commonly used diagnostic test for SARA but few studies have been published documenting its safety, and anecdotal reports of decreased milk production for 24 to 48 hours following the procedure exist. One German report revealed complications in 6% of 164 sampled cows, with hematoma and abscess formation as the most common side effects. It needs to be recognized that rumenocentesis is a transient planned hardware except the wire transverses the rumen wall from outside-in, compared with the typical hardware case in which the wire transverses the reticular wall from inside-out and stays in that location for some time. Rumenocentesis does not appear to be any more painful or stressful than restraint or injection of local anesthetic agent in the same location[10]; consequently there does not appear to be a need to infiltrate the abdominal musculature and skin with local anesthetic at the proposed cite for rumenocentesis.

A hypodermic needle of 2.1 (outer diameter) × 80 mm (length) is inserted into the ventral rumen and rumen contents aspirated with a syringe. Landmarks for the puncture site are the left side, on a horizontal line level with the top of the patella about 15 to 20 cm posterior to the last rib. The hair of the site is clipped and prepared using a standard scrub. The cow is restrained in a stanchion or head-gate and one assistant elevates the tail of the cow while another assistant inserts a "nose leader" and pulls the cow's head to the right side. The needle will usually become obstructed by ingesta, which is cleared by forcing a small amount of air or fluid back through the needle. When the needle becomes obstructed, it is important to avoid creating a negative pressure within the syringe because carbon dioxide will leave the fluid and increase the pH. Typically, 3 to 5 mL of rumen fluid can be collected with minimal difficulty.

The pH is measured immediately using a pH meter with a digital readout. Samples should be collected when the pH is likely to be near the lowest point of the day. If the ration is fed as separate components, rumenocentesis should be performed 2 to 4 hours after the cows are fed the primary concentrate of the day. If the ration is fed as a total mixed ration, the samples should be collected 4 to 8 hours after the start of feeding. A pH of 5.5 is recommended as the cut-point between normal and abnormal, but this cut point has not been validated against any performance metric. At least 12 or more cows should be sampled from any group in which acidosis is suspected. If 30% of 10 or more sampled cows are below 5.5, the group is classified as in a state of ruminal acidosis. A subsample of 12 cows from a herd or diet group and a critical number of three cows with a ruminal pH ≤5.5 may effectively differentiate between herds with 15% or less or greater than 30% prevalence of cows with a low ruminal pH.

Ruminal Protozoa

Microscopic examination of a few drops of ruminal fluid on a glass slide (with a coverslip) at low power will reveal the absence of ruminal protozoa, particularly medium- and large-sized protozoa, which is a reliable indicator of an abnormal state of the rumen that is usually acidosis. The predominantly gram-negative bacterial flora of the rumen is replaced by a gram-positive one.

Serum Biochemistry

The degree of hemoconcentration, as indicated by hematocrit, increases with the amount of fluid withdrawn from the extracellular fluid space into the rumen and probably provides the best single indicator of clinical severity in ruminal acidosis.[11] The hematocrit rises from a value of approximately 34% to 50% to 60% in the terminal stages and is accompanied by a fall in blood pressure. The acute phase reactants serum amyloid A (SAA) and haptoglobin are markedly increased within 6 to 12 hours and 18 to 36 hours, respectively, of experimental induction of acute ruminal acidosis, whereas a much smaller increase in serum fibrinogen concentration was present after 24 hours.[12,13] The acute phase response is consistent with the presence of damaged ruminal epithelium and systemic effects of proinflammatory cytokines. Surprisingly, there is at the most only a mild increase in the white blood cell count,[12,13] and endotoxin (core lipopolysaccharide [LPS] from gram-negative bacteria) is rarely identified in the plasma of cattle with acute ruminal acidosis[11] or SARA.[3,4] This result is attributed to effective clearance by macrophages in the liver.

Increased permeability of the forestomach and possibly abomasum is present in cattle with acute ruminal acidosis, based on histologic examination of affected tissues and marked increases in plasma concentration of lactulose after its oral administration. This indicates disruption to the epithelial tight junctions and impaired epithelial barrier integrity of the forestomach.[12] Mild disruption to rumen epithelial integrity is present in cattle and sheep with SARA, and the disruption is pH dependent and more severe at a rumen pH of 5.2 than 5.5.[14,15]

Blood pH, bicarbonate, and base excess fall markedly whereas plasma L-lactate and inorganic phosphate concentrations rise. In almost all cases there is a mild hypocalcemia, which is presumably caused by a temporary decrease in feed intake and gastrointestinal motility. Serum concentrations may drop to between 6 and 8 mg/dL (1.5–2.0 mmol/L).

Fecal pH

It would appear logical that fecal pH should be directly and positively correlated with rumen pH. However, because of fermentation and buffering of ingesta in the large intestine, there is generally a poor correlation between fecal pH and ruminal pH, unless large amounts of starch escape the rumen undegraded and are fermented in the large intestine.

Urine pH

The urine pH falls to 4.5 to 5.0 in advanced cases of acute ruminal acidosis and becomes progressively more concentrated as the animal becomes more dehydrated; terminally there is anuria. An experimental study involving 40 steers with experimentally induced acute ruminal acidosis identified a good linear relationship between blood pH and urine pH ($r = 0.75$) in which blood pH = 0.062 × urine pH + 6.90. A similar linear relationship ($r = 0.80$) existed between Base excess in mEq/L and urine pH, in which Base excess = 4.44 × urine pH −32.7.[16]

Low Milk-Fat Percentage

Ruminal pH is positively correlated with milk-fat concentration for cows more than 30 days in milk, and a number of studies have indicated a **milk fat percentage to milk protein percentage of <1.15:1** is indicative of the presence of SARA in lactating dairy cattle. This index is readily available with monthly herd tests and is underutilized as a monitoring tool, mainly because it is only available on a monthly basis. The proposed mechanism is SARA, which is associated with increased intraruminal propionate production; once absorbed, propionate is energy sparing resulting in increased lipogenesis in

fat tissues and lowered milk fat content. This mechanism is particularly active in cattle past peak milk that are not in a state of negative energy balance. The increased production of transoctadecenoic acids in the rumen of cattle with lower rumen pH may also play a role in SARA-induced milk-fat depression.

An argument can be made that rumen pH measurements obtained by rumenocentesis provide no more additional information to that provided by the milk fat to protein ratio on the same day. A good rule of thumb is that additional investigation is indicated if more than 10% of cows have a lower milk-fat percentage than milk-protein percentage.

NECROPSY FINDINGS

In acute cases in which the animal dies in 24 to 48 hours, the contents of the rumen and reticulum are thin and porridge-like and have a typical odor suggestive of fermentation. The cornified epithelium may be mushy and easily wiped off, leaving a dark, hemorrhagic surface beneath. This change may be patchy, caused probably by the production of excess lactic acid in pockets in which the grain collects, but is generally restricted to the ventral half of the sacs. Abomasitis and enteritis are also evident in many cases. The abomasum may contain large quantities of grain. There is a pronounced thickening and darkening of the blood, and the visceral veins stand out prominently.

In cases that have persisted for 3 to 4 days the wall of the reticulum and rumen may be gangrenous. This change is again patchy but may be widespread. In affected areas the wall may be three or four times the normal thickness, show a soft black mucosal surface raised above surrounding normal areas, and have a dark red appearance visible through the serous surface. The thickened area is very friable and on cutting has a gelatinous appearance. Histologic preparations show infiltration of the area by fungal mycelia and a severe hemorrhagic necrosis. A fungal hepatitis is common in those with fungal rumenitis. In the nervous system, in cases of 72 hours' or more duration, demyelination has been reported. A terminal ischemic nephrosis is present in varying degrees in most fatal cases of more than several days' duration.

If the examination takes place less than an hour after death, estimation of ruminal pH may be of value in confirming the diagnosis, but after 1 hour the pH of the rumen contents begins to increase and its measurement may not be reliable. A secondary enteritis is common in animals that have been ill for several days.

DIFFERENTIAL DIAGNOSIS

When outbreaks of the disease with an appropriate history are encountered, the diagnosis is usually readily obvious and confirmed by the clinical findings and examination of the ruminal fluid for pH and rumen protozoa.

When the disease occurs in a single animal without a history of engorgement, the diagnosis may not be readily obvious. The anorexia, depression, ruminal stasis with gurgling fluid sounds from the rumen, diarrhea, and a staggery gait with a normal temperature are characteristics of rumen overload.

Acute and subacute carbohydrate engorgement must be differentiated from the following:

- **Simple indigestion**. The consumption of large quantities of palatable feed, such as ensiled green feed offered to cattle for the first time, may cause simple indigestion, which may resemble grain overload. The rumen is full, the movements are reduced in frequency and amplitude, and there may be mild abdominal pain from the distension, but the ruminal pH and protozoan numbers and activity are normal.
- **Parturient paresis**. Severe cases that are recumbent may resemble parturient paresis, but in the latter the feces are usually firm and dry, marked dehydration does not occur, the absolute intensity of the heart sounds is reduced, and the response to calcium injection is favorable.
- **Toxemias**. Common toxemias of cattle that may resemble ruminal overload include peracute coliform mastitis and acute diffuse peritonitis, but clinical examination will usually reveal the cause of the toxemia.
- **Subacute ruminal acidosis** must be differentiated from diseases of dairy cows in early lactation in which there is reduced appetite and milk production. These include simple indigestion, left-side displacement of the abomasum, and ketosis, as well as other causes of suboptimal milk production in dairy cows in early lactation. Feeding management problems such as poor-quality forage or poor feeding bunk management are common causes of suboptimal performance in lactating dairy cows that are not affected with SARA.

TREATMENT

The following are principles of treatment:

- Correct the ruminal and systemic acidosis and prevent further production of lactic acid.
- Restore fluid and electrolyte losses and maintain circulating blood volumes.
- Restore forestomach and intestinal motility to normal.

There are at least two common clinical situations encountered. One is when cattle have been found accidentally eating large quantities of grain, are not yet ill, and all appear similar clinically except for varying degrees of distension depending on the amount each animal has consumed. In the other situation, the engorgement occurred 24 to 48 hours previously and the animals have clinical evidence of lactic acidosis.

When cattle are found engorging themselves, the following procedures are recommended:

- Prevent further access to feed.
- Monitor water intake and prevent the rapid intake of excessive quantities of water.
- Offer a supply of good-quality palatable hay equal to one-half of the daily allowance per head.
- Exercise all animals every hour for 12 to 24 hours to encourage movement of the ingesta through the digestive tract.

Those cattle that have consumed a toxic amount of grain will show signs of anorexia, inactivity, and depression in approximately 6 to 8 hours and should be identified and removed from the group for individual treatment. Those cattle that did not consume a toxic amount are usually bright and alert and will usually begin eating hay if it is offered. Not all cattle found engorging themselves with grain will have consumed a toxic dose, and careful monitoring over a 24- to 48-hour period will usually distinguish between those that need treatment and those that do not.

After 18 to 24 hours, those cattle that have continued to eat hay may be allowed free access to water. Those with clinical evidence of grain overload must be identified and treated accordingly. They will engorge themselves with water if allowed free access to it. The rumen becomes grossly distended with fluid and affected cattle may die 18 to 24 hours later from electrolyte disturbances and acid-base imbalance.

In certain situations, if feasible and warranted by economics, such as when finished beef cattle have accidentally engorged on grain, **emergency slaughter** may be the most economical course of action.

Triage

The recommendations for treatment given in Table 8-8 are guidelines. In an outbreak, some animals will not require any treatment, whereas severely affected cases will obviously need a rumenotomy. For those that are not severely affected, it is often difficult to decide whether to treat them only medically with alkalinizing agents orally and systemically or to do a rumenotomy. Each case must be examined clinically and the most appropriate treatment selected. The degree of mental depression, muscular strength, degree of dehydration, heart rate, body temperature, and rumen pH are clinical parameters that can be used to assess severity and to determine the treatment likely to be most successful.

Rumenotomy

In severe cases, in which there is recumbency, severe depression, hypothermia, prominent ruminal distension with fluid, a heart rate of 110 to 130 beats/min and a rumen pH of 5 or below, a rumenotomy

Fig. 8-7 Rumenotomy of a beef bull with grain overload. Forty kilograms of barley was removed and 10 L of fresh rumen fluid and some chopped grass hay was placed back into the rumen.

is the best course of action (Fig. 8-7). Descriptions of the surgical procedures are available.[17,18]

The rumen is emptied, washed out with a siphon and examined for evidence of and the extent of chemical rumenitis, and rumen transfaunation (10–20 L of rumen juice) placed in the rumen along with a few handfuls of hay for "scratch factor." The rumenotomy will usually correct the ruminal acidosis and prevent subsequent production of L-lactate and D-lactate and an alkalinizing agent in the rumen is not necessary. A large quantity of the lactic acid and its substrate can be removed. The oral or intraruminal administration of compounds such as magnesium oxide or magnesium hydroxide to cattle following complete evacuation of the rumen may cause metabolic alkalosis for up to 24 to 36 hours (see section on simple indigestion in this chapter). Not all of the feed consumed will be removed because considerable quantities may have moved into the omasum and abomasum in which fermentation may also occur. The major disadvantages of a rumenotomy are time, cost, and access to appropriate facilities, particularly when many animals are involved.

Intravenous Sodium Bicarbonate and Fluid Therapy

The systemic acidosis and the dehydration are treated with intravenous solutions of 5% sodium bicarbonate at the rate of 5 L for a 450-kg animal given initially over a period of about 30 minutes. This will usually correct the systemic acidosis. This is followed by isotonic sodium bicarbonate (1.3%) at 150 mL/kg BW intravenously over the next 6 to 12 hours. Cattle that respond favorably to the rumenotomy and fluid therapy will show improved muscular strength, begin to urinate within 1 hour, and attempt to stand within 6 to 12 hours.

Rumen Lavage

In less severe cases, in which affected cattle are still standing but are depressed, their heart rate is 90 to 100 beats/min, there is moderate ruminal distension, and the rumen pH is between 5 and 6, an alternative to a rumenotomy is rumen lavage if the necessary facilities are available. A large 25- to 28-mm inside-diameter rubber tube is passed into the rumen and warm water is pumped in until there is an obvious distension of the left paralumbar fossa; the rumen is then allowed to empty by gravity flow after creating a siphon. The rumen can be almost completely emptied by 10 to 15 irrigations, but there is the risk of aspiration pneumonia and cattle may become recumbent during the procedure. Challenges with completing this on many animals is access to warm water, a knowledgeable assistant, and physical fatigue. With successful gastric lavage, alkalinizing agents are not placed in the rumen, but the systemic acidosis is treated as described earlier.

Intraruminal Alkalinizing Agents

In moderately affected cases, the use of 500 g of magnesium hydroxide per 450 kg BW or magnesium oxide in 10 L of warm water pumped into the rumen, followed by kneading of the rumen to promote mixing, will usually suffice.

Magnesium hydroxide is a potent alkalinizing agent for use in ruminants as an antacid and mild laxative. It can significantly decrease rumen microbial activity and should be used only in cattle with confirmed ruminal acidosis and not for symptomatic therapy of idiopathic rumen disorders or hypomagnesemia. The oral administration of boluses of magnesium hydroxide (162 g) or a powdered form (450 g) dissolved in 3.5 L of water daily for 3 days resulted in a significant increase in rumen pH after 48 and 24 hours, respectively. Both the boluses and the powder forms of magnesium hydroxide decreased rumen protozoal numbers and increased methylene blue reduction times compared with baseline values. There was no change in

blood pH, bicarbonate, or base excess values. Serum magnesium values were significantly increased in cows receiving the powder.

Ruminal Transfaunation

It is widely thought that animals with acute ruminal acidosis benefit from rumen transfaunation, but randomized clinical trials are lacking. General recommendations are to transfer at least 5 L of fresh rumen fluid from a healthy animal[19] to adult cattle with acute ruminal acidosis, but only after rumen lavage or rumenotomy has been performed, excessive amounts of grain have been removed, and ruminal pH is within the normal range of 6.0 to 7.0.

Large volumes of rumen fluid can be obtained by use of specially constructed rumen fluid collection tubes (such as the Dirksen or Geishauser tubes).[20] Alternatively, large dairies may maintain one animal with a large-diameter rumen cannula that is readily available to provide up to 20 L of rumen fluid at a time. In some regions, producers join together to maintain a rumen-fistulated cow for joint use. Descriptions for the surgical procedure for rumen cannula placement in cattle and sheep are available.[21,22]

Ancillary Therapy

Ancillary treatment has included antihistamines for laminitis, NSAIDs for their antiinflammatory and analgesic effects, thiamin or brewer's yeast to promote the metabolism of lactic acid, and parasympathomimetics to stimulate gut motility. Their efficacy has been difficult to evaluate, and it is unlikely that any of them would be of much value. Calcium borogluconate is used widely because there is a mild hypocalcemia and a beneficial but temporary response does occur, but it is of doubtful value.

Orally administered antimicrobials, including penicillin and the tetracyclines, have been used to control growth of the bacteria that produce lactic acid, but they appear to be of limited value.

Monitor Response to Therapy

Regardless of the treatment used, all cases must be monitored several times daily until recovery is obvious for evidence of unexpected deterioration. Following treatment, cattle should begin eating hay by the third day, some ruminal movements should be present, large quantities of soft feces should be passed, and they should maintain hydration. In those that become worse, the heart rate increases, depression is marked, the rumen fills with fluid, and weakness and recumbency occur. During treatment, the water supply should be restricted because some cattle, either immediately after they have engorged themselves or once they become ill, appear to have an intense thirst and will drink excessive quantities of water and die precipitously within a few hours.

The fungal rumenitis that may occur about 3 to 5 days after engorgement is best prevented by early effective treatment of the ruminal acidosis. There are no randomized clinical trials supporting the administration of antifungal agents to affected animals.

CONTROL AND PREVENTION

Cattle can be started, grown, and finished on high-level grain rations successfully, provided that they are allowed a **gradual period of adaptation** during the critical period of introduction. The important principle of prevention is that the ruminant can adapt to an all-concentrate ration. For animals that have just arrived in the feedlot, the length of the adaptation period required will depend on the immediate nutritional history of the animals, their appetite, and the composition of the ration to be used. Dietary management should emphasize ensuring adequate fiber, a sufficiently long daily chewing time, and a "grazing" eating behavior rather than "slug" feeding.

Total Mixed Rations

One of the safest procedures is to feed a milled mixed ration, consisting of 50% to 60% roughage and 40% to 50% grain, as the starting ration for 7 to 10 days and monitor the response. If results are satisfactory, the level of roughage is decreased by 10% every 2 to 4 days down to a level of 10% to 15% roughage, with the remainder grain and vitamins-mineral-salt supplement. The use of roughage–grain mixtures ensures that cattle do not engorge themselves on grain, and adaptation can occur in about 21 days.

Small Incremental Increases in Concentrate

Another method is to begin with small amounts of concentrate 8 to 10 g/kg BW, which is increased every 2 to 4 days by increments of 10% to 12%. A source of roughage is supplied separately. The disadvantages of this system are that hungry or dominant cattle may eat much more than their calculated share and there is no assurance that sufficient roughage will be consumed. In this system, on a practical basis, the cattle are usually fed twice daily and brought up to a daily intake of concentrate that satisfies their appetite and then the concentrate ration is offered free choice from self-feeders. Unless there is sufficient feeding space in the self-feeders, competitive and dominant animals will often overeat, so careful monitoring is necessary.

Feedlot Starter Rations

Feedlot starter rations consisting of a mixture of roughage and grain, offered free choice along with hay and gradually replaced by a finishing ration have successfully adapted cattle in 10 days. The starter ration contains about 2500 kcal (10,460 kJ) digestible energy (DE) per kilogram of feed. The finishing ration contains about 3100 kcal (12,970 kJ), and controlling the rate of increase of DE concentration of the ration was a major factor in getting cattle on feed.

A comparison of the effect of rapid or gradual grain adaptation on subacute acidosis and feed intake by feedlot cattle indicates a range of individual responses to grain challenge and current management strategies for preventing acidosis in pens of cattle are based on responses of the most susceptible individuals. Using this approach requires consideration of individual animal responses. The data suggest that most cattle can be rapidly adapted to high-grain diets in few incremental steps; minimizing acidosis in the most susceptible individuals requires decreasing the pace of grain adaptation for the entire group.

Dietary Buffers

The incorporation of buffers, such as sodium bicarbonate, into the ration of feedlot cattle has been studied extensively, but the results are inconclusive and reliable recommendations cannot be made. A level of 2% dietary sodium bicarbonate, sodium bentonite, or limestone provided some protection from acidosis during the early adaptation phase of high-concentrate feeding; but they were no more effective than 10% alfalfa hay. Buffers have been most effective in reducing acidosis early in the feeding period and have little or no effect later. Buffers may also be associated with an increased incidence of urinary calculi, bloat, and vitamin deficiencies. The experimental results are conflicting. Some trials indicate that buffers maintain a gram-negative rumen flora in sheep fed grain compared with a shift to gram-positive rumen flora in animals not fed buffers. Live weight performance is also improved in some trials but not in others fed 0.75, 1.0, or 2.25% of diet as sodium bicarbonate.

The potential efficiency of products for the control of ruminal acidosis has been examined through the measurement of the increase in buffer capacity and acid-consuming capacity. Sodium bicarbonate provided the highest increment in buffering capacity and acid-consuming capacity compared with calcium carbonate. Magnesium oxide provided higher acid-consuming capacity but had no effect on buffer capacity.

Dietary supplementation of sodium bicarbonate at a level of 1.5% for 90 days in high-concentrate diets fed to lambs improved cellulose digestibility, ciliate protozoal number, ruminal pH, and total nitrogen concentration, resulting in improved growth of lambs maintained on a high-concentrate diet.

Ionophores

The ionophores salinomycin, monensin, and lasalocid have been compared for their protective effects, and salinomycin is more effective than the other two; monensin also shows

some promise. Laidlomycin propionate does not prevent ruminal acidosis but may reduce the severity of ruminal acidosis during adaptation to a 100% concentrated diet. Monensin decreases meal size and therefore increases the frequency of eating, both of which minimize the daily range in rumen pH and should therefore be beneficial in addressing SARA.

Subacute Ruminal Acidosis in Dairy Cattle

The basic principles of preventing SARA in dairy herds include the following:

- Limiting the intake of rapidly fermentable carbohydrates
- Providing adequate ruminal buffering
- Allowing for ruminal adaptation to high-grain diets

Prevention of SARA includes **proper adaptation of rumen papillae during the prepartum period, adequate intake of forage in early lactation, and adequate fiber nutrition throughout lactation**. Successful management of energy balance through the **periparturient transition period** depends on providing adequate energy density in the prepartum diet. Increasing energy density of the prepartum diet also promotes dry matter intake before and after calving. The energy density in the prepartum diet should be 1.54 to 1.63 Mcal/kg NE_l.

Dry cows should be fed according to their needs; cows in the early and middle portion of the dry period (far-off cows) and cows in the final 3 weeks before calving (prefresh cows) have different nutritional requirements to achieve optimal milk production and maintain the health and fertility of early-lactation cows.

Prepartum diets should be offered, starting at least 3 weeks before calving. Because of the different calving dates of dry cows fed in groups, the use of a prepartum diet over a prepartum feeding period of 21 days will usually allow each cow to consume the diet for a minimum of 5 days. The nutrient requirements for the prefresh dry cow are controversial. The National Research Council does not provide recommendations for prefresh cows, and it is recommended that a dairy cattle nutritionist be consulted for formulation of such rations. Generally, a prefresh diet will provide about 0.50 to 0.75% BW per day as concentrates. Prefresh diets should be similar to early lactation diets so that the transition occurs effectively. The forages fed in the prefresh diet should be similar to those fed in early lactation.

Dairy cows are usually fed total mixed rations in which the concentrates and forages are mixed and fed as a total ration or separate component rations in which the concentrates and forage are fed independently. In herds using separate component diets, the concentrates in the prefresh diet should be gradually introduced over a period of 3 to 5 days and preferably fed individually. Forages should also be fed individually so that intake can be evaluated. Delivering new feed twice daily facilitates dairy cattle to take more frequent but smaller meals, and moving on the continuum from slug feeding to grazing, which should minimize large changes in ruminal pH.

Limiting the Intake of Rapidly Fermentable Carbohydrates

As a guideline, cows should not receive more than 8 to 12 lb (3–5 kg) of dry matter from grain in the first week after calving. Grain feeding should then increase by about 0.25 to 0.50 lb (110–220 g) per cow per day until peak grain feeding is reached at 6 to 8 weeks postcalving.

The physical form of the feed ingredients is as important as their chemical composition in determining how rapidly and completely they are fermented in the rumen. Grains that are finely ground, steam-flaked, extruded, and/or very wet will ferment more rapidly and completely in the rumen than unprocessed or dry grains. Starch from wheat or barley is more rapidly and completely fermented than starch from corn (maize). Corn silage that is very wet, finely chopped, or kernel processed is also a greater risk for SARA than drier, coarsely chopped, or unprocessed corn silage. Particle size analysis of grains is a useful adjunct test when assessing the risk for SARA in a dairy herd. Grain particle size length can be determined using metal sieves.

Providing Adequate Ruminal Buffering

Ruminal buffering includes dietary and endogenous buffering. **Dietary buffering** is the inherent buffering capacity of the diet and is dependent on the dietary cation–anion difference (DCAD). Diets high in sodium and potassium relative to chloride and sulfur have higher DCAD concentrations, tend to support higher ruminal pH, and increase dry matter intake and milk yield. Optimal DCAD ((Na + K) − (Cl + S)) for early lactation diets is approximately +400 mEq/kg dry matter (40 mEq/100 g of dry matter). Midlactation cows have an optimal DCAD of +275 to +400 mEq/kg (28–40 mEq/100 g of dry matter). Formulating diets with a high DCAD requires the addition of buffers such as sodium bicarbonate. Alfalfa forages have a higher DCAD than corn (maize) silage, depending on the mineral composition of the soil. Concentrate feeds typically have a low or negative DCAD, which adds to their already high potential to cause ruminal acidosis because of their high fermentable carbohydrate content.

Endogenous buffers are produced by the cow and secreted into the rumen via saliva. The amount of physical fiber in the diet determines the extent of buffer production by the salivary glands. Coarse, fibrous feeds contain more effective fiber and stimulate more saliva production during eating than do finely ground feeds or fresh pasture. Coarse, fibrous feeds also make up the mat layer of the rumen, which is the stimulus for rumination. Fiber particles must be at least 4 cm in length to contribute to mat layer formation. Rumination promotes a great deal of chewing activity and the secretion of large amounts of saliva into the rumen. Ruminal pH increases during bouts of rumination.

The ability of a diet and feeding program to promote maximal amounts of ruminal buffering must be evaluated in herds with SARA. Wet chemistry analysis of a carefully collected total mixed ration bunk sample can be used to determine the DCAD of the diet actually consumed by the cows. Diets with measured DCAD ((Na + K) − (Cl + S)) values below +275 to 400 mEq/kg of dry matter (28–40 mEq/100 g dry matter) should be supplemented with additional buffers to provide more Na or K relative to Cl and S.

Endogenous buffering can be estimated by observing the number of cows ruminating (a goal is at least 40% of cows ruminating at any given time) and by measuring the particle length of the total mixed ration actually consumed by the cows using the Pennsylvania State Forage Particle Separator. Diets with less than 7% long particles render cows at increased risk of SARA, especially if the diets are also borderline or low in chemical fiber content. Diets with excessive (over 15%) long forage particles can paradoxically increase the risk of SARA if the long particles are unpalatable and sortable. Sorting of the long particles occurs soon after delivery of the feed, resulting in the cows consuming a diet low in physically effective fiber after feeding. The diet consumed later in the feeding period is then excessively high in physically effective fiber and low in energy. Socially dominant cows are particularly susceptible to SARA in this situation because they are likely to consume more of the fine total mixed ration particles soon after delivery of the feed. Cows lower on the social order then consume a very low-energy diet. Limiting feed bunk space to less than 75 cm per cow exacerbates the effect of total mixed ration sorting in a group of cows.

Allowing for Ruminal Adaptation to High-Grain Diets

Cows in early lactation are susceptible to SARA if they are poorly adapted for the lactation diet. Ruminal adaptation to diets high in fermentable carbohydrates depends on microbial adaptation (particularly the lactate-utilizing bacteria, which grow more slowly than the lactate-producing bacteria) and the length of the ruminal papillae (longer rumen papillae promote greater volatile fatty acid absorption and thus lower ruminal pH).

In herds with total mixed rations, the prefresh diets can be offered to prefresh cows as they approach calving, usually with success.

With total mixed rations, cows cannot eat excessive quantities of concentrate at the expense of forage. Cows that have become adapted on a well-formulated precalving total mixed ration during the prepartum period can go directly on to the high-producing lactating total mixed ration after calving without any further adaptation.

In summary, one of the most challenging aspects of diet formulation for lactating dairy cows is balancing for carbohydrates. Adequate effective fiber must be provided to stimulate chewing and secretion of salivary buffers. However, effective fiber is more filling than other nutritional components of the diet, and the filling effect often limits the energy intake of high-producing cows. Therefore diets for high-producing cows should be balanced to provide adequate effective fiber with the least filling effect. A balance must also be attained for ruminal carbohydrate fermentation, which is desirable to provide nutrients for microbial growth and protein. However, the fermentability of the diet must be limited to prevent excessive production of acids of fermentation.

Feeding Management in Early Lactation

This consists of ensuring that concentrates are introduced gradually, and preferably at the same rate as dry matter intake increases in the first 6 weeks of lactation. Formulation strategies for feeding concentrates in the first 6 weeks of lactation without compromising fiber nutrition have been developed. Weekly dry matter predictions were used, and the proper increase in concentrate feeding is only 0.9 to 1.6 kg/week. At the same time, it is necessary to ensure that cows receive adequate dietary energy to prevent primary acetonemia.

Routine monitoring of the dry matter content of feed ingredients is an important strategy in preparing total mixed rations for dairy cattle. Electronic silage testers are available and recommended.

Ionophores, such as monensin sodium, alter rumen metabolism and have the potential to control ruminal acidosis in dairy cattle, increase milk production, modify milk composition, and improve health. Monensin alters the volatile fatty acid profile in the rumen toward increased propionate production, which induces glucogenesis. Milk production is increased but the percentage of milk fat is depressed, which is effective in reducing the incidence of ketosis. Monensin decreases the population of *S. bovis* in the rumen, resulting in a reduction in the production of lactic acid; it increases the clearance of lactate from the rumen and increases ruminal pH. This has the potential to reduce the incidence of SARA in dairy cattle and the sequelae of rumenitis, laminitis, and hepatic abscessation. Monensin also decreases ruminal methanogenesis, ruminal ammonia, and blood levels of ketone bodies. Thus monensin has the potential to improve the health of dairy cows and prevent ruminal acidosis during the transition period of the periparturient cow as described previously. Ionophores have not yet been approved for use in lactating dairy cows in North America, but extensive studies are under way.

Vaccination Against Lactic Acidosis

Some preliminary research has investigated the immunization of cattle against lactic-acid–producing bacteria, *S. bovis,* and *Lactobacillus.* Immunization induced high levels of persistent saliva antibody responses against *S. bovis* and *Lactobacillus,* which reduced the risk of lactic acidosis in cattle.

TREATMENT AND CONTROL

Treatment

Triage to determine which animals need medical treatment, rumen lavage, or rumenotomy (R-1)

Provide palatable grass hay and access to water (R-1)

Transfaunate selected cases with at least 5 L of fresh rumen fluid (R-1)

Correct ruminal and systemic acidosis with alkalinizing agents orally (magnesium hydroxide) or parenterally (1.3% sodium bicarbonate, Ringers solution) depending on severity (R-1)

Administer parenteral procaine penicillin G or oxytetracycline to severely affected cases to treat presumed rumenitis and as a preventative against liver abscess development (R-2)

Administered vitamin B_1 to assist in metabolizing L-lactate (R-2)

Control

Prevent accidental access to grain (R-1)

Introduce dietary changes gradually over 7–14 days (R-1)

Feed two times a day if confinement housed (R-2)

Use of ionophores in feed to alter rumen metabolism (R-2)

RUMINAL PARAKERATOSIS

Parakeratosis of the ruminal epithelium is associated with subacute lactic acidosis and ruminal tympany in calves, and its presence indicates a lack of fiber and rumen buffering. Opinions vary as to whether parakeratosis has a direct effect on weight gain and productivity. There is evidence that the development of parakeratosis increases and then reduces the absorption of volatile fatty acids from the rumen and that the addition of volatile fatty acids to a calf starter ration increases the incidence of the condition. The abnormality is most common in cattle and sheep fed high-concentrate rations of alfalfa pellets that have been subjected to heat treatment, and it does not occur in cattle fed on rations containing normal quantities of unpelleted roughage. The incidence of the disease does not appear to be related to the feeding of antibiotics or protein concentrates.

In affected rumens the rumen papillae are enlarged, leathery, dark in color, and often adhered to forming clumps (Fig. 8-8). Histologically there is an increase in thickness of the cornified portion of the ruminal epithelium and a persistence of nuclei in the cornified cells. Some of the affected cells contain vacuoles. The greatest severity of lesions is present on the dorsal surface of the rumen about the level of the fluid ruminal contents, and parakeratosis in the region of the cardia is thought to increase the likelihood of ruminal tympany because receptors in this

Fig. 8-8 Ruminal parakeratosis in the dorsal rumen of a 3-month-old Holstein Friesian calf with recurrent free gas bloat and poor weight gain. Note the clumping of rumen papilla and excessive cornification of papilla.

region can no longer detect the presence of free gas. This supposition needs to be verified. It is thought that parakeratosis is caused by the lowered pH and the increased volatile fatty acid content in the rumen liquor. The fact that unprocessed, whole grain—on which animals gain weight as readily as on processed grain—does not lead to the development of the disease is probably related to the higher pH and higher concentration of acetic versus longer chain volatile fatty acids in the ruminal liquor. The incidence of affected animals in a group may be as high as 40%.

RUMINAL TYMPANY (BLOAT)

Ruminal tympany is abnormal distension of the rumen and reticulum caused by excessive retention of the gases of fermentation, either in the form of a persistent foam mixed with the rumen contents or as free gas separated from the ingesta. Normally, gas bubbles produced in the rumen coalesce, separate from the rumen contents to form pockets of free gas above the level of the contents, and finally are eliminated by eructation.

SYNOPSIS

Etiology Ingestion of bloating forages or interference with eructation mechanism.

Epidemiology Primary ruminal tympany (frothy bloat) is a major problem in cattle pastured on bloating forages (legumes) and in feedlot cattle fed high-level grain rations with minimal roughage. Occurs within a few days after turning into bloating pasture. High morbidity and mortality possible and cost of control makes pasture bloat an economically important disease. Bloating forages most dangerous in prebloom stage and when covered with dew in the morning. Feedlot bloat common when feed contains 80% grain and is ground fine. Secondary ruminal tympany (free-gas bloat) occurs in single animals caused by interference with eructation because of physical obstruction of esophagus or eructation mechanism, as in reticular adhesions.

Clinical signs Cattle may be found dead on pasture. Mild to marked distension of left abdomen, which is tympanic; when severe it distends right abdomen also. Severe distress, dyspnea, protrusion of tongue. Passage of stomach tube in frothy bloat reveals froth and failure to release a significant amount of gas; in secondary free-gas bloat, large quantities of gas released with ease. If severe, animal may die within a few hours if tympany not relieved.

Lesions Marked congestion and hemorrhages of tissues of cranial aspect of body (tongue, nasal sinuses, lymph nodes, and proximal part of esophagus—bloat line) compared with caudal because of ruminal tympany. Distended rumen, frothy contents if examined early; later the froth dissipates.

Diagnostic confirmation Excessive quantity of froth or free gas in rumen.

Differential diagnosis Primary bloat is easily recognizable, and there are no other diseases of the reticulorumen that result in ruminal tympany. Secondary bloat must be differentiated from causes of failure of eructation, including esophageal obstruction, chronic reticuloperitonitis, vagus indigestion, and tetanus.

Treatment Remove animals from bloating pasture. In severe cases, emergency rumenotomy. In less severe cases, passage of stomach tube or trocar and cannula to release rumen gas. Antifoaming agents into rumen

Control *Pasture bloat* Management strategies to reduce rate of rumen fermentation. Use of grass–legume mixtures. Delay grazing each day until dew is off; feed hay before grazing. Feed forage supplements before grazing. Strategic use of antifoaming agents to pastured cattle. Sustained-release antifoaming agents such as monensin. *Feedlot bloat* Use total mixed rations containing chopped roughage and grain

ETIOLOGY

Primary Ruminal Tympany (Frothy Bloat)

Primary ruminal tympany or frothy bloat is caused by the production of a stable foam that traps the normal gases of fermentation in the rumen. The essential feature is that coalescence of the small gas bubbles is inhibited and intraruminal pressure increases because eructation cannot occur.

Pasture and Feedlot Bloat

Leguminous or pasture bloat is caused by the foaming qualities of the soluble leaf proteins in bloating legumes and other bloating forages ingested by cattle on pasture. Alfalfa hay may also cause bloat.

Feedlot bloat is caused by feeding finely ground grain, which promotes frothiness of rumen contents. The cause of this is not clear. Feeding large quantities of grain to cattle results in marked changes in the total numbers and proportions of certain ruminal protozoa and bacteria. Some species of encapsulated bacteria increase in numbers and produce a slime that may result in a stable foam. Feedlot bloat may also be of the free-gas type based on the observations that gas may be easily released with a stomach tube. Feedlot cattle are susceptible to esophagitis, ruminal acidosis, rumenitis, overfill, and ruminal atony, each of which can interfere with eructation and cause secondary ruminal tympany and free-gas bloat.

Frothy Rumen Contents

Frothiness of the ruminal contents is the vital factor in **pasture bloat**. The froth in the rumen contents is not a true foam but rather a dispersion of gas and particles in liquid. The liquid lamellae between the bubbles are wide, and fragments of chloroplast membranes are dispersed in the fluid. The stable dispersion of small feed particles is primarily responsible for the frothiness of the rumen fluid. The concentration of chloroplast membrane particles (measured as chlorophyll) is higher in frothy rumen fluid than in nonfrothy liquid.

The soluble leaf cytoplasmic proteins were once considered to be the principal foaming agents, but their role is now questioned. It is now accepted that bloat-causing legumes are more rapidly digested by rumen microflora than nonbloat-causing forages and that rupture of leaf mesophyll cells leads to the release of chloroplast particles. These particles are readily colonized by rumen microflora and gas bubbles are trapped among the particles, which prevent coalescence of bubbles by preventing drainage of rumen fluid from the liquid lamellae between the bubbles. The higher foam production in bloat-prone cattle is attributed to slower rates of passage of the liquid phase of ruminal contents. The slower clearance enhances microbial activity and promotes gas production, which contributes to stable foam formation. Rapid clearance decreases microbial gas production, enhances protein bypass, and reduces the probability of bloat. **Generally, bloat-causing legumes are susceptible to rapid digestion by rumen microflora, whereas bloat-safe legumes are digested more slowly.**

The condition of the rumen before feeding is an important factor in the immediate susceptibility of an animal to pasture bloat. **A predisposed rumen is characterized by an excess of dispersed particulate matter with adherent microbes, which provides an active inoculum for the fermentation of incoming feedstuffs.** The soluble leaf protein may contribute to the frothiness but is not the primary foaming agent. The chloroplast particles in the rumen have a slower

rate of clearance from the rumen in bloating animals than in nonbloating ones. It is also known that bloating animals have larger rumen volumes than nonbloating animals. Because chloroplast particles are negatively charged, it is possible that the concentrations of ions such as sodium, potassium, calcium, and magnesium in the rumen fluid before feeding are associated with the onset of bloat.

The **froth in feedlot bloat** is associated with high-level grain diets. The viscosity of the ruminal fluid is markedly increased because of the production of insoluble slime by certain species of bacteria that proliferate to large numbers in cattle on a high-carbohydrate diet. The slime may entrap the gases of fermentation. The delay in occurrence of feedlot bloat suggests that a gradual change in the microbial population of the rumen may be an important factor in explaining the cause. The physical form of a grain ration appears to be related to grain bloat. As in frothy legume bloat, in which a rapid release of leaf nutrients is important in producing bloat, it seems likely that the small particle size of ground feed could have the same effect.

Fine particulate matter can markedly increase foam stability. The feeding of ground grain of fine particle size (geometric mean particle size 388 µm) was associated with more rumen froth than the use of a coarse particle size (715 µm). The pH of the rumen contents also plays an important part in the stability of the foam (maximum stability occurs at a pH of about 6), and the composition of the diet and the activity and composition of the rumen microflora are known to influence this factor.

Role of Saliva

The rate of flow and composition of the saliva has an effect on the tendency for bloat to occur. Saliva may have a buffering effect on the pH of the rumen contents or it may influence the contents because of variation in its content of mucoproteins. The physical effects of dilution of ruminal ingesta by saliva may also be important. There is a negative correlation between the moisture content of the feed and the incidence of bloat. Feed of a low fiber and high water content depresses the volume of saliva secreted. Also, bloat-susceptible cows secrete significantly less saliva than nonsusceptible cows, and there are differences in the composition of saliva that are genetically determined.

In summary, **primary frothy pasture bloat occurs when there is rapid digestion of leaf material by rumen microorganisms, leading to the release of chloroplast particles into the liquid phase of the rumen contents, which prevents the coalescence of the gas bubbles.** In addition, there is a slower rate of clearance of these particles from the rumen in bloating cows, which also have larger rumen volumes. In primary frothy feedlot bloat, the fine particle size of the feed and the presence of rumen microorganisms that produce slime may be important factors.

Secondary Ruminal Tympany (Free-Gas Bloat)

Physical obstruction to eructation occurs in esophageal obstruction caused by a foreign body, by stenosis of the esophagus, by pressure from enlargements outside the esophagus, such as tuberculous lymphadenitis or bovine viral leukosis involvement of bronchial lymph nodes, or by obstruction of the cardia. Interference with esophageal groove function in vagus indigestion and diaphragmatic hernia may cause chronic ruminal tympany and the condition also occurs in tetanus, particularly in young animals and in poisoning with the fungus *Rhizoctonia leguminicola,* probably as a result of spasm of the esophageal musculature. Carcinoma, granulomatous lesions associated with *Actinomyces bovis* near the esophageal groove and in the reticular wall, and papillomata of the esophageal groove and reticulum are less common causes of obstructive bloat. **Tetanus** in cattle is usually accompanied by secondary free-gas bloat caused by spasm of the esophagus and inability to eructate normally.

Interference with the nerve pathways responsible for maintenance of the eructation reflex may also occur. The receptor organs in this reflex are situated in the dorsal aspect of the reticulum and can discriminate between gas, foam, and liquid. The afferent and efferent nerve fibers are contained in the vagus nerve, but the location of the central coordinating mechanism has not been defined. Depression of this center or lesions of the vagus nerve can interrupt the reflex, which is essential for removal of gas from the rumen.

Normal tone and motility of the musculature of the rumen and reticulum are also necessary for eructation. In anaphylaxis, bloat is common because of ruminal atony and is relieved by the administration of epinephrine or antihistamine drugs. A sudden marked change in the pH of the rumen contents caused by either acidity or alkalinity causes ruminal atony but the tympany that results is usually of a minor degree only, probably because the gas-producing activity of the microflora is greatly reduced. Hypocalcemia in milk fever of cattle is commonly associated with secondary free-gas bloat caused by ruminal atony, which is reversible following treatment with calcium salts.

Although most cases of feedlot bloat associated with outbreaks are of the frothy type (primary) and cannot be easily relieved with a stomach tube, sporadic cases are of the free-gas type, which suggests that they are secondary. Possible causes of the ruminal atony and failure of eructation include **esophagitis**, **acidosis**, **rumenitis,** and **failure of rumination because of an all-grain diet**. Feedlot cattle on high-level grain diets for long periods will not ruminate normally, and their rumen movements are significantly reduced.

Chronic Ruminal Tympany

Chronic ruminal tympany occurs in calves up to 6 months of age. Persistence of an enlarged thymus, continued feeding on coarse indigestible roughage, and the passage of unpalatable milk replacer into the rumen in which it undergoes fermentation and gas production, instead of into the abomasum, have all been suggested as causes, but the condition usually disappears spontaneously in time and in most cases the cause is undetermined. Necropsy examination of a number of cases has failed to detect any physical abnormality, although a developmental defect appears to be likely because of the age at which it occurs. Unusual postures, particularly lateral recumbency, are commonly characterized by secondary tympany. Cattle may die of secondary tympany if they become accidentally cast in dorsal recumbency in handling facilities, crowded transportation vehicles, irrigation ditches, and other restrictive positions.

In some cases of vagus indigestion characterized by ruminal hyperactivity the secondary bloat may be of the frothy type because of ruminal hyperactivity.

EPIDEMIOLOGY

Occurrence

Pasture Bloat

Pasture bloat occurs in both dairy and beef cattle that graze pastures consisting of bloating forages. The incidence is highest when the pasture is lushest. Spring and autumn are the most dangerous seasons, when the pastures are lush and young and the leaves of the plants contain a high concentration of soluble proteins. Dry hot conditions and matured plants, and thus midsummer, are the forerunners of a decline in incidence. Sheep can also be affected but appear to be much less susceptible than cattle.

Feedlot Bloat

Feedlot bloat occurs in feedlot cattle during the 50 to 100 days when cattle are fed large quantities of grain and small quantities of roughage. In some cases the use of pelleted, finely ground feed has been associated with outbreaks of feedlot bloat. High-producing dairy cows that are fed 12 to 22 kg of grain daily may also develop grain bloat.

Morbidity and Case Fatality

Pasture Bloat

Reliable current field data on the incidence of pasture bloat in cattle are not available. Canadian observations in 1975 indicated that cattle fed fresh alfalfa typically bloat on 35% of the feeding days and 10% of the total

animal days. Frothiness of rumen contents, observed in fistulated cattle, occurs on about 50% of the feeding days and 25% of the animal days. In dairy herds in New Zealand, the average death rate from legume pasture bloat has ranged from 0.3% to 1.2%. A survey of 312 dairy farms in New Zealand over a period of 2 months revealed that 87% of all farms experienced bloat, ranging from mild to severe. The percentage of lactating cows dying of bloat in the spring of 1986 averaged 0.8%. The highest death rate of milking cows in an individual herd was 16% and in young stock 48%. The majority of variation among farms in bloat severity was not accounted for by any of the management, soil, or pasture factors measured.

Feedlot Bloat

In a survey of Kansas feedlots (60 feedlots totaling 450,000 head of cattle) the incidence of deaths from bloat was 0.1%; 0.2% of cattle had severe bloat and 0.6% moderate bloat. In a Colorado feedlot, during one full year, bloat was the cause of 3% of all mortalities. In the same study, bloat was among the four most common causes of sudden death or of cattle found dead without having been obviously ill. Outbreaks of feedlot bloat are usually of the frothy type (primary), whereas the sporadic cases are of the free-gas type and secondary to lesions that cause dysfunction of eructation.

Risk Factors That Influence the Occurrence of Primary Ruminal Tympany

Several risk factors have an influence on the occurrence of primary bloat and possibly contribute to its causation. Dietary, weather, and animal factors have received the most attention.

Dietary Risk Factors

Bloating Forages

Alfalfa (*Medicago sativa*), **red clover** (*Trifolium pratense*), and **white clover** (*T. repens*) are the principal bloat-causing legumes. Alfalfa has been recognized for its superior yield and quality in seeded pastures. Alfalfa is the most productive and most widely adapted forage species and is considered the "queen of forages." Sweet clover and alsike clover are also bloat-causing forages.

Bloat also occurs occasionally when cattle are grazed on cereal crops; rape; cabbages; leguminous vegetable crops, including peas and beans; and young grass pasture with a high protein content. An increasing occurrence of bloat is noted when cattle are grazed on young green cereal crops such as **winter wheat**, especially if it is heavily fertilized and irrigated.

Frothy bloat may also occur in cattle fed alfalfa hay, even when mixed with cereal grains and another hay. Outbreaks are commonly associated with particular lots of hay, often containing fine particles. Alfalfa hay produces a frothy bloat with a typical viscous consistency of the rumen contents, but it is commonly more subacute and chronic rather than acute and peracute as in pasture bloat.

Nonbloating Forages

Bird's foot trefoil (*Lotus corniculatus*), cicer milkvetch (*Astragalus cicer*), arrowleaf clover (*T. vesiculosum*), sainfoin (*Onobrychis vicifolia*), and crown vetch (*Coronilla varia*) are the bloat-safe forages. These contain tannins that bind with soluble proteins and inhibit microbial digestion.

Crop Maturity

The maturity of the forage is the major plant factor affecting the incidence of pasture bloat. Grazing very succulent pasture—immature, rapidly growing legumes in the prebloom stage—is the biggest single risk of bloat in cattle. The bloat potential of alfalfa varies significantly with the phenologic stage of the plant. The greatest risk to cattle occurs during the vegetative stage of growth, and the risk declines during the bud stage and may be absent during the bloom stage. Feeding cattle freshly chopped alfalfa herbage daily at different stages of growth resulted in animal-days of bloat of 62, 10, and 0, respectively, for the vegetative, bud, and bloom stages of the alfalfa. The leaf:stem ratio decreased from 1.2 to 0.5 and 1.5 to 0.4 in two different years as the crop matured from vegetative to bloom stage. The absence of bloat during bloom can be attributed to the much lower leaf:stem ratio at that stage. As most chloroplasts are within the leaves, the lower leaf:stem ratio at bloom would reduce the concentration of these fragments. A leaf:stem ratio of less than 0.5 (1:2) could be used as an indicator of a low potential for bloat in alfalfa.

The rapid rate of digestion of the immature bloating forages results in the production of a stable foam. In the summer months, especially under irrigated conditions when the growth rate of alfalfa is rapid, bloat occurs in cattle fed alfalfa herbage at the **vegetative to prebud stages of growth**. Alfalfa's potential for causing bloat is highest when moisture conditions are optimal for vegetative growth. Under these conditions the stems become turgid and fleshy but not fibrous; the leaves are soft and easily crushed between the fingers. In autumn, the growth rate of alfalfa is slower because of lower temperatures. A rapid rate of growth of the alfalfa is a necessary condition for bloat. Field observations of the relationship between plant factors to alfalfa bloat found that the percentages of dry matter and acid detergent fiber were lower, and the concentration of chlorophyll, total nitrogen, and soluble nitrogen were higher on days when bloat occurred.

Ingestion of the more succulent parts of plants and avoidance of the more mature portions can be a precipitating factor, and tympany is less likely to occur if the crop is harvested and fed than if it is grazed. Restriction of the grazing area has a similar effect; it forces the cattle to eat the entire plants. A high incidence is recorded when pasture is wet, but this is probably caused by the rapid growth of the plants during heavy rainfall periods rather than to the physical wetness of the crop. Under experimental conditions the production of tympany is not influenced by the water content of clover or by wilting. Other plant factors that are known to be associated with an increased tendency to bloat are liberal administration of urea to the pasture; a high intake of glucose, calcium, and magnesium; and a high nitrogen intake.

A high herbage potassium to sodium ratio can increase the risk of bloat in cattle, which may be caused by digestion rate. There is some indication that sodium fertilizer can affect the digestion rate of perennial ryegrass and white clover. Sodium fertilizer increased maximum gas output from grass and rate of production, which was associated with an increase in grass digestibility; however, in clover it had the opposite effect, potentially reducing bloat in cows fed a high-legume diet.

The risk of bloat is reduced by waiting until the dew was off the alfalfa before allowing cattle to graze, leading to the practice of many cattlemen of delaying morning grazing "until the dew has dried." Bloat was observed 2 to 17 times more often when cattle were fed between 0700 and 0800 hours than when they were fed 4 hours later in both grazing and feedlot trials. Ruminal chlorophyll was higher before the early feeding than before the late feeding, suggesting that feeding later in the morning reduced the predisposition of cattle to bloat by increasing particle clearance from the rumen. The risk of bloat was also reduced when cattle grazed alfalfa continuously than when grazing was interrupted and cattle were allowed to graze for only 6 hours daily. Pasture management systems that promote continuous and rapid ruminal clearance (more bypass and less gas production) are most likely to reduce the incidence of bloat.

Weather Risk Factors

The relationship of weather conditions to the occurrence and incidence of pasture bloat has been examined under conditions in Canada. Under ordinary grazing conditions, bloat occurs sporadically over large parts of the growing season. The occurrence of pasture bloat was not associated with a simple, unique weather variable. The effect of temperature on the incidence of bloat is complex. Bloat seems to occur when moderate daytime temperatures (20°C–25°C) permit optimum vegetative growth. Cool overnight temperatures in combination with moderate daytime temperatures may induce bloat in the fall. Cool temperatures delay maturation and extend the vegetative growth

phase of forage crops and optimize conditions for bloat. On a daily basis, bloat tended to be preceded immediately by nights and days that were cooler than usual. Bloat can also occur after a killing frost.

Feedlot Bloat

Feedlot bloat occurs in hand-fed cattle confined in feedlots and barns when insufficient roughage is fed or the feed is too finely ground. Two separate sets of circumstances conducive to feedlot bloat have been identified. In one, the cattle are being fed a **high-level grain finishing ration** in which grain comprises more than 80% of the weight of the ration. The effect of these rations on the rumen is a tendency to acidity and a shortage of rumen-stimulating roughage, which may interfere with motility and eructation. In the other situation, grain comprises 30% to 70% of the ration, with the same but less marked effect as mentioned previously, but the **roughage component is alfalfa hay** with its own bloat-inducing capacity.

Animal Risk Factors

Cattle vary in their susceptibility to primary ruminal tympany, especially that caused by legumes, and this individual susceptibility may be inherited. Cows can be classified according to their susceptibility to pasture bloat into **high or low susceptibility** and their progeny are similar. Total exchange of rumen contents between high-susceptibility and low-susceptibility animals produces a temporary exchange of susceptibilities that lasts about 24 hours. A number of inherited characteristics are related to bloat. They include ruminal structure and motility, composition of salivary proteins, rate of salivation, and the greater capacity of the rumen contents of high-susceptibility animals to degrade mucoproteins that would either reduce antifoaming activity or increase foam-stabilizing activity. A salivary protein, bSP30, is correlated with susceptibility to bloat in cattle herds selected for high or low bloat susceptibility. One obvious application for such a protein marker for bloat would be to screen cattle to eliminate highly susceptible herds. Blood and urinary metabolites in cattle have also differed with respect to susceptibility to bloat.

There may also be differences between animals in the rate and extent of physical breakdown of feed in the rumen and the rate of passage of solids out of the rumen. However, neither differences in gas production nor foam production nor the stability of the foam are important factors in distinguishing between high-susceptibility and low-susceptibility cows. One major physiologic difference between high and low susceptibility is the volume of rumen fluid. It is suggested that low-susceptibility cows do not bloat because they have a lower relative volume of rumen digesta than high-susceptibility cows.

Under experimental conditions the production of tympany is not influenced by the rate of intake or the total intake of dry matter. Susceptibility increases with time when a tympany-producing diet is fed for a relatively short period. However, animals accustomed over very long periods to grazing bloating pastures may be less susceptible than other animals. Accordingly, the mortality rate in young cattle is much higher than in mature animals.

There may be a common biological basis for partial preference for grass and clover in sheep and cattle. Dairy heifers select between 50% and 65% white clover when given a free choice between adjacent ryegrass and white clover monocultures. There is also a diurnal pattern to preference, with a stronger preference for clover in the morning, with the preference for grass increasing toward evening. Providing animals with antibloat treatment (slow-release monensin capsules) did not have any effect on the proportion of clover selected.

Economic Importance

Primary ruminal tympany causes heavy losses through death, severe loss of production, and the strict limitations placed on the use of some high-producing pastures for grazing. For example, it is estimated that bloat costs the dairy industry in New Zealand $50 million annually. The incidence of the disease has increased markedly with the improvement of pastures by heavy applications of fertilizers and the use of high-producing leguminous pasture plants, and losses in cattle at times have reached enormous proportions.

The most obvious form of loss is sudden death. Although this is the dramatic loss, especially when a large number of cattle are unexpectedly found dead, an equivalent loss occurs as the result of reduced food intake. For example, on clover-dominant pasture (60%–80% white clover) in which bloat was common the weight gains of cattle grazing it were 20% to 30% less than normal. It has been argued that the returns achieved by good bloat prevention in pastured cattle would not compensate for the costs incurred, but the opposite view is strongly held.

PATHOGENESIS

Normally, gas bubbles produced in the rumen fluid coalesce, separate from the rumen contents to form pockets of free gas above the level of the contents, and are finally eliminated by eructation. Much of the gas of fermentation will be eructated. A grass-fed cow can produce 100 L during the first hour of feeding. A cow maintained on a legume diet may produce 200 L/h. In **frothy bloat**, the gas bubbles remain dispersed throughout the rumen contents, producing an abnormal increase in the volume of the ruminoreticular contents and, consequently, **inhibiting eructation.** The characteristic frothiness of ruminal contents is caused by **inadequate coalescence of gas bubbles.** In **free-gas bloat** the gas bubbles coalesce and separate from the rumen fluid, but the animals cannot eructate the pockets of free gas because of abnormalities of the reticulorumen or esophagus.

Most cases of naturally occurring pasture or feedlot bloat are not accompanied by ruminal atony. In the early stages there is unusually pronounced hypermotility. Most of the gas is mixed with the solid and fluid ruminal contents to form a dense, stable froth. Some free gas is present but the amount that can be removed by a stomach tube or trocar and cannula does little to relieve the distension of the rumen. Generally, free-gas bloat characterized by the accumulation of free gas is caused by esophageal obstruction or ruminal atony. If the **eructation reflex is functional**, the experimental introduction of very large amounts of gas does not cause tympany, because eructation removes the excess. Bloat-producing forages do not produce more gas than safe feeds, and the simple production of excessive gas is known not to be a precipitating factor.

Frothiness of the ruminal contents interferes with **function of the cardia** and inhibits the eructation reflex. Rumen movements are initially stimulated by the distension, and the resulting hypermotility exacerbates the frothiness of the ruminal contents. Terminally there is a loss of muscle tone and ruminal motility.

The most distinctive aspect of bloated cattle is abdominal distension, particularly the left abdomen, caused by distension of the rumen. Experimentally there is a relationship between reticulorumen volume, intraruminal pressure, and the abdomen of cows fed fresh alfalfa. The volumes of gas in a bloated cow are large, 50 to 70 L, and there is an exponential increase in intraruminal pressure with increasing rumen volume, especially as the potential for further increases in the abdomen diminishes. Most severely bloated cows will attempt to urinate and defecate when intraruminal pressures exceed 25 cmH_2O but some cows can tolerate pressures in excess of 50 cmH_2O. As the intraruminal pressure increases, occlusion of the vena cava occurs, causing congestion of the caudal part of the body. In addition, the pressure exerted by the distended rumen on the diaphragm is very high, which results in reduced lung capacity and death from hypoxia.

CLINICAL FINDINGS

Primary Pasture or Feedlot Bloat

Bloat is a common cause of **sudden death** (or **found dead**) in cattle. **Pastured beef cattle** that die of bloat are usually found dead because they are not observed as regularly as dairy cattle. **Feedlot cattle** that die of bloat are commonly found dead in the morning, which may be from their relative inactivity

during the night or to the lack of observation, detection, and treatment. **Dairy cattle** that are being milked and observed regularly will commonly begin to bloat within 1 hour after being turned into a bloat-producing pasture. There is commonly a lag period of 24 to 48 hours before bloating occurs in cattle that have been placed on a bloat-producing pasture for the first time. They may bloat on the first day but more commonly they bloat on the second and third days. A similar situation has been observed in pastured beef cattle that have been on a particular pasture for several days or weeks before bloat occurs. This is always a surprise to the owner and the veterinarian, who find it difficult to explain why bloat suddenly becomes a problem on a pasture that cattle have grazed safely for some time.

In **primary pasture bloat**, obvious distension of the rumen occurs quickly, sometimes as soon as 15 minutes after going on to bloat-producing pasture, and the animal stops grazing. The distension is usually more obvious in the upper left paralumbar fossa, but the entire abdomen is enlarged. There is discomfort and the animal may stand and lie down frequently, kick at its abdomen, and even roll. Frequent defecation and urination are common. Dyspnea is marked and is accompanied by mouth breathing, protrusion of the tongue, salivation, and extension of the head. The respiratory rate is increased up to 60 breaths/min. Occasionally, projectile vomiting occurs and soft feces may be expelled in a stream.

In **mild bloat**, the left paralumbar fossa is distended, the animal is not in distress, and 5 to 7 cm of skin over the left paralumbar fossa may be easily grasped and "tented," which provides a measure of the degree of abdominal distension and tautness of the skin. In **moderate bloat**, a more obvious distension of the abdomen is evident, the animal may appear anxious and slightly uncomfortable, and the skin over the paralumbar fossa is usually taut but some can be grasped and tented. In **severe bloat**, there is prominent distension of both sides of the abdomen and the animal may breathe through its mouth and protrude the tongue. The animal is usually uncomfortable, anxious, and may be staggering. The skin over the left flank is very tense and cannot be grasped and tented.

Ruminal contractions are usually increased in strength and frequency in the early stages and may be almost continuous, but the sounds are reduced in volume because of the frothy nature of the ingesta. Later, when the distension is extreme, contractions are decreased and may be completely absent. The low-pitched tympanic sound produced by percussion over the rumen is characteristic. Before clinical tympany occurs, there is a temporary increase in eructation, but this disappears in the acute stages. The course in ruminal tympany is short but death does not usually occur in less than 3 to 4 hours of the onset of clinical signs. Collapse and death almost without struggle occur quickly.

If animals are treated by **trocarization or the passage of a stomach tube, only small amounts of gas are released** before froth blocks the cannula or tube. In a group of affected cattle, some will be bloated and the remainder will have mild to moderate distension of the abdomen. These animals are uncomfortable, graze for only short periods, and their milk production is decreased. The drop in production may be caused by depression of food intake or by failure of milk letdown.

Secondary Bloat

In secondary bloat, the excess gas is present as a **free gas cap** on top of the ruminal contents, although frothy bloat may occur in vagus indigestion with increased ruminal motility (see vagus indigestion). There is usually an increase in the frequency and strength of ruminal movements in the early stages followed by atony. Passage of a stomach tube or trocarization results in the release of large quantities of gas and subsidence of the ruminal distension. If an esophageal obstruction is present, it will be detected when the stomach tube is passed.

Dyspnea and Tachycardia in Severe Bloat

In both severe primary and secondary bloat there is dyspnea and a marked elevation of the heart rate up to 100 to 120 beats/min in the acute stages. A systolic murmur may be audible, caused probably by distortion of the base of the heart by the forward displacement of the diaphragm. This murmur has been observed in ruminal tympany associated with tetanus, diaphragmatic hernia, vagus indigestion, and esophageal obstruction and disappears immediately if the bloat is relieved.

CLINICAL PATHOLOGY

Laboratory tests are not necessary for the diagnosis of ruminal tympany.

NECROPSY FINDINGS

In cattle that have died from bloat within an hour previously there is protrusion and congestion of the tongue; marked congestion and hemorrhages of lymph nodes to the head and neck, epicardium, and upper respiratory tract; friable kidneys; and mucosal hyperemia in the small intestine. The lungs are compressed and there is congestion and hemorrhage of the cervical portion of the esophagus, but the thoracic portion of the esophagus is pale and blanched. Generally, congestion is marked in the front quarters and less marked or absent in the hindquarters. The rumen is distended but the contents are much less frothy than before death. A marked erythema is evident beneath the ruminal mucosa, especially in the ventral sacs. The liver is pale because of expulsion of blood from the organ. Occasionally, the rumen or diaphragm have ruptured. In animals dead for several hours there is subcutaneous emphysema, almost complete absence of froth in the rumen, and exfoliation of the cornified epithelium of the rumen with marked congestion of submucosal tissues.

TREATMENT

The approach to treatment depends on the circumstances in which bloat occurs, whether the bloat is frothy or due to free gas, and whether or not the bloat is life-threatening.

First-Aid Emergency Measures

Emergency Rumenotomy

It is often necessary to advise an owner to use some first-aid measures before the veterinarian arrives on the farm. All animals should be removed immediately from the source of the bloating pasture or feed. In severe cases in which there is gross distension, mouth-breathing with protrusion of the tongue, and staggering, an emergency rumenotomy is necessary to save the life of the animal. Once the animal falls down, death occurs within a few minutes, and many animals have died unnecessarily because owners are unable or reluctant to do an emergency rumenotomy. Using a sharp knife, a quick incision 10 to 20 cm in length is made over the midpoint of the left paralumbar fossa through the skin and abdominal musculature and directly into the rumen. There will be an explosive release of rumen contents and marked relief for the animal. There is remarkably little contamination of the peritoneal cavity, and irrigation and cleaning of the incision site followed by standard surgical closure usually results in uneventful recovery with only occasional minor complications.

DIFFERENTIAL DIAGNOSIS

When presented with ruminating cattle with a distended abdomen and marked distension of the left paralumbar fossa, the most obvious diagnosis is ruminal tympany.

- **Primary bloat** is likely if the dietary conditions are present and the passage of a stomach tube reveals the presence of froth and the inability to release gas.
- **Secondary bloat** is likely if the history indicates that distension of the abdomen and left flank has been present for a few days or if the bloat has been intermittent within the last several days. Passage of a stomach tube will detect esophageal obstruction or stenosis, both of which are accompanied by difficult swallowing and, in acute cases, by violent attempts at vomiting.
- In secondary bloat associated with **vagus indigestion,** the history usually indicates that distension of the abdomen has been

Continued

progressive over the last several days or few weeks with loss of weight and scant feces. In addition, the rumen is grossly enlarged and the ventral sac is commonly enlarged and distends the right lower flank.

- **Tetanus** is manifested by limb and tail rigidity, free-gas bloat, prolapse of the third eyelid, and hyperesthesia.
- **Carcinoma** and **papillomata** of the esophageal groove and reticulum and actinobacillosis of the reticulum cannot usually be diagnosed antemortem without exploratory rumenotomy.
- **Animals found dead**. One of the difficult situations encountered in veterinary practice is the postmortem diagnosis of bloat, especially in animals found dead at pasture in warm weather. **Blackleg**, **lightning strike**, **anthrax,** and **snakebite** are common causes of cattle being found dead, and the necropsy findings are characteristic. A diagnosis of bloat must depend on an absence of local lesions characteristic of these diseases, the presence of marked ruminal tympany in the absence of other signs of postmortem decomposition, the relative pallor of the liver, and the other lesions described earlier.

Trocar and Cannula

The trocar and cannula have been used for many years for the emergency release of rumen contents and gas in bloat. However, the standard-sized trocar and cannula does not have a large enough diameter to allow the very viscous stable foam in peracute frothy bloat to escape quickly enough to save an animal's life. A larger-bore instrument (2.5 cm in diameter) is necessary, and an incision with a scalpel or knife must be made through the skin before it can be inserted into the rumen. If any size of trocar and cannula fails to reduce the intraruminal pressure and the animal's life is being compromised by the pressure, an emergency rumenotomy should be performed. If the trocar is successful in reducing the pressure, the antifoaming agent of choice can be administered through the cannula, which can be left in place until the animal has returned to normal in a few hours. Owners should be advised on the proper use of the trocar and cannula, the method of insertion and the need for a small incision in the skin, and the care of cannulas left in place for several hours or days.

A corkscrew-type trocar and cannula has been recommended for long-term insertion in cases of chronic bloat that occur in feedlot cattle and in beef calves following weaning. The etiology of these is usually uncertain; insertion of a cannula for several days or use of a rumen fistula will often yield good results.

Promote Salivation

For less severe cases, owners may be advised to tie a stick in the mouth like a bit on a horse bridle to promote the production of excessive saliva, which is alkaline and may assist in denaturation of the stable foam. Careful drenching with sodium bicarbonate (150–200 g in 1 L of water) or any nontoxic oil as described later is also satisfactory.

Stomach Tube

The passage of a stomach tube of the largest bore possible is recommended for cases in which the animal's life is not being threatened. The use of a Frick oral speculum and passage of the tube through the oral cavity permits the passage of tubes measuring up to 2 cm in diameter, whereas this may not be possible if passed through the nasal cavity. In free-gas bloat, there is a sudden release of gas and the intraruminal pressure may return to normal. While the tube is in place, the antifoaming agent can be administered. In frothy bloat, the tube may become plugged immediately on entering the rumen. A few attempts should be made to clear the tube by blowing through the proximal end of the tube and moving it back and forth in an attempt to locate large pockets of rumen gas that can be released. However, in frothy bloat it may be impossible to reduce the pressure with the stomach tube, and the antifoaming agent should be administered while the tube is in place.

If the bloat cannot be relieved but an antifoaming agent has been administered, the animal must be observed closely for the next hour to determine whether the treatment has been successful or if the bloat is becoming worse, which requires an alternative treatment.

Feedlot Bloat

In an outbreak of feedlot bloat, the acute and peracute cases should be treated individually as necessary. There may be many **"swellers,"** which are moderate cases of bloat that will usually resolve if the cattle are coaxed to walk. After a few minutes of walking they usually begin to eructate. Shaking of experimentally reproduced foam results in loss of stability of foam and coalescence into large bubbles and the movement of walking has the same effect. If walking is effective in reducing the foam, the animals should be kept under close surveillance for several hours for evidence of continued bloating, which is unusual.

Antifoaming Agents

Details of the oils and synthetic surfactants used as antifoaming agents in treatment are described in the section on control because the same compounds are used in prevention. Any nontoxic oil, especially a mineral one that persists in the rumen, that is not biodegradable, is effective and there are no other significant differences between them. Their effect is to reduce surface tension and foam. A dose of 250 mL is suggested for cattle but doses of up to 500 mL are commonly used. An emulsified oil or one containing a detergent such as dioctyl sodium sulfosuccinate is preferred because it mixes effectively with ruminal contents. Of the **synthetic surfactants**, **poloxalene** is the one in most general use for leguminous bloat, and a dose of 25 to 50 g is recommended for treatment. Poloxalene is not as effective for feedlot or grain bloat. **Alcohol ethoxylates** are also used as bloat remedies and both poloxalene and the ethoxylates are more effective and faster than oil, which is relatively slow and better suited to prevention than treatment. All three are recommended as satisfactory for legume hay bloat, but **poloxalene is not recommended for feedlot bloat**. All of them can be given by drench, stomach tube, or through a ruminal cannula. The effect of all treatments is enhanced if they are thoroughly mixed with the ruminal contents; if rumen movements are still present mixing will occur. If the rumen is static, it should be kneaded through the left flank while the animal is encouraged to walk.

A polyoxypropylene-polyoxyethylene glycol surfactant polymer (Alfasure), which is a water-soluble pluronic detergent available in Canada, is effective for the treatment of alfalfa bloat when 30 mL is given intraruminally using a 6-cm 14-gauge hypodermic needle directly into the rumen through the abdominal wall in the middle of the paralumbar fossa. The median time of disappearance after treatment was 25 minutes; the swelling returned to normal within 52 minutes.

Return to Pasture or Feed

Following the treatment of the individual cases of bloat. The major problem remaining is the decision about whether or not, or when, or under what conditions, to return the cattle to the bloat-producing pasture or to the concentrate ration in the case of feedlot cattle. The possible preventive measures are presented under control but, unless one of the reliable ones can be instituted, the cattle should not be returned until the hazardous period has passed. This is difficult on some farms because the bloat-producing pasture may be the sole source of feed.

CONTROL

Pasture Bloat

Management Strategies to Reduce Rate of Rumen Fermentation

The prevention of pasture bloat is challenging. Grazing management strategies are the principal methods used for the prevention of pasture bloat, along with controlling pasture yields and quality. Several different management practices have been recommended, including the prior feeding of dry, scabrous hay, particularly Sudan grass, cereal hay and straw, or orchardgrass hay,[1] restricting the grazing to 20 minutes at a time or until the first cow stops eating, harvesting the crop and feeding it in troughs, and strip grazing to ensure that all available pasture is used each

day. **The principle of each of these strategies is to decrease the rate of rumen fermentation.** These methods have value when the pasture is only moderately dangerous but may be ineffective when the bloat-producing potential is high. In these circumstances the use of simple management procedures is unreliable because the occurrence of bloat is unpredictable. In other cases, the strategies such as limited grazing are impractical. Generally, the farmer does not know if the pastures are dangerous until bloat occurs and, once effective prophylactic methods are being used, it is difficult to know when they are no longer required. The bloat-producing potential of a pasture can change dramatically almost overnight, and the management strategy can be quickly nullified.

Stage of Growth

The probability of legume bloat decreases with advancing stages of plant maturity because of a decrease in the soluble protein content of the legume. Alfalfa at the vegetative stage of growth results in the highest incidence of bloat compared with the bud and bloom stages, with moderate and no bloat, respectively. These results indicate the potential for grazing management through selection of plant phenology (periodic phases of plant growth) as a method of bloat control. In practice, it would be essential to recognize the predominant stage of growth of the stand before turning cattle into the pasture. The leaf:stem ratio should also be considered as a factor.

Choice of Forages

Seeding cultivated pastures to grass–legume mixtures is the most effective and least costly method of minimizing pasture bloat, particularly for beef herds grazing over large areas under continuous grazing systems. In a grass–legume mixture, a legume content of 50% is suggested as the maximum bloat-safe level. However, this ratio may be impractical for large areas, especially on rolling terrain, in which it is impossible to maintain a uniform 50:50 stand. If cattle have a tendency to avoid the grass and select the legume, the potential for bloat increases. Bloat can occur in mixed pastures in which the proportion of legume is less than 15%, possibly because of selective grazing.

Because of the potential for causing bloat, grasses alone or nonbloating forages may be used. Sainfoin, bird's foot trefoil, cicer milkvetch, and crown vetch are useful bloat-safe legumes in regions in which they are adapted. However, their yield, vigor, regrowth, winter-hardiness, and persistence are well below the superior growth and production characteristics of alfalfa. Seeding grasses alone avoids the problem of bloat but the benefits of including a legume in the mixture include much greater production, higher protein and nutritional value, and lower fertilization costs. A decision to use grass with or without bloat-safe legumes should be based on the economic benefits of the greater protein from alfalfa or clover compared with the possible losses from bloat. At present, a pasture comprising equal quantities of clovers and grasses comes closest to achieving this ideal, but with available pasture plants and current methods of pasture management this clover:grass ratio is not easy to maintain. Research work in this area is directed toward selecting cattle that are less susceptible to bloat. More practical are the moves being made to breed varieties of legume that are low on bloat-producing potential. The incidence of frothy bloat can be substantially reduced if alfalfa herbage contains as little as 25% orchardgrass.

Alternative Temperate Forages

Forages comprise a major proportion of the diet in most ruminant animal–production systems. Grazed forages are used especially during the late spring, summer, and early autumn in many countries, whereas in some regions, such as Australasia and South America, ruminant animal production is based on year-round grazing of forages, with no indoor housing. Grazing systems are generally based on swards of which the major portion consists of grasses (perennial ryegrass [*Lolium perenne*] in the case of New Zealand), with a legume (white clover [*T. repens*] in the case of New Zealand) forming a minor portion (approximately 20%), mainly to fix atmospheric nitrogen and to provide a higher quality feed. Different grasses and legumes form the grazed pastures in other countries. The grazing of alternative forages is being developed for the sustainable control of internal parasites, with reduced anthelmintic use, for increasing reproductive performance in sheep and the growth rate in young animals, and for reducing the incidence of bloat in cattle.

It has been long accepted in ruminant nutrition that the feeding value of legumes is greater than that of grasses, because of their more rapid particle breakdown, faster rumen fermentation, lower rumen mean retention time and, consequently, greater voluntary feed intake. Despite these advantages, legumes have never attained their true potential in many grazing systems because of three principal disadvantages: legumes generally grow slowly in winter, producing less feed per hectare than grasses; rumen frothy bloat in cattle is caused by rapid solubilization of protein in many legumes; and the presence in some legumes of estrogenic substances depresses reproductive performance when grazed by ewes during the breeding season. Thus the identification of legumes that could overcome these limitations would offer major advantages.

Grazing Management

Uniform and regular intake is the key to managing cattle on legume pastures. Waiting until the dew is off before placing animals on pasture is a common practice and is probably useful when animals are first exposed to a legume pasture. Before animals are placed on a legume pasture they should be fed coarse hay to satiety. This prevents them from gorging themselves and overeating the fresh and lush legume forage. Thereafter, they should stay on pasture. Mild bloat may occur on first exposure, but the problem should disappear in a few days because animals usually adapt to legume pastures with continuous grazing. If the legume pasture continues to have a high bloat potential, the animals should be removed until the legume becomes more mature and less bloat provoking.

Grazing Patterns and Strip Grazing

Bloat is often associated with discontinuous grazing such as removal of animals from the legume pasture for a period of time, e.g., overnight. Similarly, outbreaks may occur when grazing is interrupted by adverse weather, such as storms, and by biting flies or other insect pests. These factors alter normal grazing habits, generally resulting in more intensive, shorter feeding periods that may increase the incidence of bloat.

In **strip grazing,** the field is grazed in strips that are changed every 1 to 3 days. This is done by careful placement of an electric fence so that the grazing strip is moved further and further away from the entrance. In this way the animals are forced to graze a greater proportion of the entire plant, which increases the dry matter intake and proportionately decreases the intake of soluble protein, which results in a decrease in the rate of digestion in the rumen. In some situations, the most reliable methods for the prevention of bloat in dairy cows are either strip grazing of pasture sprayed daily with oil or pluronics, or twice-daily drenching with the same preparations.

Swathing and Wilting

The frequency of alfalfa bloat can be decreased by grazing pastures that have been swathed and wilted. Wilting swathed alfalfa for 24 hours produces changes in the protein configuration of the sulfhydryl and disulfide content of the proteins. Compared with feeding a fresh swath, wilting a swath for 24 or 48 hours reduces the incidence of alfalfa bloat. The reduction is greatest by 48 hours and may be eliminated after 48 hours. A reduction in moisture content during wilting may be sufficient to eliminate the risk of bloat. Alfalfa silage is virtually bloat free because of protein degradation by proteolysis during ensiling.

Alfalfa Hay Bloat Prevention

The bloat potential of alfalfa hay is unpredictable. The best indicators are leafy, immature hay with soft stems. Hay grown under cool, moist conditions is more likely to cause bloat than hay produced in hot, dry areas.

Reports of bloat on damp, moldy hay are common but not documented and are unexplained. Because fine particles and leaves are especially dangerous, chopping hay can increase the incidence of bloat. When alternative roughages are available, a coarse grass hay, cereal grain hay, or straw can be substituted for a portion of the bloat-causing hay. In dairy herds, alfalfa hay can be fed in the morning and grass hay in the evening. Animals should be adjusted gradually to new lots of alfalfa hay; old and new lots should be mixed for the first 5 days of feeding.

Rations containing a 50:50 mixture of alfalfa hay and grain are most dangerous, but the risk of bloat is low when grain consists of less than 35% of the mixture.

Antifoaming Agents

One satisfactory strategy for the prevention of pasture bloat is the administration of antifoaming agents.

Oils and Fats

Oils and fats have achieved great success for the control of pasture bloat in New Zealand and Australia.

Individual Drenching

Individual drenching is sometimes practiced but because of the time and labor involved it is most suited to short-term prophylaxis. It is popular as an effective standard practice in pastured cattle in New Zealand. The common practice is to administer the antifoaming agent (antibloat drench) at the time of milking using an automatic dose syringe that is moved up and down to reach each cow in the milking parlor. Cows become conditioned quickly and turn their heads to the operator to receive their twice-daily dose of 60 to 120 mL of the oil. The duration of the foam-preventing effect is short, lasting only a few hours, and increasing the dose does not significantly lengthen the period of protection.

The combined use of sodium chloride and antibloat drenching of lactating dairy cows in New Zealand may stimulate the closure of the reticular groove, causing the swallowed fluid to bypass the reticulorumen, rendering the drenching with the antibloat solution ineffective. The proportion of antibloat–sodium-chloride fluid bypassed was considered to be of no practical significance to the protection from bloat in most animals. However, there may be decreased protection in 10% to 15% of drenched cows. Thus cows should be drenched with these compounds at separate times, morning for one, evening for the other, or, if drenching at the same milking, drench with the antibloat solution first, followed by a separate drench with sodium chloride.

Application of Oil to Pasture

If the oil or fat is emulsified with water it can be sprayed onto a limited pasture area that provides part or all of the anticipated food requirements for the day. Back-grazing must be prevented, and care is required during rainy periods when the oil is likely to be washed from the pasture. The method is ideal where strip-grazing is practiced on irrigated pasture but is ineffective when grazing is uncontrolled.

Addition to Feed and Water

The oil can be administered at the rate of 120 g per head in concentrates fed before the cattle go on to the pasture or by addition to the drinking water to make a 2% emulsion. Oil can be added to water in all available troughs, turning off the water supply and refilling the troughs when they are emptied. However, the actual intake of the oil cannot be guaranteed. Climatic conditions also cause variations in the amount of water that is taken, with consequent variation in the oil intake. Thus it is best to make provision for a daily intake of 240 to 300 g of oil per head during those periods when the risk of bloating is highest. The recommended procedure is to provide an automatic watering pump that injects antifoaming agents into all the drinking water supplies in amounts that will maintain a concentration of 1% of the antifrothing agent. Hand replenishment means that the preparation must be added twice daily. Surfactants are preferred to oils because of their faster action, the smaller dose rates (5–8 mL in 10–20 mL of water), and their longer period of effectiveness (10–18 hours).

Application to Flanks

Antifoaming agents can be applied with a large paintbrush to the flanks of cows as they go out of the milking shed. A preparation that is palatable to cattle and encourages them to lick their flanks is preferred. This has been a popular method of controlling bloat in dairy cows in Australia, but failures are not infrequent, especially in individual cows.

Types of Oil

Many different oils have been used and most vegetable oils, mineral oil, and emulsified tallow are effective. The choice of oil to be used depends on local availability and cost. If the oils are to be used over an extended period, some consideration must be given to the effects of the oil on the animal. Continued administration of mineral oil causes restriction of carotene absorption and reduces the carotene and tocopherol content of the butter produced. Linseed oil, soya oil, and whale oil have undesirable effects on the quality and flavor of the milk and butter. Peanut oil and tallow are the most satisfactory. In most areas the tympany-producing effect of pasture is short-lived and may last for only 2 to 3 weeks. During this time the pasture can be grazed under the protection of oil administration until the bloat-producing period is passed.

Water-Soluble Feed Supplements

Commercially available sources of Proanthocynanidins (condensed tannins), and plant extracts of *Yucca schidigera* (yucca) are a natural source of steroidal saponins. Both compounds were ineffective in preventing bloat in cattle fed fresh alfalfa herbage when used as a water-soluble feed supplement added to the drinking water or given as a top-dressing.

Synthetic Nonionic Surfactants

Polyoxythylene-Polyoxypropylene Block Polymer

Poloxalene is a nonionic surfactant (surface active agent) that has been used successfully for the prevention of leguminous bloat for more than 30 years. It is a polyoxythylene-polyoxypropylene block polymer that is highly effective for use in cattle grazing lush legume pasture or young cereal crops such as wheat pasture. Poloxalene moderates the ingestive behavior of cattle grazing immature alfalfa. In cattle the recommended daily level for prevention of bloat is 2 g/100 kg BW. In high-risk situations it may be advisable to administer the drug at least twice daily. Poloxalene is unpalatable and its use in drinking water was not possible until the introduction of the pluronic L64, which is suitable for mixing with drinking water and is effective. It needs to be introduced to the cattle several weeks before the bloat season commences. It is commonly used as an additive to grain mixtures, in feed pellets, and in mineral blocks. The use of pluronics administered by mixing with molasses to be licked from a roller drum was popular for a short period of time for the control of bloat in pastured beef cattle, but consumption was erratic and the control of bloat unreliable. The alternative of mixing pluronics with the drinking water is also not dependable.

Polyoxypropylene-Polyoxyethylene Glycol Surfactant Polymer (Alfasure)

Alfasure, a polyoxypropylene-polyoxyethylene glycol surfactant polymer, is very effective for the prevention of bloat when used at 0.05% in drinking water of cattle fed fresh alfalfa herbage and when added as a top-dressing. An Alfasure spray on pasture is completely effective in eliminating the occurrence of bloat in cattle grazing alfalfa at the vegetative to bud stage of growth.

Alcohol Ethoxylate Detergents

These products are known to have equal foam-reducing qualities to poloxalene and have the advantage of better palatability so that they can be administered by a voluntary intake method such as medicated blocks. Small-scale field trials show that these blocks are palatable and attractive and should be satisfactory in reducing the severity and prevalence of bloat. Not all cattle visit them voluntarily, so some cases of bloat are likely to occur. The blocks contain 10% of the

alcohol ethoxylate, known as Teric, and a daily consumption of 17 to 19 g of it is usual. Application of Teric to the flanks of cows has not been as successful as a bloat prevention as other similar application of oils. Alcohol ethoxylate and pluronic detergents controlled the occurrence of bloat in sheep fed freshly harvested alfalfa in confinement and in grazing studies in which the products were added to the water supply. In cattle grazing early to late bud alfalfa stands, the addition of the products to the water supplies prevented the occurrence of bloat.

Ionophores

Rumen modifiers such as the ionophore monensin have been used to control bloat using controlled-release capsules and liquid formulations.

Controlled-Release Monensin Capsules

Sustained-release capsules containing antifoaming agents are available for the control of pasture bloat. The capsule is administered into the rumen, where it opens, exposing an antifoaming agent, which diffuses slowly from a matrix. Monensin, a polyether ionophore antibiotic, is potentially an important agent for bloat relief in dairy cows grazing legume-based pasture. A monensin controlled-release intraruminal capsule is available that releases approximately 300 mg per head per day for 100 days. Experimental and field studies indicate that monensin can reduce the severity of bloat and increase milk production in dairy cows grazing legume pastures. In dairy farms in Australia, sustained-release monensin capsules were effective in reducing the incidence of clinical bloat in pasture-fed cattle. There was also a significant decrease in the use of pasture spraying, drinking water administration, and flank-spraying of antifoaming agents on the farms using the capsules, with no compensatory rise in the use of other bloat-prevention techniques.

A controlled-release monensin capsule reduced the incidence of bloat by about 50% in experimental steers fed alfalfa at the vegetative to early bud stages of growth.

Liquid Formulation of Monensin

Oral drenching with a liquid formulation of monensin is effective in reducing bloat in milking cows grazing white-clover–ryegrass or red-clover pastures. A daily dose of 300 mg per cow given as an oral drench in a volume of 100 mL daily provided protection for 24 hours.

Feedlot Bloat

Roughage in Ration

Feedlot high-level grain rations should contain at least 10% to 15% roughage, which is cut or chopped and mixed into a complete feed. This ensures that cattle will consume a minimum amount of roughage. The roughage should be a cereal grain straw or grass hay. The use of leafy alfalfa hay may be hazardous. The roughage may be fed separately in the long form as a supplement to the grain ration, but this practice is dangerous because the voluntary intake of roughage will vary considerably. The more palatable the grain ration, the less total roughage will be eaten, and outbreaks of feedlot bloat may occur.

Consistency of Grain

The best results in feedlot bloat are achieved by the incorporation of nonbloating roughages in the grain ration at a level of at least 10% and avoiding fine grinding of the grain. Grains for feedlot rations should be only rolled or cracked, not finely ground. If the grain is very dry, the addition of water during processing will prevent pulverization to fine particles. The use of pelleted rations for feedlot cattle cannot be recommended, because a fine grind of the grain is normally necessary to process a solid pellet. When the pellet dissolves in the rumen, a fine pasty rumen content forms, which may be associated with the development of a stable foam. In addition, it is difficult to incorporate a sufficient quantity of roughage into a pellet.

Antifoaming Agents

The use of dietary antifoaming agents for the prevention of feedlot bloat has had variable success. The addition of tallow at the level of 3% to 5% of the total ration has been successful and judged empirically, but controlled trials did not reduce bloat scores. If animal fats are effective in preventing feedlot bloat, they would be useful as a source of energy and for the control of dust in dusty feeds. Poloxalene is ineffective for the prevention of feedlot bloat.

Dietary Salt

The addition of a 4% salt to feedlot rations has been recommended when other methods are not readily available. However, feed intake and rate of BW gain will be reduced. A high salt diet increased water intake, causes an alteration in the proportion of disrupted cells in the forage due to changes in fermentation, and increases the rate of flow of particulate material out of the rumen. Other management factors considered to be important in the prevention of feedlot bloat generally include **avoid overfeeding after a period of temporary starvation** (e.g., after bad weather, machinery failure, transportation, or feed handling failure), and **ensure that the water supply** is available at all times.

Genetic Control of Pasture Bloat

Because of the high costs of bloat from deaths, lost production, treatment costs, and extra labor, one possible long-term solution is to breed cattle with reduced susceptibility to bloat. Bloat score on a single day is heritable, but the required testing procedures are expensive in labor and can put the lives of otherwise valuable animals at risk. Selection on bloat score has been achieved successfully in an experimental herd, and genetic markers and candidate genes for bloat susceptibility are now being explored. The ultimate aim is to assist the dairy industry to identify bloat-susceptible animals, so that they can be culled or used less frequently as parents in the national herd. Work in New Zealand suggests that the prospects are good for providing the dairy industry with a means of removing bloat-susceptible cattle. Carrier sires could be identified, using a marker, and these sires could be withheld from the teams of widely used proven sires available for commercial use. The use of noncarrier artificial insemination sires in the dairy cattle industry could minimize the bloat problem in one generation by removing all homozygous bloat-susceptible progeny from the population. There has been no recent research on this aspect of bloat in cattle.

General Comments

Apart from the impressive reduction in clinical and fatal cases of ruminal tympany resulting from the prophylactic use of oils, there are the added advantages of being able to use dangerous pasture with impunity and the reduction of subclinical bloat and its attendant lowering of food intake. Production may rise by as much as 25% in 24 hours after the use of oil. Nevertheless, these preventive methods should be considered as temporary measures only. The ultimate aim should be the development of a pasture of high net productivity in which the maximum productivity is consistent with a low incidence of bloat and diarrhea.

TREATMENT AND CONTROL

Treatment of pasture bloat

Immediately remove animals from bloating pasture (R-1)

In severe cases, emergency trocar/cannula (2.5-cm diameter) into left paralumbar fossa to release rumen foam (R-1)

In less severe cases, passage of stomach tube to release rumen foam and administer synthetic antifoaming agents (such as polyoxythylene-polyoxypropylene block polymer, alcohol ethoxylate, or polyoxypropylene-polyoxyethylene glycol) into rumen (R-1)

Treatment of feedlot bloat

Passage of stomach tube to release rumen foam and administer antifoaming agent (mineral oil preferred) into rumen, followed by walking for 20 minutes to disperse antifoaming agent (R-1)

Control of pasture bloat

Strategic daily use of synthetic antifoaming agents or sustained-release antifoaming

Continued

agents such as monensin to pastured cattle (R-1)

Use of grass–legume mixtures (R-2)

Delay grazing each day until dew is off (R-2)

Feed hay before grazing (R-2)

Control of feedlot bloat

Increase ingestion of coarse roughage and minimize sorting of feed (R-2)

TRAUMATIC RETICULOPERITONITIS

Perforation of the wall of the reticulum by a sharp foreign body initially produces an acute local peritonitis, which may spread to cause acute diffuse peritonitis or remain localized to cause subsequent damage, including vagal indigestion and, in rare cases, diaphragmatic hernia. The penetration of the foreign body may proceed beyond the peritoneum and cause involvement of other organs resulting in pericarditis; cardiac tamponade; pneumonia; pleurisy and mediastinitis; and hepatic, splenic, or diaphragmatic abscess. These sequelae of traumatic perforation of the reticular wall are shown diagrammatically in Fig. 8-9.

This complexity of development makes diagnosis and prognosis difficult, and the possibility that a number of syndromes may occur together further complicates the picture. For convenience and to avoid repetition, all these entities except endocarditis are dealt with together here, even though many of them are diseases of other systems.

ETIOLOGY

Traumatic reticuloperitonitis is caused by the penetration of the reticulum by metallic foreign objects that have been ingested in prepared feed. Baling or fencing wire that has passed through a chaff cutter, feed chopper, or forage harvester is one of the most common causes. In one series of 1400 necropsies, 59% of lesions were caused by pieces of wire, 36% by nails, and 6% by miscellaneous objects. The metal objects may be in the roughage or concentrate or may originate on the farm when repairs are made to fences, yards, and in the vicinity of feed troughs.

The wire from motor vehicle radial tires may be the cause. Used tires are commonly used to hold down plastic sheeting over silage piles. The wire is gradually released from the tires, which are in a state of deterioration, and is mixed with the feed supply, or the tires may be inadvertently dropped into a feed mixer wagon and become fragmented, mixing the pieces of wire throughout the ration.

SYNOPSIS

- **Etiology** Penetration of reticulum by metallic foreign objects such as nails and pieces of wire, including tire wire, which were ingested by the animal and located in the reticulum.
- **Epidemiology** Most common in adult dairy cattle fed prepared feeds.
- **Signs** Sudden anorexia and fall in milk yield, mild fever, ruminal stasis, and local pain in the abdomen. Rapid recovery may occur, or the disease may persist in a chronic form or spread widely to produce an acute, diffuse peritonitis.
- **Clinical pathology** In acute local peritonitis, neutrophilia and regenerative left shift; in chronic form, leukopenia and degenerative left shift. Peritoneal fluid contains marked increase in nucleated cells and total protein. Plasma protein concentration increased. Ultrasonography and radiography of the anteroventral abdomen.
- **Lesions** Localized reticuloperitonitis and varying degrees of locally extensive fibrinous adhesions. Abnormal peritoneal fluid. Abscesses and adhesions possible throughout the peritoneal cavity

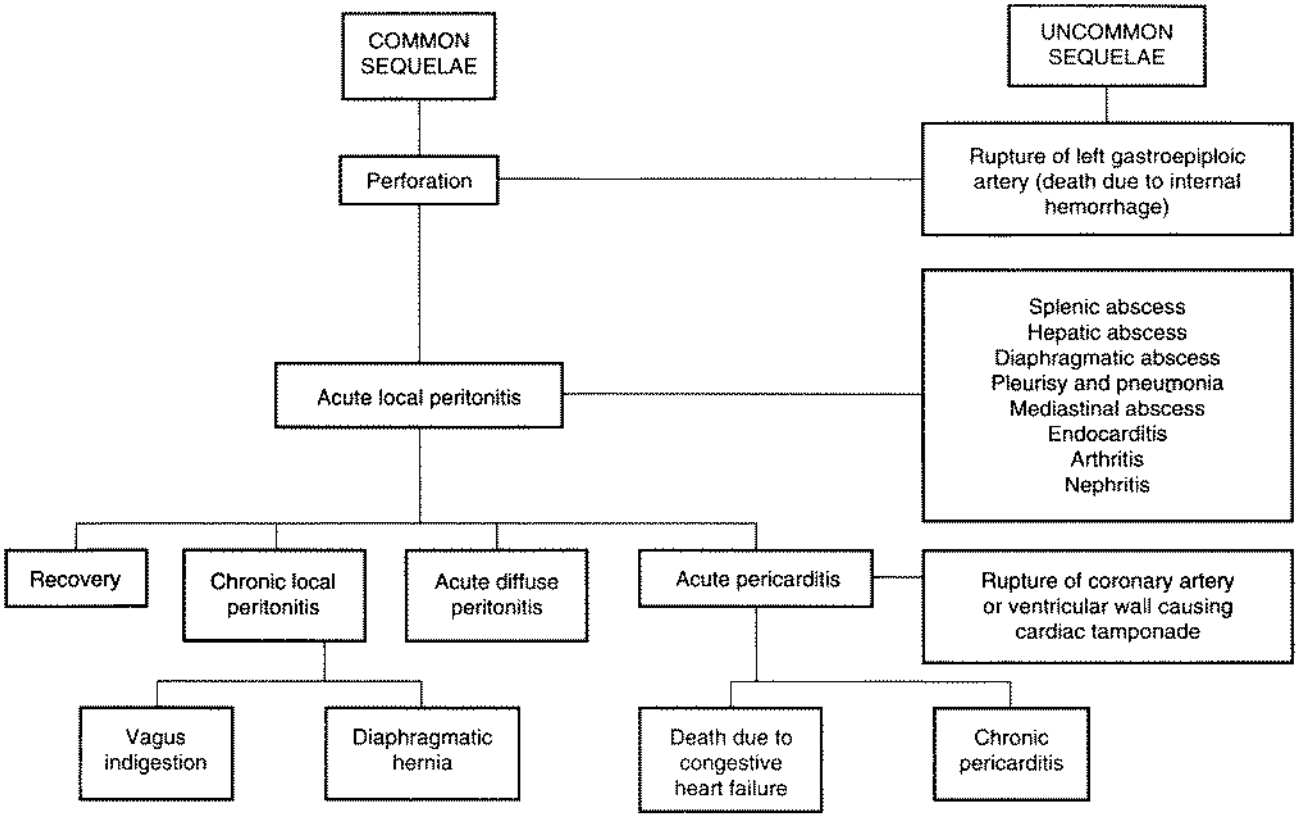

Fig. 8-9 Sequelae of traumatic perforation of the reticular wall.

- **Diagnostic confirmation** Reticuloperitonitis and metallic foreign body.
- **Differential diagnosis list:**
  - *Acute local traumatic reticuloperitonitis* must be differentiated from simple indigestion, acute carbohydrate engorgement, acute intestinal obstruction, abomasal volvulus, pericarditis, acute pleuritis, perforated abomasal ulcer, postpartum septic metritis, pyelonephritis acute hepatitis, and acetonemia.
  - *Acute diffuse or generalized peritonitis* must be differentiated from those diseases causing severe toxemia or acid-base imbalance, dehydration, and shock, which include the following: carbohydrate engorgement, acute intestinal obstruction, advanced vagus indigestion, abomasal volvulus, perforated abomasal ulcer, and miscellaneous causes of generalized peritonitis.
  - *Chronic traumatic reticuloperitonitis* must be differentiated from early stages of vagus indigestion, hepatic abscessation, traumatic splenitis, chronic pneumonia and pleuritis, and miscellaneous causes of chronic peritonitis such as peritoneal abscesses secondary to intraperitoneal injections.
- **Treatment** Antimicrobials daily for several days, reticular magnet, and immobilization in stall to promote adhesions. Rumenotomy to remove foreign body if medical treatment is unsuccessful or in valuable animal.
- **Control** Prevent exposure of cattle to metallic foreign objects that can be ingested. Feed-processing equipment should be equipped with magnets to remove metallic foreign bodies.

In an abattoir survey of the gastrointestinal tract of 1491 slaughter cows in Denmark, foreign bodies were found in 16% of the cows. Of 286 foreign bodies, 11% were tire wires, 14% fencing wires, 5% screws, 9% nails, 37% mixed pieces of metal, 2% copper, and 22% remnants of boluses containing antiparasitic drugs. A significant association was found between the type of foreign body and the presence of lesions, and a significant association between the cross-section of the foreign body and the presence of lesions. There was also an association between the end shape of the foreign body and the presence of lesions. Tire wire was the most common traumatizing foreign body, because 81% of all lesions were associated with tire wires.

EPIDEMIOLOGY

Occurrence

Adult dairy cattle are most commonly affected because of their more frequent exposure but cases occur infrequently in yearlings, beef cattle, dairy bulls, sheep, and goats. In the series of 1400 referred to earlier, 93% were in cattle over 2 years old and 87% were in dairy cattle. In the Danish abattoir survey of cows (see earlier in Etiology), foreign body lesions were present in 10% of the cows. Magnets were found in only 7% of the cows. All magnets collected iron filings and fencing wire (30%), and "other pieces of metal" (39%) were the predominant contents of the magnet. There were no lesions in 97% of the cows with magnets, and a significant association was found between the use of magnets and the absence of lesions.

Reticuloperitonitis is much more common in cattle fed on prepared feeds, especially those fed inside for part of the year. It is almost unknown in cattle fed entirely on pasture. Accordingly, it is much more common in the winter months in the Northern Hemisphere. The incidence is much lower in sheep and goats because they are rarely fed chopped forages.

The incidence is usually sporadic but outbreaks have occurred when sources of wire have become mixed into feed supplies, as in the case of perforation of the alimentary tract by pieces of tire wire. Over a period of 6 months, 30% of 170 lactating dairy cows in one herd exhibited clinical signs suggestive of hardware disease associated with the ingestion of tire wire in the feed supplies.

Risk Factors

There are few studies of the epidemiology of traumatic reticuloperitonitis. The effects of 23 veterinary diagnoses, host characteristics, and production were examined on the risks of ruminal acidosis and traumatic reticuloperitonitis. The lactational incidence risk for the disease in Finnish Ayrshire dairy cattle was 0.6%, which is similar to observations made in Holstein Friesian cows. The risk of the disease in the former study increased with early metritis, nonparturient paresis, ketosis, acute and chronic mastitis, and foot and leg problems. It is unknown how metritis and mastitis could be risk factors for traumatic reticuloperitonitis. The median day of occurrence was on 113 days after calving, which makes it unlikely that calving was a risk factor. Similarly, dystocia was not found to be a risk factor.

When several or more cases occur in a cluster outbreak, the nature of the feed supply should be considered as a risk factor. The use of used tires to secure plastic sheeting over silage piles may be an important risk factor.

Economic Importance

The disease is economically important because of the severe loss of production it causes and the high mortality rate. Many cases go unrecognized and many more make spontaneous recoveries. In industrialized countries, metallic foreign bodies may be present in the reticulum in up to 90% of normal cattle, and residual traumatic lesions may be present in as many as 70% of dairy cows. Among the clinically affected animals, about 25% develop incurable complications. The other 75% can be expected to recover completely with conservative treatment or routine surgical intervention.

PATHOGENESIS

Ingestion of Foreign Body

Lack of oral discrimination by cattle leads to the ingestion of foreign bodies that would be rejected by other species. Swallowed foreign bodies may lodge in the upper esophagus and cause obstruction or in the esophageal groove and cause vomiting, but in most instances they pass to the reticulum. Radiologic examination of goats that have been fed foreign bodies experimentally indicate that they may first enter various sacs of the reticulorumen before reaching the reticulum. Many lie there without causing harm but the honeycomb-like structure of the reticulum provides many sites for fixation of the foreign body, and contractions of the reticulum are sufficient to push a sharp-pointed object through the wall.

Penetration of Reticulum

Most perforations occur in the lower part of the cranial wall of the reticulum but some occur laterally in the direction of the spleen and medially toward the liver.

If the reticular wall is injured without penetration to the serous surface, no detectable illness occurs, and the foreign body may remain fixed in the site for long periods and gradually be corroded away. A piece of wire can disappear in 6 weeks, but certain nails last much longer and are unlikely to corrode away in less than 1 year. The ease with which perforation occurs has been illustrated by the artificial production of the disease. Sharpened foreign bodies were given to 10 cows in gelatin capsules. Of 20 pieces of wire and 10 nails, 25 were found in the reticulum. Of the 20 pieces of wire, 18 had perforated or were embedded in the wall or plicae. Only one of the nails was embedded. Complete perforations were caused by 13 foreign bodies and incomplete by 6. All cows suffered at least one perforation, showed clinical signs of acute local peritonitis, and recovered after surgical removal of the foreign bodies.

Many foreign bodies may not remain embedded but are commonly found free in the reticulum if surgery is performed about 72 hours after illness commences. This may be from necrosis around the penetrating object and the reticular contractions moving the foreign body back into the reticulum. Objects that are deeply embedded or have kinks, barbs, or large diameters tend to remain in situ and cause persistent peritonitis.

Acute Local Peritonitis

The initial reaction to perforation is one of acute local peritonitis and, in experimentally

induced cases, clinical signs commence about 24 hours after penetration. The peritonitis causes ruminal atony and abdominal pain. If the foreign body moves back into the reticulum, spontaneous recovery may occur.

Resolution of acute fibrinous local peritonitis is characterized by the development of **fibrous adhesions**, which gradually become long, stringy strands over a period of weeks and months; **motility of the reticulum is restored** and the animal may recover fully. Follow-up ultrasonographic examinations of cows with traumatic reticuloperitonitis in which rumenotomies were done showed that the adhesions disappeared in most of the animals by 6 months.

Depending on the severity of the local peritonitis, the ventral aspect of the reticulum becomes adherent to varying degrees to the abdominal floor and diaphragm. This results in **decreased reticular motility**. Ultrasonography of cows with traumatic reticuloperitonitis reveals that the **biphasic contractions of the reticulum are slower than normal or indistinct and the number of contractions are reduced**. **Reticular abscesses are common complications** and may be located between the reticulum and the ventral body wall, between the reticulum and the right thoracic wall, and between the reticulum and the spleen. **Persistent local peritonitis** with or without abscesses results in reduced reticulorumen motility, inappetence to anorexia, a capricious appetite (may eat hay not concentrate), chronic ruminal tympany, persistent mild fever, abdominal pain on deep palpation, and changes in the hemogram and feces. Immobilization of the reticulum impairs the clearance function of the reticulum, which results in the passage of poorly comminuted feces characterized by an increased proportion of large particles.

Generalized Peritonitis and Extension of Disease

Spread of the inflammation causing **generalized or diffuse peritonitis** may occur in cows that calve at the time of perforation and in cattle that are forced to exercise. Immobility is a prominent clinical finding and may be a protective mechanism so that adhesions are able to form and localize the peritonitis. Animals made to walk or transported long distances frequently suffer relapses when these adhesions are broken during body movements. Generalized peritonitis results in toxemia, alimentary tract stasis, dehydration, and shock.

During the initial penetration of the reticulum, the foreign body may penetrate beyond the peritoneal cavity and into the **pleural or pericardial sacs**. This may be more common in cows in advanced pregnancy than in nonpregnant cows, because of the gravid uterus, although this is uncertain. Complications such as pericarditis are most common in cows after the sixth month of pregnancy.

Details of the pathogenesis of the more common complications are presented under **traumatic pericarditis**, **vagus indigestion**, **diaphragmatic hernia,** and **traumatic abscess of the spleen and liver.** Less common sequelae include laceration or erosion of the left gastroepiploic artery causing sudden death from internal hemorrhage and the development of a diaphragmatic abscess, which infiltrates tissues to the ventral abdominal wall at the xiphoid process, rupturing to the exterior and sometimes discharging the foreign body. Hematogenous spread of infection from a diaphragmatic abscess or chronic local peritonitis is a common cause of endocarditis and its sequelae of polysynovitis and arthritis, nephritis, and pulmonary abscessation. Penetration into the pleural cavity causes acute **suppurative pleuritis and pneumonia.** In rare cases the infection is localized to the mediastinum causing abscessation, which causes pressure on the pericardial sac and congestive heart failure. Rarely, the foreign body penetrates to the abomasum, causing abomasitis, pyloric stenosis, and abomasal ulceration. Even more rarely, puncture of the reticular vein by a migrating metal wire may lead to fatal hemorrhage causing sudden death.

CLINICAL FINDINGS

Acute Local Peritonitis

Characteristically, the onset is sudden with **complete anorexia** and a **marked drop in milk yield**, usually to about one-third or less of the previous milking. These changes occur within a 12-hour period and their abrupt appearance is typical. **Subacute abdominal pain** is common in most cases. The animal is reluctant to move and does so slowly. Walking, particularly downhill, is often accompanied by grunting. Most animals prefer to remain standing for long periods and lie down with great care; habitual recumbency is characteristic in others. **Arching of the back** occurs in about 50% of cases, along with the appearance of tenseness of the back and the abdominal muscles so that the animal appears gaunt or "tucked-up." **Defecation and urination cause pain,** and the acts are performed infrequently and usually with grunting. This results in constipation, scant feces, and in some cases retention of urine. Rarely, acute abdominal pain with kicking at the belly and stretching occurs. In others there is recumbency and reluctance to stand.

A **moderate systemic reaction is common** in acute localized peritonitis. The temperature ranges from 39.5°C to 40°C (103°F–104°F), rarely higher, the heart rate is about 80 beats/min, and the respiratory rate about 30 per minute. Temperatures above 40°C (104°F) accompanied by heart rates greater than 90 beats/min suggest severe complications. The respirations are usually shallow and, if the pleural cavity has been penetrated, are painful and accompanied by an audible expiratory grunt.

Rumination is absent and reticulorumen movements are markedly depressed and usually absent. The rumen may appear to be full because of the presence of a **free-gas bloat** with moderate distension of the left paralumbar fossa. On palpation of the fossa, the ruminal gas cap is usually larger than usual and the rumen contents more doughy than normal. Deep palpation of the gas cap in the fossa may be required to feel the rumen pack below the gas cap.

Pain can be elicited by deep palpation of the abdominal wall just caudal to the xiphisternum. Palpation is done using short, sharp pushes with the closed fist or knee over an imaginary band about 20 cm wide covering the ventral third of the abdomen from the left to the right side with the cranial border of the band being the point just caudal to the xiphisternum. This area should be probed with at least six deep palpations on both sides of the abdomen while listening with a stethoscope over the trachea for evidence of a grunt. Pinching the withers to cause depression of the back and eliciting a grunt is also an effective diagnostic aid, except in large adult cows and bulls; for these the sharp elevation of a solid rail held horizontally under the abdomen is a useful method for eliciting a grunt. A positive response to any of these tests is a grunt of pain, which may be audible some distance away but is best detected by auscultation of the trachea. Rarely, a grunt may also be audible by auscultation over the trachea when infrequent reticulorumen contractions occur.

The course of acute local peritonitis is short and the findings described previously are most obvious on the first day; in most cases they subside quickly and may be difficult to detect by the third day. In these cases, in addition to persistent anorexia and ruminal atony, the most constant finding is the abdominal pain, which may require deep palpation for its demonstration. In cases that recover spontaneously or respond satisfactorily to conservative treatment there may be no detectable signs of illness by the fourth day.

Chronic Local Peritonitis

In chronic peritonitis the appetite and milk yield do not return to normal after prolonged therapy with antimicrobials. The body condition is usually poor, the feces are reduced in quantity, and there is an increase in undigested particles. In some cases, the temperature may be within the normal range, which makes the diagnosis uncertain. A persistent slightly elevated temperature is supportive evidence of the presence of a chronic inflammatory lesion. The grunt test may be positive or negative; often it is uncertain. The gait may be slow and careful and, occasionally, grunting may occur during rumination,

defecation, and urination. Rumination activities are infrequent, the rumen is usually smaller than normal, chronic moderate bloat is common, and there is ruminal atony or some moderate reticulorumen activity.

Reticular abscesses in cows are characterized by poor body condition, a relatively full rumen but with reduced ruminal contractions or almost complete ruminal atony, persistent mild bloat, an arched back with a tense abdomen and a grunt indicating abdominal pain, and undigested particles in the feces. Most have a clinical history of not responding to prolonged therapy with antimicrobials. These can be diagnosed with radiography and ultrasonography.

Rectal Examination

Rectal examination of cattle with acute or local traumatic reticuloperitonitis may cause a painful grunt when the animal strains during the examination. The feces are usually dry and firm and covered by a thin coating of mucus because of prolonged retention. In acute localized peritonitis the rumen may feel larger than normal and the gas cap is easily palpable. In acute and chronic generalized peritonitis, fibrinous adhesions may be palpable between the rumen and the left abdominal wall or between loops of intestine, or in the pelvic cavity.

Acute Diffuse (Generalized) Peritonitis

Acute diffuse peritonitis is characterized by the appearance of profound toxemia within a day or two of the onset of local peritonitis. Alimentary tract motility is reduced, mental depression is marked, and the temperature is elevated or subnormal in severe cases, especially those that occur immediately after calving. The heart rate increases to 100 to 120 beats/min and a painful grunt may be elicited by deep digital palpation at almost any location over the ventral abdominal wall. This stage is usually followed by rapid collapse and peripheral circulatory failure and an absence of pain responses. Terminally, recumbency and depression are common.

Sudden Death

There is a record of sudden death in a 20-month-old pregnant heifer in which the reticular vein was punctured by a migrating piece of metal wire, causing fatal hemorrhage into the reticulum. At necropsy, a large blood clot was present in the reticulum, the rumen contents were red-brown, and no reticular adhesions were present.

Iatrogenic Reticulitis

There is a record of iatrogenic reticulitis that occurred as a result of the oral administration of intraruminal anthelmintic boluses, which may have lodged in the reticulum and become filled with other foreign objects ingested by the animal, resulting in a syndrome similar to acute traumatic reticuloperitonitis. Inappetence, reduced milk production, reduced reticulorumen motility, abdominal pain, and scant feces were present. On exploratory rumenotomy the reticulum contained two cylindrical boluses filled with stones, nuts, and bolts. Removal of the boluses was followed by prompt recovery.

CLINICAL PATHOLOGY

Hemogram

The total and differential leukocyte counts provide useful diagnostic and prognostic data. The differential leukocyte count is usually considerably more indicative of acute peritonitis than the total count.

In **acute local peritonitis** a neutrophilia (mature neutrophils above 4000 cells/μL) and a left shift (immature neutrophils above 200 cells/μL) are common. This is a **regenerative left shift**. Both the neutrophilia and the left shift will be increased on the first day and will last for up to 3 days, when in uncomplicated cases the count begins to return to normal. In chronic cases the levels do not return completely to normal for several days or longer periods and there is usually a moderate leukocytosis, neutrophilia, and a monocytosis.

In **acute diffuse peritonitis** a leukopenia (total count below 4000 cells/μL) with a greater absolute number of immature neutrophils than mature neutrophils (**degenerative left shift**) occurs, which suggests an unfavorable prognosis if severe. The degree of lymphopenia (lymphocyte count below 2500–3000 cells/μL) is an indication of a stress reaction to inflammation.

Plasma Protein, Fibrinogen, Acute Phase Reactants, and Coagulation Profile

There is a significant difference in total plasma protein (TPP) levels between cattle with traumatic reticuloperitonitis and those with other diseases of the gastrointestinal tract that might be confused with the former. The mean plasma protein concentrations, measured before surgery, were 88 ± 13 g/L for traumatic reticuloperitonitis and 77 ± 12 g/L for controls. In severe diffuse peritonitis the fibrinogen levels may be increased up to 10 to 20 g/L.

Cutoff points for TPP and plasma fibrinogen (PF) were determined to differentiate between traumatic reticuloperitonitis and other gastrointestinal diseases with similar clinical findings. There was moderate negative dependence between sensitivities of TPP and PF at the 8.8 g/dL and 766 mg/dL cutoff points, and mild negative dependence between their specificities at the 7.8 g/dL and 691 mg/dL cutoff points, respectively. Acceptable accuracy (98% or 86% specificity with 62% or 88% sensitivity, respectively) was obtained with serial interpretation of the tests.

Cattle with active peritonitis caused by traumatic reticuloperitonitis have an acute phase response, manifested as an increased plasma concentration of SAA and haptoglobin, and a decreased plasma albumin concentration. Optimal cut points for the diagnosis of traumatic reticuloperitonitis were >68 μg/mL for SAA (sensitivity = 1.00; specificity = 0.86) and >0.74 g/L for serum haptoglobin concentration (sensitivity = 1.00; specificity = 0.86),[1] with PF concentration > 380 mg/dL having a lower test sensitivity and specificity.

Affected cattle have prolonged prothrombin time, thrombin time, and activated partial thromboplastin time and thrombocytopenia, indicating the presence of abnormal coagulation.[2] This was attributed to diffuse peritonitis and hepatocellular dysfunction. Cattle with traumatic reticuloperitonitis also have increased serum nitric oxide concentration and decreased total antioxidant capacity, which probably reflects the diverse bacterial population associated with the peritonitis.[3]

Abdominocentesis and Peritoneal Fluid

Abdominocentesis and analysis of peritoneal fluid can be a valuable diagnostic aid. The best site for abdominocentesis is uncertain because the rumen occupies a large portion of the ventral abdominal wall and avoiding penetration of it is difficult. Cattle have a low volume of peritoneal fluid and failure to obtain a sample is not unusual. Empirically, the best sites are those in which, on an anatomic basis, there are recesses between the forestomachs, abomasum, diaphragm, and liver. These are usually 10 to 12 cm caudal to the xiphisternum and 10 to 15 cm lateral to the midline. A blunt-ended teat cannula is recommended, but with care and caution a 16-gauge or 18-gauge 5-cm hypodermic needle may also be used. The hair of the site is clipped, the skin is prepared aseptically, and a local anesthetic is applied. The skin in incised with a stab scalpel and the cannula is pushed carefully and slowly through the abdominal wall. The latter will twitch and a "pop" will be felt when the peritoneum is punctured. When the cannula is in the peritoneal cavity, the fluid may leak out without the aid of a vacuum. If it does not, a syringe may be used to apply a vacuum while the needle is manipulated in an attempt to locate some fluid.

If no fluid can be obtained, a trocar and cannula 80 mm long and with a 4-mm internal diameter can be used with success. The trocar and cannula are inserted into the abdomen, the trocar is removed and an 80-cm long 10-French gauge infant feeding tube is inserted into the abdomen through the cannula, leaving about 10 to 20 cm outside. The tube acts as a wick and within several minutes fluid can be collected into vials. At least three different sites should be attempted to obtain peritoneal fluid. Peritonitis in cattle is characterized by a marked fibrinous response and localization of a

lesion, and the amount of exudative fluid available at the abdominocentesis sites may be minimal. Thus the failure to obtain fluid does not preclude the presence of peritonitis.

Laboratory evaluation of peritoneal fluid consists of determinations of total white blood cell count, differential cell count, total protein, and culture for pathogens. The interpretation of the analysis of the peritoneal fluid can be unreliable because only a few correlations have been made between the laboratory findings and the presence or absence of peritoneal lesions. A nucleated cell count above 6000 cells/μL and total protein above 3 g/dL is consistent with the diagnosis of peritonitis in 80% of cases. Using a differential cell count, a relative neutrophil count more than 40% and a relative eosinophil count less than 10% was frequently associated with the diagnosis of peritonitis. A D-dimer concentration of peritoneal fluid higher than the reference range (0–0.6 mg/L) provides an excellent method for identifying the presence of peritonitis in cattle, with sensitivity = 0.96 and specificity = 0.99.[4]

RADIOGRAPHY OF CRANIAL ABDOMEN AND RETICULUM

Radiologic examination of the reticulum is an accurate diagnostic method for the evaluation of cattle with suspected traumatic reticuloperitonitis and should be done with the animal standing. Although there are some reports of reticular radiography with the cow in dorsal recumbency, this method is not recommended because of the potential for breaking down adhesions and disseminating peritonitis throughout the entire abdomen, as well as decreased diagnostic accuracy. There are also technical difficulties in positioning an unsedated animal in dorsal recumbency, and sedatives are not recommended because of the risk of aspiration pneumonia. The availability of ultrasonographic equipment and lack of adequate radiographic equipment in private veterinary practices has resulted in the decreased use of radiography to diagnose traumatic reticuloperitonitis. However, the technique provides clinically useful information for valuable animals that may warrant referral to a veterinary medical center.

The **cranioventral abdomen of cattle** can be evaluated using two cranial abdominal and one caudal thoracic radiograph. An x-ray machine with a capacity of 1000 to 1250 mA and 150 kV is necessary, which is usually only available in veterinary teaching hospitals. However, such techniques may be appropriate in valuable animals in which an accurate diagnosis and prognosis for surgical treatment may be desirable. In a consecutive series of standing lateral cranial abdominal radiographs, the sensitivity and specificity for detecting traumatic reticuloperitonitis or pericarditis was 83% and 90%, respectively. These values are higher than those achieved with the animal being placed dorsal recumbency. In standing lateral radiographs, an enlarged reticulum was associated with a final diagnosis of vagal indigestion. Alteration in reticulodiaphragmatic separation does not correlate with any specific disease process. The presence of focal perireticular gas collections and reticular foreign bodies greater than 1 cm in length unattached to a magnet were good indicators of traumatic reticuloperitonitis. Radiography is best suited for identification of radiodense foreign bodies in and outside the reticulum (these cannot be visualized ultrasonographically). A magnet should be administered before radiographs are taken in cattle with a magnet; orally administered magnets rapidly find their way to the reticulum and in this location provide a helpful anatomic landmark and indicate if wire located in the reticulum is free floating or imbedded in the reticular wall (see Fig. 8-16). There is minimal value in performing a rumenotomy if radiographs identify that a wire is fully attached to a magnet and therefore not capable of repenetration of the reticulum.

Features found to be reliable in the diagnosis of traumatic reticuloperitonitis using lateral radiographs of the reticulum include the following:

- **Atypically positioned foreign bodies**
- **Abnormal gas shadows in the region of the reticulum**
- **Depressions in the cranioventral margin of the reticulum**

The reticulum is often markedly displaced caudally from the diaphragm or dorsally or caudodorsally from the ventral abdominal wall. Space-occupying masses of the density of soft tissue, with or without gas inclusions, gas shadows, and gas–fluid interfaces in the region of the reticulum, were highly predictive of peritonitis (specificity 97%, positive predictive value 96%).

ULTRASONOGRAPHY OF THE RETICULUM

Ultrasonography is a suitable method for investigation of reticular contractions in healthy ruminants and in cattle for the diagnosis of traumatic reticuloperitonitis.

The reticulum and adjacent organs of cows can be examined with ultrasonography using a 3.5-MHz linear transducer applied to the ventral midline of the thorax over the sixth and seventh intercostal spaces and from the left and right sides of the midline. It may not be possible to image the reticulum in large cows in good body condition because of the high proportion of fat in the muscle layers. In older cows, calcification of the xiphisternum may interfere with imaging. The most common reason for being unable to visualize the reticulum in sick animals is the displacement of the reticulum by a markedly distended rumen or by space-occupying lesions such as abscesses and fibrin-containing effusions. The pattern, number, amplitude, and duration of the interval between contractions can be visualized. The contour of reticulum, the reticular contractions, and the organs adjacent to the reticulum can be imaged. The biphasic reticular contractions can be visualized at the rate of four contractions during a 4-minute period. During the first incomplete contraction, the reticulum contracts by a mean of about 7.2 cm, and during the second contraction the reticulum disappears from the screen.

Ultrasonography for Traumatic Reticuloperitonitis

In contrast to radiography, ultrasonography provides more precise information about the contour of the reticulum and reticular motility. In cattle with traumatic reticuloperitonitis, ultrasonography can be used to identify morphologic changes in the region of the cranial, ventral, or caudal reticular wall. The caudoventral reticular wall is the most frequently affected, often in association with the craniodorsal blind sac of the rumen. The changes in the contour of the reticulum depend on the severity of the inflammatory changes.

The reticulum can be visualized in more than 90% of cows in spite of interference by the ribs and sternum. In cows with disturbed reticular motility, biphasic contractions are slower than normal, or indistinct, and the number of contractions is reduced. Fibrinous material appears as echogenic deposits, sometimes accompanied by hypoechogenic fluid. Reticular abscesses have an echogenic capsule with a hypoechogenic center. Involvement of the spleen, omasum, liver, and abomasum may also be imaged. Neither magnets nor foreign bodies can be visualized by ultrasonography.

Reticular activity is almost always affected in cattle with traumatic reticuloperitonitis. The frequency, amplitude, or velocity of contractions, singly or combined, may be abnormal. The frequency can be reduced from 3 to 2, 1, or no contractions per 3 minutes (normal rate is approximately one contraction per minute). The reticular contraction rate is increased to 1.5 per minute at the onset of feeding. The reduction in the amplitude of contractions varies: when formation of adhesions is extensive, reticular contractions appear indistinct. Although the pattern of biphasic contraction is often maintained, the reticulum contracts only 1 to 3 cm. The velocity of reticular contractions may be normal but can be markedly reduced. In cattle with reticuloomasal obstruction caused by a foreign body, the frequency of reticular contractions may be increased.

Reticular abscesses associated with traumatic reticuloperitonitis can be visualized by ultrasonography (Fig. 8-10). The amplitude of reticular contractions is reduced to only 1 to 3 cm, the reticulum is displaced from

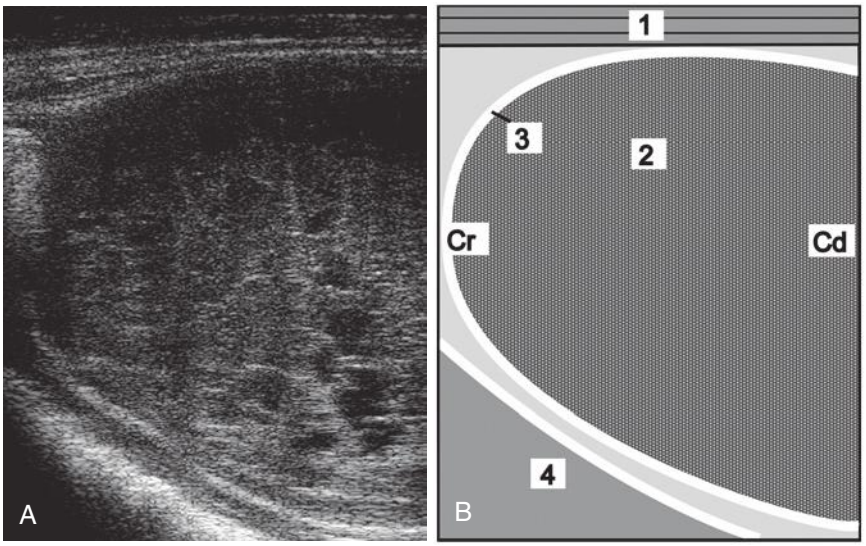

Fig. 8-10 **A, and B,** Ultrasonogram and schematic of a reticular abscess in a cow with chronic traumatic reticuloperitonitis. The abscess is between the reticulum and the ventral abdominal wall. The ultrasonogram was obtained from the sternal region with a 5.0-MHz linear transducer. *1,* Ventral abdominal wall; *2,* abscess; *3,* capsule of the abscess; *4,* reticulum; *Cr,* cranial; *Cd,* caudal. the ventral body wall, and the abscesses have hypoechogenic centers and echogenic capsules.

Peritoneal effusion is visible as an accumulation of fluid without an echogenic margin and restricted to the reticular area. Depending on the fibrin and cell content, the fluid may be anechoic or hypoechogenic. Fibrinous deposits are easily identified in the fluid, and bands of fibrin are sometimes seen within the effusion. Occasionally, the peritoneal effusion is considerable and extends to the caudal abdomen.

The spleen, particularly its distal portion, is often affected. Fibrinous changes are frequently seen as echogenic deposits of varying thickness, often surrounded by fluid, between the spleen and reticulum or rumen. The spleen may be covered by fibrinous deposits. Occasionally, one or more splenic abscesses are visible, and the vasculature may be dilated, indicating splenitis.

Ultrasonography and Radiography of Cattle With Traumatic Reticuloperitonitis

These two techniques have been compared in cows with traumatic reticuloperitonitis. The major advantages of radiography are that metallic foreign bodies can be visualized and their position determined. It has a specificity of 82%, a positive predictive value of 88%, and a sensitivity of 71%. Abnormal gas shadows or gas–fluid interfaces observed on radiographs are highly diagnostic for the disease and have a specificity of 97% and positive predictive value of 88%. However, they are seldom seen on radiographs and their sensitivity is only 19%. The position of the reticulum is a good criterion for the diagnosis of traumatic reticuloperitonitis, with a specificity of 80% and a positive predictive value of 82%. Thick-walled changes or abscessation should be suspected when the reticulum is displaced caudodorsally from the sternum. Changes in the contour of the reticulum such as indentations are highly suggestive of inflammation, with a specificity of 95% and positive predictive value but a low sensitivity of only 34%.

The major advantage of ultrasonography is being able to visualize and assess reticular motility. Even in the presence of severe adhesions and abscessation, the reticulum may maintain its basic contractile rhythm, but it will be quite reduced. Abscesses have an echogenic capsule of varying width and a central cavity filled with hypoechogenic material. Purely fibrous deposits are echogenic, and fibrinous deposits containing an accumulation of fluid from inflammatory processes are echogenic interspersed with hypoechogenic accumulations of fluid (Fig. 8-11). Radiography and ultrasonography complement each other, and the combined results can be used to decide whether an exploratory laparotomy is indicated, if the animal should be treated conservatively with antibiotics, or if it should be slaughtered for salvage.

METAL DETECTION

Metal detectors were used at one time to aid in the diagnosis of traumatic reticuloperitonitis. Ferrous metallic foreign bodies can be detected with metal detectors but the instruments are of limited use because most dairy cows eating chopped forages are positive for metal over the reticular area.

LAPAROSCOPY

Right flank laparoscopy using a flexible fiberoptic laparoscope, 14 mm in diameter and 1.1 m in working length, is a reliable diagnostic aid for the presence of traumatic reticuloperitonitis, but the diagnostic technique has been replaced by ultrasonography of the reticular region.

NECROPSY FINDINGS

Localized traumatic reticuloperitonitis is characterized by varying degrees of locally extensive fibrinous adhesions between the cranioventral aspects of the reticulum and the ventral abdominal wall and the diaphragm. Adhesions and multiple abscesses may extend to either side of the reticulum involving the spleen, omasum, liver, abomasum, and ventral aspects of the rumen. Large quantities of turbid, foul-smelling peritoneal fluid may be present, containing fibrinous clots. Some cases of reticular abscesses are solitary and there are adhesions between the reticulum, diaphragm, and ventral body wall, which are strictly localized. The size of the abscess varies. It may be from 5 to 10 cm in diameter or a single one may be irregularly shaped and measure 30 × 10 × 10 cm, along with multiple smaller ones measuring around 3 × 3 × 3 cm. The foreign body can usually be found perforating the cranioventral aspect of the reticulum, although it may have fallen back into the reticulum, leaving only the perforation site and its surrounding inflammation as evidence of the site of penetration. A reticular magnet with many pieces of metallic foreign bodies stuck to it may be present in the reticulum, the mucosa of which is usually normal.

In **acute diffuse peritonitis** a fibrinous or suppurative inflammation may affect almost the entire peritoneal cavity with extensive fibrinous adhesions of various stages of development involving the forestomach, abomasum, small and large intestines, liver, bladder, reproductive tract, and pelvic cavity. Large quantities of turbid, foul-smelling fluid containing clots of fibrin are usually present. Loops of intestine and omenta are commonly stuck together by thick layers of fibrin.

DIFFERENTIAL DIAGNOSIS

Typical acute traumatic reticuloperitonitis is characterized by a sudden onset of complete anorexia, marked drop in milk production, mild fever, ruminal atony, pain on deep palpation of the ventral abdomen, an elevated leukocyte count with a left shift in the hemogram, and a peritoneal fluid sample that indicates inflammation.

However, the times at which cases of traumatic reticuloperitonitis are seen varies from day 1, when the syndrome is typical, to day 3 or 4, by which time the acuteness has subsided so much clinically that confusion with other diseases is a significant possibility. The sudden onset of anorexia and marked drop in milk production will usually be noted in lactating dairy cattle but not in dry dairy cattle or beef cattle, including mature bulls whose feed intake and behaviors are not monitored daily. In these animals the clinical findings can change in a few days and be characterized by anorexia to inappetence, normal temperature, ruminal hypotonicity or atony, and no evidence of abdominal pain on deep palpation of the abdomen.

The clinician must review the history carefully, conduct a thorough clinical examination, and attempt to intensify the diagnostic efforts on those abnormalities that are present.

The differential diagnosis of gastrointestinal dysfunction of cattle is summarized in Table 8-2. An algorithm for the causes of grunting in cattle is shown in Fig. 8-12.

Acute local traumatic reticuloperitonitis

Acute local traumatic reticuloperitonitis must be differentiated from those diseases in which sudden anorexia, sudden drop in milk production, ruminal atony, abdominal pain, and abnormal feces are common. They include the following:

- **Simple indigestion** characterized by sudden anorexia or inappetence, normal mental state, full rumen but atonic, perhaps uncomfortable if ingested large quantities of palatable feed like fresh silage, normal vital signs, abnormal feces, and spontaneous recovery in 24 hours are typical.
- **Obstruction of reticuloomasal orifice** with a foreign body such as a roll of polyethylene twine causes intermittent inappetence, a slightly enlarged rumen with normal motility, slight reduction in the amount of feces, a decrease in milk yield for 24–48 h followed by a return to normal and then subsequent relapses. A grunt is not present; the temperature, heart, and respiratory rates are normal; and the hemogram is normal. Obstruction of the reticuloomasal orifice with foreign bodies such as rope can cause distension and hypermotility of the rumen and persistent

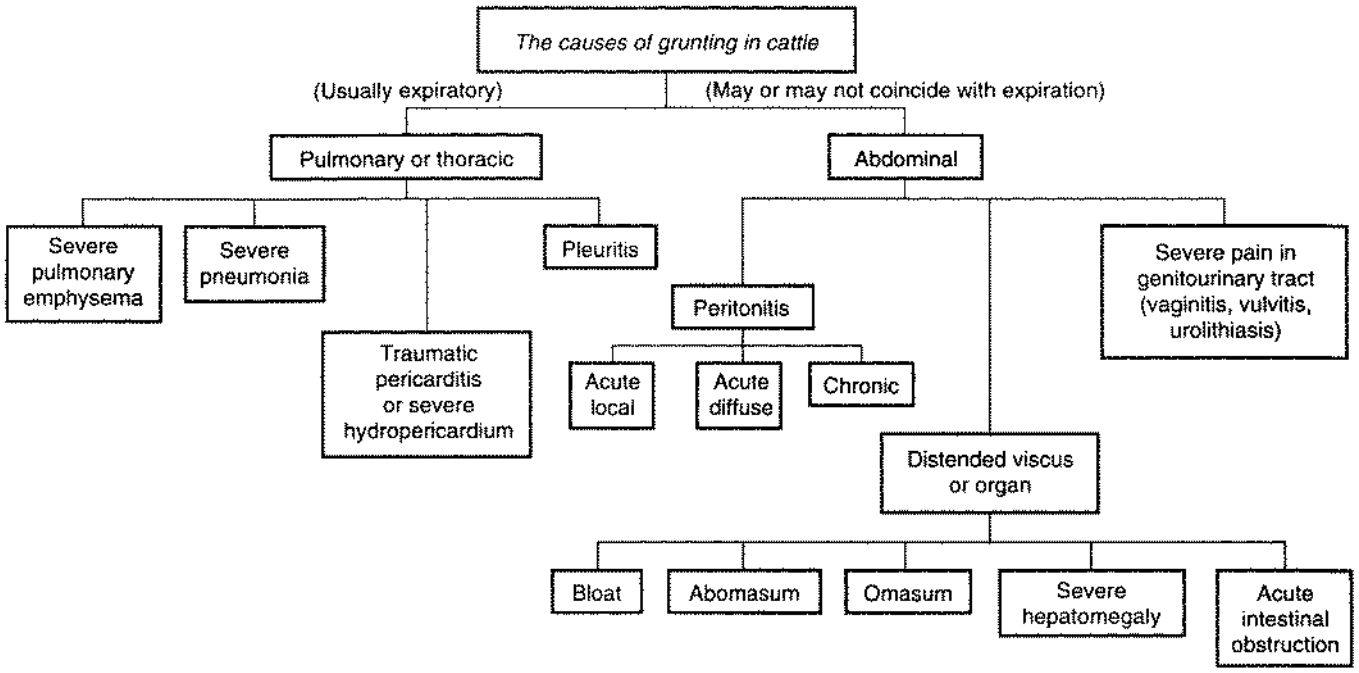

Fig. 8-12 Causes of grunting in cattle.

vomiting. A rumenotomy must be done to make the diagnosis.

- **Acute carbohydrate engorgement** characterized by sudden anorexia, diarrhea and dehydration, weakness, tachycardia, staggering, ruminal distension and atony, fluid-splashing sounds in the rumen with a rumen pH of less than 5, and a history of access to grain.
- **Acute intestinal obstruction** characterized by sudden anorexia, mild abdominal pain perhaps with kicking at the abdomen and stretching, ruminal atony, mild dehydration, scant feces or complete absence of feces, straining on rectal examination, dark bloodstained feces, and perhaps distended loops of intestine palpable on rectal examination.
- **Abomasal volvulus (following right-side dilatation)** characterized by anorexia, dehydration, tachycardia, distended right abdomen, ping audible over right flank, distended viscus palpable on rectal examination. Usually in lactating dairy cows a few weeks after parturition and following the clinical findings of right-side dilatation of the abomasum that lasts several days culminating in the volvulus but may occur spontaneously in some cows with no immediate history of previous illness.
- **Pericarditis.** Continued high fever, toxemia, anorexia, tachycardia, and muffled heart sounds suggest pericarditis, which is marked by markedly elevated total leukocyte and neutrophil counts. In pericarditis, the heart sounds are muffled and the typical to and fro fluid-splashing sounds are audible. The jugular veins are engorged and other signs of congestive heart failure such as anasarca are present. Pericardiocentesis to obtain foul-smelling, turbid fluid is diagnostic.
- **Acute pleuritis** is characterized by a fever, toxemia, anorexia, painful respirations that may be accompanied by a grunt, pain on digital palpation of intercostal spaces, ruminal atony, and abnormal and muffled lung sounds. Fluid on thoracentesis.
- **Perforated abomasal ulcer** causes acute local peritonitis characterized by marked pain on palpation over a much larger area of the abdominal wall, and in the early stages is most marked on the right-hand side. If, as is usual, the peritonitis becomes diffuse, the syndrome cannot be distinguished clinically from that caused by traumatic reticuloperitonitis. Extension from a metritis to involve the peritoneum is suggested by other signs of the primary disease.
- **Postpartum septic metritis** occurs a few days after parturition and is characterized by anorexia, fever, tachycardia, ruminal hypotonicity to atony, reduced amount of feces and foul-smelling vaginal discharge, and retained placenta may be present. Very important to examine the uterus vaginally for the presence of the placenta, which may be protruding through the cervix.
- **Acute local peritonitis** caused by penetration of the uterine wall by a catheter or of the rectal wall by a foreign body thrust sadistically into the rectum may be difficult to differentiate unless the painful area of the peritoneum can be determined. Acute local peritonitis can be differentiated from indigestion, acute ruminal impaction and acetonemia by the presence of fever, local abdominal pain, and the abrupt fall in milk yield and appetite.
- **Pyelonephritis** is occasionally accompanied by mild abdominal pain but can be distinguished by the presence of pus and blood in the urine.
- **Acute hepatitis** or **severe hepatic abscess** is characterized by anorexia, fever, decreased ruminal movements, reluctance to move, a painful grunt on deep palpation over the cranial aspects of the right lower flank, icterus if obstruction of the bile ducts has occurred, and a poor response to therapy. A marked neutrophilia is typical of hepatic abscessation secondary to traumatic reticuloperitonitis.
- **Acetonemia**. Traumatic reticuloperitonitis usually causes a secondary acetonemia when it occurs during early lactation, and the presence of ketonuria should not be used as the sole basis for differentiation of the diseases. Differentiation may be extremely difficult if the peritonitis is of 3–4 days' duration. Response to treatment may also serve as a guide. The history is often helpful; the appetite and milk yield fall abruptly in traumatic reticuloperitonitis but slowly over a period of several days and not to the same degree in acetonemia.

Acute diffuse or generalized peritonitis

Acute diffuse peritonitis is characterized by anorexia, fever, toxemia, tachycardia, dehydration, weakness leading to recumbency, distended abdomen, ruminal atony, spontaneous grunting or a grunt on deep palpation over the abdomen, fluid-splashing sounds and pings on auscultation and percussion or ballottement of the abdomen caused by ileus, scant feces, perhaps palpable fibrinous adhesions on rectal palpation, profuse quantities of abnormal peritoneal fluid, and marked changes in the hemogram. It must be differentiated from those diseases causing severe toxemia or acid-base imbalance, dehydration, and shock, which include carbohydrate engorgement, acute intestinal obstruction, advanced vagus indigestion, abomasal volvulus, perforated abomasal ulcer, and miscellaneous causes of generalized peritonitis.

Chronic reticuloperitonitis

The clinical findings of chronic traumatic reticuloperitonitis are not typical. Each chronic case may have a different combination of clinical findings, which makes the diagnosis uncertain. The clinical findings that may be present include inappetence to anorexia, mild fever, loss of body condition, lack of rumination, ruminal hypotonicity to atony, moderate bloat, scant feces containing increased amounts of undigested feed particles, possibly a grunt on deep palpation of the abdomen, and changes in the hemogram. The presence of abnormal peritoneal fluid is highly supportive. It must be differentiated from early stages of vagus indigestion, hepatic abscessation, traumatic splenitis, chronic pneumonia and pleuritis, and miscellaneous causes of chronic peritonitis such as peritoneal abscesses secondary to intraperitoneal injections.

TREATMENT

Two methods of treatment are in general use: conservative treatment with or without the use of a magnet and rumenotomy. Both have advantages and each case must be considered when deciding on the form of treatment to be used.

Conservative Medical Therapy

Conservative treatment comprises immobilization of the animal, administration of antimicrobials for the inflammation, and the oral administration of a magnet to immobilize the foreign body. Despite the decreased reticuloruminal motility, 85% of magnets are in the reticulum 1 to 4 days after administration, and 32% of penetrating foreign bodies are attached to the magnet. The cow is tied, stanchioned, or confined in a box stall for several days. Immobilization of the animal facilitates the formation of adhesions.

Antimicrobials

Penicillin or broad-spectrum antimicrobials given parenterally daily for 3 to 5 days are widely used with empirical success. Because of the high probability that a mixed gastrointestinal flora is the cause of the lesion, it is more rational to use a broad-spectrum antimicrobial such as the tetracyclines or trimethoprim-potentiated sulfonamides rather than procaine penicillin, which is commonly used because of cost and a short withdrawal period in the event that the animal does not respond favorably in a few days. For lactating dairy cattle, those antimicrobials with a short milk withdrawal period are desirable. However, there are no published clinical trials to indicate the preferential value of any particular antimicrobial. The general effect appears to be good and a high rate of recovery is recorded with antimicrobials parenterally combined with immobilization provided treatment is begun in the early stages of the disease.[5] Cows past their sixth month of pregnancy are unlikely to recover completely and commonly relapse.

Rumenotomy

Surgical removal of the foreign body through a rumenotomy incision is the optimal initial treatment and is, consequently, widely used as a primary treatment.[6] It has the advantage of being both a diagnostic procedure in the first instance and a definitive but satisfactory treatment. The recovery rate varies, depending on when the surgery is done relative to the

time of initial penetration, but is approximately the same as that obtained with the conservative treatment described earlier. In both instances, 80% to 90% of animals recover compared with about 60% in untreated animals. Failure to improve is usually from involvement of other organs or to the development of locally extensive peritonitis and reticular abscesses associated with persistent penetration of the foreign body or, uncommonly, generalized peritonitis.

Based on follow-up ultrasonography of cows that had surgery for traumatic reticuloperitonitis, the inflammatory adhesions resolved and disappeared in the majority of animals by 6 months. As a consequence, reticular function normalizes. In animals with severe adhesions, there is a marked disturbance of digesta passage and, in these animals, extensive abscesses are present.

Persistent penetration by the foreign body necessitates removal for optimum results, but a rumenotomy is necessary to determine the extent of the lesion. Radiography and ultrasonography as described earlier may assist in determining the presence and location of the foreign body. A single preoperative dose of antimicrobial such as potassium penicillin G at 10 million IU given intravenously is recommended to avoid complications after a rumenotomy in cattle.

The recovery rate after surgery is likely to be much lower if only complicated cases are selected for rumenotomy and conservative treatment is given to the early mild cases. In one series the recovery rate in the cases treated conservatively was 84% and in those difficult cases treated surgically it was 47%.

Drainage of Reticular Abscesses

Reticular abscesses may be drained through an ultrasound-guided transcutaneous incision.

Choice of Treatment

The choice of treatment is largely governed by economics and the facilities and time available for surgery. A rumenotomy, satisfactorily performed, is the best treatment but is unnecessary in many cases because of the tendency of the foreign body to return to the reticulum. A commonly used practice is to treat the animal conservatively for 3 days and if marked improvement has not occurred by that time to consider a rumenotomy. A rumenotomy is highly desirable in cows in the last 3 months of pregnancy if severe sequelae are to be avoided. Movement of the cow during the early stages of the disease is undesirable because of the risk of disrupting the adhesions that localize the infection.

Cases of chronic traumatic reticuloperitonitis are best treated by rumenotomy because of the probability that the foreign body is still embedded in the wall. Acute diffuse peritonitis is highly fatal, but if detected early daily treatment with broad-spectrum antimicrobials may be effective.

PREVENTION

All processed feed should be passed over magnets to remove metallic material before being fed to cattle. The use of synthetic string instead of wire has resulted in a major decrease in the incidence of the disease.

Reticular Magnets

Small cylindrical or bar magnets, 7.5 cm long by 1.0 to 2.5 cm diameter with rounded ends, are used to prevent reticuloperitonitis but are also used in acute cases to minimize penetration of the foreign body. When given orally to normal healthy animals, the magnets locate in the reticulum within a few days, where they remain indefinitely and maintain their magnetic pull. The magnets attract foreign bodies, which then do not penetrate the reticular wall as easily as when they are free. The extensive prophylactic use of these magnets in a dairy herd has reduced the incidence of the disease and its complications by 90% to 98%. The magnets are given to herd replacement heifers at 18 months to 2 years of age as part of a herd health program.

The effects of magnets in traumatic reticulitis was examined in the Danish study of cows at slaughter (see under Etiology). Two magnets tested were cylindrical cage magnets with different fields of magnetic force. Magnet I had a magnetic force of attraction of 110 mT; magnet II had a force of 210 mT. Magnets were found in only 7% of the cows. There were no lesions in 97% of the cows with magnets. Magnet II was superior to magnet I in attracting all types of foreign bodies, including tire wires. Thus the prophylactic use of magnets should be promoted to reduce the occurrence of foreign body lesions.

It is unlikely that magnets will extract a firmly embedded foreign body from the wall of the reticulum, but loosely embedded ones with long free ends may be returned to the reticulum and loose foreign bodies will be immobilized. The position of the foreign body within the reticulum greatly influences the efficacy of treatment with a magnet. A foreign body at an angle to the ventral aspect of the reticulum of more than 30 degrees is less likely to become attached to a magnet than a foreign body situated horizontally on the ventral aspect of the reticulum. There have been only a few reports of physical injury to the wall of the reticulum being caused by the magnets or the foreign bodies that may be attached to them. A compass can be used to locate the presence and position of the magnet.

TREATMENT AND CONTROL

Treatment

Oral administration of the strongest magnet possible to cattle without a magnet (check with compass) (R-1)

Procaine penicillin 22,000 U/kg BW IM daily for at least 5 days (R-1)

Oxytetracycline 16.5 mg/kg IV daily for at least 5 days (R-2)

Minimize movement by keeping confined in a small stall (R-2)

Rumenotomy and wire removal for cattle of higher economic value or after 3 days of medical treatment with no improvement (R-2)

Control

Routine oral administration of the strongest magnet possible to dairy cattle eating chopped feed (R-2)

Ensure feed chopping equipment have magnets attached to remove metal from feed (R-2)

BW, body weight; IM, intramuscularly; IV, intravenously.

VAGUS INDIGESTION

SYNOPSIS

Etiology Reticular adhesions from traumatic reticuloperitonitis and failure of passage of ingesta from the reticulorumen or abomasum resulting in accumulation of fluid in the forestomach and abomasum. Abomasal emptying defect in sheep (uncertain etiology).

Epidemiology Primarily mature dairy cattle; also in mature beef cows and bulls. Also occurs in sheep as abomasal emptying defect of uncertain etiology.

Signs Gradual distension of abdomen, especially left upper abdomen and bilateral aspects of ventral abdomen. Inappetence to anorexia and scant feces containing undigested long particles. Large L-shaped rumen viewed from rear. Hypermotility or hypomotility of the rumen and reticulum determined by auscultation or ultrasonography, respectively. Dehydration.

Clinical pathology Hemoconcentration, metabolic alkalosis with hypochloremia and hypokalemia, increased ruminal chloride levels.

Lesions Reticular adhesions. Enlarged rumen containing pasty and frothy material or fluid contents. Abomasum impacted with semidry ingesta.

Differential diagnosis
Ruminal distension with hypermotility: indigestion of late pregnancy, obstruction of the reticuloomasal orifice.
Ruminal distension with atony: chronic traumatic reticuloperitonitis.
Abomasal impaction: abomasal impaction, dietary in origin.
Omasal impaction: phytobezoars blocking the abomasal pylorus, abomasal ulceration without melena.

Treatment Fluid and electrolyte therapy, rumen lavage with large diameter tube, rumenotomy, drain reticular abscess, slaughter for salvage.

Control Prevent traumatic reticuloperitonitis.

ETIOLOGY

The etiology of vagus indigestion has been controversial but has been divided into two major subcategories of complications of traumatic reticuloperitonitis: vagal nerve injury and reticular adhesions, with the latter being the most common cause. In addition, there are some other causes.

Complications of Traumatic Reticuloperitonitis

Vagal Nerve Injury and Dysfunction

Historically, it was thought that vagal indigestion was caused by vagal nerve dysfunction caused by injury to the vagus nerve injury associated with complications of traumatic reticuloperitonitis. It was hypothesized that the inflammatory and scar tissue lesions affected vagal nerve fibers supplying the forestomach and abomasum. The naturally occurring syndrome was similar to the Hoflund syndrome created by experimentally sectioning the vagus nerves and thus the term "vagal indigestion" was coined.

The prevailing explanation was that dorsal vagal nerve injury resulted in **achalasia of the reticuloomasal orifice** (**anterior stenosis**) and inhibited the passage of ingesta from the reticulorumen into the omasum and abomasum, resulting in an enlarged rumen with abnormal rumen contents. Similarly, injury of the pyloric branch of the ventral vagus nerve resulted in achalasia of the **pylorus** (**posterior stenosis**) and inhibited the flow of ingesta from the abomasum resulting in abomasal impaction. Both abnormalities resulted in scant feces containing undigested long feed particles.

However, although in many cases of vagal indigestion there are extensive adhesions between the reticulum and adjacent organs, there is little evidence of vagal nerve injury. It is also known that the syndrome can occur without any gross evidence of inflammation of the serosa of the forestomach and abomasum over which the vagus nerves are located. In the absence of gross lesions, it has been suggested that microscopic lesions of the medial reticular wall in which vagal tension receptors are located may interfere with forestomach motility and esophageal groove reflexes.

New information based on clinicopathologic examination of clinical cases has questioned the long-held view that vagal nerve injury is an important cause of this syndrome.

Reticular Adhesions

Mechanical impairment of reticular motility and esophageal groove dysfunction as a result of reticular adhesions is probably **the most important cause of vagal indigestion syndrome**. An examination of 42 dairy cows with complications of traumatic reticuloperitonitis found that the primary mechanism was a **disturbance in particle-separation processes in the reticulorumen attributable to mechanical inhibition of reticular motility associated with extensive inflammatory parareticular adhesions**. Based on examination of necropsy tissue grossly and histologically, there was no evidence of vagal nerve injury. Definitive evidence for this being the primary mechanism was provided by a study in sheep in which the placement of magnets in the reticulum inducing abomasal impaction and forestomach distension and long particles in the feces; removal of the magnet (and therefore removal of the reticular "fixation") led to resolution of the abomasal impaction, return to normal feces, and reduction in ruminal volume.

Other Causes

Several causes unrelated to traumatic reticuloperitonitis have been recorded. Actinobacillosis of the rumen and reticulum is a less common cause. Perireticular abscesses near the reticuloomasal orifice of cattle can cause the disease. In sheep, peritonitis associated with *Sarcosporidia* and *Cysticercus tenuicollis*[1] may be a cause. **Fibropapillomas of the cardia** can mechanically occlude the distal esophagus and cause interference with forestomach motility, and there is one report of vagal indigestion caused by a fibromyxoma of the reticuloomasal orifice of a cow.[2] **Abomasal impaction in sheep** has been recorded, but the etiology and pathogenesis have not been determined.

Disturbances similar to those that occur under natural conditions have been produced by sectioning the vagus nerve. Following surgery for abomasal volvulus, some cattle develop a vagal indigestion-like syndrome characterized by anorexia, scant feces, ruminal distension, and abdominal distension. It has been suggested that distension of the abomasum and thrombosis of its vessels may have caused injury to the ventral vagus nerve, which has been documented in a small number of cases.

Pyloric achalasia is described as part of a secondary indigestion caused by septicemia and toxemia, but this is not well documented. There is also ruminal distension with fluid material, abomasal reflux into the reticulorumen, dehydration, hypochloremia, hypokalemic metabolic alkalosis, and uremia.

Indigestion of late pregnancy of cows is considered a type of vagus indigestion (type IV) in which the rumen and abomasum are grossly distended, but the cause is uncertain.[3] There is no direct evidence that the effects of an advanced pregnancy alone will cause a vagal indigestion–like syndrome; however, in some pregnancies the uterus is located entirely within the omental sling, decreasing abomasal emptying rate.

Peripheral nerve sheath tumors, such as a **solitary schwannoma,** have been described causing a syndrome similar to vagus indigestion in a mature cow.

A **vagal indigestion–like syndrome may be a postsurgical complication of AV**. Gastric wall injury, peritonitis, and vagal nerve lesions may be causative factors. It occurs in 14% to 21% of cases, and only 12% to 20% of cases return to normal production (see under right-side displacement of the abomasum and abomasal volvulus).

EPIDEMIOLOGY

Vagal indigestion is most common in dairy cows that have a history of traumatic reticuloperitonitis, which may have occurred several weeks or a few months previously. The disease is not restricted to dairy cows; it also occurs in beef cattle and in mature bulls.

PATHOGENESIS

The syndrome of vagal indigestion is characterized by disturbances in the passage of ingesta through the reticuloomasal orifice (**failure of omasal transport and anterior functional stenosis**) and disturbances in the passage of ingesta through the pylorus (**pyloric stenosis and posterior functional stenosis**). *Stenosis* is a misnomer because there is no evidence of stenosis but achalasia of the sphincters may occur, which mimics a functional stenosis. The characteristic clinical findings are distension of the rumen with pasty or frothy contents because of increased time and maceration in the reticulorumen; alterations in reticulorumen motility, with consequences such as dehydration; an increase in undigested particles in the feces; scant feces; acid-base imbalance; and secondary starvation. It is an **outflow abnormality of the reticulorumen and abomasum**.

Based on careful clinicopathologic observations of 42 cows with complications of traumatic reticuloperitonitis including vagal indigestion, it is now proposed that the disturbances in the flow of ingesta are associated with particle separation in the reticulorumen caused by mechanical inhibition of reticular motility associated with

extensive adhesions of the reticulum. Experimentally impaired reticular contractions in sheep support the central role of reticular motility for the separation of particles in the forestomach, the outflow of digesta from the reticulorumen, and transpyloric digesta flow.

Normally, reticulorumen motility results in **stratification of ruminal contents into three layers of ingesta** in addition to the most dorsal gas pocket. The **top layer**, consisting of firm fibrous material of **low-density** particles (coarse hay), floats on the **middle layer** of liquid ingesta, consisting of particles of **medium density**; the **bottom layer** consists of fine particles of **high density**. The solid material remains in the rumen and is digested until the particle size is sufficiently small (1–4 mm in cattle) to pass through the reticuloomasal orifice. The size of the digested plant fragments in ruminant feces can be considered an indirect measurement of forestomach function. In cows, the presence of large plant particles (>0.5 cm) in the feces indicates inadequate rumination or abnormalities in forestomach motility.

In normal cattle, the mean retention time of particles in the reticulorumen depends on particle size and density. The density of large feed particles is low because of their air-filled interior. During biphasic reticular contractions, most of these large, light particles are pushed caudodorsally in the rumen. Thus large particles are retained in the reticulorumen, because outflow through the reticuloomasal orifice occurs mainly during the maximum portion of the second reticular contraction. Feed particles with a high density (small and well digested) are moved out of the reticulorumen preferentially, because the majority of them remain in the reticulum during the biphasic contraction.

If **reticular motility is inhibited**, the balance of particle retention time and particle outflow in the reticulorumen is disturbed. Immobilization of the reticulum experimentally causes a decrease in feed intake, an increase in ruminal volume, a decrease of mean retention time of light plastic particles, a fourfold increase in mean retention time of heavy plastic particles, a marked increase in the amount of large particles in the feces, and an increase in abomasal volume. Such changes reflect the changes occurring in naturally occurring vagus indigestion. An increase in the amount of large particles in the feces of cows with traumatic reticuloperitonitis is indicative of inhibited clearance function of the reticulum.

Liquid consistency of the abomasal contents is important to ensure physiologic transpyloric flow. In cows with uncomplicated traumatic reticuloperitonitis, the process of particle separation in the reticulorumen is disturbed, which results in an increase in the amount of large particles in the feces. In uncomplicated traumatic reticuloperitonitis, the reticulorumen is not large and the abomasum is not impacted because the fluid outflow is probably adequate to flush even large particles out of the abomasum.

In cows with pyloric stenosis and an increase in the size of the abomasum, the rumen contents are homogeneous and pasty and not stratified. Thus consistency of rumen outflow contents changes markedly. Normally, transpyloric digesta flow depends predominantly on hydrodynamic factors, especially viscosity. Even small increases in viscosity of abomasal contents may cause a marked decrease in abomasal outflow.

Disturbances of the passage of digesta in cows with traumatic reticuloperitonitis develop in three phases.

- In the **first phase**, reticulorumen motility is decreased because of immobilization of the reticulum caused by the inflammation, pain, and fever. Immobilization of the reticulum impairs clearance function of the reticulum, resulting in poorly comminuted feces.
- The **second phase** occurs when the adhesions are extensive enough to cause additional impairment of reticular motility. Particle distribution within the reticulorumen is changed, resulting in a loss of stratification. Although feed intake decreases, the volume of the reticulorumen increases because rumen outflow is decreased. During the second phase, comparatively small amounts of rumen outflow contents can exit the abomasum, because the dry matter content of the material is similar to that of a clinically normal cow. During this phase, the rumen may become hypermotile because of excitation of low-threshold tension receptors as a consequence of moderate rumen distension.
- The **third phase** is characterized by a further change in the consistency of rumen contents, resulting in a homogeneous pasty mass of relatively high viscosity. The increase in dry matter content of the rumen outflow material inhibits transpyloric digesta flow. The abomasum enlarges, and reflux of abomasal contents may occur. It is suggested that the primary underlying process of reflux of abomasal contents in cows with posterior stenosis is a disturbance of ruminal outflow.

In summary, the current hypothesis for the pathogenesis indicates that disturbances of the passage of ingesta consist of two phases of the same syndrome. Pyloric stenosis represents the phase with the most severe clinical consequences. The prognosis is poorer for cows with anterior stenosis than for those with uncomplicated traumatic reticuloperitonitis and is poorer for cows with posterior stenosis than for those with anterior stenosis. Only a small percentage of cows with traumatic reticuloperitonitis develop disturbances of digesta passage through the reticuloomasal orifice and not all cows with anterior stenosis develop posterior stenosis. The extent and location may determine the course of the syndrome and how rapidly it develops. In cows with acute traumatic reticuloperitonitis, the consistency of the adhesions changes from a widespread fibrous type to a stringy type after several months, and with time the reticulum may regain sufficient motility to provide its clearance function.

Anterior Functional Stenosis (Achalasia)

This is characterized by accumulation of ingesta in the reticulorumen, known also as failure of omasal transport. If the ruminal wall is atonic, the ingesta accumulates without bloat occurring; if it has normal motility, the ruminal wall responds to the distension by increased motility and the production of frothy bloat. Ruminal motility will be almost continuous (3–6 contractions per minute) but the contractions are ineffective in propelling the ingesta into the omasum. As a result, the rumen enlarges to fill the majority of the abdomen, which accounts for the gross distension of the abdomen. The dorsal sac of the rumen enlarges to the right of the midline, and the ventral sac enlarges to fill most or all of the right lower quadrant of the abdomen; this results in the "L-shaped" rumen as viewed from the rear of the animal. The continuous rumen contractions also result in frothy rumen contents, which can be fatal if progressive and not relieved. Occasionally there is free gas bloat. Bradycardia is common and has been attributed to increased vagal tone of the injured nerve, causing parasympathetic slowing of the heart, but it is much more likely to be caused by decreased feed intake.

Obstruction of the reticuloomasal orifice by foreign bodies such as polyethylene twine ingested by the animal may cause a syndrome indistinguishable from anterior functional stenosis.

Posterior Functional Stenosis (Achalasia)

This is characterized by failure of transpyloric outflow resulting in abomasal impaction with large particles. Abomasal fluid containing hydrochloric acid may reflux into the rumen if the fluid does not move from the abomasum into the small intestines. This is known as the **abomasal reflux syndrome**. The chloride concentrations in the rumen fluid increase and there is a hypochloremia and hypokalemia. Bile acids may also reflux from the duodenum into the rumen of animals with an ileus of the small intestine. Associated with pyloric achalasia there is, in some cases, an apparent failure of the esophageal groove to permit the passage of ingesta into the rumen, with this organ containing only fluid. The syndrome observed depends on the stage of the disease at which the animal is first examined.

Metabolic Alkalosis and Abomasal Reflux

Depending on the location and severity of the functional obstruction and distension or impaction, there will be varying degrees of dehydration and a tendency toward a **metabolic hypochloremic, hypokalemic alkalosis.** In pyloric stenosis with abomasal impaction, there is sequestration of abomasal fluid in the abomasum and a reflux of abomasal contents into the rumen, resulting in a ruminal chloride concentration of more than 20 mmol/L. In anterior stenosis, the abomasal fluid can pass into the duodenum and neither metabolic alkalosis nor dehydration can be expected.

Postsurgical Complication in Abomasal Volvulus

A vagal indigestion–like syndrome may occur in cattle treated for AV. Possible mechanisms include vagus nerve injury, overstretching of the abomasal wall during prolonged distension resulting in neuromuscular junction alterations and autonomic motility modification, thrombosis and abomasal wall necrosis, and peritonitis.

Abomasal Impaction in Sheep

Abomasal emptying defects associated with dilatation and impaction of the abomasum in Suffolk sheep and other sheep breeds have been reported. The electrolyte imbalances that occur in cattle with abomasal impaction do not occur in sheep.

CLINICAL FINDINGS

Three similar but separate clinical syndromes have been recognized, with some clinical findings characteristic of all three, including the following:

- Inappetence for several days or complete anorexia with evidence of loss of BW.
- An enlarged papple-shaped abdomen (pear-shaped on the right and apple-shaped on the left) with or without bloat (Fig. 8-13). The upper left abdomen is distended and the lower half of the abdomen is distended bilaterally.
- Dehydration and electrolyte imbalance with metabolic alkalosis.
- Enlarged rumen palpable on rectal examination.
- Scant feces with an increase in undigested particles.
- Enlarged ingesta-impacted or fluid-distended abomasum palpable through right flank or on rectal examination (except cannot be easily palpated in advanced pregnancy).
- Vital signs within the normal range.
- Inadequate response to treatment.

Ruminal Distension With Hypermotility

The occurrence of ruminal distension with hypermotility is not particularly related to pregnancy or parturition. Moderate to severe bloat is common. There is evidence of loss of BW. The animal has usually been inappetent or anorexic intermittently for the past few weeks. The abdomen is prominently distended and the rumen movements represented by the **abdominal ripples** are often unusually prominent and may occur at the rate of **4** to **6 per minute.** The sounds of the rumen contractions are often reduced or almost absent in spite of hyperactivity because the rumen contents are pasty and frothy. Initially, this contradiction is misleading because the hyperactivity of the rumen tends to indicate normal reticulorumen activity. Fluid-splashing sounds may be audible on ballottement of the left and right flanks if the rumen is distended with excessive quantities of fluid. The feces are scant and pasty and contain undigested particles. The temperature is usually normal and bradycardia (44–60 beats/min) may be present because of decreased feed intake and not because of stimulation of the vagus nerve. A systolic murmur that waxes and wanes with respiration, being loudest at the peak of inspiration, may be present because of the ruminal distension and tympany causing compression of the heart and distortion of the valves. The murmur disappears when the tympany is relieved.

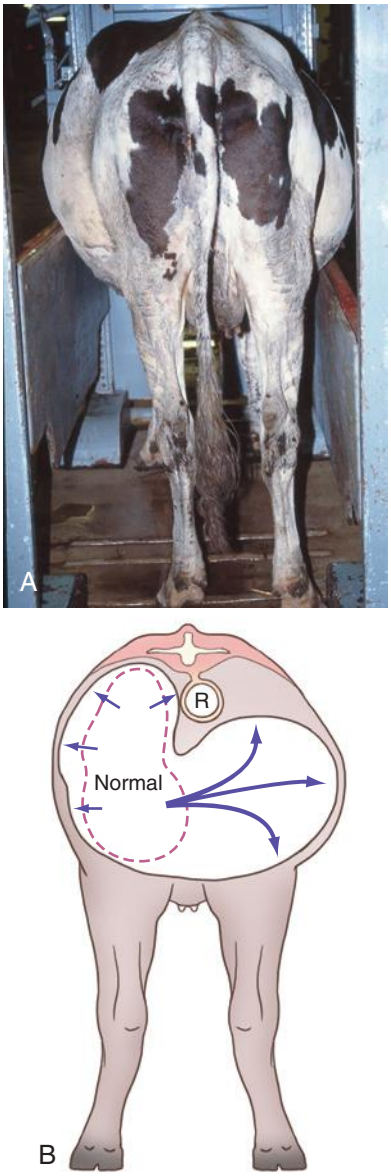

Fig. 8-13 **A,** Classic papple shaped abdominal profile of vagal indigestion in a Holstein Friesian cow, with an apple on the left and a pear on the right. **B,** Figure depicting the rumen enlargement that causes the classic papple-shaped abdominal profile of vagal indigestion (pear on the right side, apple on the left side). *R,* rectum. (Reproduced with permission from Constable PD, Hoffsis GF, Rings DM. *Compend Contin Educ Pract Vet* 1990; 12:1169-1174.)

Ruminal distension is obvious on rectal examination. The dorsal sac of the rumen is grossly distended to the right of the midline and is pushed back against the brim of the pelvis; the ventral sac is also enlarged and occupies much of the right lower quadrant of the abdomen. This may be difficult to appreciate in advanced pregnancy. Viewed from the rear the enlarged rumen is **L-shaped**, giving an external silhouette with the left flank distended from top to bottom and the right flank distended only in the lower half—the papple-shaped abdomen.

An important aspect of the clinical history of vagal indigestion cases is that standard treatments for ruminal tympany and impaction usually have no effect on the course of the disease. If the acid-base imbalances can be corrected and hydration maintained and adequate nutritional status maintained until parturition occurs in these cows, the prognosis is favorable and the recovery rate is high.

The frequency of reticular contractions determined using ultrasonography ranges between 2.7 and 4.5 per 3 minutes. Of 144 cattle with vagal indigestion, 15% had <2.7 contractions per 3 minutes, and 41% had >4.5 contractions per 3 minutes; the latter finding was more commonly associated with proximal functional stenosis.[4]

Ruminal Distension With Atony

Ruminal distension with atony is most common in late pregnancy and may persist after calving. The cow is clinically normal in all respects except that she is anorexic; passes only scant amounts of soft pasty feces; and has a distended abdomen and will not respond to treatment with purgatives, lubricants, or parasympathetic stimulants.[3] Ruminal movements are seriously reduced or absent and there may be persistent mild bloat. Fluid-splashing sounds may also be audible on ballottement of the left and right flanks if the rumen is distended with excessive quantities of fluid. The temperature and heart rate are usually normal. There is no pain on deep palpation of the ventral

abdomen. On rectal examination the primary abnormality is gross distension of the rumen, which may almost block the pelvic inlet. The animal loses weight rapidly, becoming weak and recumbent. At this stage the heart rate increases markedly. The animal dies slowly of inanition.

Pyloric Obstruction and Abomasal Impaction

Most cases of abomasal impaction also occur late in pregnancy and are manifested by anorexia and a reduced volume of pasty feces. There may be no abdominal distension and no systemic reaction until the late stages, when the heart rate rises rapidly. The distended and impacted abomasum may be palpable in the lower right abdomen as a heavy, doughy viscus. On rectal examination the impacted abomasum may be palpable as a doughy viscus that pits on pressure in the right lower quadrant. If the animal is in advanced pregnancy, the impacted abomasum may not be palpable through the abdominal wall or by rectal palpation, but the gravid uterus may feel as if it is displaced into the pelvic cavity by the enlarged abomasum. Rumen movements are usually completely absent. As in the first type, affected animals usually become weak and recumbent and die slowly of inanition and electrolyte and acid-base imbalances. In some cases, the impacted abomasum may rupture and cause death in a few hours.

Combinations of these types may occur; in particular, distension of the rumen with atony combined with abomasal impaction is the most commonly observed syndrome.

Indigestion of late pregnancy in cattle characterized by distension and hypermotility of the rumen with distension of the abomasum has been described but is probably not caused by advanced pregnancy alone. In late pregnancy, the abomasum is difficult to examine clinically either through the abdominal wall or by rectal examination. The presence of fluid-splashing sounds on ballottement and auscultation over the right lower flank is indirect evidence of distension of the abomasum with fluid. The distended abomasum can be palpated and evaluated by left or right side laparotomy (celiotomy).

CLINICAL PATHOLOGY

Hemogram

In most cases there are no abnormalities on hematological examination although a moderate neutrophilia, a shift to the left, and a relative monocytosis may suggest the presence of chronic traumatic reticuloperitonitis. Hemoconcentration is common, associated with the clinical dehydration. TPP concentrations may be increased and a positive glutaraldehyde test and hyperfibrinogenemia is present, similar to traumatic reticuloperitonitis.[5,6]

Peritoneal Fluid

Peritoneal fluid be indicative of a chronic reticuloperitonitis.

Serum Biochemistry

In abomasal impaction there is metabolic hypochloremic, hypokalemic alkalosis.

Ruminal Chloride Concentrations

Ruminal chloride concentrations are normally below 30 mmol/L and stay low in cattle with proximal functional stenosis (reticuloomasal stenosis). Rumen chloride concentrations are increased in posterior stenosis to above 40 mmol/L caused by abomasal reflux.[5] Levels of 66 mmol/L have been recorded in cows with indigestion of late pregnancy.

NECROPSY FINDINGS

The rumen is grossly enlarged and the contents are pasty and may be frothy and may have undergone some putrefaction. In some cases the rumen is grossly distended with liquid rumen contents containing floating large particles of ingesta. The reticulum and omasum are usually grossly enlarged and the reticuloomasal orifice is commonly dilated and filled with rumen contents. The omasum may be almost twice its normal size and is firmer than normal. Sectioning of the omasum reveals rumen contents impacted between its leaves. The abomasum may be up to twice its normal size and firm on palpation. It is impacted and grossly distended with semidry partially digested ingesta that resembles partially dried rumen contents. Erosions and ulcers may be present in the pyloric part of the abomasum. The intestines may be relatively empty and the feces in the large intestine are pasty, containing an increased amount of undigested particles.

Lesions between the reticulum and ventral abdominal floor and the diaphragm vary considerably from thick fibrinous suppurative adhesions to multiple abscesses containing a foreign body or noninflammatory fibrous bands and strings.

DIFFERENTIAL DIAGNOSIS

The salient clinical features of vagal indigestion in cattle are inappetence for several days leading to anorexia; a gradually enlarging abdomen, especially on the left side; scant feces; failure to respond to common medical therapy; loss of body condition and varying degrees of dehydration. Obtaining an accurate history is of paramount importance. Most cases of vagal indigestion have been affected for at least several days or a few weeks. The diagnosis can be perplexing in those cases that occur in late pregnancy because the animal has usually been housed and fed with other dry cows and daily observation of feed intake and fecal output have not been made, so it is difficult to obtain an accurate and helpful history. The clinical examination should focus on the state of the rumen and the abomasum. In valuable animals, a left-side exploratory laparotomy and rumenotomy will often be necessary to make a diagnosis. This will allow the determination of the presence of reticular adhesions, obstructions of the reticuloomasal orifice and the state of the abomasum.

The various forms of vagal indigestion must be differentiated from diseases of the forestomach and abomasum resulting in distension and hypermotility or atony of the rumen and enlargement of the abomasum.

- **Ruminal distension with hypermotility** is typical of vagus indigestion and, if accompanied by anorexia, dehydration, scant and abnormal feces, and a large L-shaped rumen on rectal examination, it must be differentiated from:
  - *Indigestion of late pregnancy:* characterized by anorexia; lethargy; dehydration; grossly distended papple-shaped abdomen; ruminal distension with hypermotility; abomasal distension with fluid; elevated ruminal chloride levels and hypochloremic, hypokalemic alkalosis.
  - *Obstruction of the reticuloomasal orifice* by ingested baling twine, plastic sleeves and bags may cause distension of the rumen indistinguishable from vagus indigestion. The rumen is moderately distended but its size will vary daily and reticulorumen motility is normal. The animal is bright and alert but the feed intake, amount of feces, and milk production varies daily from normal to subnormal for no obvious reason. Rumenotomy is the only method of making the diagnosis. The ruminal foreign body will be floating in the rumen or may be partially lodged in the reticuloomasal orifice
- **Ruminal distension with atony** must be differentiated from diseases of the forestomach and abomasum in which there is failure of passage of ingesta. These include:
  - **Chronic traumatic reticuloperitonitis**, which is characterized by inappetence to anorexia, a usually smaller than normal rumen with atony. but in some cases the rumen feels larger than normal with free-gas bloat, loss of body weight, persistent slight fever, perhaps the presence of a grunt, an absence of rumination, scant feces with an increased amount of undigested particles, and changes in the hemogram indicating chronic inflammation.

- **Abomasal impaction in vagal indigestion**, characterized by a papple-shaped abdomen; perhaps prominent enlargement of the right lower abdomen; ruminal distension with hypermotility or atony; the presence of a palpable heavy viscus in the right lower abdomen; scant feces with long undigested particles of ingesta; loss of body weight; dehydration; and hypochloremic, hypokalemic alkalosis. The gravid uterus is easily palpable on rectal examination, and the fetus may be displaced into the pelvic cavity because of the impacted and enlarged abomasum. Ruminal chloride levels are elevated.
- **Abomasal impaction dietary in origin** caused by ingestion of straw or sand occurs in cattle with unlimited access to chopped straw during cold weather or consuming tuber crops contaminated with sand. The rumen is grossly distended with coarse ruminal ingesta or liquid contents and is atonic. Ballottement of the rumen elicits fluid-splashing sounds. The right flank is distended and the impacted abomasum can be palpated as a heavy, firm viscus in the right lower flank (except in late pregnancy when it cannot be palpated). Hypochloremic, hypokalemic alkalosis is present.
- **Omasal impaction** occurs sporadically and is usually part of the vagus indigestion syndrome, but its cause is uncertain. Anorexia, ruminal distension and atony, scant inadequately digested feces.
- **Phytobezoars** blocking the abomasal pylorus cause loss of body weight; abomasal distension with fluid-splashing sounds on ballottement over the right lower flank; ruminal distension and hypotonicity; anorexia; and hypochloremic, hypokalemic alkalosis. Right flank laparotomy and abomasotomy is necessary to make the diagnosis.
- **Abomasal ulceration without melena** is uncommon but occurs in dairy cows with a history of chronic inappetence and decreased milk production. There is distension of the abomasum with fluid-splashing sounds on ballottement, ruminal hypotonicity, inappetence and loss of body weight, occult blood, and moderate dehydration. Diagnosis is only made surgically or at necropsy.
- **Peripheral nerve sheath tumors** of the vagus nerve may cause a syndrome similar to vagus indigestion. Clinically, there is chronic ruminal stasis and tympany, persistently distended loops of intestine palpable per rectum, and inappetence to anorexia and progressive loss of body weight. The diagnosis cannot be made clinically; lesions are present on the vagus nerve above the base of the heart.

TREATMENT

The prognosis in most cases in unfavorable but also unpredictable. The problem is to determine the location and extent of the lesion, which may be difficult or impossible even on exploratory laparotomy or rumenotomy.

Rumen Lavage

If the rumen is grossly distended with fluid or mushy rumen contents, it can be emptied using a large-diameter (25-mm inside diameter) stomach tube followed by flushing warm water into the rumen and lavaging it by gravity flow. The contents are usually well macerated and foul smelling. Emptying the rumen not only relieves the pressure but allows for easier examination of the abdomen (Fig. 8-14).

Fluid and Electrolyte Therapy and Laxatives

Some cases respond beneficially following fluid and balanced electrolyte therapy for 3 days combined with the oral administration of mineral oil (5–10 L) daily for 3 days or dioctyl sodium sulfosuccinate as described under the treatment of abomasal impaction of dietary origin. Other cases do not respond, but there is no reliable method of knowing which ones will respond other than by attempting treatment for a few days. Valuable pregnant cows near parturition may be maintained on fluid and electrolyte therapy for several days or until near enough to term to induce parturition and hopefully obtain a live calf. Some cows will recover following parturition, but the syndrome may recur in the next pregnancy.

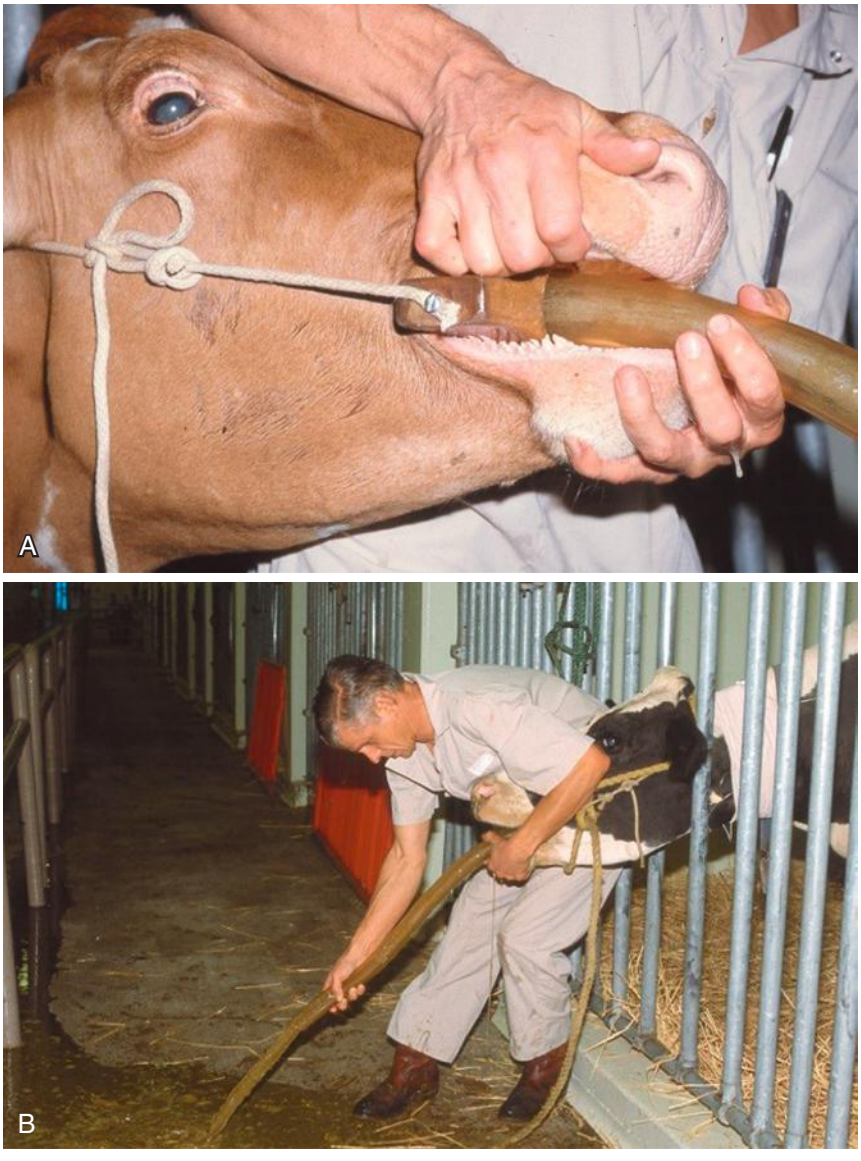

Fig. 8-14 **A,** Passage of a large-diameter tube through a wooden mouth gag to decompress the rumen in a Guernsey cow with vagal indigestion. **B,** Rapid emptying of ruminal contents through a large-diameter tube.

Rumenotomy

Rumenotomy and emptying of the rumen is usually followed by slow recovery over a period of 7 to 10 days when there is ruminal hypermotility. The creation of a permanent ruminal fistula to permit the escape of gas in cases in which gas retention is a problem may cause dramatic improvement. Surgical correction of abomasal distension or impaction by abomasotomy is usually unsatisfactory because the motility of the abomasum does not return. Surgical drainage of perireticular abscesses into the reticulum or omasum at the site of the lesion through a rumenotomy incision has been successful in prolonging survival of affected cattle for at least 1 year. Reticular abscesses may be drained successfully by ultrasound-guided transcutaneous incision. For some cases of vagal indigestion, the most satisfactory procedure may be to recommend slaughter for salvage. In suspected cases of obstruction of the reticuloomasal orifice by rope or twine, an exploratory rumenotomy is required to remove the foreign object. Descriptions of different approaches to rumenotomy in cattle are available.[7,8]

PREVENTION

Prevention is dependent on preventing traumatic reticuloperitonitis through management of the environment and the administration of reticular magnets.

TREATMENT AND CONTROL

Treatment

Rumen decompression using large-diameter tube or rumenotomy (R-1)

Daily administration of 4 L of mineral oil for 3 days (R-1)

Correction of fluid, electrolyte, and acid-base imbalances (R-1)

Control

Prevent ingestion of metallic and nonmetallic objects (R-1)

Administer rumen magnet to all animals eating chopped forage or with access to metal objects (R-2)

DIAPHRAGMATIC HERNIA

Herniation of a portion of the reticulum through a diaphragmatic rupture causes chronic ruminal tympany, anorexia, and displacement of the heart.

ETIOLOGY

Most cases of diaphragmatic hernia occur because of weakening of the diaphragm by lesions of traumatic reticuloperitonitis, but diaphragmatic rupture can occur independently of a foreign body and congenital defects of the diaphragm may be a cause in some animals. An unusually high incidence of herniation of the reticulum through the diaphragm, sometimes accompanied by the abomasum, has been recorded in water buffalo.

PATHOGENESIS

The usual syndrome is similar to that of vagus indigestion in which ruminal hypermotility is present. It seems probable that there is either achalasia of the reticuloomasal sphincter caused by involvement of the vagus nerve or impairment of function of the esophageal groove caused by the fixation of the reticulum to the ventral diaphragm. The disturbance of function in the forestomachs suggests that food can get into the rumen but cannot pass from there to the abomasum. The hypermotility is thought to be caused by overdistension of the rumen and to be the cause of frothy bloat.

There is usually no interference with respiration without major herniation, but displacement and compression of the heart is common.

CLINICAL FINDINGS

There is a capricious appetite and loss of condition for several weeks before abdominal distension caused by accumulation of fluid and froth in the rumen, persistent moderate tympany of the rumen, occurs. Grinding of the teeth may occur, and the feces are pasty and reduced in volume. Rumination does not occur but occasionally animals regurgitate when a stomach tube is passed.

The temperature is normal and bradycardia may be present (40–60 beats/min). Breathing is usually normal. A systolic murmur may be present and the intensity of the heart sounds may suggest displacement of the heart, usually anteriorly or to the left. Reticular sounds are audible just posterior to the cardiac area in many normal cows, and they are not significantly increased in diaphragmatic hernia.

A more severe syndrome is recorded in cases in which viscera other than a portion of the reticulum is herniated. Peristaltic sounds may be audible in the thorax and there may be interference with respiration and signs of pain with each reticular contraction. Affected animals usually die of inanition in 3 to 4 weeks after the onset of bloat.

CLINICAL PATHOLOGY

Laboratory examinations are of no value in diagnosis. Radiologic examination after a barium meal has facilitated diagnosis but requires a radiographic unit that is only available at referral centers.

NECROPSY FINDINGS

The majority of cases are complications of traumatic reticuloperitonitis and a fistulous tract is often found in the vicinity of the diaphragmatic rupture, which is usually 15 to 20 cm in diameter. A portion of the reticulum protrudes into the right pleural cavity to form a spherical distension usually 20 to 30 cm in diameter, but is more extensive in some cases. The reticulum is very tightly adherent to the hernial ring, which is thickened by fibrous tissue. The omasum and abomasum are relatively empty but the rumen is overfilled with frothy, porridge-like material, which contains very little fiber. Less common cases are those in which part of the reticulum, the omasum, and part of the abomasum are herniated.

DIFFERENTIAL DIAGNOSIS

- Other causes of chronic bloat must be considered in the differential diagnosis, especially vagus indigestion with hypermotility, which is also often accompanied by a systolic murmur. The two can only be differentiated by rumenotomy, but there is the hazard that cases of diaphragmatic hernia are not relieved by the operation and tympany returns rapidly, sometimes necessitating a permanent ruminal fistula.
- Passage of a stomach tube is usually necessary to determine whether or not a physical obstruction is present in the esophagus. Regurgitation is likely to occur in cases of diaphragmatic hernia, and this occasionally causes blockage of the esophagus with ingesta, simulating choke.
- Causes of diaphragmatic hernia other than traumatic reticuloperitonitis include violent trauma to the abdomen and straining at parturition. In both instances, there is probably a primary weakness of the diaphragm. In water buffalo, this is thought to be an anatomic characteristic of the species, with the weakness located in the right half of the diaphragm.

TREATMENT

Most recorded attempts at surgical repair in cattle have been unsuccessful and treatment is not usually been recommended. The animals could not be left as they were, so salvage by slaughter has been the usual outcome. Successful treatment of diaphragmatic hernia in water buffalo has been recorded.

The ruminal contents are frothy, and trocarization or passing a stomach tube has virtually no effect in reducing the tympany, nor

have standard antifrothing agents. The tympany is usually not sufficiently severe to require emergency rumenotomy. The signs may be partly relieved by keeping the animal confined with the forequarters elevated.

TRAUMATIC RETICULOPERICARDITIS

Perforation of the pericardial sac by a sharp foreign body originating in the reticulum causes pericarditis with the development of toxemia and congestive heart failure. Tachycardia, fever, engorgement of the jugular veins, anasarca, hydrothorax and ascites, and abnormalities of the heart sounds are the diagnostic features of the disease.

SYNOPSIS

Etiology Perforation of pericardial sac by foreign body originating from the reticulum.

Epidemiology Usually mature cattle; may have had history of traumatic reticuloperitonitis.

Signs Depression, toxemia, fever, inappetence to anorexia, engorged jugular veins, brisket edema, heart sounds muffled and accompanied by pericardial friction rubs and to-and-fro fluid movement sounds.

Clinical pathology Marked neutrophilia. Pericardiocentesis yields foul-smelling and turbid fluid.

Lesions Distension of pericardial sac, foul-smelling, grayish fluid containing fibrin. Adhesions and sinus tracts to reticulum.

Diagnostic confirmation Pericardiocentesis.

Differential diagnosis Common causes of congestive heart failure in cattle include endocarditis, myocardiopathy (lymphomatosis), and congenital cardiac defect.

Treatment Pericardial drainage and lavage by indwelling catheter or fifth rib resection. Rumenotomy to remove metallic foreign body. Antimicrobials. Prognosis poor. Euthanasia commonly recommended.

ETIOLOGY

Traumatic pericarditis is caused by penetration of the pericardial sac by a migrating metal foreign body from the reticulum. The incidence is greater during the last 3 months of pregnancy and at parturition than at other times. Approximately 8% of all cases of traumatic reticuloperitonitis will develop traumatic pericarditis. Most affected animals die or suffer from chronic pericarditis and do not return to completely normal health.

PATHOGENESIS

Penetration of the pericardial sac may occur with the initial perforation of the reticular wall. However, the animal may have had a history of traumatic reticuloperitonitis sometime previously, followed by pericarditis, usually during late pregnancy or at parturition. In this case it is probable that the foreign body remains in a sinus in the reticular wall after the initial perforation and penetrates the pericardial sac at a later date. Physical penetration of the sac by a metallic foreign body is not essential to the development of pericarditis, and infection sometimes penetrates through the pericardium from a traumatic mediastinitis.

Introduction of a mixed bacterial infection from the reticulum causes a severe local inflammation, and persistence of the foreign body in the tissues is not essential for the further progress of the disease. The first effect of the inflammation is hyperemia of the pericardial surfaces and the production of friction sounds synchronous with the heart beats. Two mechanisms then operate to produce signs: the toxemia caused by the infection and the pressure on the heart from the fluid that accumulates in the sac and produces congestive heart failure. In individual cases one of these two factors may be more important. Depression is characteristic of the first and edema of the second. Thus an affected animal may be severely ill for several weeks, with edema developing only gradually, or extreme edema may develop within 2 to 3 days. The rapid development of edema usually indicates early death.

If chronic pericarditis persists, there is restriction of the heart action caused by adhesion of the pericardium to the heart. Congestive heart failure results in most cases, but some animals may recover. An uncommon sequel a after perforation of the pericardial sac by a foreign body is laceration of a coronary artery by the wire or rarely rupture of the ventricular wall. Death usually occurs suddenly caused by acute, congestive heart failure from compression of the heart by the hemopericardium, and often without premonitory illness.

CLINICAL FINDINGS

Depression, anorexia, habitual recumbency, and rapid weight loss are common. Diarrhea or scant feces may be present and grinding of the teeth, salivation, and nasal discharge are occasionally observed. The animal stands with the back arched and the elbows abducted. Respiratory movements are more obvious, and are mainly abdominal and shallow with an increase in rate to 40 to 50 beats/min and often accompanied by grunting. **Bilateral distension of the jugular veins and edema of the brisket and ventral abdominal wall are common** (Fig. 8-15) and in severe cases there may even be edema of the conjunctiva with grapelike masses of edematous conjunctiva hanging over the eyelids. A prominent jugular venous pulse is usually visible and extends proximally up the neck.

Pyrexia (40°C–41°C, 104°F–106°F) is common in the early stages, and an increase in the heart rate to 100 beats/min and a diminution in the pulse amplitude are constant.[1] Rumen movements are usually present but depressed. Pinching of the withers to depress the back or deep palpation of the ventral abdominal wall behind the xiphoid sternum commonly elicits a marked painful grunt. A grunt and an increased area of cardiac dullness can also be detected by percussion over the precordial area, preferably with a plexímeter and hammer.

Auscultation of the thorax reveals the diagnostic findings. In the early stages before effusion commences, the heart sounds

Fig. 8-15 Holstein Friesian dairy cow with right-sided heart failure (brisket edema) caused by traumatic reticulopericarditis.

are normal but are accompanied by a **pericardial friction rub**, which may wax and wane with respiratory movements. Care must be taken to differentiate this from a pleural friction rub caused by inflammation of the mediastinum. In this case the rub is much louder and the heart rate will not be so high. Several days later when there is marked effusion, the **heart sounds are muffled** and there may be **gurgling, splashing, or tinkling sounds**. In all cases of suspected pericarditis, careful auscultation of the entire precordium on both sides of the thorax is essential as abnormal sounds may be audible only over restricted areas. This is especially so in chronic cases.

Lateral radiographs of the ventral thorax and cranial abdomen with the animal standing are very helpful in directing treatment but can only be performed at referral centers (Fig. 8-16). A diagnosis of traumatic reticulopericarditis is made when a foreign body is present that perforates the cranial reticular wall and diaphragm or is located entirely in the thoracic cavity. Dorsoventral radiographs to confirm the location of the foreign body in the pericardium are not possible because of the tissue mass. Gas formation is commonly present in the caudoventral thorax.

Ultrasonography is the preferred method for documenting the presence of pericardial effusion and facilitating pericardiocentesis. It is performed with the cow standing and front legs advanced cranially using soft ropes. A 5-MHz sector or convex transducer is applied from the left and right intercostal spaces. Cattle with traumatic reticulopericarditis typically have a large amount of hypoechogenic fluid in the thorax and pericardial sac; the latter occasionally contains fibrin tags. Ultrasound of the ventral reticular region is performed to confirm the presence of traumatic reticuloperitonitis, including decreased reticular motility and variable echogenicity. Most affected animals die within a period of 1 to 2 weeks, although a small proportion persist with chronic pericarditis. The obvious clinical findings in the terminal stages are **gross edema**, **dyspnea**, **severe watery diarrhea**, **depression**, **recumbency,** and **complete anorexia. Enlargement of the liver** may be detectable by palpation behind the upper part of the right costal arch in the cranial part of the right paralumbar fossa. Death is usually caused by asphyxia and toxemia.

Animals that have recovered from an initial pericarditis are usually affected by the chronic form of the disease. Body condition is poor, the appetite is variable, there is no systemic reaction, and the demeanor is bright. Edema of the brisket is usually not prominent, but there is jugular engorgement. Auscultation reveals variable findings. The **heart sounds are muffled and fluid splashing sounds** may be heard over small discrete areas corresponding to the loculi of fluid in the sac,[1] or there may be a cardiac arrhythmia. The heart rate is rapid (90–100 beats/min), and the pulse is small in amplitude. These animals remain unthrifty and are unlikely to withstand the stress of another pregnancy or lactation.

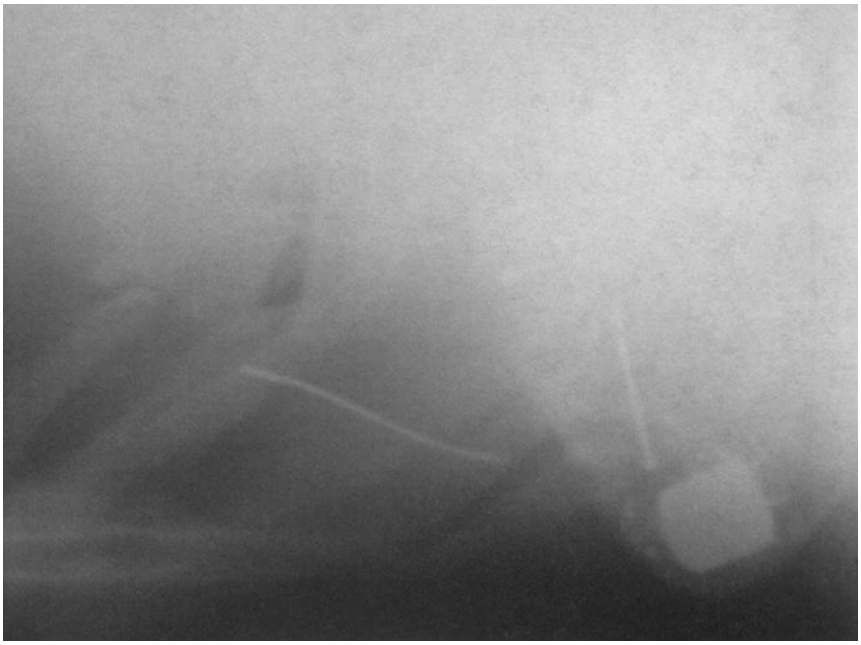

Fig. 8-16 Left-lateral radiograph of the caudoventral thorax and cranioventral abdomen in a cow with traumatic reticulopericarditis. The reticulum with a vague honeycomb pattern is on the right and contains a magnet with a vertically aligned wire that does not appear attached to the magnet. This is consistent with a diagnosis of traumatic reticuloperitonitis. A separate foreign body is present cranial to the reticulum and diaphragm (not visible) with a dorsal gas pocket. This is consistent with a diagnosis of traumatic reticulopericarditis, although traumatic reticulopleuritis could not be ruled out. CLINICAL PATHOLOGY

Hemogram

A pronounced leukocytosis with a total count of 16,000 to 30,000 cells/μL accompanied by a neutrophilia and eosinopenia is usual although less dramatic changes are recorded in one series of cases.[1] Hyperfibrinogenemia and marked increases in serum total protein concentration are frequently present in longstanding advanced cases, as is a shortened time for the glutaraldehyde clotting test.[1]

Pericardiocentesis

When gross effusion is present the pericardial fluid may be sampled by centesis with a 10-cm 18-gauge needle over the site of maximum audibility of the heart sound, usually in the fourth or fifth intercostal space on the left side. In midstage pericarditis, the fluid is usually easily obtained and is **foul-smelling (similar to a severe metritis in cattle caused by a retained placenta) and turbid, which is diagnostic for pericarditis**. In chronic pericarditis, only small amounts may be present and a sample may not be obtainable.

NECROPSY FINDINGS

In acute cases there is gross distension of the pericardial sac with foul-smelling, grayish fluid containing flakes of fibrin, and the serous surface of the sac is covered by heavy deposits of newly formed fibrin. A cordlike, fibrous sinus tract usually connects the reticulum with the pericardium. Additional lesions of pleurisy and pneumonia are commonly present. In chronic cases the pericardial sac is grossly thickened and fused to the pericardium by strong fibrous adhesions surrounding loculi of varying size, which contain pus or thin straw-colored fluid.

DIFFERENTIAL DIAGNOSIS

The typical clinical findings in pericarditis are chronic illness, toxemia, fever, congestive heart failure, and muffled heart sounds. The major causes of congestive heart failure in cattle are pericarditis, endocardial disease, myocardiopathy, and cor pulmonale (pulmonary hypertension caused by chronic pulmonary disease). Endocarditis, lymphosarcoma with cardiac involvement caused by bovine leukosis virus infection, and congenital cardiac defects are all likely to be confused with traumatic pericarditis because of the similarity of the abnormal heart sounds.

- **Endocarditis** is usually associated with a suppurative process in another organ, particularly the uterus or udder, and although the abnormal heart sounds are typical bruits rather than pericardial friction

sounds, this may be difficult to determine when extensive pericardial effusion has occurred.

- **Lymphosarcoma** is usually accompanied by lesions in other organs or the presence of a marked leukocytosis and lymphocytosis.
- **Congenital cardiac defects** may not cause clinical abnormality until the first pregnancy but can be diagnosed by the presence of loud murmurs, a pronounced cardiac thrill, and an absence of toxemia.
- Less common causes of abnormal heart sounds include thoracic tumors and abscesses, thymic lymphosarcoma, diaphragmatic hernia, and chronic bloat, which may cause pleural effusion, constriction of the cranial vena cava, distortion of the atria, and atrioventricular orifices. They are associated with other diagnostic signs, particularly displacement of the heart.
- In severely debilitated animals or those suffering from severe anemia a hemic murmur that fluctuates with respiration may be audible.
- Occasional cases of hematogenous pericarditis are encountered, and in some cases of pasteurellosis a fibrinous pericarditis may be present, but there is usually serious involvement of other organs and the pericarditis is only secondary.

TREATMENT

The results of treatment are usually unsatisfactory but salvage in a small percentage of cases can be achieved by placement of a pericardial catheter and daily pericardial lavage with dilute iodine solutions in 0.9% NaCl and long-term systemic treatment with antimicrobials. Rapid onset of generalized edema represents a poor prognosis. One-time drainage of the pericardial sac may temporarily relieve the edema and respiratory embarrassment, but relapse usually occurs within a few days. Selected cases of traumatic pericarditis have been treated satisfactorily by pericardiotomy using a fifth rib resection.

PREVENTION

Prevention depends on preventing traumatic reticuloperitonitis through management of the environment and the administration of reticular magnets.

TREATMENT AND CONTROL

Treatment

Prognosis poor and euthanasia commonly recommended

Chronic effective pericardial drainage and lavage via an indwelling flexible pericardial catheter (R-1)

Systemic antimicrobials such as procaine penicillin or oxytetracycline (R-1)

Rumenotomy to remove metallic foreign body if portion of wire still in reticulum (R-1)

Left fifth rib resection and pericardial marsupialization in advanced cases that are unresponsive to pericardial lavage (R-2)

Control

See control of traumatic reticuloperitonitis

TRAUMATIC RETICULOSPLENITIS AND RETICULOHEPATITIS

Traumatic reticulosplenitis and reticulohepatitis are relatively uncommon as sequelae to traumatic reticuloperitonitis and are manifested either by continuation of the illness caused by the initial perforation or by apparent recovery followed by relapse several weeks later. The prominent clinical findings include fever (39.5°C–40.5°C, 103°F–105°F), tachycardia, and gradual decrease in feed intake and milk yield, but ruminal movements may be present and may be normal. Percussion of the abdomen over the site usually used to detect the pain of traumatic reticuloperitonitis gives a negative response although deep, forceful palpation may elicit a mild grunt. The diagnostic sign is pain on palpation with the thumb in the last two intercostal spaces halfway down the abdomen on the right side when there is hepatic involvement and on the left side when the spleen is affected.

The total leukocyte count is elevated (above 12,000 cells/µL) with a marked neutrophilia and a left shift. Left-sided exploratory laparotomy and rumenotomy is not usually undertaken except for diagnostic purposes and to remove a penetrating wire if one is still present. Treatment with antibacterial drugs such as oxytetracycline or procaine penicillin is effective if commenced sufficiently early.

IMPACTION OF THE OMASUM

The omasum is usually spherical in shape and located to the right of the midline in the central third of the abdomen. The main functions of the omasum are to absorb short chain volatile fatty acids (acetate, propionate, and butyrate), electrolytes, and water. The omasum can vary in size in cattle for unknown reasons and is typically firmer on palpation than the rumen or reticulum. The omasum of cattle on a percent BW basis is larger than in sheep or goats.

The omasum cannot be directly examined in adult cattle by auscultation, percussion, external palpation, and palpation per rectum, or by radiography or laparoscopy. It can be palpated directly during a right flank laparotomy with the cow standing and indirectly through the medial wall of the rumen during a rumenotomy. Occasionally during an exploratory laparotomy of adult cattle, the omasum feels excessively firm and is painful when manipulated or palpated. The clinical significance of this finding has not been determined. The omasum of sheep and goats can occasionally be identified with deep palpation under the right costochondral arch.

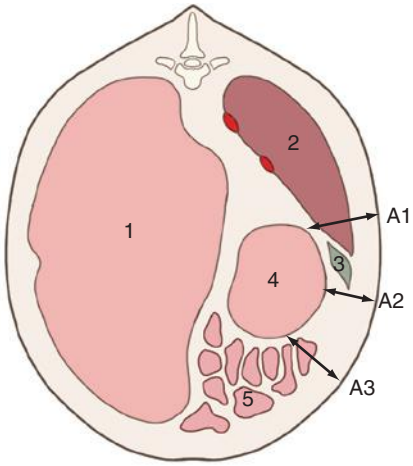

Fig. 8-17 Schematic diagram of a cross-sectional view of the bovine abdomen at the level of the ninth intercostal space. *1,* Rumen; *2,* Liver; *3,* gallbladder; *4,* omasum; *5,* small intestine. The distance between the abdominal wall and the dorsal limit of omasum *(A1),* the closest distance to the omasum *(A2),* and the ventral limit of the omasum *(A3)* are identified. (Reproduced with permission from Braun U, Blessing S. *Vet Rec* 2006; 159:812.)

The margins of the omasum in cattle have been identified using a 3.5-MHz linear transducer, with the right ninth intercostal space providing the best acoustic window to determine omasal dimensions (Fig. 8-17); the omasum was also closest to the right abdominal wall in this location.[1] Weight of the omasum was moderately correlated (r = +0.55) with omasal dimensions in the right ninth intercostal space; this may provide the best method to monitor change in omasal size over time. Omasal motility was not observed ultrasonographically in healthy cattle but was visible in 3/6 cows with vagal indigestion caused by reticuloomasal stenosis.[1,2] Omasal size was smaller in cattle with vagal indigestion caused by reticuloomasal stenosis, RDA, AV, and intestinal hypomotility or ileus.[2]

Omasal impaction as a clinical entity is difficult to define and is usually diagnosed at necropsy or right flank exploratory laparotomy or during rumenotomy when the omasum is enlarged and excessively firm.[3] It seems unlikely that omasal impaction could cause death and is frequently observed in

animals dying of other disease. Omasal impaction is reputed to occur when feed is tough and fibrous, particularly when wheat straw is fed, but is also reported when cattle and sheep are fed alfalfa stalks and loppings from fodder trees, or under drought feeding conditions in sheep that are fed on the ground. In the latter, the impaction is caused by the accumulation of soil in the omasum. Omasal impaction appears very rare in goats. Chronic recurrent bouts of indigestion occur in cattle and are manifested by decreased rumen motility, infrequent and scanty feces, refusal to eat grain, and a negative ketone test. Pain may be elicited and the hard distended viscus palpated on deep pressure under the right costal arch or in the seventh to ninth intercostal spaces on the right side. Serum concentrations of gastrin and motilin are increased in cattle with omasal impaction,[4] suggesting that prokinetic agents such as erythromycin will not be effective in treating affected animals. In cattle with a large firm omasum detected during rumenotomy, a flexible tube can be passed through the reticuloomasal orifice and warm water used to flush the omasum while it was kneaded though the medial rumen wall to soften and break up the impacted mass.[3] Repeated dosing with mineral oil (4 L/day for at least 3 days) is recommended as treatment and appears to be effective, but randomized clinical trials have not been performed to confirm this impression.

At necropsy, the omasum is grossly distended; patches of necrosis may be present on the leaves and peritonitis may be evident. Necrosis of the ruminal lining may also be present. Clinically the disease is manifested by complete anorexia, cessation of defecation, an empty rectum, and subacute abdominal pain with disinclination to move or lie down.

The number of omasal laminae in cattle ranges from 122 to 69. There is one report of congenital hypoplasia of the omasal laminae in a Japanese Black steer with persistent bloat and poor growth rate.[5] It appears that the congenital omasal defect impeded omasal transport of ingesta.[5]

Diseases of the Abomasum

Diseases of the abomasum are common in adult dairy cattle, and consist of five important entities:

1. **Left displaced abomasum**
2. **Right displaced abomasum**
3. **Abomasal volvulus (historically called abomasal torsion)**
4. **Abomasal impaction**
5. **Abomasal ulcers**

There appears to be an increase in occurrence of LDA, RDA, and AV that is associated with management, environmental, and genetic factors. Dairy cattle are being selected for high milk production and are being fed large quantities of grain and kept more often in total confinement in which exercise is limited. All of this may contribute to abomasal hypomotility, which is the precursor of abomasal displacements. A number of general comments are summarized here that apply to most diseases of the abomasum.

CLINICAL EXAMINATION OF THE ABOMASUM

PHYSICAL EXAMINATION

The normal abomasum cannot usually be examined by the standard techniques of clinical examination except indirectly by simultaneous auscultation and percussion, as well as by abdominal paracentesis. In **LDA**, the tympanitic sounds (**pings**) audible on auscultation and percussion between the middle to upper third of the 9th and 13th ribs and over the anterior aspect of the left paralumbar fossa are characteristic. In **RDA**, the tympanitic sounds (**pings**) audible on auscultation and percussion between the lower third of the 9th and 13th ribs and extending into the anterior aspect of the right paralumbar fossa, and the **fluid-splashing sounds** audible on auscultation and ballottement of the right lower to middle third of the abdomen, are characteristic. An enlarged abomasum may be palpable on rectal examination deep in the right lower quadrant of the abdomen, depending on the size of the animal and the size of the distended abomasum, and provided the animal is not in advanced pregnancy.

In AV, the clinical findings are similar to right-side displacement but much more severe. On rectal palpation a fluid-filled abomasum feels tense; an impacted abomasum pits on digital pressure. In abomasal impaction, the enlarged, firm, doughy viscus can usually be palpated behind the lower aspect of the right costal arch, but the gravid uterus of later pregnancy commonly makes this difficult. Following parturition, the abomasum is more readily detectable by palpation through the abdominal wall or rectally.

ULTRASONOGRAPHY OF THE ABOMASUM

The abomasum can be visualized by ultrasonography over the ventral midline caudal to the xiphoid process and from both left and right paramedian regions lateral to the midline site. It can be clearly differentiated from adjacent viscera because of its contents, which appear as a heterogeneous, moderately echogenic structure with echogenic stippling. Abomasal motility cannot be observed ultrasonographically, but the relative size and anatomic location of the abomasum can be detected (Figs. 8-18 and 8-19).[1]

Contrary to most pictorial representations of the shape of the abomasum within a cow's abdomen, the abomasum in adult cows is always wider than it is longer and it is always located predominantly to the right of the midline.[1] Marked changes in abomasal dimensions and position occur in dairy cattle during the last 3 months of gestation and first 3 months of lactation. The abomasal length decreases and the width increases during the last 3 months of gestation, resulting in a more transverse orientation of the abomasum within the abdomen compared with nongravid cattle or cattle in early gestation. These changes appear to be a direct response to cranial expansion of the gravid uterus. Within 14 days after parturition the abomasum returns to a caudal and right sagittal position, similar to that at the beginning of the last 3 months of gestation.[1]

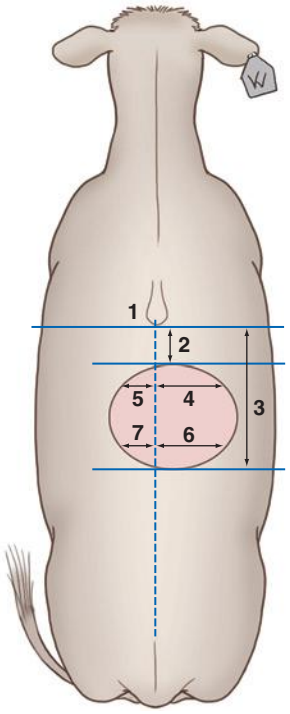

Fig. 8-18 Illustration of transabdominal ultrasonographic measurements of abomasal margins on the ventral abdominal wall (dorsal view) in Holstein Friesian heifers and cows. The numbers indicate anatomic landmarks and measurements: *1,* xiphoid process; *2,* cranial abomasal margin; *3,* caudal abomasal margin; *4,* right lateral extension in cranial region; *5,* left lateral extension in cranial region; *6,* right lateral extension in caudal region; *7,* left lateral extension in caudal region. Ultrasonographic examination of the abomasum of neonatal lambs provides an immediate indication of whether or not the lambs have sucked and may be useful in investigations of neonatal mortality.

ABOMASOCENTESIS

Centesis of abomasal contents is a safe procedure if done carefully. Percutaneous ultrasound-guided abomasocentesis can be done to evaluate the nature and chemical composition of abomasal contents. The procedure is done at a site in which the abomasum is large and no other viscera are located. The optimum site for abomasocentesis is 20 cm caudal to the xiphoid process and 5 to 10 cm lateral to the midline on the right, equivalent to 12 finger widths caudal to the xiphoid process and 3 to 6 finger widths to the right of the midline.[1] A spinal needle (0.12 × 9.0 cm) with a stylet is guided by ultrasonography through the skin and abdominal wall and into the abomasum. Abomasal fluid is assessed for color, smell and the presence of blood, and pH. Normally, the color ranges from olive green to gray, and the fluid has a sour smell. The pH varies from 1.4 to 4.5. Higher values occur with abomasal hemorrhage, the presence of bile, or chronic abomasitis caused by ostertagiasis.

APPLIED ANATOMY AND PATHOPHYSIOLOGY OF THE ABOMASUM

In a healthy, nonpregnant cow, the abomasum is positioned below the rumen in the ventral part of the abdomen and is predominantly located on the right side of the animal. During pregnancy, the enlarging uterus forces the abomasum into a more cranial position, with a greater leftward extension of the abomasum. This change is assumed to contribute to the development of an LDA, which generally occurs during the first 3 weeks after parturition.

The flow of rumen fluid into the abomasum can result in the production of carbon dioxide and methane gases, which when their absorption or the motility of the abomasum is decreased, are unable to escape from the blind pocket in the abomasum and may be a major factor in the pathogenesis of left-side displacement. This may explain why 90% of abomasal displacements occur toward the left side.

Diseases of the abomasum that cause hypomotility and accumulation of ingesta, fluid, and gas in the viscus result in varying degrees of dehydration, metabolic alkalosis, hypochloremia, and hypokalemia. The metabolic alkalosis and hypokalemia are often accompanied by muscular weakness and paradoxical aciduria. When these changes are severe, as in right-side dilatation, AV, and abomasal impaction, intensive fluid therapy is usually necessary for a favorable response.

Abomasal luminal pressure is increased in left-side displacement and in volvulus of the abomasum. This may be associated with the pathogenesis of ulceration in long-standing cases of LDA and with the prognosis of survival in AV. The luminal pressure is high in AV and higher in cattle that die or are sold for slaughter than in cattle that survive and are retained in the herd. Thus measurement of luminal pressure during surgery for volvulus may be of value in formulating prognosis for survival.

Abomasal hypomotility and a decreased rate of abomasal emptying are thought to be important factors in the etiology and pathogenesis of several diseases of the abomasum of adult cattle and calves. Because abomasal hypomotility has been associated with hypocalcemia, endotoxemia, acidosis and alkalosis, hyperinsulinemia, and hyperglycemia, the approach in treatment of suspected abomasal hypomotility in adult cattle and calves has been the correction of acid-base and electrolyte imbalances, control of the effects of endotoxemia, and elimination of gram-negative bacterial infections. Neostigmine, metoclopramide, or erythromycin have been used in ruminants for the treatment of abomasal hypomotility on the basis that these drugs have a prokinetic effect in other animals; however, neostigmine and metoclopramide are not effective in ruminants in improving abomasal emptying rate. Prokinetic agents have the ability to stimulate, coordinate, and restore gastric, pyloric, and small-intestinal motility.

Erythromycin is an effective prokinetic agent in healthy sucking milk-fed calves similar to its effects in humans, dogs, and horses.[1] Intramuscular administration of erythromycin at 8.8 mg/kg increased the frequency of abomasal luminal pressure waves and the mean abomasal luminal pressure and decreased the half-time of abomasal emptying by 37%. Metoclopramide, neostigmine, and low-dose (0.88 mg/kg) erythromycin did not alter abomasal motility, mean luminal pressure, or emptying rate. Additional studies have demonstrated that all macrolide formulations have prokinetic activity, although none of them are as effective as erythromycin at the labeled treatment dose.[2-7] It should be remembered that it is not appropriate to use an antimicrobial agent such as erythromycin for a nonantimicrobial use, and alternative prokinetic agents that are potentially as effective as erythromycin are currently under investigation.

Abomasal emptying rate and volume in calves has been determined using nuclear scintigraphy and acetaminophen absorption methods. Ultrasonography has also been used to evaluate abomasal volume, location, and emptying rate in sucking calves.

ABOMASAL REFLUX

Reflux of abomasal fluid into the omasum and reticulorumen occurs when the abomasal fluid fails to move aborally through the pylorus into the duodenum. This is most common in diseases of the abomasum, left-side displacement, AV, and vagal indigestion. Reflux may also occur in peritonitis, compression of the abomasum in advanced pregnancy, intussusception, and toxemias. The rumen chloride concentrations increase from a normal of 10 to 25 mmol/L to 80 to 100 mmol/L, and the buffering capacity of the rumen is decreased from 80 to 110 mmol/L to less than 50 mmol/L. Hypochloremic, hypokalemic metabolic alkalosis occurs. Treatment consists of removing excessive quantities of fluid from the rumen and the administration of large quantities of balanced electrolytes or simply saline intravenously.

Duodenal–abomasal reflux occurs normally in cattle and may increase during abomasal displacement; the influx is lower in LDA than in RDA. The concentration of bile acids in the abomasum is twice as high in LDA and RDA as in healthy cattle.

The administration of apomorphine to sheep causes expulsion of acidic abomasal contents back into the preabomasal compartments without expulsion of gastric contents through the mouth, or "internal vomiting." In sheep, it is estimated that approximately 280 g of sodium bicarbonate given orally would be necessary to return the ruminal pH to the neutral range.

LEFT-SIDE DISPLACEMENT OF THE ABOMASUM

ETIOLOGY

The cause of LDA in cattle is multifactorial but is related primarily to feed intake before and after calving. The transition period occurring 2 weeks prepartum through 2 to 4 weeks postpartum is the major risk period in the etiology of LDA. The prepartum depression of feed intake and the slow postpartum increase in intake are risk factors causing decreased ruminal fill, reduced forage to concentrate ratio, and increased incidence of other postpartum diseases. Excessive amounts of concentrate during the prepartum period increase the risk of LDA, which may occur from the decreased ruminal fill caused by greater prepartum intake depression and reduced forage to concentrate ratio, decreased ruminal motility from lower ruminal fill and higher volatile fatty acid concentration, and decreased abomasal emptying. The feeding of high levels of concentrate to dairy cattle results in a decrease in abomasal motility and increased accumulation of abomasal gas.

SYNOPSIS

Etiology Gaseous distension and hypomotility of abomasum possibly caused by feeding high levels of concentrate to dairy cattle in late pregnancy.

Epidemiology High-producing dairy cows within 6 weeks of calving. Insufficient crude fiber and roughage in ration. Concurrent disease such as hypocalcemia and ketosis may be risk factors, but this is uncertain.

Signs Inappetence, ketosis, decreased milk production, abdomen usually smaller than normal, reticulorumen movements not clearly audible or absent, rumen pack not easily palpable, ping over left paralumbar fossa and cranial to it. Hepatic lipidosis and abomasal ulceration are possible complications.

Clinical pathology Ketonemia, ketonuria. Normal hemogram.

Lesions Not usually fatal, deaths usually from concurrent disease conditions.

Diagnostic confirmation Laparotomy to confirm displacement.

Differential diagnosis Left displaced abomasum must be differentiated from those common diseases of the forestomach and abomasum that cause inappetence to anorexia, ketosis, reduced or abnormal reticulorumen motility, and abnormal sounds on percussion and auscultation of the left abdomen. They are simple indigestion, primary ketosis, traumatic reticuloperitonitis, vagus indigestion, and fat mobilization syndrome.

Treatment Open and closed surgical techniques to replace abomasum and secure in normal position.

Control Avoid negative energy balance prepartum, avoid overconditioning of cows prepartum, provide optimal feed bunk management, and maximize dry matter intake in late pregnancy.

EPIDEMIOLOGY

Occurrence

LDA is most common in large, high-producing adult dairy cows immediately after parturition. Approximately 90% of cases occur within 6 weeks following parturition. Occasional cases occur a few to several weeks before parturition. The disease is common worldwide where dairy cattle are fed grain for high milk production and the animals are usually housed for part of the year or kept under confinement (zero grazing and loose housing). The disease is uncommon in Australia and New Zealand, where much less concentrate is fed to dairy cattle and the animals are usually on pasture for most of the year. However, LDA can occur in pasture-fed dairy cattle, and the incidence has increased in Australia and New Zealand associated with the increased use of North American genetic stock. The importance of exercise in the etiology of LDA has not been explored. The incidence of LDA is higher during late winter and early spring, which may be a reflection of a higher frequency of calving, relative inactivity, or nutritional effects of feeding long-stored rations.

The much higher incidence of LDA in the first month of lactation does not appear to be associated with an intrinsic decrease in the abomasal emptying rate in healthy dairy cows at this stage of the lactation cycle caused by periparturient changes in plasma hormone concentrations.[1]

Calves

LDA has been recorded in calves up to 6 months of age and, rarely, in heifer calves 4 and 8 weeks of age in which abomasal ulceration perforation and peritonitis, and perforation of the abdominal wall occurred. It was not possible to determine whether the ulceration led to the atony with subsequent displacement of the abomasum, or if the displacement facilitated the ulceration.

Lactational Incidence Rate

The lactational incidence of LDA for dairy herds in North America is estimated to range from 3% to 5%. A common goal in North America is to keep the annual incidence of LDA below 3%. The mean lactation incidence in German Holstein herds is estimated at 1.6%.

Case Fatality

In one series of observations, the case–fatality rate was much higher (21%) in cows with LDA and diarrhea than in cows with LDA and normal feces (8%). Typical case–fatality rates at referral hospitals are approximately 5%, with most of the mortality caused by concurrent disease.

Risk Factors

Dietary Risk Factors

Prepartum Nutrition and Management

Based on observations in dairy herds, significant associations were found between negative energy balance prepartum, as reflected by increased nonesterified fatty acid concentrations, and the occurrence of LDA. High body condition scores, suboptimal feed bunk management, prepartum diets containing more than 1.65 Mcal of NE_l/kg of dry matter, winter and summer seasons, high genetic merit, and low parity were significant risk factors. Cows fed these high-energy diets during the dry period may become obese, which may result in a **decline in dry matter intake** before calving. Calving during hot summer months also decreases dry matter intake. It is suggested that hepatic lipidosis may be an important risk factor for LDA. Herds with a high mean predicted transmitting ability were associated with a high occurrence of LDA, suggesting a genetic component associated with high milk production.

Ketosis diagnosed before the occurrence of LDA has been frequently implicated as the major risk factor for developing LDA. This may reflect a mechanistic causal relationship, in that ketosis is associated with low dry matter intake, which would reduce rumen fill and volume, reducing forestomach motility and, potentially, abomasal motility. A low rumen volume also offers less resistance to LDA. Alternatively, it could be that many of these cases of ketosis actually had an LDA that was not auscultable. A study in four cows with LDA suggests this is unlikely because LDA occurs rapidly over a 12-hour period.[2] However, with the widespread availability of ultrasound units and information regarding the normal anatomic location of the abomasum in late gestation and early lactation,[1] it would appear that ketotic dairy cows in early lactation without an

auscultable left-sided ping consistent with an LDA could benefit from ultrasonographic determination of the abomasal position.

High-Level Grain Feeding

LDA is a disorder of throughput because of its relationship to diseases associated with high milk production and concentrate feeding. The practice of beginning to feed concentrates to high-producing dairy cattle during the last few weeks of the dry period in preparation for the transition to lactation after parturition (**lead feeding**) may be a high risk factor for LDA. Cows dried off in high body condition scores are at increased risk of LDA because of inadequate dry matter intake around the time of parturition.

High-level grain feeding increases the flow of ruminal ingesta to the abomasum, which causes an increase in the concentration of volatile fatty acids, which can inhibit the motility of the abomasum. This inhibits the flow of digesta from the abomasum to the duodenum so that ingesta accumulates in the abomasum. The large volume of methane and carbon dioxide found in the abomasum following grain feeding may become trapped there, causing its distension and displacement. However, the role of an increase in abomasal volatile fatty acid concentration as the cause of the abomasal atony is controversial.

Dietary Crude Fiber

A crude fiber concentration of less than 16% to 17% in the diet of dairy cows was considered a significant risk factor for LDA. Some initial epidemiologic studies indicated that cows affected with LDA were higher producers than their herdmates, and they were from higher-producing herds than herds without LDAs. The affected cows were also older and heavier than the average for cows examined in the survey.

The feeding of an experimental **completely pelleted ration** to dairy cattle resulted in an increased incidence of LDA: 17% compared with 1.6% in cows receiving loose alfalfa hay, sorghum silage, and an 18% crude protein concentrate. The pelleted ration was finely ground and the short length of the dietary fiber may have been a risk factor by increasing volatile fatty acid and gas production.

In summary, feeding rations high in carbohydrates, inadequate levels of roughage, and crude fiber levels below 17% during the last few weeks of pregnancy are probably important dietary risk factors.

Animal Risk Factors

A hospital-based case-control study of LDA and AV in cattle based on the medical records of 17 North American veterinary teaching hospitals over a period of 10 years compared risk factors for the two diseases.

Breed and Age of Cow

LDA occurs predominantly in Holstein Friesian, Guernsey, and Jersey cows. The breed disposition for LDA has been controversial. Some studies have found higher risk of LDA occurring in Holstein Friesian cattle and a lower risk in Brown Swiss cattle compared with the risk in Simmental Red Holstein cross cows in Switzerland. In other studies, a breed disposition for displaced abomasum was found in Ayrshire, Canadienne, Guernsey, Holstein Friesian, and Jersey cattle. In vitro studies of contractile activity of the abomasal wall of healthy cows of different breeds did not find any differences between breeds of cattle.

The ratio of LDA to AV cases was 7.4 to 1. The risk for the two diseases increased with age with **greatest risk at 4 to 7 years of age**. Dairy cattle were at higher risk of developing LDA than beef cattle, with an odds ratio of 95. Female cattle were at a higher risk of developing LDA than male cattle, with an odds ratio of 29.

Season of the Year

The odds of both diseases varied considerably throughout the year, with the lowest number of cases in the autumn. The **odds of AV and LDA were highest in January and March**, respectively. The **greater incidence of the disease in the spring** may also be related to the depletion of roughage supplies on farms in the Midwest region of the United States. In other regions of the world, the disease occurs throughout the year independently of the incidence of parturition.

Influence of Weather

The possible effects of weather on the incidence of abomasal displacement has been examined. In a study over a period of 2 years, on 26 farms with a total of 6500 Holstein Friesian lactating cows, 373 cases of abomasal displacement occurred. A change from sunny, warm, and dry days to cool, overcast, and humid days was associated with an increased incidence of displacement. There were no effect of either wind velocity or atmospheric pressure.

Milk Production

The relationship between high milk yield or high milk yield potential and LDA has been examined in several studies and the results are inconclusive. In some observations, a higher incidence of the disease occurred in high-yielding cows. Later studies found no difference in herd milk yield between high- and low-incidence herds. Genetic correlations between LDA and production of milk and protein are very small and should be independent for selection. In some studies, dairy herds with a high mean PTA milk index were associated with a high occurrence of LDA.

Late Pregnancy

Because parturition appears to be the most common precipitating factor, it has been postulated that during late pregnancy the rumen is lifted from the abdominal floor by the expanding uterus and the abomasum is pushed forward and to the left under the rumen. Following parturition, the rumen subsides, trapping the abomasum, especially if it is atonic or distended with feed, as it is likely to be if the cow is fed heavily on grain. A longitudinal ultrasound study identifying changes in abomasal position from 3 months before to 3 months after calving failed to provide support for this widely held belief.[1]

Proportionately fewer cases of AV than LDA occurred during the first 2 weeks after parturition (28% and 57%, respectively). Because proportionately fewer cases of AV develop in the immediate postpartum period it is suggested that the rumen volume may directly influence the direction of abomasal displacement. On the basis of these findings, it is suggested that abomasal atony is a prerequisite for AV and LDA, and that existence of a less than full abdomen because of reduced rumen volume is a major risk and facilitates development of AV and LDA. It is suggested that normal rumen volume is an effective barrier against LDA and that the high incidence of LDA in lactating dairy cattle is the result of the additive effects of decreased rumen volume, increased **abdominal void** immediately after parturition, and increased exposure to factors that induce abomasal hypomotility. Additional indirect evidence for the **rumen barrier** hypothesis is that feeding a high-roughage diet, containing at least 17% crude fiber, immediately before parturition is a commonly recommended and successful strategy for minimizing the incidence of LDA.

Concurrent Diseases

Cows with an LDA are more likely to have had retained placenta, ketosis, stillborn calf, metritis, twins, or parturient paresis than control cows. Concurrent diseases were present in 30% of AV cases and 54% of LDA cases. The greater incidence of concurrent disease in LDA suggests that inappetence and anorexia results in **decreased rumen volume**, which would predispose to displacement to the left. Diseases of the wall of the abomasum (secondary ulceration) and ketosis and fatty liver are common concurrent diseases in dairy cows with LDA.

Preexisting Subclinical Ketosis and Hepatic Lipidosis

Ketosis is one of the most common complications of LDA, but whether or not preexisting subclinical ketosis is a risk factor for LDA has been controversial. Some clinical studies have reported that subclinical ketosis is a risk factor for LDA. The serum activity of

aspartate transaminase (AST) and the serum concentration of β-hydroxybutyrate may be used in dairy cows during the first and second weeks after parturition as tests to predict the subsequent diagnosis of LDA. Serum AST activities between 100 and 180 U/L, and serum β-hydroxybutyrate concentrations between 1.0 and 1.6 mmol/L were associated with an increased odds ratio and likelihood ratio of LDA. The predictive ability of serum AST activity and serum β-hydroxybutyrate concentration has been confirmed in a study in Iran; serum nonesterified fatty acid, calcium, sodium, and potassium concentrations were also identified as being significant predictors of an increased risk of LDA development.[3] Hypokalemia may decrease abomasal contraction activity via its effect on the resting membrane potential of abomasal smooth muscle cells.[4] The presence of hepatic lipidosis is related to postoperative outcome; cattle with increased serum concentrations of AST are more likely to have an increased liver fat percentage.[5]

The evaluation of two milk ketone tests as predictors of LDA in dairy cows within 2 weeks of parturition (median of 6 days postpartum and 12 days before the diagnosis of LDA) found high specificity but low sensitivity for prediction of subsequent occurrence of LDA. Increased ketone body concentration in milk is claimed to be a significant risk factor for LDA. This correlates with an increased fat to protein ratio in the first milk dairy herd improvement test as a predictor of subsequent LDA. However, the studies that conclude that preexisting subclinical ketosis occurs before the occurrence of LDA, and is a risk factor (cause-and-effect relationship), do not provide evidence that the cause of the ketosis was not a preexisting LDA. It is possible for the LDA to develop over a period of several days to a few weeks in susceptible cows, which would affect feed intake and contribute to the pathogenesis of ketosis. In addition, the sensitivity and specificity of the clinical diagnostic techniques (auscultation and percussion) are unknown, and it is plausible that some cases of LDA are not recognized in their very early stages when the fundus of the abomasum has moved only a small distance up along the left lateral abdominal wall. The studies did not describe how the diagnosis of LDA was made. Cows with LDA are also twice as likely to have another disease as cows without LDA, and the presence of those diseases could be risk factors for ketosis.

Hypocalcemia

Hypocalcemia, which is common in mature dairy cows at the time of parturition, has been suggested as an important contributing factor in LDA. Blood calcium levels affect abomasal motility; motility is normal down to a threshold value of 1.2 mmol total calcium/L and below that level abomasal motility is absent. In a series of 510 dairy cows, those with hypocalcemia 12 hours before parturition (serum ionized calcium concentrations <4.0 mg/dL or total serum calcium concentration <7.9 mg/dL) had a 4.8 times greater risk of developing LDA than did normocalcemic cows. Other studies concluded that hypocalcemia is not an important risk factor for LDA. In cows with LDA, the ionized calcium is not significantly different from controls.

Metabolic Predictors of Left-Side Displacement of Abomasum

There is a predictive association of prepartum nonesterified fatty acids (NEFA) and postpartum β-hydroxybutyrate concentrations with LDA. In cows with subsequent LDA, mean NEFA concentrations began to diverge from the means of cows without LDA 14 days before calving, whereas mean serum NEFA concentrations did not diverge until the day of calving. Prepartum, only NEFA concentration was associated with the risk of subsequent LDA. Between 0 and 6 days before calving, cows with NEFA concentration of 0.5 mEq/L or less were 3.6 times more likely to develop LDA after calving. Between 1 and 7 days postpartum, retained placenta, metritis, and increasing serum concentration of β-hydroxybutyrate and NEFA were associated with increased risk of subsequent LDA. Serum β-hydroxybutyrate was a more sensitive and specific test than NEFA concentration. The odds of LDA were eight times greater in cows with serum β-hydroxybutyrate levels of 1.2 mmol/L or higher. Cows with a milk β-hydroxybutyrate concentration of 1.2 mmol/L or higher were 3.4 times more likely to develop LDA. Serum calcium concentration was not associated with LDA. In summary, the strategic use of metabolic tests to monitor transition dairy cows should focus on NEFA in the last week prepartum and β-hydroxybutyrate in the first week postpartum.

Endotoxemia appears to play a role in the periparturient period via alterations in metabolism and the immune response. The results of an experimental study in periparturient dairy cows indicated that intermittently induced endotoxemia was associated with an increased incidence of LDA.[6]

Genetic Predisposition

The prevalence of LDA is positively associated with milk yield, milk-fat yield, and milk protein yield.[7] LDA is associated with specific sires and dams, and it is generally accepted that genetic predisposition is a risk factor for abomasal displacement. Most estimates for heritability (h^2) of LDA range from 0.2 to 0.5. Relative to Holstein Friesian cattle, the German Fleckvieh has a much lower incidence of LDA despite being feed similar rations.[8,9] Holstein Friesian cows have a lower content of the vasoactive intestinal polypeptide, substance P, than German Fleckvieh cows, and this might provide an explanation for their predisposition to abomasal displacement.[8]

Recent studies have identified single nucleotide polymorphism (SNP) and an insertion mutation associated with an increased risk of LDA via decreased expression of the motilin gene in the abomasum.[9-11] Motilin is a potent natural prokinetic agent (erythromycin is an agonist), and a biologically plausible hypothesis is that dairy cattle with the SNP defect have abomasal hypomotility and are therefore at increased risk of developing LDA. A gene locus at the *SLITRK5* gene has also been associated with LDA; this gene is involved in neurologic activities such as axonogenesis and synaptic transmission.[12] This gene also has a biologically plausible association with abomasal hypomotility.

Cattle with LDA have a deeper abdomen and greater vertical distance between the ventral abdomen and descending duodenum.[13] This vertical distance represents the luminal pressure that must be generated within the abomasum for emptying to occur; the greater the distance the greater is the intraluminal pressure required for emptying, therefore, the contractile ability of the abomasum must be greater. As such, abomasal hypomotility is more likely to result in abomasal displacement in cattle with deep abdomens, and skeletal structure is moderately heritable.

Miscellaneous Animal Risk Factors

Unusual activity, including jumping on other cows during estrus, is a common history in cases not associated with parturition. Occasional cases occur in calves and bulls, and the disease occurs only rarely in beef cattle. Retained fetal membranes, metritis, and mastitis are common with LDA but a cause-and-effect relationship has been difficult to establish. In one retrospective study, the disease was associated in terms of increased relative risk with periparturient factors such as stillbirth, twins, retained placenta, metritis, aciduria, ketonuria, and low milk yield in the previous lactation.

Economic Importance and Effects on Production and Survivorship

The economic losses from the disease include lost milk production during the illness and postoperatively, and the cost of the surgery. The effects of LDA on test-day milk yields from 12,572 cows from parities 1 to 6 over a 2-year period were evaluated. From calving to 60 days after diagnosis, cows with LDA yielded on average 557 kg less milk than cows without LDA and 30% of the losses occurred before diagnosis. Milk loss increased with parity and productivity and milk losses were greatest in the highest yielding cows. Cows with LDA were nearly twice

as likely to have another disease as were cows without LDA. Cows with LDA are more likely to be removed from the herd at any point in time after the diagnosis than their herdmates. Cows with LDA survived a median of 18 months, and control cows survived a median of 27 months. Low milk production is a common reason for removal of cows with an LDA and the probability of removal increased as the lactation number increased.

PATHOGENESIS

In the nonpregnant cow, the abomasum occupies the ventral portion of the abdomen very nearly on the midline with more to the right of the midline, with the pylorus extending to the right side caudal to the omasum. As pregnancy progresses, the enlarging uterus occupies an increasing amount of the abdominal cavity. The uterus begins to slide under the caudal aspects of the rumen, reducing rumen volume by one-third at the end of gestation. This also forces the abomasum forward and slightly to the left side of the abdomen, although the pylorus continues to extend across the abdomen to the right side.[14] After calving, the uterus retracts caudally toward the pelvic inlet, which under normal conditions allows the abomasum to return to its normal position (see earlier section on ultrasonography of the abomasum). During LDA, the pyloric end of the abomasum slides completely under the rumen to the left side of the abdomen. The relative lack of rumen fill and abomasal hypomotility permits the abomasum to distend and move into the left side of the abdomen.

Normally, the abomasum contains fluid and is located in the ventral part of the abdomen. In postpartum cows, the abomasum may shift to the left without causing any clinical signs. **Abomasal hypomotility and gaseous distension are considered to be the primary dysfunctions in LDA**. A decline in plasma concentration of calcium around the time of parturition may contribute to the abomasal hypomotility. The existence of abomasal hypomotility precedes distension and displacement of the abomasum. The gas accumulated in the abomasum consists mainly of methane (70%) and carbon dioxide. In a normal abomasum, the gas production is equal to the clearance in an oral or aboral direction. When motility of the abomasum is inadequate, accumulation of gas occurs. The origin of the excess gas is uncertain, but there is evidence that the gas in the abomasum originates from the rumen in association with increased concentrate feeding and an increase in volatile fatty acid concentrations in the abomasum. A high-grain, low-forage diet can promote the appearance of volatile fatty acids in the abomasum by reducing the depth of the ruminal mat or raft (consisting primarily of the long fibers of forages). Physical reduction of forage particle length by chopping forages too finely before ensiling or overzealous use of mixer wagons also can contribute to loss of rumen raft. The rumen raft captures grain particles so that they are fermented at the top of the ruminal fluid. The volatile fatty acids produced at the top of the ruminal fluid are generally absorbed from the rumen with little volatile fatty acid entering the abomasum. In cows with an inadequate rumen raft, grain particles fall to the ventral portion of the rumen and reticulum in which they are fermented or pass on to the abomasum. The volatile fatty acids produced in the ventral rumen can pass through the ruminoreticular orifice to enter the abomasum before the rumen can absorb them. A thick ruminal raft is generally present during the dry period, when cows are fed a high forage diet, but the depth of the raft is rapidly reduced in early lactation, especially if dry matter intake decreases. Also, when cows are fed a higher grain ration, there is less regurgitation of the cud and mastication, and less saliva produced, which affects buffering of the rumen. The amount of effective fiber determines the consistency and depth of the rumen raft and stimulates rumen contractions. Total mixed rations that are easily sorted by cows may affect the ratio of forage to concentrate of total feed consumed, which contributes to the development of an LDA.

The atonic gas-filled abomasum becomes displaced under the rumen and upward along the left abdominal wall, usually lateral to the spleen and the dorsal sac of the rumen. It is primarily the fundus and greater curvature of the abomasum that becomes displaced, which in turn causes displacement of the pylorus and duodenum. Based on epidemiologic observations, it is hypothesized that a reduced rumen volume in the immediate postpartum period when there is some abdominal void allows this displacement to occur. The omasum, reticulum, and liver are also displaced to varying degrees. The displacement of the abomasum invariably results in rupture of the attachment of the greater omentum to the abomasum. In some cases, the LDA resolves spontaneously; such cases are known as "**floaters**."

LDA can be experimentally induced by placement of a stomach tube through the nasal passage into the rumen. A rumenotomy is then performed and the tube guided through the reticuloomasal orifice and omasal canal into the abomasum. The tube is then secured to a halter placed on the animal to prevent tube migration. The rumenotomy and abdomen are closed, and the animal cast using ropes into right lateral recumbency. While maintaining this position, the abomasum is distended with air and the animal encouraged to stand. At this time, an LDA is present and readily auscultable.[15] Right-side displaced abomasum can be induced using a similar method but casting the animal into left lateral recumbency.[15]

Insulin resistance is common in cows with an LDA, but direct comparisons with the disease in humans cannot be made because lactating cattle metabolize a large amount of glucose that enters mammary epithelial cells through noninsulin-dependent pathways. As a consequence, interpretation of plasma glucose-insulin concentrations in lactating dairy cows must consider the impact of the level of milk production on that relationship. Mild increases in plasma insulin concentrations associated with hyperglycemia but independent of ketosis are common in cows with LDA, but these animals also have decreased milk production. In vitro studies of abomasal motility indicate that the contractions of the longitudinal muscle from the pyloric myenteric plexus of cows with an LDA or RDA are significantly reduced compared with muscle from normal cows. In cows with an LDA and high concentrations of blood glucose and insulin, the myoelectrical activity of the abomasum was reduced, but it increased following surgical correction along with a decrease in the concentrations of glucose and insulin.

In cattle with LDA, there is probably some interference with the function of the esophageal groove caused by slight rotation of all the stomachs in a clockwise direction as viewed from behind the cow, and this impedes forward passage of digesta. The obstruction of the displaced segment is incomplete and, although it contains some gas and fluid, a certain amount is still able to escape and the distension rarely becomes severe. There is no interference with blood supply to the trapped portion of the LDA, so the effects of the displacement are entirely those of interference with digestion and movement of the ingesta, leading to a state of chronic inanition.

A mild metabolic alkalosis with hypochloremia and hypokalemia are common, probably because of the abomasal hypomotility, continued secretion of hydrochloric acid into the abomasum, and impairment of flow into the duodenum. Affected cattle usually develop secondary ketosis which, in fat cows, may be complicated by the development of the fat mobilization syndrome and hepatic lipidosis. Endotoxemia does not occur in LDA or RDA.

Abomasal Luminal Gas Pressure, Volume, and Perfusion in Cows With Left Displaced Abomasum or Abomasal Volvulus

The luminal pressure in LDA is increased (median 9 mm Hg; range 4–21 mm Hg), which may contribute to the pathogenesis of abomasal ulceration. Abomasal luminal pressure and volume is higher in cattle with an AV than in cattle with an LDA. Abomasal perfusion decreases as luminal pressure increases in cattle with an AV or LDA.

Perforating Abomasal Ulceration

Perforating abomasal ulceration and acute local peritonitis with fibrinous adhesions also occur in some cases of LDA. Abdominal pain and pneumoperitoneum are common sequelae. The ulcers may perforate acutely and cause rapid death from acute diffuse peritonitis. Duodenal ulceration has also been associated with LDA.

CLINICAL FINDINGS

General Appearance and Ketosis

Usually within a few days or a week following parturition there will be inappetence, sometimes almost complete **anorexia**, a marked **drop in milk production,** and varying degrees of **ketosis**, based on ketonuria and other clinical findings of ketosis. It is not uncommon to diagnose an LDA that was treated for ketosis, improved for a few days, and then relapsed.

On inspection of the abdomen, the left lateral abdomen appears "**slab-sided**" because the rumen is smaller than normal and displaced medially by the abomasum. The temperature, heart rate, and respirations are usually within normal ranges. The feces are usually reduced in volume and softer than normal, but periods of profuse diarrhea may occur.

Status of Reticulorumen and Spontaneous Abomasal Sounds

Ruminal movements are common but decreased in frequency and intensity and sometimes inaudible, even though there are movements of the left paralumbar fossa indicating rumen motility. In some cases, the rumen pack is palpable in the left paralumbar fossa, and the rumen contractions and sounds can be detected in the fossa as in normal cows. However, the rumen sounds may not be audible over an area anterior to the fossa in which they are also audible in normal cows. The absence of normal ruminal sounds in the presence of abdominal ripples suggests the presence of an LDA.

Auscultation of an area below an imaginary line from the center of the left paralumbar fossa to just behind the left elbow reveals the presence of **high-pitched tinkling sounds**, which often have a progressive peristaltic character. These are **abomasal sounds** and may occur several times per minute or infrequently (as long as 5 minutes apart). They are not related in occurrence to ruminal movements, and this can be ascertained by simultaneous auscultation over an area between the upper third of the 9th and 12th ribs and palpation of the left paralumbar fossa for movements of the dorsal sac of the rumen. While auscultating over the same area and ballotting the left lower abdomen just below the fossa, high-pitched fluid-splashing sounds of the LDA are commonly audible.

Pings of the Left Displaced Abomasum

Percussion, using a flick of the finger or a plexor, and **simultaneous auscultation over an area between the upper third of the 9th and 12th ribs of the abdominal wall** commonly elicits the high-pitched tympanitic sounds (**pings**) that are characteristic of LDA. These pings may not be present if the cow has just previously been transported to a clinic for surgery but they will commonly reappear in 24 to 48 hours. Occasionally, careful, repeated, time-consuming examinations using percussion and simultaneous auscultation are necessary to elicit the pings.

Acute Left Displaced Abomasum

In rare cases there is initially a sudden onset of anorexia accompanied by signs of moderate abdominal pain and abdominal distension. These are the acute cases, which are uncommon. An obvious bulge caused by the distended abomasum may develop in the anterior part of the upper left paralumbar fossa and this may extend up behind the costal arch almost to the top of the fossa. The swelling is tympanitic and gives a resonant note on percussion. In acute cases the temperature may rise to 39.5°C (103°F) and the heart rate to 100 beats/min, but in the more common subacute cases the temperature and pulse rate are normal. The appetite returns but is intermittent and selective, with the animal eating only certain feeds, particularly hay. There may be transitory periods of improvement in appetite and disappearance of these sounds, especially after transport or vigorous exercise.

Concurrent Perforating Abomasal Ulceration

Perforating abomasal ulceration occurs concurrently in some cases of LDA, resulting in localized peritonitis and pneumoperitoneum. Affected cattle have the ping over the left abdomen typical of an LDA, but a ping over both the right and left paralumbar fossae caused by pneumoperitoneum is also common. Abdominal pain caused by the local peritonitis is characterized by tensing of the abdominal wall, grunting, and arching of the back on deep palpation over the abomasal area. The peritonitis is associated with a fever. The prognosis in these cases is unfavorable.

Other Clinical Features

Ultrasound Examination

Ultrasound examination can assist in the diagnosis of abomasal displacements. In cattle with LDA, the abomasum is seen between the left abdominal wall and the rumen. The LDA contains fluid ingesta ventrally and a gas cap of varying size dorsally. Occasionally, the abomasal folds are seen in the ingesta. In cattle with AV, the liver is displaced medially from the right abdominal wall by the abomasum, which has an ultrasonographic appearance similar to that described for left displacement. Whether the liver is displaced or not is an important component of differentiating an RDA (liver not displaced) from an AV (liver displaced).

Rectal Examination

On rectal examination a sense of emptiness in the upper right abdomen may be appreciated. The rumen is usually smaller than expected and displaced to the right of the midline in cattle with a large LDA. Only rarely is the distended abomasum palpable to the left of the rumen, and in these circumstances usually it is a small cow, a large LDA, and a small rumen. Occasionally, there is chronic ruminal tympany.

Secondary Ketosis and Hepatic Lipidosis

Cows in fat body condition at parturition commonly have severe ketosis and the fat mobilization syndrome secondary to LDA. The disease can be fatal unless aggressively treated.

Atrial Fibrillation

A paroxysmal atrial fibrillation is present in some cases, which is considered to be caused by a concurrent hypochloremic, hypokalemia metabolic alkalosis. Following surgical correction and normalization of acid-base and electrolyte abnormalities, the arrhythmia usually disappears within 5 days.

Course of Left-Side Displacement of the Abomasum

The course of an LDA is highly variable. Undiagnosed cases usually reach a certain level of inanition and may remain at an equilibrium for several weeks or even a few months. Milk production decreases to a small volume and the animal becomes thin, with the abdomen greatly reduced in size.

Unusual Cases of Left-Side Displacement

Occasional cases occur in cows that are clinically normal in all other respects. In one case, a cow had an LDA, which was confirmed at necropsy, for 1.5 years, during which time she calved twice and ate and produced milk normally.

Left-Side Displacement of the Abomasum in Calves

In calves, the clinical findings include inappetence, reduced weight gain, recurrent distension of the left paralumbar fossa and a metabolic ping, and fluid-splashing sounds on auscultation and percussion of the left flank.

CLINICAL PATHOLOGY

Hemogram

There are no marked changes in the hemogram unless there is concurrent disease,

particularly metritis, mastitis, or pneumonia. There is usually a mild hemoconcentration evidenced by elevations of the packed cell volume (PCV), hemoglobin, and total serum protein.

Serum Biochemistry

A mild metabolic alkalosis with slight hypochloremia and hypokalemia are usually present. A moderate to severe ketonuria is always present, but the plasma glucose concentration is usually within the normal range or elevated. Ketosis is the most common complication of LDA and severe cases of ketosis are commonly accompanied by fatty liver. The serum activity of **AST** and **β-hydroxybutyrate** can be measured in dairy cows during the first and second weeks after parturition as possible tests to predict the subsequent diagnosis of LDA. Serum AST activity between 100 and 180 U/L and serum β-hydroxybutyrate concentration between 1.0 and 1.6mmol/L were associated with increased odds ratio and likelihood ratio of LDA.

In cows with fatty liver, plasma lipoprotein concentrations are decreased. Cows with LDA may have varying degrees of fatty liver. Fat degeneration is present in liver biopsy samples from 55% of cows with LDA. In some cows with LDA, liver biopsies found 31% fat infiltration and in those same animals, serum AST and γ-glutamyl transferase activities were increased. In addition to those of lipoprotein lipids, concentrations of **apolipoprotein B-100** (**apo-100**), the major apoprotein in very low-density lipoproteins and low-density lipoproteins, and **apolipoprotein A-1** (**apoA-1**), the predominant protein constituent of high-density lipoprotein, are reduced in cows with fatty liver. Decreased serum concentrations of apo-100 and apoA-I occur in cows with ketosis and LDA and may be used during the stages of nonlactation and early lactation to predict cows susceptible to ketosis and LDA. Dairy cows with LDA also have low plasma and liver α-tocopherol content, and plasma vitamin E concentrations may decrease in cows with increased liver triglyceride content.

A mild hypocalcemia is usually present, but parturient hypocalcemia is uncommon.

The acute phase reactants Serum Amyloid A (SAA) and haptoglobin are increased in dairy cows with LDA.[16,17] This does not necessarily reflect the presence of an inflammatory condition, because cows with LDA have mild to moderate hepatic lipidosis, based on a liver fat percentage of 9%, and SAA and haptoglobin concentrations are most strongly associated with liver fat percentage.[16] **Ghrelin**, **motilin**, and **gastrin** are gastrointestinal motility hormones that have an increased serum concentration in cattle with LDA.[18] The increase in ghrelin concentration may reflect decreased feed intake or the presence or a partial obstruction to abomasal emptying. The increase in motilin concentration may also be related to a partial obstruction to abomasal emptying. Finally, hypergastrinemia is most likely from the presence of abomasal distension.

Cowside Tests of Blood β-Hydroxybutyrate Concentration and Urinary Ketones

For **urine ketones** the Ketostix (urine nitroprusside strip detecting acetoacetate) is used routinely to provide a cost-effective method to detect subclinical ketosis. For more details on testing for ketosis please read the ketosis section in Chapter 17. **Blood β-hydroxybutyrate** tests are available using a point of care device and whole blood. **Milk ketone** tests are not as clinically useful as urine or blood ketone tests and are now rarely used.

Peritoneal Fluid Analysis

The peritoneal fluid in dairy cattle with LDA is within reference limits, although the mean fibrinogen concentration is increased relative to controls.[19] This change is consistent with fibrin deposition on parts of the displaced abomasum; fibrin deposition is particularly evident on the cranial aspect of the pyloric antrum within 1 to 2 cm of the pylorus.

Abomasocentesis

Centesis of the displaced abomasum through the 10th or 11th intercostal space in the middle third of the left abdominal wall may reveal the presence of fluid with no protozoa and a pH of 2. Ruminal fluid will have protozoa and a pH of between 6 and 7. Fluid is not always present in appreciable quantity in the abomasum and a negative result on puncture cannot be interpreted as eliminating the possibility of abomasal displacement.

NECROPSY FINDINGS

The disease is not usually fatal but carcasses of affected animals are sometimes observed at abattoirs. The displaced abomasum is trapped between the rumen and the ventral abdominal floor and contains variable amounts of fluid and gas. In occasional cases, it is fixed in position by adhesions, which usually arise from a perforated abomasal ulcer with local peritonitis. Fatty liver is common in cows that died from complications of LDA within a few days of parturition or following surgery.

DIFFERENTIAL DIAGNOSIS

Left-side displacement of the abomasum is most common in cows within 2 weeks of parturition and is characterized by gauntness, a relatively slab-sided left abdomen, and secondary ketosis. The characteristic pings can usually be elicited by percussion and auscultation. The presence of secondary ketosis in a cow immediately after parturition should arouse suspicion of the disease. Primary ketosis usually occurs in high-producing cows 2–6 weeks after parturition. The response to treatment of primary ketosis is usually permanent when treated early, whereas the response to treatment of the ketosis because of left-displaced abomasum is temporary and a relapse in a few days is common.

Left-side displacement of the abomasum must be differentiated from those common diseases of the forestomach and abomasum that cause inappetence to anorexia, ketosis, reduced or abnormal reticulorumen motility, and abnormal sounds on percussion and auscultation of the left abdomen.

Common differentials

- **Simple indigestion** is characterized by normal vital signs, inappetence to anorexia, history of change of feed, reduced milk production, a relatively full rumen with reduced frequency and intensity of contractions, the absence of pings, and spontaneous recovery in 24 h.
- **Primary ketosis** is characterized by inappetence, decline in milk production, strong ketonuria, normal vital signs, full rumen with reduced frequency and intensity of contractions, dry but normal amount of feces, and response to therapy with dextrose and propylene glycol in 12–24 h.
- **Traumatic reticuloperitonitis** in its acute form is characterized by ruminal stasis, mild fever, a grunt on deep palpation over the xiphoid sternum, and a slight neutrophilia with a regenerative left shift. However, in subacute and chronic traumatic reticuloperitonitis a painful grunt may be absent, the temperature and hemogram may be normal, and on auscultation and percussion the atonic rumen may be mistaken for a left-displaced abomasum. The tympanitic sounds of an atonic rumen occur over a larger area than with left-displaced abomasum and are not as high-pitched as those of left-displaced abomasum—they have been called "pungs." An exploratory laparotomy may be necessary to distinguish between the two, although laparoscopy, ultrasonography, and abdominocentesis are alternatives.
- **Vagal indigestion** is characterized by progressive abdominal distension caused by a grossly distended rumen with or without an enlarged abomasum; it is more common before parturition. Dehydration is also common.
- **Fat cow syndrome** at parturition is characterized by excessive body condition, inappetence to anorexia, ketonuria, and reduced to absent reticulorumen motility, but there are usually no pings over the rumen.

TREATMENT

Surgical correction is now commonly practiced and several techniques have been devised with emphasis on avoidance of recurrence of the displacement.[20] There is one report of a 93% cure rate at 1 week in 72 cattle with LDA by rolling the cow and then performing moxibustion (acupuncture with heating of selected acupoints).[21]

Open Surgical Techniques

The right paralumbar fossa omentopexy is the most widely used means of correcting left displacement of the abomasum. The right paralumbar fossa omentopexy is popular because the animal is standing, an excellent exploratory laparotomy can be performed, and the surgeon can work alone without assistance. More skill is required than for the right paramedian abomasopexy. **Right paramedian** abomasopexy is technically simpler but is declining in popularity. The major disadvantages with this procedure are the cow is placed in dorsal recumbency, which increases the potential for aspiration pneumonia, and the number of people required to restrain the animal in this position. An additional disadvantage is that the ventral incision in cows with right paramedian abomasopexy appears to be painful to the cow when in sternal recumbency, leading to an increase in standing time postoperatively compared with right flank omentopexy.[22] A **left flank abomasopexy** can also be performed with the cow in a standing position, but this technique requires an assistant and should only be used in cattle with a prominent LDA ping.

Laparoscopic Techniques

Two laparoscopic techniques have been developed, a two-step (Janowitz) method and a one-step method.[22-24] The main advantage of these methods are their minimally invasive nature. Abomasal emptying rate is faster immediately after laparoscopy-guided abomasopexy than after omentopexy via right flank laparotomy.[25] Rumen contraction rate and milk yield increased more quickly after laparoscopy-guided abomasopexy, compared with values obtained after omentopexy.[25] Moreover, there is less muscle damage with laparoscopic surgery based on postoperative increases in creatine kinase activity, relative to right flank laparotomy and omentopexy or left flank laparotomy and omentopexy.[26] As a consequence, some producers prefer the laparoscopic technique because cows more rapidly return to full appetite and expected milk production. The laparoscopic techniques require at least one assistant and expensive laparoscopic equipment and are most frequently performed in northern Europe.

Closed Suture Techniques

A few closed suturing abomasopexy techniques have been advocated because they are rapid and inexpensive, but the complications that can occur indicate that laparotomy and omentopexy are desirable. In the blind suture technique, the precise location of insertion of the sutures is unknown. Complications include peritonitis, cellulitis, abomasal displacement or evisceration, complete forestomach obstruction, and thrombophlebitis of the subcutaneous abdominal vein. The roll-and-toggle-pin suture, a modification of the closed suture technique, is also available and has the advantage that the abomasum is identified by the presence of abomasal gas (burnt almond spell). Closed suture techniques are associated with higher culling rates at 14 and 60 days (10% and 20%, respectively) than surgical correction by a flank incision with the cow in a standing position (3% and 7%, respectively).[27] As a consequence, closed suture techniques are not recommended for cattle that are expected to be retained in the milking herd.

Prokinetic and Analgesic Administration

As expected, abomasal emptying is slower in dairy cows with LDA than healthy cows at the same stage of lactation. An interesting finding is that the abomasal emptying rate is further reduced immediately after surgical correction of LDA via right flank laparotomy and omentopexy.[1] This finding suggests that the postoperative course may be improved by the administration of a **prokinetic**, which is a therapeutic agent that stimulates, coordinates, and restores gastrointestinal motility.

The results of clinical trials and experimental studies indicate that the most effective prokinetic for abomasal hypomotility in cattle is erythromycin (8.8–10 mg/kg, intramuscularly). Cows treated with the motilin agonist erythromycin (10 mg/kg, intramuscularly) once before surgery had an increased rate of abomasal emptying immediately after surgery and greater milk production on postoperative days 1 and 2 than did control cows. This provides strong support for the routine administration of prokinetic agents in the immediate postoperative period.[28] The prokinetic effect of erythromycin is sufficiently strong to warrant a clinical trial of its use in the medical treatment of LDA in conjunction with rolling the cow and repositioning the abomasum to the ventral midline. Four other macrolides (spiramycin, tilmicosin, tulathromycin, and tylosin) are also effective prokinetic drugs in healthy ruminants,[29] but their motility-promoting effects are milder than erythromycin and have not been proven in a clinical trial of diseased cattle to be clinically significant. Parenteral administration of erythromycin and other macrolides as prokinetic agents constitutes extralabel drug use. It is clearly inappropriate to administer an antimicrobial for a nonantimicrobial effect (such as increasing abomasal emptying rate) because such use may unnecessarily promote the development of antimicrobial resistance.

The available evidence indicates that the direct acting parasympathomimetic agent bethanechol (0.07 mg/kg subcutaneously) can result in a general increase in gastrointestinal tract tone, which may not necessarily facilitate abomasal emptying. In fact, a generalized increase in intestinal smooth muscle tone may impede abomasal emptying in ruminants administered an effective prokinetic agent. Parasympathomimetics cannot be currently recommended as prokinetic agents in promoting abomasal motility because of the lack of controlled clinical trials demonstrating their effectiveness. Calcium and potassium are likely to be effective prokinetic agents in cattle with marked hypocalcemia and hypokalemia, respectively. The available evidence indicates that metoclopramide is not an effective prokinetic drug in cattle, and its use cannot be recommended.

Postoperative administration of the nonsteroidal antiinflammatory agent ketoprofen (3 mg/kg BW intramuscularly at the end of surgery and 24 hours later) did not alter heart rate and rumen motility or blood β-hydroxybutyrate concentrations.[30] The nonsteroidal antiinflammatory agent flunixin meglumine (2.2 mg/kg BW intravenously) once immediately before surgery increased the rumen contraction rate on day 1 after surgery compared with untreated animals.[28] The results of other clinical trials indicate that flunixin meglumine is not an effective treatment for abomasal hypomotility.

Survivorship Following Surgery to Correct Left-Side Displacement of the Abomasum

In a series of 564 cases of displaced abomasum (466 LDA and 98 RDA), survival after surgery was evaluated after 10 days and 15 months. More LDA than RDA cows were discharged as cured (82% versus 74%). However, survival after the early postsurgical period was similar for RDA and LDA cows. In LDA cows, the factors associated with a favorable prognosis were a short duration of disease; an undisturbed general condition; good appetite; normal feces; a higher BW; lower hematocrit, hemoglobin, and erythrocyte counts; lower urea and bilirubin concentrations and AST activity; and higher serum sodium, potassium, and chloride concentrations compared with cows with an unfavorable prognosis. A thorough clinical and laboratory examination with special emphasis on general physical condition, liver function, and dehydration status are important in determining the prognosis of abdominal surgery in LDA.

Longevity in the herd at 1 year following corrective surgery is associated with higher blood β-hydroxybutyrate and serum magnesium concentrations at the time of surgery.[31]

Treatment of Ketosis

Parenteral dextrose and oral propylene glycol are necessary for treatment of the ketosis and

to avoid fatty liver as a complication. Postsurgical convalescence of cows with LDA is clearly related to disturbances in energy metabolism and fatty liver. During convalescence, in cows with no fatty liver or moderate fatty liver, the feed intake and daily milk production increases steadily. In cows with severe fatty liver, feed intake remains low. This emphasizes the need for effective treatment of excessive lipomobilization, ketosis, and fatty liver along with surgical correction of the LDA. All cases of LDA should be corrected as soon as possible to minimize the incidence of peritoneal adhesions and abomasal ulcers, which may perforate and cause sudden death.

Rumen Transfaunation Following Surgery for Left-Side Displacement of the Abomasum

The administration of 10 L of rumen fluid via a stomach tube immediately after surgical correction of an LDA, and on the next day, resulted in a beneficial effect characterized by a greater feed intake, less degree of ketonuria, and higher milk yield compared with control cows given water. This technique is covered in more detail in the section in this chapter on acute ruminal acidosis.

CONTROL

The transition period occurring 2 to 3 weeks before and after calving is a major risk period in the etiology of LDA. The prepartum depression of dry matter intake and the slow postpartum increase in dry matter intake are risk factors causing lower ruminal fill, reduced forage to concentrate ratios (in non-total mixed ration feeding systems), and increased incidence of other postpartum diseases. Retained fetal membranes, metritis, and either clinical or subclinical ketosis and hypocalcemia are probable risk factors for LDA. Excessive amounts of concentrate, or too rapid an increase in concentrate feeding during the peripartum period, increases the risk of LDA, because higher volatile fatty acid concentration in the abomasal contents leads to decreased abomasal motility and emptying and excess gas in the abomasum. (See further details of importance of crude fiber in the rumen and its effect on the abomasum under Pathogenesis.)

Prepartum Nutrition and Management

Reduction of the incidence of LDA in a dairy herd can be achieved by optimal nutrition and management during the dry period. The following principles are important:

- Avoid a negative energy balance prepartum by avoiding overconditioning and by providing optimal feed bunk management to cows in late gestation.
- Feed some concentrates before calving to ensure development of ruminal papillae.
- Maximize dry matter intake in the immediate postpartum period.
- Ensure palatable feed and water are available to periparturient cows at all times.
- Feed bunk management must ensure that cows have adequate access to fresh feed at all times to maximize dry matter intake in late pregnancy and thus improve energy balance.
- Energy density of prepartum diets should not exceed 1.65 Mcal of NE_l/kg of dry matter.

Every effort should be made to minimize dietary alterations near parturition that could result in indigestion. The amount of grain and corn (maize) silage fed prepartum should be kept at a minimum, whereas other forages are fed ad libitum.

Several experiments have shown no response in production to feeding large quantities of grain or concentrates (lead feeding) before parturition when cows were in good condition at drying-off and were fed well following parturition. Consequently, there seems little reason to continue the practice of "steaming-up" cows before parturition.

Crude Fiber Intake

Ensuring an adequate intake of a high-fiber diet to dairy cows during the "far-off" and "close-up" periods in late pregnancy and the immediate "postfreshening" period is of critical importance to the prevention of this disease. The high-fiber diet will physically expand the rumen and provide a barrier against abomasal migration. The basic principle is to maintain adequate ruminal filling before and after calving. This requires careful **analysis and implementation** of the dry cow feeding program. Readers are referred to National Research Council (2001; see Further Reading literature) for details on feeding programs for dairy cattle.

The emphasis in the dry cow feeding program must be on increasing dry matter intake, increasing particle length, and effective fiber content of the ration. Feeding a high-roughage diet is consistent with one of the most commonly recommended and successful management strategies for minimizing LDA during the postparturient period. This means ensuring adequate fiber content of at least 17%. An adequate level of fiber will also aid in the control of SARA, which may occur when dairy cows are fed grain in the latter part of the dry period in preparation for lactation.

Monensin in Controlled-Release Capsule Prepartum

Monensin is an ionophore antibiotic that alters volatile fatty acid production in the rumen in favor of propionate, which is a major precursor for glucose in the ruminant. A monensin controlled-release capsule is available as an aid in the prevention of subclinical ketosis in lactating dairy cattle. The device delivers 335 mg of monensin per day for 95 days. A monensin controlled-release capsule has been shown to decrease the incidence of subclinical ketosis, displaced abomasum, and multiple illnesses when administered to dairy cows 3 weeks before calving. It is likely that these effects on clinical health are mediated by improved energy balance in monensin-supplemented cows. There are improvements in energy indicators such as increased glucose and decreased β-hydroxybutyrate after calving.

The administration of a monensin controlled-release capsule to cows 3 weeks prepartum significantly decreased NEFA and β-hydroxybutyrate and significantly increased concentrations of serum cholesterol and urea in the week immediately precalving. No effect of treatment was observed for calcium, phosphorus, or glucose in the precalving period. After calving, concentrations of phosphorus were lower and β-hydroxybutyrate tended to be lower, and cholesterol and urea were higher in monensin-treated cows. There was no effect of treatment on NEFA, glucose, or calcium in the first week after calving. Monensin treatment administered precalving significantly improved indicators of energy balance in both the immediate precalving and postcalving periods. The prevalence of subclinical ketosis as measured by cowside tests was lower in monensin-treated cows. These findings indicate more effective energy metabolism in monensin-treated cows as they approach calving, which is important for the prevention of retained placenta, clinical ketosis, and displaced abomasum. Generally, a 40% reduction in both LDA and clinical ketosis can be expected with precalving administration of monensin controlled-release capsules. In addition, a 25% decrease in retained placenta may occur.

Genetic Selection

LDA is a moderately heritable trait; therefore the incidence of LDA should be lowered by genetic selection. It is likely that genetic tests will be developed for the SNPs associated with LDA, and that a test and cull approach will be used for bulls extensively used in artificial insemination programs.

TREATMENT AND CONTROL

Treatment

Perform open or closed (blind) surgical techniques to replace and secure the abomasum in a normal position (R-1)

Treat concurrent diseases such as ketosis, metritis, and mastitis (R-1)

Return acid-base, electrolyte, and hydration status to normal (R-1)

Continued

Control

Avoid negative energy balance prepartum (R-1)

Avoid overconditioning in prepartum (R-1)

Provide optimal feed bunk management (R-1)

Control milk fever and subclinical hypocalcemia (R-1)

Minimize ketosis and subclinical ketosis in periparturient period (R-1)

Maximize dry matter intake and ensure adequate fiber intake in late gestation (R-1)

RIGHT-SIDE DISPLACEMENT OF THE ABOMASUM AND ABOMASAL VOLVULUS

SYNOPSIS

Etiology Abomasal atony associated with high-level grain feeding. Cause in calves unknown.

Epidemiology Mature dairy cows within a few weeks of calving. Abomasal volvulus usually preceded by right-side displacement of abomasum but not a necessary precursor. Occurs in calves spontaneously.

Signs Inappetence to anorexia, depression, absence of rumination, scant abnormal feces, distension of right abdomen, ping over right flank, fluid-splashing sounds on ballottement of right flank, and distended abomasum may be palpable rectally. Abomasal volvulus manifested by anorexia, abdominal pain, tachycardia, absence of feces, ping, fluid-splashing sounds, severe dehydration and shock, and distended and tense abomasum rectally that displaces the liver medially. High case–fatality rate unless surgically corrected.

Clinical pathology Hypokalemia, hypochloremia, metabolic alkalosis, and severe dehydration.

Lesions Gross distension and/or torsion of abomasum.

Diagnostic confirmation Laparotomy.

Differential diagnosis

Dilatation and displacement of abomasum: impaction of abomasum in vagal indigestion, abomasal ulceration with dilatation, and cecocolic volvulus, and chronic or subacute traumatic reticuloperitonitis.

Abomasal volvulus: intestinal obstruction and acute diffuse peritonitis.

Pings in right abdomen: Right-side displacement of abomasum, abomasal volvulus, cecal dilatation, intestinal obstruction, dilatation of descending colon and rectum, and pneumoperitoneum.

Treatment It is difficult to differentiate right displaced abomasum from abomasal volvulus. Medical treatment if detected early. Deflation of distended abomasum. Surgical correction. Fluid and electrolyte therapy. Oral fluid and electrolyte therapy.

Control Nothing reliable.

ETIOLOGY

The etiology of RDA is not well understood, but it is probably similar to LDA. **Abomasal atony is thought to be the precursor of dilatation and displacement, and consequently AV.** The cause of the abomasal atony and gaseous distension is thought to be related to the feeding of grain and the production of excessive quantities of gas and volatile fatty acids. The dilatation is thought to be the result of primary distension of the abomasum occurring because of either obstruction of the pylorus or primary atony of the abomasal musculature. In adult cattle with RDA, there is no obstruction of the pylorus and hypomotility of the abomasum seems to be the more likely cause, similar to LDA, with a full rumen making RDA more likely. In calves, there may be an obstruction of the pylorus resulting in dilatation.

EPIDEMIOLOGY

Occurrence and Incidence

Lactating Dairy Cows

Dilatation, RDA, and AV occur primarily in adult dairy cows, usually within the 3 to 6 weeks after calving. The disease is recognized with increased frequency because of improvements in diagnostic techniques and perhaps because more cows are being fed intensively for milk production. Incidence rates on individual dairy herds are not available, but based on cases of abomasal disease admitted to a veterinary teaching hospital, the ratio of AV to LDA was 1 to 7.4.

Beef Cattle

Abomasal displacement and volvulus has been described in beef cattle breeds from 1 month to 6 years of age with a median age of 10 months. The typical case was under 1 year of age.

Calves

AV occurs in young calves from a few weeks of age up to 6 months, usually without a history of previous illness, which suggests that the cause may be accidental. Abomasal bloat occurs in calves with no apparent predisposing cause.

Mature Bulls and Pregnant Cows

AV has also occurred in bulls and pregnant cows but to a much lesser degree.

Risk Factors

There is little information available on the epidemiology of RDA and AV. Most of the risk factors described for LDA are relevant to RDA and AV. The feeding of high levels of grain to high-producing dairy cows in early lactation is considered to be a major risk factor. However, there are no good reliable data to support this cause-and-effect relationship. Why the disease occurs in a small percentage of high-producing dairy cattle being fed high-level grain rations is unknown.

When this disease was originally described, the incidence appeared to be higher in Scandinavian countries. The risk factors in those situations were not identified, but it was thought that indoor winter feeding and the shift of the acid-base balance to an alkalotic state during the winter months might be important factors. In Denmark, the ingestion of large quantities of soil particles on unwashed root crops used as feed is

considered to be significant. This may be the reason for the higher incidence of the disease in the later part of the winter. However, attempts to reproduce the condition by feeding large quantities of sand have been unsuccessful. Because atony is often associated with vagal indigestion, a relationship between the two has been suspected, but there are usually no lesions affecting the reticulum or vagus nerves.

A hospital-based epidemiologic study of the risk factors for AV and FDA was performed using the medical record abstracts derived from the veterinary teaching hospitals of 17 North American veterinary schools. The risk for AV increased with increasing age, with a greater risk in dairy cows 4 to 7 years of age. Dairy cattle were at a much higher risk than beef cattle. Approximately 28% of cases of AV occurred within the first 2 weeks and 52% within 1 month following parturition. This indicates that proportionately fewer cases of AV than left displacement occur during the first 2 weeks following parturition. The hospital case–fatality rate for AV and LDA was 24% and 6%, respectively.

It is currently thought that abomasal atony is a prerequisite for the development of right-side displacement and AV, and that following parturition the abdominal void and decreased rumen volume facilitates such development. The direction of the displacement could be influenced predominantly by the volume of the forestomach. Immediately after parturition, displacement occurs to the left because of a reduction in the size of the rumen volume. Several weeks later the dilated abomasum moves caudally and dorsally in the right abdomen because the volume of the forestomach is much larger, providing an effective barrier (rumen barrier).

AV has also occurred following correction of LDA by casting and rolling.

PATHOGENESIS

Definition of Right Displaced Abomasum and Abomasal Volvulus

Many of the reports related to RDA and AV are confusing because they lack a clear case definition. The following definition was proposed in 1991 and should be used as the standard definition for different clinical entities or departures from this definition.

The following criteria should be used to differentiate four abomasal conditions, namely RDA, AV, omaso-abomosal volvulus (OAV), and reticuloomaso-abomosal volvulus (ROAV). RDA is diagnosed when (1) a distended viscus (abomasum) is in the right cranial abdominal quadrant without displacement of the liver, such that the diaphragmatic surface of the liver still contacts the right abdominal wall; (2) the serosal surface of the abomasum visible through the incision may or may not be covered by omentum, depending on the nature of the displacement; (3) a firm twist is not palpated at either the omasal-abomasal or reticuloomasal junction; and (4) clockwise rotation of the abomasum is not observed from the right side of the animal during gas decompression, but it is observed when looking from behind the animal. AV is diagnosed if (1) a distended viscus (abomasum) is identified in the right cranial abdominal quadrant displacing the liver medially, such that the diaphragmatic surface of the liver no longer contacts the right abdominal wall; (2) the serosal surface of the abomasum visible through the incision is not covered by omentum; (3) a firm twist is palpated, primarily involving the omasal-abomasal junction; and (4) surgical correction required clockwise rotation of the abomasum when viewed from the right side of the animal. OAV was diagnosed if Conditions (1) and (2) for AV are true and (3) a firm twist is palpated and determined to be located primarily at the reticuloomasal junction; (4) the omasum is ovoid or partially flattened instead of being spherical; and (5) surgical correction requires clockwise rotation of both the abomasum and omasum when viewed from the right side of the animal. ROAV is very rare and is most accurately diagnosed at necropsy; a diagnosis includes Conditions (1) and (2) for AV, as well as the presence of a firm twist located primarily at the reticuloomasal junction and a flattened omasum.[1]

Dilatation and Displacement Phase

In RDA, abomasal atony occurs initially, resulting in the accumulation of fluid and gas in the viscus leading to gradual distension and displacement in a caudal and dorsal direction on the right side (dilatation phase). This is best appreciated as a counterclockwise rotation of the abomasum as viewed from behind the cow and is therefore a mirror image of LDA. During the dilatation phase, which commonly extends over several days, there is continuous secretion of hydrochloric acid, sodium chloride, and potassium into the abomasum, which becomes gradually distended and does not evacuate its contents into the duodenum. This leads to dehydration and metabolic alkalosis with hypochloremia and hypokalemia. These changes are typical of a functional obstruction of the upper part of the intestinal tract and occur in experimental RDA and experimental obstruction of the duodenum in calves. An RDA is a surgical emergency because the abomasum is unstable and can quickly move into an AV.

Volvulus Phase

Following the dilatation and displacement phase, the distended abomasum may twist in a clockwise (viewed from the right side) direction in a vertical plane around a horizontal axis passing transversely across the body in the vicinity of the omaso-abomasal orifice. The volvulus will usually be of the order of 180° to 270° and causes a syndrome of acute obstruction with local circulatory impairment and ischemic necrosis of the abomasum. Abomasal volvulus is the correct term; use of the term abomasal torsion is discouraged because a torsion is a twist along the longitudinal axis and an AV has a twist along its longitudinal axis as well as a mesenteric axis.

The **abomasal luminal pressure** in naturally occurring AV is increased (median 12 mm Hg; range 4–32 mm Hg). Increased luminal pressure in AV could cause mucosal injury by local vascular occlusion and affect the prognosis. Among cattle with AV, the abomasal luminal pressure was significantly higher in those that died or were sold following surgery (median 21 mm Hg) than in cattle that recovered and were retained in the herd (median 11 mm Hg). Calculation of likelihood ratios suggests that selecting cattle with a value of 16 mm Hg for luminal pressure optimized the distribution of cattle into productive and nonproductive groups.

The abomasal luminal gas pressure and volume were higher in cattle with an AV than in cattle with an LDA. As luminal gas pressure increases, abomasal perfusion decreases, resulting in varying degrees of ischemia to the abomasal mucosa. In cows with an AV, L-lactate concentration in the gastroepiploic vein was greater than that in the jugular vein, whereas no difference in L-lactate concentrations was detected in cows with an LDA. This indicates that cattle with a large and tensely distended abomasum associated with a volvulus or LDA should have the viscus decompressed as soon as possible to minimize the potential for ischemia-induced injury to the abomasal mucosa, which may result in ulcers and perforations.

Up to 35 L of fluid may accumulate in the dilated abomasum of a mature 600-kg cow, resulting in dehydration, which will vary from 5% to 12% of BW. In uncomplicated cases, there is only slight hemoconcentration and a mild electrolyte and acid-base imbalance, with moderate distension of the abomasum. These cases are reversible with fluid therapy. In complicated cases there is severe hemoconcentration, hypovolemia, and dehydration and marked metabolic alkalosis with a severely distended abomasum. The degree of dehydration is a reliable preoperative prognostic aid. The hypovolemia, compression of the caudal vena cava, and stimulation of the sympathetic nervous system in response to distension and twisting of the abomasum results in tachycardia, which is also a reliable preoperative prognostic aid.

In cattle with severe and prolonged AV, a metabolic acidosis may develop and be superimposed on the metabolic alkalosis, leading to a low base excess concentration of extracellular fluid. In experimental disease in

sheep, the metabolic acidosis observed terminally was associated with an increase in plasma L-lactate concentration probably caused by hypovolemic shock and anaerobic metabolism. These severe cases require surgery and intensive fluid therapy. A **paradoxical aciduria** may occur in cattle affected with metabolic alkalosis associated with abomasal disease. This is most likely caused by the concurrent presence of dehydration and the need for sodium retention (hence low urine sodium concentration), hypokalemia and the need for potassium retention (hence the low urine potassium concentration), and hypochloremia, with the net result a decrease in urine strong ion difference and therefore urine pH.[2]

Postsurgical Complication in Right-Side Displacement of the Abomasum or Abomasal Volvulus

The postoperative survival rate of cattle with AV was 87% and that of OAV was 55% in one case series. The postoperative survival rate of cattle with ROAV is likely to be 0%. Part of the difference in survival rate is caused by the magnitude and severity of the ischemic damage to the abomasal wall, and some cases may be caused by excessive stretching to the vagus nerve as it courses around the medial aspect of the reticulum. Affected cattle may exhibit clinical signs consistent with vagal indigestion syndrome; however, necropsy examination of these animals usually demonstrates the presence of thrombosis, abomasal wall necrosis, and peritonitis.

CLINICAL FINDINGS

Right Displaced Abomasum and Abomasal Volvulus (Adult Cattle)

In right-side dilatation and displacement there is usually a history of calving within the last few weeks with inappetence and decreased milk production; the feces are reduced in amount and are abnormal. The cow may have been treated for an uncertain disorder of the digestive tract within the last several days and in many instances the clinical signs are identical to those for LDA, except that the ping detected during simultaneous percussion and auscultation is located on the right side instead of the left side. **Percussion and simultaneous auscultation over the right middle to upper third of the abdomen commonly elicits a characteristic high-pitched ping with variable fluid splash** The ping rarely extends to the eighth rib because a ping in this location indicates displacement of the liver medially by a distended viscus (the abomasum), meeting the case definition for AV.

AV usually develops several days after the onset of dilatation of the abomasum, but it is usually not possible to distinguish precisely the stages of the disease. However, in AV that consists of a continuum of clinical signs, it is helpful to identify early and advanced cases. In early cases there is usually depression, dehydration, no interest in feed, perhaps increased thirst, and sometimes muscular weakness. Affected cows will commonly sip water continuously. The temperature is usually normal, the heart rate will vary from normal to 100 beats/min, and the respirations are usually within the normal range. The mucous membranes are usually pale and dry. The reticulorumen is atonic, and the rumen contents (the rumen pack) feel excessively doughy. The distended abomasum may be detectable as a tense viscus on palpation immediately behind and below the right costal arch. Ballottement of the middle third of the right lateral abdomen immediately behind the right costal arch along with simultaneous auscultation will reveal fluid-splashing sounds, suggesting a fluid-filled viscus. In many cases the dilatation continues and after 3 to 4 days the abdomen is visibly distended on the right side and the abomasum can be palpated on rectal examination. It may completely fill the right lower quadrant of the abdomen and feel tense and filled with fluid and gas.

The clinical findings are usually much more severe in advanced cases of AV. The abdomen is visibly distended, depression and weakness are marked, dehydration is obvious, the heart rate is 100 to 120 beats/min, and respirations are increased. Recumbency with a grossly distended abdomen and grunting may occur and represents a poor prognosis. A rectal examination is very important at this stage. In the early stage the partially distended abomasum may be palpable with the tips of the fingers in the right lower quadrant of the abdomen. It may not be palpable in large cows. In the advanced stage, the distended tense viscus is usually palpable in the right abdomen anywhere from the upper to the lower quadrant and there is prominent fluid splash on succussion.

The feces are usually scant, soft and dark in color, and become bloodstained or melenic in the ensuing 48 hours if the cow lives long enough. The soft feces must not be mistaken for diarrhea, as is commonly done by the owner of the animal. Cattle with AV that is not surgically corrected will become recumbent and death usually occurs in 48 to 96 hours from shock and dehydration. Rupture of the abomasum may occur and cause sudden death.

Acute Abomasal Volvulus (Calves)

In calves with acute AV, there is a sudden onset of anorexia, acute abdominal pain with kicking at the belly, depression of the back, bellowing, and straining. The heart rate is usually 120 to 160 beats/min, the abdomen is distended and tense, and auscultation and percussion over the right abdomen reveals distinct high-pitched pings. Palpation behind the right costal arch reveals a tense viscus that is painful on even moderate palpation.

Postsurgical Complication in Abomasal Volvulus

The most frequent complication encountered following surgical correction of RDA and AV resembles vagal indigestion, which occurs in 14% to 21% of cases. The case–fatality rate of cattle exhibiting postoperative signs consistent with vagal indigestion is high, with only 12% to 20% of affected animals returning to normal production. In affected cattle, there is ruminal distension, rumen hypermotility or atony, and abnormal feces (usually scant and dry).

CLINICAL PATHOLOGY

Serum Biochemistry

There are varying degrees of hemoconcentration (increased PCV and total serum proteins), metabolic alkalosis, hypochloremia, and hypokalemia.[3]

The severity of volvulus can be classified, and the prognosis evaluated, according to the amount of fluid in the abomasum and the increase in heart rate:

- **Group 1:** abomasum distended principally with gas, normal heart rate, excellent prognosis
- **Group 2:** abomasum distended with gas and <20 L of fluid, heart rate <100 beats/min, good prognosis
- **Group 3:** abomasum distended with gas and ≥20 L of fluid, heart rate ≥100 beats/min, moderate prognosis

The heart rates before surgery are also valuable prognostic aids. Cows having pulse rates of 100 beats/min or more have a moderate prognosis.

A cross-sectional study of the serum electrolyte and mineral concentrations in dairy cows with abomasal displacement or volvulus at the time of on-farm diagnosis found lower serum potassium, chloride, calcium, magnesium, and phosphorus concentrations and an increase in the anion gap compared with controls.

Urinalysis

Paradoxical aciduria may also be present.

Hemogram

The total and differential leukocyte count may indicate a stress reaction in the early stages, and in the later stages of volvulus there may be leukopenia with a neutropenia and degenerative left shift caused by ischemic necrosis of the abomasum and early peritonitis.

Ultrasonography of Right Abdomen

Ultrasound can be used but seldom provides any clinically useful examination from that provided by the physical examination.[4,5] In particular, ultrasonography provides similar information to that provided by simultaneous percussion and auscultation, specifically whether there is displacement of the liver medial by a distended viscus (the abomasum), consistent with a large ping that

extends to the eighth rib and indicative of the presence of AV.

Peritoneal Fluid Analysis

Peritoneal fluid is usually readily obtained in cattle with AV but is not required to make a diagnosis. Peritoneal fluid changes generally reflect changes in plasma concentrations, and as such most peritoneal fluid components provide no additional information to that provided by plasma biochemical analysis. Cattle with AV have an increase in the percentage of peritoneal fluid neutrophils that appeared necrotic or apoptotic.[6] They also have increased concentrations of D-dimer and fibrinogen in peritoneal fluid, which is consistent with abdominal inflammation.

Abomasocentesis

Centesis of the distended abomasum will yield large quantities of fluid without protozoa and a pH of 2 to 4. The fluid may be serosanguineous when volvulus is present.

PROGNOSTIC INDICATORS

Several clinical and laboratory findings have been examined as prognostic indicators of cows affected with RDA and AV. In a prospective study of 80 cattle with AV, the heart rate, hydration status, period of inappetence, and serum alkaline phosphatase activity were the best preoperative prognostic indicators. An anion gap of 30 mEq/L was indicative of a poor prognosis and was more accurate than either serum chloride concentration or base excess values. The surgical and postoperative findings in cattle with AV are good prognostic indicators of outcome. Cattle with OAV have a worse prognosis than those without omasal involvement. Large abomasal fluid volume, venous thrombosis, and blue or black abomasal color before decompression are all indicative of a poor prognosis.

The evaluation of the degree of circulatory insufficiency, dehydration, and levels of base excess and blood L-lactate concentration are also used as preoperative prognostic indictors. A preoperative blood L-lactate concentration ≦2 mmol/L is a good indicator of a positive outcome, whereas cattle with blood L-lactate concentration ≧6 mmol/L have a poor prognosis.[7] Postoperative decreases in blood L-lactate concentration are also a positive sign,[8] whereas postoperative decreased gastrointestinal motility is an unfavorable prognostic sign.

NECROPSY FINDINGS

In abomasal dilatation the abomasum is grossly distended with fluid and some gas. The rumen may contain an excessive amount of fluid. In some cases there may be impaction of the pylorus with particles of soil or sand and there may be an accompanying pyloric ulcer. In AV the abomasum is grossly distended with brownish, sanguineous fluid and is twisted. In complete volvulus the wall of the abomasum is grossly hemorrhagic and gangrenous and may have ruptured.

DIFFERENTIAL DIAGNOSIS

The diagnosis and differential diagnosis of right displaced abomasum and abomasal volvulus is dependent on consideration of the presence or absence of pings in the right abdomen, the findings on rectal examination, and the other clinical findings, including the history. Detecting a ping on percussion and auscultation of the right abdomen must be accompanied by a rectal examination to determine the presence and nature of a gas-filled viscus to account for the ping.

Dilatation and displacement of abomasum

The characteristic features of dilatation and right-sided displacement of the abomasum are recent calving, a vague indigestion since calving, soft scant feces, a ping over the right abdomen, and the presence of the distended tense viscus in the right lower abdomen. It must be differentiated from the following:

- **Impaction of the abomasum associated with vagal indigestion** is characterized by an enlarged abomasum that pits on digital palpation and feels like a doughy mass behind the lower aspect of the costal arch, situated on the floor of the abdomen, whereas most cases of dilatation are situated more dorsally adjacent to the right paralumbar fossa. Pings are not present in abomasal impaction. A laparotomy may be required to distinguish between them.
- **Subacute abomasal ulceration with moderate dilatation** of the abomasum in a recently calved cow may not be distinguishable clinically from RDA. The presence of melena suggests abomasal ulcers, but these may be present as secondary complications in dilatation and RDA.
- **Cecocolic volvulus** is characterized by distension of the right flank, tympanitic sounds on auscultation and percussion, and the distended large intestine can usually be palpated and identified tentatively, on rectal examination, as more than one cylindrical, tense tube (10–20 cm in diameter).
- **Fetal hydrops** is characterized by bilateral distension of the lower abdomen and an enlarged gravid uterus palpable on rectal examination.
- **Chronic or subacute traumatic reticuloperitonitis** may resemble abomasal dilatation, but in the former there may be a grunt on deep palpation, the feces are usually firm and dry, the abdomen is gaunt, and a mild fever may be present. However, a laparotomy may be necessary to make the diagnosis. Abdominocentesis may be useful.
- **Abomasal volvulus** is characterized by abdominal distension of the right side, pings on percussion and auscultation, dehydration, weakness, and shock with a heart rate up to 120 beats/min. The distended viscus can usually be palpated in the right lower quadrant of the abdomen. It must be differentiated from the following:
  - *Intestinal obstruction* is characterized by a history of sudden onset of anorexia; abdominal pain; scant feces, which may be blood-tinged; and the affected portion of the intestines or loops of distended intestine may be palpable rectally.
  - *Acute diffuse peritonitis* as a sequel a to local peritonitis in a cow soon after calving may be indistinguishable from acute abomasal volvulus. There is severe toxemia, tachycardia, dehydration, abdominal distension, grunting, weakness, recumbency, and rapid death. Paracentesis of the peritoneal cavity will assist in the diagnosis.

Pings over the right abdomen

Diseases resulting in pings over the right abdomen include dilatation and distension of the abomasum, cecum, cranial duodenum, parts of the small intestine, descending colon, and rectum and pneumoperitoneum.

The evaluation of a ping is dependent on the size of the area and location of the sound elicited by percussion and simultaneous auscultation. The common clinical characteristics of these pings are as follows:

- **Dilatation and right-side displacement of the abomasum:** the ping is usually audible between the 9th and 12th ribs extending from the costochondral junction of the ribs to their proximal third aspects. Rarely will the ping extend into the paralumbar fossa in right-side dilatation and displacement.
- **Abomasal volvulus:** the area of the ping is typically larger than that of the RDA and extends more cranially to the 8th rib and caudally, often extending into the right paralumbar fossa but not completely filling the fossa. Also, the ventral border of the ping area in an abomasal volvulus is variable, and is often horizontal because of the level of fluid within the abomasum.
- **Cecal dilatation:** the ping is usually confined to the dorsal paralumbar fossa and caudal one or two intercostal spaces. In dilatation and torsion of the cecum the ping usually fills the paralumbar fossa and extends cranially and caudally the equivalent of two rib spaces. The ascending colon is often involved in a torsion of the cecum, which will result in an enlarged ping area extending from the paralumbar fossa. In dilatation of the ascending colon the ping may be centered over the proximal aspects of the 12th and 13th ribs.
- **Intestinal obstruction:** the presence of multiple, small areas of ping that vary in pitch and intensity is characteristic of dilatation of the jejunoileum caused by intussusception or intestinal volvulus.
- **Dilatation of descending colon and rectum:** a ping in the right caudal

Continued

abdomen just ventral to the transverse processes of the vertebrae indicates dilatation of the descending colon and rectum, which is commonly heard following rectal examination.

- **Pneumoperitoneum:** pings may be audible over a wide area of the dorsal third of the abdomen bilaterally. In one study, the sensitivity and predictive values of abomasum as the source of the ping were 98% and 96%, respectively; for cecum and/or ascending colon, the sensitivity and predictive values were both 87%.

TREATMENT

The prognosis in RDA and AV is favorable if the diagnosis is made within a few days after the onset of clinical signs and before large quantities of fluid accumulate in the abomasum. The immediate treatment for both conditions should be surgical (right flank laparotomy with the cow standing) because RDA cannot be reliably differentiated from AV without performing surgery.

Surgical Correction

A right flank laparotomy for correction of the right displacement or volvulus is the preferred surgical method. Intensive fluid therapy is usually necessary preoperatively and for several days postoperatively to correct the dehydration and metabolic alkalosis and to restore normal abomasal motility.

Prokinetic Administration

Electromyographic studies of the postoperative abomasal and duodenal motility in cattle with surgically corrected AV reveal loss of motility, some retrograde motility, and loss of spike activity. This is associated with a decreased rate of abomasal emptying.[9]

These findings suggest that the postoperative course may be improved by the administration of a **prokinetic**, which is a therapeutic agent that stimulates, coordinates, and restores gastrointestinal motility.

The results of clinical trials and experimental studies indicate that the most effective prokinetic for abomasal hypomotility in cattle is erythromycin (8.8–10 mg/kg, intramuscularly). Cows treated with the motilin agonist erythromycin (10 mg/kg, intramuscularly) once before surgical correction of AV had an increased rate of abomasal emptying immediately after surgery and greater milk production on postoperative days 1 and 2 than did control cows. This provides strong support for the routine administration of prokinetic agents in the immediate postoperative period to cattle with RDA or AV. Four other macrolides (spiramycin, tilmicosin, tulathromycin, and tylosin) are also effective prokinetic drugs in healthy ruminants, but their motility-promoting effects are milder than erythromycin and have not been proven in a clinical trial of diseased cattle to be clinically significant.[10] Parenteral administration of erythromycin and other macrolides as prokinetic agents constitutes extralabel drug use. It is clearly inappropriate to administer an antimicrobial for a nonantimicrobial effect (such as increasing abomasal emptying rate) because such use may unnecessarily promote the development of antimicrobial resistance.

Cholinergic agents have been used to help restore motility but are not effective and are not recommended. Empirical treatment with 500 mL of 25% calcium borogluconate intravenously may yield good results. The rationale for the calcium administration is to improve abomasal motility.

Rumen transfaunation to restore rumen function and appetite will provide a more effective stimulus to restore gastrointestinal tract motility. Cattle are also offered good-quality hay but no grain for 3 to 5 days after surgery and monitored daily.

Postsurgical complications resembling a vagal-indigestion–like syndrome have been described (see under Clinical findings, above).

Fluid and Electrolyte Therapy

The composition of the fluids and electrolyte solutions that are indicated in RDA and AV has been a subject of much investigation. There are varying degrees of **dehydration**, **metabolic alkalosis**, **hypochloremia,** and **hypokalemia**. With the aid of a laboratory it is possible to monitor the serum biochemistry during administration of the fluids and electrolytes and to correct certain electrolyte deficits by adding ("spiking") the appropriate electrolytes to the fluids. Without a laboratory, the veterinarian has no choice but to use the solutions that are considered safe and judicious. **Balanced electrolyte solutions containing sodium, chloride, potassium, calcium, and a source of glucose will usually suffice**. A mixture of 2 L of isotonic saline (0.85%), 1 L of isotonic potassium chloride (1.1%), and 1 L of isotonic dextrose (5%) given at the rate of 4 to 6 L/h intravenously is also recommended and reliable. Experimentally induced hypochloremic, hypokalemic metabolic alkalosis in sheep has been corrected using 0.9 (300 mOsm/L), 3.6 (1200 mOsm/L), and 7.2% (2400 mOsm/L) of sodium chloride solutions given intravenously over a 2-hour period with the administered volume determined by the estimated total extracellular fluid chloride deficit. Significant difference was not found among treatments, with all solutions resulting in the return of clinicopathologic variables to preexperimental values within 12 hours. The rapid intravenous replacement of chloride with small volumes of hypertonic saline solution is safe and effective for correction of experimentally induced hypochloremic, hypokalemic metabolic alkalosis in sheep.

A randomized clinical trial investigated the efficacy of rapid intravenous infusion of hypertonic saline solution (7.2%, 2 L over 10 minutes, equivalent to 3.4 mL/kg) followed by 10 L of 0.9% NaCl for 50 minutes for resuscitating cattle with AV.[11] Hypertonic saline treatment was compared with conventional intravenous fluid therapy using an equivalent sodium load in a large-volume isotonic solution (26 L of 0.9% NaCl in 65minutes, equivalent to 400 mL/min). Cattle treated with hypertonic saline were more rapidly and effectively resuscitated at lower cost. This field study strongly supports the use of hypertonic saline in the treatment dehydration and dairy cattle.[11]

Oral Therapy

Oral electrolyte therapy has been recommended, particularly in the postoperative period following surgical drainage of the distended abomasum. A mixture of sodium chloride (50–100 g) and potassium chloride (50–120 g) is given orally daily postoperatively along with the parenteral fluids as necessary. Treatment with potassium chloride (120 g/day) orally can be continued daily until the cow resumes her normal appetite.

Deflation of Distended Abomasum in Calves

Gas can be removed from a grossly distended (bloated) abomasum of calves as an emergency measure before surgical correction by laparotomy. The calf is placed in dorsal recumbency and the abdomen is punctured with a 16-gauge 12-cm hypodermic needle at the highest point of the distended abdomen between the umbilicus and the xiphoid. After the distension is relieved and fluid therapy is begun, the need for a laparotomy can be assessed and performed if necessary.

CONTROL

No reliable information is available on the control of right-side dilatation, displacement, and volvulus of the abomasum. Because its pathogenesis is similar to LDA it would seem rational to recommend feeding programs that are used for the control of LDA.

ABOMASAL IMPACTION IN CATTLE

Abomasal impaction is defined as the presence of drier than normal abomasal contents and a larger than normal abomasal volume.[1] Abomasal impaction of cattle may be a **primary disorder** or develop secondary to another condition, such as traumatic reticuloperitonitis (see section on vagal indigestion syndrome) or ingestion of an abnormal diet (**dietary abomasal impaction**).[1] Primary abomasal impaction is most common in postparturient dairy cattle and appears to be under diagnosed because the specific findings can only be determined during right flank exploratory laparotomy.

Dietary abomasal impaction occurs in cattle in the prairie provinces of western Canada during the cold winter months, and elsewhere with similar circumstances, when the animals are fed poor-quality roughage. The disease is most common in pregnant beef cattle, which increase their feed intake during extremely cold weather in an attempt to meet the increased needs of a higher metabolic rate. The disease has also occurred in feedlot cattle fed a variety of mixed rations containing chopped or ground roughage (straw and hay) and cereal grains and in late pregnant dairy cows on similar feeds.

SYNOPSIS

Etiology Abomasal hypomotility in periparturient dairy cattle. Ingestion of abnormal diet, including large quantities of low-quality roughage during cold weather.

Epidemiology Periparturient dairy cattle (primary abomasal impaction). Pregnant primiparous beef cattle during cold weather consuming low-quality roughage (dietary abomasal impaction).

Signs Anorexia, scant feces, distension of abdomen, and loss of body weight. Normal vital signs initially. Rumen full and atonic. Right lower flank distended and may be able to palpate abomasum through abdominal wall and rectally in advanced cases. Periparturient dairy cattle with primary abomasal impaction may look very much like a left displaced abomasum, but a ping cannot be detected on the left side. Gradually become weak and recumbent.

Clinical pathology hypochloremia, hypokalemia, metabolic alkalosis.

Lesions Gross enlargement of abomasum impacted with dry, rumen-like contents; enlargement may be confined to pyloric antrum.

Diagnostic confirmation Laparotomy.

Differential diagnosis Impaction of abomasum associated with vagal indigestion, impaction of the omasum, diffuse peritonitis, and intestinal obstruction.

Treatment Medical treatment with mineral oil or dioctyl sodium sulfosuccinate. External massage of impacted pyloric antral contents and injection of dioctyl sodium sulfosuccinate (100 mL) directly into abomasal lumen during right flank laparotomy. Abomasotomy in extensive cases.

Control Provide nutrient requirements for pregnant beef cattle during cold weather.

ETIOLOGY AND EPIDEMIOLOGY

Primary Abomasal Impaction

Affected animals have distension and impaction of the pyloric antrum region only, or pyloric antrum and body. This appears to have a very similar epidemiology to that of LDA, with abomasal hypomotility likely to play a central role in the condition.

Dietary Abomasal Impaction

The consumption of excessive quantities of poor-quality roughage, which are low in both digestible protein and energy, is the primary cause. Outbreaks of impaction with sand have occurred in which up to 10% of cattle at risk were affected. Impaction of the abomasum with sand can also occur in cattle if they are fed hay on sandy soils or root crops that are sandy or dirty, or sand is accidentally mixed into silage while it is being packed; in one herd outbreak it was estimated that cattle fed this silage were ingesting 0.7 kg of sand each day.[2] There is one report of severe sand abomasal impaction in five periparturient dairy cows housed in free stalls bedded with sand.[3] The diet fed to these dairy cows during late gestation was too acidogenic based on measured DCAD and urine pH. In this case the sand ingestion was attributed to pica.

The disease is most common in young pregnant beef cows that are kept outdoors year-round, including during the cold winter months, when they are fed roughages consisting of either grass or legume hay or cereal straw, which may or may not be supplemented with some grain. In these circumstances cows commonly lose 10% to 15% of their total BW from October to May and even more during very cold winters. In one retrospective study of the necropsy reports of cattle that died with abomasal impaction, 20% of the animals had lesions of traumatic reticuloperitonitis, 60% were thought to be caused by the ingestion of too much poor-quality roughage without a supplement of concentrate, and 20% did not fit into either category.

When large quantities of long roughage without sufficient grain are fed during very cold weather, the cattle cannot eat sufficient feed to satisfy energy needs, so the roughage is then provided in a chopped form. The chopped roughage is commonly mixed with some grain in a mix mill but usually at an insufficient level to meet the energy requirements. Cattle can and do eat more of these chopped roughage–grain mixtures than of long roughage because the smaller particles pass through the forestomach at a more rapid rate. Impaction of the abomasum, omasum, and rumen may occur because of the relative indigestibility of the roughage. Outbreaks may occur affecting up to 15% of all pregnant cattle on individual farms when the ambient temperature drops to −5°C to −10°C (14°F to −22°F) for several days.

Omasal and abomasal impaction has occurred in a group of beef suckler cows in late gestation housed in straw yards and fed solely on pea haulm. The disease has also occurred in feedlot cattle fed similar rations (e.g., 80% roughage, 20% grain) in an attempt to reduce the high cost of grain feeding and to satisfy beef grading standards that put the emphasis on producing a smaller amount of fat cover. With these constraints and the increased emphasis on roughage feeding, it is possible that the incidence of abomasal impaction may increase in feedlot cattle. The feeding of almond shells to dairy replacement heifers has also resulted in abomasal impaction.

The ingestion of gravel (stones) by dairy cattle kept in drylot facilities can result in complete, nonstrangulating intraluminal obstruction of the abomasum and duodenum. The gravel, consisting of sand and small stones, may be inadvertently mixed with the feed when it is being scraped from bunker silos. It is also possible that some cows may ingest the gravel when attempting to eat all available feed.

PATHOGENESIS

A description of the likely pathogenesis of primary abomasal impaction is given in the section pathogenesis of LDA, and it is thought to be similar to that for abomasal displacement. In dietary abomasal impaction, chopped roughage and finely ground feeds pass through the forestomach of ruminants more quickly than long roughage, and perhaps in this situation the combination of low digestibility and excessive intake leads to excessive accumulation in the forestomach and abomasum. When large quantities of sand are ingested, the omasum, abomasum, large intestine, and cecum can become impacted. The sand that accumulates in the abomasum causes abomasal atony and chronic dilatation.

Once impaction of the abomasum occurs in both primary and dietary causes, a state of subacute obstruction of the upper alimentary tract develops. Hydrochloric acid continues to be secreted into the abomasum in spite of the impaction and hypomotility, resulting in hypochloremia and increased

strong ion difference (strong ion or metabolic alkalosis). Varying degrees of dehydration occur because fluids are not moving beyond the abomasum into the duodenum for absorption. Potassium ions are also sequestered in the abomasum, resulting in a hypokalemia. Almost no ingesta or fluids move beyond the pylorus, and dehydration, alkalosis, electrolyte imbalance, and progressive starvation occur. The impaction of the abomasum is usually severe enough to cause extensive distension, which impedes return of normal motility.

CLINICAL FINDINGS

Periparturient dairy cattle with primary abomasal impaction have identical clinical signs to that of cattle with LDA, except that a ping is not auscultated in the left flank.

Complete anorexia, scant feces, and moderate distension of the abdomen are the usual presenting complaints given by the owner in cattle with dietary abomasal impaction. The onset is usually slow and progressive over a period of several days. Cattle that have been affected for several days have lost considerable weight and are too weak to rise. The body temperature is usually normal but may be subnormal during cold weather, which suggests that the specific fermentative action of the rumen is not sufficient to meet the energy needs of basal metabolism. The heart rate varies from normal to 90 to 100 beats/min and may increase to 120 beats/min in advanced cases in which hypochloremia, alkalosis, and dehydration are marked. The respiratory rate is commonly increased and an expiratory grunt caused by the abdominal distension may be audible, especially in recumbent cattle. A mucoid nasal discharge usually collects on the external nares and muzzle, which is usually dry and cracking because of the failure of the animal to lick its nostrils and the effects of the dehydration.

The rumen is usually static and full of dry rumen contents, or it may contain an excessive quantity of fluid in those cattle that have been fed finely ground feed. The pH of the ruminal fluid is usually within the normal range (6.5–7.0). The rumen protozoan activity ranges from normal to a marked reduction in numbers and activity as assessed on a low-power field. The impacted abomasum is usually situated in the right lower quadrant of the abdomen on the floor of the abdominal wall. It usually extends caudally beyond the right costal arch but may or may not be easily palpable because of the gravid uterus, but an impacted omasum may also be palpable. It may be impossible, however, to distinguish between an impacted abomasum and an impacted omasum. In feedlot steers and nonpregnant heifers the impacted abomasum and omasum may be easily palpable on rectal examination. Deep palpation and strong percussion of the right flank may elicit a "grunt," which is common in acute traumatic reticuloperitonitis, and this is probably caused by overdistension of the abomasum and stretching of its serosa.

The course of the disease in dietary abomasal impaction depends on the extent of the impaction when the animal is first examined and the severity of the acid-base and electrolyte imbalances. Severely affected cattle will die in 3 to 6 days after the onset of signs. Rupture of the abomasum has occurred in some cases, and death from acute diffuse peritonitis and shock occurs precipitously in a few hours. In sand impaction, there is considerable weight loss, chronic diarrhea with sand in the feces, weakness, recumbency, and death within a few weeks.

Severe impaction and distension of the rumen and the abomasum can occur in cattle given access to large quantities of finely chopped straw during the cold winter months. There is gross distension of the abdomen, anorexia, and scant dry feces, and affected animals will drop large, dry, fibrous cuds. The rumen is grossly distended and usually static.

Cows fed solely on pea haulm are dull and anorexic with grossly distended abdomens and varying degrees of bloat. Cattle with obstruction of the abomasum and duodenum with gravel are anorexic, depressed, and weak. The abdomen may be distended and rumen hypomotility or atony is present. The feces are scant. The obstruction cannot usually be felt on rectal examination, and a right flank laparotomy is necessary to make the diagnosis. A marked hypochloremic, hypokalemic metabolic alkalosis is characteristic.

CLINICAL PATHOLOGY

A metabolic alkalosis, hypochloremia, hypokalemia, hemoconcentration, and a total and differential leukocyte count within the normal range are common. Hypochloremia is more severe in cattle with primary impaction confined to the pyloric antrum compared with cattle with primary impaction of the pyloric antrum and body.[1]

NECROPSY FINDINGS

Cattle with primary abomasal impaction confined to the pyloric antrum are rarely necropsied because the condition responds well to treatment during surgery.

At necropsy of cattle with primary abomasal impaction that extends to the abomasal body or dietary abomasal impaction the abomasum is commonly grossly enlarged to up to twice normal size and impacted with dry rumen-like contents. The omasum may be similarly enlarged and impacted with the same contents as in the abomasum. The rumen is usually grossly enlarged and filled with dry ruminal contents or ruminal fluid. The intestinal tract beyond the pylorus is characteristically empty and has a dry appearance. Varying degrees of dehydration and emaciation are also present. If rupture of the abomasum occurs, lesions of acute diffuse peritonitis are present. Abomasal tears, ulcers, and necrosis of the walls of the rumen, omasum, or abomasum may occur.

TREATMENT

The challenge in treatment is to be able to recognize the cases that will respond to treatment and those that will not and should therefore be slaughtered immediately for salvage.

Dairy cattle in early lactation with primary abomasal impaction confined to the pyloric antrum respond extremely well to treatment during right flank laparotomy and have a similar postoperative course to cattle with LDA that have been surgically corrected.[1]

Cattle that have a severely impacted abomasum and are weak with a marked tachycardia (100–120 beats/min) are poor treatment risks and should be euthanized if they are of low economic value. Rational treatment would appear to consist of correcting the metabolic alkalosis, hypochloremia, hypokalemia, and dehydration and attempting to move the impacted material with lubricants such as mineral oil or dioctyl sodium succinate, or surgically emptying the abomasum. Balanced electrolyte solutions are infused intravenously on a continuous basis for up to 72 hours at a rate of 100 to 150 mL/kg BW over a 24-hour period. Some cases will respond remarkably well to combined medical treatment of intravenous fluid therapy and oral mineral oil and begin ruminating and passing feces in 48 hours.

DIFFERENTIAL DIAGNOSIS

The clinical diagnosis of impacted abomasum depends on the nutritional history, the clinical evidence of impaction of the abomasum, and the laboratory results. The disease must be differentiated from abomasal impaction as a complication of vagal indigestion, omasal impaction, diffuse peritonitis, and acute intestinal obstruction caused by intestinal accidents or enteroliths and lipomas.

- **Impaction of the abomasum as a complication of traumatic reticuloperitonitis** usually occurs in late pregnancy, and commonly only in one animal; a mild fever may or may not be present and there may be a grunt on deep palpation of the xiphoid. The rumen is usually enlarged and may be atonic or hypermotile. Depending on the lesion present a neutrophilia may be present, which is suggestive of a chronic infection. A hypochloremia is common, as in dietary impaction. In many cases it is impossible to distinguish between the two causes of impacted abomasum, and a laparotomy may be necessary to explore the abdomen for evidence of peritoneal lesions. Cattle with abomasal impaction as a complication

of traumatic reticuloperitonitis are usually a single incident and have usually been ill for several days, whereas those with dietary impaction have usually been ill for only a few days and more than one may be affected.

- **Impaction of the omasum** occurs in advanced pregnancy and is characterized by anorexia, scant feces, normal rumen movements, moderate dehydration, and an enlarged omasum that is usually only palpable during an exploratory laparotomy. The serum electrolyte concentrations may be within reference limits if the abomasum is normal.
- **Diffuse peritonitis** is characterized by anorexia, toxemia, dehydration, scant feces, and a grunt on deep palpation and percussion. However, in peracute cases the abdominal pain may be absent. Fibrinous adhesions may be palpable on rectal examination, and paracentesis may yield some diagnostic peritoneal exudate, but a negative result cannot rule out peritonitis. The presence of a marked leukopenia and neutropenia or a neutrophilia may assist in the diagnosis, but it is often necessary to perform an exploratory laparotomy to confirm the diagnosis.
- **Intestinal obstructions** caused by intestinal accidents or enteroliths result in anorexia, scant feces, dehydration, and abdominal pain, and the abnormality may be palpable on rectal examination. The rumen is usually static and filled with doughy contents. Fluid and gas accumulations in the intestines anterior to the obstruction may be detectable as fluid-splashing sounds by using simultaneous auscultation and succussion of the abdomen.

Dioctyl sodium sulfosuccinate is administered into the rumen by stomach tube at a dose rate of 120 to 180 mL of a 25% solution for a 450-kg animal repeated daily for 3 to 5 days. It is **mixed with 10 L of warm water and 5 L of mineral oil.** A beneficial response cannot be expected in less than 24 hours, and most cattle that do respond will show improvement by the end of the third day after treatment begins. The presence of increased fecal volume that is well mixed with mineral oil is usually a good clinical sign. Cholinergics such as neostigmine, physostigmine, and carbamylcholine have been used but do not appear to alter the outcome. Research studies indicate poor efficacy of cholinergics in healthy animals and cattle with displaced abomasum. Erythromycin is the best prokinetic agent available, but antimicrobials should not be administered for a nonantimicrobial effect (see section on LDA in this chapter for more information on prokinetic agents).

Surgery

Surgical correction of impaction of the pyloric antrum consists of external massage of impacted pyloric antral contents and injection of dioctyl sodium sulfosuccinate (100 mL) directly into abomasal lumen during right flank laparotomy.

Surgical correction of impaction of the abomasal body consists of an abomasotomy through a right paramedian approach and removal of the contents of the abomasum. The results are often unsuccessful, probably because of abomasal atony that exists and that appears to worsen following surgery. An alternative approach may be to do a rumenotomy, empty the rumen, and infuse dioctyl sodium sulfosuccinate directly into the abomasum through the reticuloomasal orifice in an attempt to soften and promote the evacuation of the contents of the abomasum. The placement of a nasogastric tube into the omasal groove and into the abomasum through a rumenotomy procedure is described. Mineral oil can then be pumped into the abomasum at the rate of 2 L/day for several days. Recovery should occur within 5 to 7 days. A rumenotomy and emptying of the rumen is necessary in the case of severe straw impaction of the rumen.

The induction of parturition using 20 mg of dexamethasone intramuscularly may be indicated in affected cattle that are within 2 weeks of parturition and in which the response to a few days' treatment has been unsuccessful. Parturition may assist recovery as a result of a reduction in intraabdominal volume. In sand impaction, affected cattle should be moved off the sandy soil and fed good hay and a grass mixture containing molasses and minerals. Severely affected cattle should be treated with large daily doses of mineral oil (at least 15 L/day).

Gravel or sand obstruction of the abomasum and duodenum can be corrected surgically by right flank laparotomy and by removing all of the gravel or sand.

CONTROL

Primary Abomasal Impaction

The major control measures are those for LDA, because the conditions are thought to have abomasal hypomotility as a primary requirement.

Dietary Abomasal Impaction

Prevention of the disease is possible by providing the necessary nutrient requirements for wintering pregnant beef cattle with added allowances for cold windy weather when energy needs for maintenance are increased. When low-quality roughage is to be used for wintering pregnant beef cattle, it should be analyzed for crude protein and DE. Based on the analysis, grain is usually added to the ration to meet the energy and protein requirements. Pregnant beef cows fed a diet of 94% barley straw for 83 days during the cold winter months may consume only 70% of their energy requirements. Such straw-based diets must be supplemented with protein and energy. During prolonged periods of cold weather, wintering pregnant beef cattle should be given additional amounts of feed to meet the increased feed requirement for maintenance, which has been estimated to be 30% to 40% greater during the colder months than during the warmer months. These increased requirements are due almost equally to the effects of reduced feed digestibility and the increased maintenance requirements.

The published nutrient requirements of beef cattle are guidelines for the nutrition of cattle under average conditions and higher nutrient levels than those indicated may be necessary to provide for maintenance requirements, particularly during periods of cold stress. **Adequate amounts of fresh drinking water** should be supplied at all times, and the practice of forcing wintering cows to obtain their water requirements from eating snow while on low-quality roughage is extremely hazardous. The question of whether or not low-quality roughages should be chopped or ground for wintering pregnant beef cattle is controversial. The daily voluntary intake of low-quality roughage can be increased by chopping or grinding but neither processing method increases quality or digestibility; in fact digestibility is usually decreased. If increased consumption during cold weather exceeds physical capacity and the nutrient requirements are still not satisfied, impaction of the abomasum may occur. Thus during the coldest period of the winter low-quality roughages must be supplemented with concentrated sources of energy such as cereal grains.

Omasal and abomasal impaction caused by the provision of excessive poor-quality roughage is preventable by supplementation with appropriate sources of energy and protein.

ABOMASAL IMPACTION IN SHEEP AND GOATS (ABOMASAL EMPTYING DEFECT)

Abomasal dilatation and impaction in sheep as a result of an **abomasal emptying defect** has been reported predominantly in adult Suffolk sheep, but also occurs sporadically in adult Hampshire, Texel, and Dorset sheep, as well as Toggenberg goats. Affected sheep are usually large-framed rams and ewes, usually 2 to 6 years of age, and the ewes are often in late gestation or recently lambed. The disease has been reported in two goats that were 8 years old.[1] The duration of illness varies from several days to a few months and affected animals may become emaciated. The diets fed to affected animals consisted of grain and good-quality hay. The etiopathogenesis is unknown but may reflect

abnormalities in autonomic innervation to the abomasum or an increased vertical distance between the ventral abdomen and proximal duodenum. Current associations between the occurrence of LDA in Holstein Friesian cattle and SNPs associated with coding for the motilin receptor suggest that a genetic disorder may contribute to the occurrence of an abomasal emptying defect in sheep and goats.

Clinical signs include progressive weight loss, anorexia, variable degrees of distension of the right lower abdomen, a large palpable mass in the right lower abdomen, increased concentrations of rumen chloride, and a grossly enlarged and impacted abomasum. Some animals have abdominal distension accompanied by ruminal hypermotility, which is evident in the left paralumbar fossa. A firm enlarged viscus can be balloted on the lower right quadrant in advanced cases. Ultrasonography of the ventral abdomen is helpful in identifying the abomasal dimensions and confirming the presence of a large distended abomasum. Hypochloremia, hypokalemia, and metabolic alkalosis are common and ruminal chloride concentrations are increased up to 39 mmol/L, suggesting reflux from the abomasum. A standing right flank laparotomy is helpful in confirming the presumptive diagnosis in equivocal cases.

Surgical treatment by emptying the abomasum via a right paramedian abomasopexy provides relief for a few months but the disease invariably returns. Affected animals may have concurrent renal disease that may reflect chronic abomasal emptying abnormalities. Medical treatment has been ineffective using parasympathomimetic agents and metoclopramide, although there are no reports describing the response to erythromycin, which is the most effective prokinetic agent in calves and adult (see section on LDA in this chapter). At necropsy, the abomasum is grossly enlarged and commonly contains up to 30 L of rumen-like contents, which are dry and doughy. In some cases the abomasum contains an excessive quantity of fluid.

There is a report of abomasal impaction with anorexia causing high mortality in young lambs. Affected lambs developed anorexia, dullness, and reluctance to walk. Sudden death occurred in lambs less than 1 month of age, and progressive loss of body condition and dehydration occurred in older lambs. Affected animals did not suck their dams normally. It is suggested that the ewes had insufficient milk for the lambs, which consequently forced them to begin consuming solid feed at an early age. The impaction was associated with the presence of phytobezoars; trichophytobezoars; and coagulated, rubber-like milk clots in the abomasum, usually at the entrance to the pylorus.

Abdominal enlargement caused by abomasal dilatation and impaction associated with multiple adenomas of the abomasal mucosa has been recorded in an adult ewe.

ABOMASAL PHYTOBEZOARS AND TRICHOBEZOARS

A velvety form of abomasal phytobezoar occurs in goats and sheep in the arid regions of southern Africa and causes significant economic loss. The composition of the bezoars resembles that of pappus hairs and stems of the Karoo bushes. They have a striking velvety appearance. Phytobezoars have been experimentally reproduced in goats and sheep by feeding the mature flowers or seeds and pappus hairs of Karoo bushes.

Trichobezoars are frequently found in calves 2 to 3 months of age when they can occasionally result in intestinal obstruction and have been associated with abomasal ulceration (addressed in the relevant sections elsewhere in the chapter). Rumenoabomasal trichobezoars have been reported in steers 20 to 24 months of age with a history of inappetence and weight loss and licking their own and other animals' hair coats. Numerous hairs (0.5- to 1.5-cm in length) were found implanted in the abomasal mucosa, especially in the region of the torus pyloricus. Areas of hair implantation were frequently accompanied by scattered and severe abomasitis, erosions, and ulcers. Thickening of the rugae and plicae of the pylorus was present. In the rumen, rumenitis and hyperkeratosis, characterized by short, reddish edematous ruminal papillae containing small numbers of trapped hairs, were present. The severity of the lesions increased with the number of hairs implanted in the mucosa.

An abomasal phytobezoar was removed surgically from a 5-year-old Holstein Friesian cow through a right flank laparotomy with the cow in a standing position.[1] Abomasotomy for removal of foreign bodies is usually performed using a right paramedian incision with the cow in left lateral recumbency.

ABOMASAL ULCERS OF CATTLE

Abomasal ulceration occurs in mature cattle and calves and may cause acute abomasal hemorrhage with indigestion, melena, and sometimes perforation, resulting in a painful acute local peritonitis or acute diffuse peritonitis and rapid death, or a chronic indigestion with only minimal abomasal hemorrhage. Some calves have abomasal ulceration at necropsy or slaughter that was subclinical.

SYNOPSIS

Etiology Cause of primary ulceration unknown. Many ulcers occur secondary to lymphoma, left-displaced abomasum, and viral diseases.

Epidemiology Mature lactating dairy cattle, hand-fed calves, nursing beef calves. Risk factors not understood. Presence of hairballs not a risk factor in calves.

Signs Melena, pallor from anemia, abdominal pain, acute local peritonitis caused by perforation.

Clinical pathology Melena, occult blood in feces, anemia.

Lesions Ulceration of mucosa, blood in abomasum. Acute local peritonitis if perforated.

Diagnostic confirmation Abomasotomy.

Differential diagnosis Duodenal ulceration, acute and chronic traumatic reticuloperitonitis if ulcer perforated, acute diffuse peritonitis if perforated, right-side dilatation of abomasum.

Treatment Antacids. Blood transfusions. Surgical excision.

Control Nothing reliable.

ETIOLOGY

Primary Ulceration

Although many different causes of primary abomasal ulceration have been suggested, the cause is unknown. Possible causes that have been considered but for which there is no reliable evidence of a cause-and-effect relationship include the following:

- **Abomasal hyperacidity** in adult cattle, although there is no direct evidence to support the hypothesis except in animals subject to **fasting**
- **Mechanical abrasion** of the pyloric antrum caused by the ingestion of coarse roughage, such as straw, or possibly the presence of trichobezoars
- **Bacterial infections** such as *C. perfringens* type A or fungi such as *Aspergillus fumigatus* and *Mucor* spp.[1]
- **Trace mineral deficiencies** such as copper deficiency (evidence is weak)
- **Concurrent stress** as in cattle with severe inflammatory processes or in severe pain that result in hypercortisolemia

Secondary Ulceration

Abomasal ulceration can occur secondary to other diseases. Reflux of bile into the abomasal lumen, particularly in ruminants with LDA or RDA, is strongly associated with abomasal ulceration.[2] Bile acids are a well-documented cause of gastric injury. Other examples include lymphoma of the abomasum and erosions of the abomasal mucosa in viral diseases such as bovine virus diarrhea (BVD) and bovine malignant catarrh. There

is one report of abomasal ulceration in a 2-month-old calf caused by a yolk sac tumor around the abomasum (a very rare germ cell tumor of cattle).[3]

EPIDEMIOLOGY

Primary Abomasal Ulcers

Primary abomasal ulcers occur in lactating dairy cows, mature bulls, hand-fed calves, veal calves, and sucking beef calves. The epidemiologic circumstances for each of these groups are presented here.

Lactating Dairy Cows

Some observations have found that acute hemorrhagic abomasal ulcers occur in high-producing mature dairy cows in early lactation, whereas others have found that most acute bleeding ulcers occurred in cows 3 to 6 months after parturition. The close relationship of the disease to parturition suggests that a combination of the stress of parturition with associated hypercortisolemia, the onset of lactation, and high-level grain feeding is associated with acute ulceration in dairy cows.

However, epidemiologic observations of acute hemorrhagic abomasal ulceration in cattle have found no association with the stress of calving. The incidence was highest in dairy cows during the summer months when the animals were grazing on pasture. There was also a direct association between amount of rainfall, amount of fertilizer used, and stocking rate, as well as the amount of milk produced by affected cows. This suggests that some factor in grass may be a risk factor in the acute disease in mature dairy cattle.

Mature high-producing dairy cows in **early lactation** may develop acute hemorrhagic ulceration of the abomasum following a prolonged illness such as pneumonia or after having been to a cattle show and sale. This suggests that **stress** and hypercortisolemia may be an important contributing cause.

The prevalence of abomasal ulcers in mature cattle varies depending on the population of animals surveyed. Of cattle admitted to a veterinary teaching hospital over a 4-year period, 2.2% had confirmed abomasal ulcers. In surveys at abattoirs the prevalence may reach 6%. The case–fatality rate for mature cattle with confirmed abomasal ulcers is about 50%, and for those with severe blood loss or diffuse peritonitis the case–fatality rate is usually 100%. Type I nonperforating abomasal ulcers were found in 21% of cows examined at the abattoir and there was no clinical evidence of the ulcers before slaughter, but 32% of the animals were anemic and 44% were hyperproteinemic, which could be expected in cattle with chronic blood loss.

Mature Bulls and Feedlot Cattle

Acute bleeding ulcers occur occasionally in mature dairy and beef bulls, particularly following long transportation, prolonged surgical procedures, and in painful conditions such as a fractured limb or rupture of the cruciate ligaments of the stifle joint. Abomasal ulcers have also been the cause of sudden death in yearling feedlot cattle. Examination of a random sample of the abomasa of feedlot cattle revealed that erosions were present in up to 33% of the animals, depending on their origin. It is hypothesized that the feeding of high levels of grain in feedlot cattle may be a risk factor associated with abomasal erosions.

Hand-Fed Calves

Ulcers of the abomasum are common in hand-fed calves when they are weaned from milk or milk replacer and begin consuming roughage. The causes of the acute ulceration are unknown, but by association it appears that some calves are susceptible when they are changing from a diet of low dry matter content (milk or milk replacer) to one of a higher dry matter content (grass, hay, and grain). Most of these ulcers are subclinical and not hemorrhagic. The incidence of abomasal ulcers in milk-fed veal calves is higher when the animals have access to roughage than when roughage is not provided. The type of roughage may also be a factor: pellets produced from corn silage were associated with more lesions than pellets produced from barley straw or alfalfa hay, suggesting that loss of pH partitioning in the abomasum may play a primary role. Occasionally, milk-fed calves under 2 weeks of age are affected by acute hemorrhagic abomasal ulcers, which may perforate and cause rapid death.

Perforating abomasal ulcers have occurred in calves up to 6 months of age, with the majority between 6 and 12 weeks of age. **LDA** was present in 70% of the cases.

Veal Calves

Abomasal ulceration is a common finding in veal calves slaughtered at 3 to 5 months of age. The incidence and severity of lesions are greatest in loose-housed calves with access to straw and fed milk substitute ad libitum. There was no evidence that erosions and ulcers found in the majority of veal calves affected their growth rate or welfare. No relationship was found between the presence of abomasal erosions and ulcers and the behavior of crated veal calves fed milk for 22 to 24 weeks.

Sucking Beef Calves

Well-nourished sucking beef calves, 2 to 4 months of age, may be affected by acute hemorrhagic and perforating abomasal ulcers while they are on summer pasture. Abomasal trichobezoars are commonly present in these calves, but whether the hairballs initiated the ulcers or developed after the ulcers is uncertain.

Abomasal ulcers and abomasal tympany occurs in range beef calves from 3 to 12 weeks of age in beef herds in the north central region of the United States, along the eastern slopes of the Rocky Mountains, and in Alberta.

In a retrospective study of 46 abomasotomies in young beef calves in western Canada, in affected herds the average incidence was 1.0% with a range among herds from 0.2% to 5.7%. In 80% of surgeries of the abomasum, abomasal ulcers were found, and hairballs were present in the abomasum of 76%, but this does not necessarily mean that hairballs are a causative agent (see later). Calves housed in pens or on stubble fields were nearly three times more likely to receive surgery for abomasal disease than those kept on pasture.

On-farm investigations of western Canadian beef herds that had reported **abomasal ulcers in calves** found that the average number of suspected and confirmed cases of fatal abomasal ulcers were 2.4 and 1.9 per farm, respectively. Most producers reported that the affected calves had died without exhibiting any clinical signs and that the affected calves were average or above average in growth performance. Most (86%) of the ulcers occurred in calves under 2 months of age. Most (93%) of the fatal ulcers were perforating, and the remainder (6.7%) were hemorrhagic ulcers. The peak number of cases occurred in April and May but this seasonal incidence reflects the age structure of the calf population in Canada, in which most beef calves are born during the late winter and early spring months. There was no sex predilection and no evidence of breed predisposition. There is minimal evidence to suggest that *C. perfringens* type A, *Helicobacter pylori*, or *Campylobacter* spp. are involved in ulcer formation.[4]

The relationship between the **abomasal hairballs** and perforating abomasal ulcers in unweaned beef calves under 4 months of age has been examined. For many years it was thought that the presence of hairballs in the abomasum abraded the mucosa, initiating an ulcerogenic process, eventually culminating in a perforating ulcer. However, finding hairballs in the abomasum of nursing beef calves with perforating ulcers does not necessarily mean that the hairballs caused the ulcer. Hairballs are present in the abomasum of the same class of calves that die of other diseases unrelated to the abomasum. Calves under 1 month of age dying of an ulcer were almost four times more likely to have an abomasal hairball than were calves dying of all other diseases. This relationship did not exist in older calves over 30 days of age, in which about 60% of all calves, regardless of the cause of death, had an abomasal hairball. The prevalence of hairballs in the young and old ulcer calves was 58% and 57%, respectively; in the old nonulcer calves it was 63%. The prevalence of hairballs in the young nonulcer calves was 20%.

Two factors may account for the lower prevalence in young nonulcer calves. First, more than half (55%) of the nonulcer calves died in the first few weeks of life, compared with only 12.5% of the ulcer calves. Thus calves in the ulcer group had more time to develop an abomasal hairball. Second, the majority (68%) of the calves died of enteritis and sepsis, making them less likely to engage in normal nursing behavior, which involves muzzling and licking the udder, resulting in the ingestion of hair. Only 57% of calves dying of perforating ulcer had a hairball, indicating that the hairballs are not necessary for an ulcer to develop. This is supported by field observations of pathologists who report that only 25% of calves with a perforating ulcer had an abomasal hairball. Another argument against the hairball theory is that 89% of perforations occurred in the body of the abomasum, a region that has a poorly developed musculature and is incapable of producing strong peristaltic contractions. It is suggested that the weak frictional forces generated in this region could exert an abrasive action on the mucosal surfaces. In summary, it is suggested that abomasal hairballs are not necessary for abomasal ulcers to develop in nursing beef calves.

Dietary Factors in Calves Fed Milk or Milk Replacer

The cause of the high prevalence of abomasal ulceration in nursing beef calves is unknown. A low abomasal luminal pH caused by the diet has been proposed as a possible factor. Experimentally, feeding dairy calves (17 days of age) cow's whole milk resulted in lower abomasal luminal pH compared with the feeding of two different milk replacers (an all milk protein or combined milk and soy protein milk replacer). It has been hypothesized that the sucking of cow's whole milk results in a lower mean abomasal luminal pH and, because fasting or infrequent sucking of milk replacer results in a sustained period of low abomasal luminal pH, this may provide evidence for primary abomasal ulceration in nursing beef calves. This may be related to the occurrence of abomasal ulceration in nursing beef calves after a period of inclement weather, during which time the frequency of nursing may be decreased.

Secondary Abomasal Ulcers

Abomasal ulcers occur secondary to left-side and right-side abomasal displacements, abomasal impaction or volvulus, lymphomatosis and vagal indigestion, or unrelated to other diseases.

PATHOGENESIS

Any injury to the gastric mucosa allows diffusion of hydrogen ions from the lumen into the tissues of the mucosa and also permits diffusion of pepsin into the different layers of the mucosa, resulting in further damage. There may be only one large ulcer, but more often there is evidence of numerous acute and chronic ulcers.

A classification of abomasal ulcers in cattle is as follows.

Type 1: Nonperforating Ulcer

In this classification there is incomplete penetration of the abomasal wall resulting in a minimal degree of intraluminal hemorrhage, focal abomasal thickening, or local serositis. Nonbleeding chronic ulcers commonly cause a chronic gastritis. This category has been expanded to include erosions in a modified categorization system: 1a = erosion with minimal mucosal defects; 1b = deeper erosions combined with local hemorrhage; and 1c = craters with a superficial coating of detritus, fibrin, or inflammatory products. However, erosions are discrete mucosal defects that do not penetrate the muscularis mucosa of the abomasum, whereas ulcers penetrate the entire thickness of the mucosa and extend into the submucosa.

Type 2: Ulcer Causing Severe Blood Loss

With the type 2 ulcer there is penetration of the wall of a major abomasal vessel, usually in the submucosa, resulting in severe intraluminal hemorrhage and anemia. In acute ulceration with erosion of a blood vessel there is acute gastric hemorrhage with reflex spasm of the pylorus and accumulation of fluid in the abomasum, resulting in distension, metabolic alkalosis, hypochloremia, hypokalemia, and hemorrhagic anemia. Usually within 24 hours there is release of some of the abomasal contents into the intestine, resulting in melena. The ruminal chloride concentration may increase in about 40% of cows with bleeding ulcers, which suggests abomasal reflux of acid into the rumen.

Plasma gastrin activity increases significantly in cattle with bleeding abomasal ulcers.

Type 3: Perforating Ulcer With Acute, Local Peritonitis

In this classification there is penetration of the full thickness of the abomasal wall, resulting in leakage of abomasal contents. Resulting peritonitis is localized to the region of the perforation by adhesion of the involved portion of abomasum to adjacent viscera, omentum, peritoneal surface, or diaphragm. Omental bursitis and empyema may develop, with the accumulation of a large quantity of exudate and necrotic debris in the omental cavity. In rare instances the abomasal acidity may erode through the diaphragm, causing an abomasal–pleural fistula.

Type 4: Perforating Ulcer With Diffuse Peritonitis

With a type 4 ulcer there is penetration of the full thickness of the abomasal wall, resulting in leakage of abomasal contents. Resulting peritonitis is not localized to the region of the perforation; thus digesta is spread diffusely throughout the peritoneal cavity.

In nursing beef calves, about 90% of perforated abomasal ulcers occur in the body of the abomasum, with a propensity for the greater curvature. In some calves the ulcers are subclinical and the factors that determine how large or how deep an ulcer will become are unknown. Based on abattoir studies it is evident that abomasal ulcers will heal by scar formation.

CLINICAL FINDINGS

The clinical syndrome varies depending on whether ulceration is complicated by hemorrhage or perforation. The important clinical findings of hemorrhagic abomasal ulcers in cattle are **abdominal pain**, **melena,** and **pale mucous membranes**. At least one of these clinical findings is present in about 70% of cattle with abomasal ulcers. The case–fatality rates for cattle with types 1, 2, 3, or 4 are 25, 100, 50, and 100%, respectively. In the common clinical form of bleeding abomasal ulcers there is a **sudden onset of anorexia**, **mild abdominal pain**, **tachycardia (90–100 beats/min)**, **severely depressed milk production,** and **melena**. Acute hemorrhage may be severe enough to cause death in less than 24 hours. More commonly there is subacute blood loss over a period of a few days with the development of hemorrhagic anemia. The feces are usually scant, black, and tarry. There are occasional bouts of diarrhea. Melena may be present for 4 to 6 days, after which time the cow usually begins to recover or lapses into a stage of chronic ulceration without evidence of hemorrhage.

Melena is almost a pathognomonic sign of an acute bleeding ulcer of the abomasum. However, the presence of normal-colored feces does not preclude the presence of chronic nonbleeding ulcers, which may be the cause of an intractable indigestion. The use of an **occult blood test on the feces** will aid in differentiating those that are equivocal. Abomasal ulceration secondary to lymphoma of the abomasum is characterized by chronic diarrhea and melena. The ulcer does not heal.

In some cases the **abomasum is grossly distended** and **fluid-splashing sounds** are audible on succussion similar to those in RDA. Moderate dehydration is common, and affected cows commonly sip water continuously and grind their teeth frequently. The prognosis in chronic ulceration is poor because of the presence of several ulcers and the development of chronic abomasal atony. Some cows improve temporarily but relapse several days later and fail to recover permanently. Duodenal ulceration and abdominal abscesses have also been described.

Perforation of Ulcer

Perforation of an ulcer is usually followed by **acute local peritonitis** unless the abomasum

is full and ruptures, when **acute diffuse peritonitis** and shock result in death in a few hours. With the development of local peritonitis, with or without omental adhesions, there is a chronic illness accompanied by a fluctuating fever, anorexia, and intermittent diarrhea. This is common in dairy cows in the immediate postpartum period. Pain may be detectable on deep palpation of the abdomen and the distended, fluid-filled abomasum may be palpable behind the right costal arch. Periabomasal abscess formation from a perforated ulcer also occurs and is similar to local peritonitis.

In calves with a perforated abomasal ulcer, abdominal distension and abdominal pain are common.

Nursing Beef Calves

Calves with abomasal ulceration may have a distended gas-filled and fluid-filled abomasum that is palpable behind the right costal arch. Deep palpation may reveal abdominal pain associated with local peritonitis caused by a perforated ulcer. Unless an abomasal ulcer has extended to the serosa, it is unlikely that it can be detected by deep palpation. Many cases of abomasal ulcers, particularly in calves, cause no apparent illness.

CLINICAL PATHOLOGY

Melena

The dark brown to black color of the feces is usually sufficient indication of gastric hemorrhage but tests for occult blood may be necessary. Results from experiments simulating abomasal hemorrhage indicate that the transit time for blood to move from the abomasum to the rectum ranges from 7 to 19 hours. The available fecal occult blood tests may not detect slow abomasal hemorrhage at any one sampling. This can be overcome by testing several fecal samples over a 2- to 4-day period and reading multiple smears per specimen. The sensitivity of the occult blood tests increases after the fecal samples have been stored at room temperature for 2 days. The predictive value of the occult blood test may be a more reliable diagnostic indicator of abomasal disease than abdominal pain or the presence of anemia. When perforation has occurred with acute local peritonitis, there is neutrophilia with a regenerative left shift for a few days, after which time the total leukocyte and differential count may be normal.

Hemogram

In acute gastric hemorrhage, there is acute hemorrhagic anemia.

Plasma Gastrin and Pepsinogen Concentration

Plasma gastrin concentration increases significantly in cattle with bleeding abomasal ulcers. The mean plasma gastrin concentration in healthy cattle was 103 pg/mL; in cattle with bleeding abomasal ulcers the mean was 1213 pg/mL.

Serum pepsinogen concentration >5.5 U/L is indicative of the presence of abomasal ulcers in cows with an appropriate anthelmintic control program.[5] However, the test sensitivity (0.65) and specificity (0.81) and area under the response operating characteristic curve (0.77) are not sufficiently high enough to make this a clinically useful test, particularly when applied to cattle with unknown parasite control programs. In contrast, serum pepsinogen does not appear to indicate the presence of abomasal ulcers in sheep.[6]

Microbiology

The microbiome of abomasal ulcers has been recently investigated using pyrosequencing. Abomasal ulcers contain a high diversity and species richness of abomasal bacteria, including the following genera: *Helicobacter, Acetobacter, Lactobacillus,* and novel *Mycoplasma*-like phylotypes.[7] Interestingly, no differences in microbiological communities attached to abomasal mucosa were detected between abomasal ulcers and normal mucosal morphology.

NECROPSY FINDINGS

Ulceration is most common along the greater curvature of the abomasum. There is a distinct preference for most of the ulcers to occur on the most ventral part of the fundic region with a few on the border between the fundic and pyloric regions. The ulcers are usually deep and well defined but may be filled with blood clot or necrotic material and often contain fungal mycelia, which may be of etiologic significance in calves. The ulcers will measure from a few millimeters to 5 cm in diameter and are either round or oval with the longest dimension usually parallel to the long axis of the abomasum. In bleeding ulcers the affected artery is usually visible after the ulcer is cleaned out.

Most cases of perforation in cattle are walled off by omentum, with the formation of a large cavity 12 to 15 cm in diameter in the peritoneal cavity that contains degenerated blood and necrotic debris. Material from this cavity may infiltrate widely through the omental fat. Adhesions may form between the ulcer and surrounding organs or the abdominal wall (**omental bursitis** and omental emphysema). Multiple phytobezoars are common in the abomasum of beef calves with abomasal ulcers. The mucosal changes associated with abomasal ulceration in veal calves reveal an increase in the depth of the mucosa with a loss of mucins in the region of erosions and ulcers.

DIFFERENTIAL DIAGNOSIS

- **Acute abomasal ulceration** in mature cattle is characterized by abdominal pain, melena, and pallor. The melena may not be evident for 18–24 h after the onset of hemorrhage. Examination of the right abdomen may reveal a distended abomasum and a grunt on deep palpation over the abomasum, caudal to the xiphoid sternum on the right side. Tachycardia is common.
- **Duodenal ulceration** may cause melena and a syndrome indistinguishable from hemorrhagic abomasal ulceration.
- **Chronic abomasal ulceration** in mature cattle is difficult to diagnose clinically if the hemorrhage is insufficient to result in melena. The clinical findings of chronic ulceration are similar to several other diseases of the forestomach and abomasum of mature cattle. An illness of several days' duration with inappetence, ruminal hypotonicity, scant feces, and dehydration are common to many of those diseases. The presence of occult blood in the feces of hemorrhagic anemia suggests ulceration. The hemorrhage may be intermittent, and repeated fecal tests for occult blood may be necessary. A positive result for occult blood may also be caused by abomasal volvulus, intestinal obstruction, or blood-sucking helminths.
- **Abomasal ulceration with perforation and local peritonitis** is indistinguishable from acute traumatic reticuloperitonitis unless hemorrhage and melena occur. However, the abdominal pain elicited on deep palpation is most intense over the right lower abdomen and lateral aspect of right lower thoracic wall.
- **Abomasal ulceration with perforation in sucking beef calves** is characterized by sudden onset of weakness, collapse, moderate abdominal distension shock, and rapid death. It must be differentiated from other causes of diffuse peritonitis and intestinal obstruction.
- **Chronic abomasal ulceration in sucking beef calves** associated with hairballs and chronic abomasitis from eating sand and dirt cannot usually be diagnosed as a separate entity.

TREATMENT

The conservative medical approach is usually used for the treatment of abomasal ulcers in cattle.

Blood Transfusions

Blood transfusions and fluid therapy may be necessary for acute hemorrhagic ulceration. The most reliable indication for a blood transfusion is the clinical state of the animal. Weakness, tachycardia, and dyspnea are indications for a blood transfusion. Hematocrits do not provide an accurate indication as to the magnitude of the blood loss until at least 4 hours after the start of hemorrhage. For this reason, although it is important to determine the hematocrit to obtain a reference point in time, a firm cut point for the

need for a blood transfusion cannot be developed. In the case of severe blood loss, a dose of 20 mL/kg BW may be necessary.

Coagulants

Parenteral coagulants are used but are of doubtful value. These are covered in detail in Chapter 4.

Antacids

The goal of antacid treatment is to create an environment that is favorable to ulcer healing. This can be done by decreasing acid secretion (oral or parenteral administration of histamine type-2 receptor antagonists [H_2 antagonists] and proton pump inhibitors) or neutralizing secreted acid (oral administration of magnesium hydroxide and aluminum hydroxide). The elevation of the pH of the abomasal contents abolishes the proteolytic activity of pepsin and reduces the damaging effect of the acidity on the mucosa.

Histamine Type-2 Receptor Antagonists

These compounds increase gastric pH through selective and competitive antagonism of histamine at the H_2-receptor on the basolateral membrane of parietal cells, reducing acid secretion. H_2-receptor antagonists are characterized pharmacologically by their ability to inhibit gastric acid secretion and kinetically by their similarity in absorption, distribution, and elimination.

Cimetidine and ranitidine are synthetic H_2 antagonists that inhibit basal as well as pentagastrin-stimulated and cholinergic-stimulated gastric acid secretion. Both have been used extensively to treat gastric ulcers in many species, including horses, dogs, and humans. Oral and parenteral administration of cimetidine and ranitidine increases abomasal pH in sheep and cattle. High doses of cimetidine (20 mg/kg BW intravenously, or 50–100 mg/kg orally) increased abomasal pH in weaned lambs for more than 2 hours. Daily oral administration of cimetidine (10 mg/kg BW for 30 days) to veal calves may facilitate healing of abomasal ulcers. Because ranitidine is three to four times more potent than cimetidine, results of studies in ruminants suggest that oral administration of cimetidine (50–100 mg/kg) and ranitidine (10–50 mg/kg) should increase abomasal pH in milk-fed calves.

Experimentally, the oral administration of cimetidine (50 mg/kg or 100 mg/kg every 8 hours) and ranitidine (10 or 50 mg/kg every 8 hours) to normal calves fed milk-replacer caused a significant dose-dependent increase in mean 24-hour abomasal luminal pH. However, the effects of these agents have not been examined in calves with known abomasal ulcers.

Alkalinizing Agents

Compounds such as magnesium hydroxide and aluminum hydroxide are weak bases that have a direct effect on gastric acidity by neutralizing secreted acids. Aluminum hydroxide directly absorbs pepsin, decreasing the proteolytic activity of pepsin in the stomach. Both compounds bind bile acids, protecting against ulceration induced by bile reflux.

Experimentally, the oral administration of commercially available preparations containing aluminum hydroxide and magnesium hydroxide to calves being fed milk replacer resulted in a short-term increase in abomasal luminal pH. However, as with the synthetic H_2 antagonists, the efficacy of these weak bases to aid in the treatment of calves with abomasal ulcers has not been determined.

Magnesium oxide (500–800 g per 450-kg BW weight daily for 2–4 days) has been successful empirically in some cases of abomasal ulceration in mature cattle. The injection or infusion of the antacid directly into the abomasum would probably be much more effective, but injections of the abomasum through the abdominal wall are not completely reliable. An abomasal cannula placed through the abdominal wall may provide a means of ensuring the infusion of antacids directly into the abomasum.

Kaolin and Pectin

Large doses of liquid mixtures of kaolin and pectin (2–3 L twice daily for a mature cow) to coat the ulcer and minimize further ulcerogenesis have been suggested and used with limited success. This treatment is no longer recommended.

Surgical Excision

Surgical excision of abomasal ulcers has been attempted, with some limited success. The presence of multiple ulcers may require the radical excision of a large portion of the abomasal mucosa and hemorrhage is usually considerable. A laparotomy and exploratory abomasotomy are required to determine the presence and location of the ulcer. The diagnostic criteria for deciding to do surgery have not been described, which makes it difficult to select cases with a favorable prognosis. Valuable animals with clinical evidence of chronic ulceration or those that relapse should be considered for surgical correction. Surgical correction of perforated abomasal ulcers in calves is possible and may be successful.

PREVENTION

Recommendations for the prevention of abomasal ulceration in cattle cannot be given because the etiology is so poorly understood.

OMENTAL BURSITIS

Inflammation of the omental bursa occurs rarely, usually in dairy cattle. The causes include perforated abomasal ulcers of the medial wall of the abomasum, penetration of the ventral wall of the blind sac of the rumen, penetration of the reticulum by a foreign body, spread of an umbilical infection to the greater omentum, and extension of an abdominal abscess and localized peritonitis, with subsequent spread to the omental bursa secondary to postpartum parametritis. Inflammation of the bursa results in the accumulation of inflammatory exudate in the bursal cavity, which enlarges beyond its normal capacity. There may also be rupture of the leaves of the greater omentum, resulting in diffuse peritonitis, ileus, or functional obstruction of the intestines.

Clinical findings include anorexia of several days' duration, chronic toxemia, dehydration, and **abdominal distension**, particularly of the right lower flank.[1] Fluid-splashing sounds may be audible on auscultation and percussion of the right flank. On rectal examination in a small number of cases a large, amorphous, spongy mass may be palpable anterior to the pelvic brim in the right upper quadrant of the abdomen. The peritoneal fluid may reveal evidence of a chronic suppurative inflammation. A neutrophilia and an increase in the serum fibrinogen concentration are common. There may also be a metabolic alkalosis with hypochloremia and hypokalemia. Most cases require a right flank exploratory laparotomy to make the diagnosis.

Treatment consists of surgical drainage and long-term therapy with antimicrobials. Successful treatment is uncommon but possible. At necropsy there is diffuse fibrinous and necrotizing peritonitis and a large accumulation of purulent exudate in the omental bursa.

ABOMASAL BLOAT (TYMPANY) IN CALVES AND LAMBS

Abomasal bloat or severe distension (tympany) occurs in calves and lambs fed milk-replacer diets. The incidence appears to have increased recently in North America, and this has been attributed to increased use of whey-based milk replacers, which have a high salt content and therefore high osmolality when fed. Both factors have been shown

to decrease abomasal emptying rate in calves.[1,2] Feeding systems that allow calves or lambs to drink large quantities of milk replacer at infrequent intervals predispose them to abomasal bloat. This situation can occur under ad libitum feeding when the supply of milk replacer is kept at about 15°C (59°F) or higher, and particularly if it is not available for several hours. Lambs fed warm milk replacer to appetite twice daily appear to be very susceptible to abomasal bloat. Ad libitum feeding of cold milk replacers containing few or no insoluble ingredients, and adequately refrigerated, results in little or no bloating.

The pathogenesis of the abomasal tympany is thought to be associated with a sudden filling of the abomasum with decreased abomasal emptying rate followed by the proliferation of gas-forming organisms such as *C. perfringens* type A, *Sarcina ventriculi,* or *Lactobacillus* spp., which release an excessive quantity of gas that cannot escape from the abomasum. Administration of high-glucose solutions or high-osmolality solutions are thought to be associated with the disease occurrence because both decrease abomasal emptying rate in milk-fed calves.[1,2] The disease has been reproduced by drenching milk-fed Holstein Friesian calves with a carbohydrate mixture containing milk replacer, corn starch, and glucose mixed in water.[3] The severe abomasal distension causes compression of the thoracic and abdominal viscera and their blood vessels. This results in asphyxia and acute circulatory failure caused by the lack of venous return. Affected calves and lambs will become grossly distended within 1 hour after feeding and die in a few minutes after the distension of the abdomen is clinically obvious. At necropsy, the abomasum is grossly distended with gas, fluid, and milk replacer, which is usually not clotted. The abomasal mucosa is hyperemic.

Abomasal bloat, hemorrhage, and ulcers occur in young lambs in Norway just before being turned onto pasture. Affected lambs are 3 to 4 weeks of age. Affected lambs, approximately 1 week before developing abomasal bloat, had significantly lower serum iron levels than unaffected lambs. The administration of iron dextran to lambs during their first week of life reduced the incidence of abomasal bloat, suggesting that iron deficiency may be a predisposing factor that results in pica. Housing these lambs on floors with built-up litter when silage is used as a roughage is a predisposing epidemiologic factor. It is postulated that affected lambs eat bedding contaminated with feces, which may result in the growth of an abnormal gas-producing microflora in the abomasum. A similar association with fecal material was observed in an outbreak of abomasal tympany in dairy calves.[4] Affected calves died suddenly with abomasal tympany and emphysema, and *C. Perfringens* type A was cultured from pooled colostrum being fed to calves, the bucket being used to collect colostrum, and the walls of the refrigerator used to store the colostrum.

The major clinical findings are tympany and colic. There is severe abdominal pain, such as stretching of the hind legs, lifted tails, repeated attempts to defecate, and anorexia. Untreated calves and lambs die within a few hours, but some are found dead without having shown any clinical signs. Some lambs are anemic and have melena.

At necropsy, there is abomasal tympany, abomasal hemorrhage, and ulceration. Lambs with ulcers had a higher frequency of trichophytobezoars than the cases without ulcers or the controls. *Sarcina*-like bacteria were found in sections of and smears from the abomasum in 79% of cases.[5] *C. fallax* and *C. sordellii* were also cultured from some cases, but their causative significance is uncertain.

Successful treatment of calves has been reported by placing them in dorsal recumbency and inserting a large-diameter needle (such as a 14 gauge) into the abomasum to relieve the gas. Placement in dorsal recumbency is considered the key to success because attempting to percutaneously deflate the bloat with the calf standing is often ineffective and may facilitate leakage of abomasal fluid into the abdomen. Calves should be administered parenteral antibiotics with good efficacy against *Clostridium* spp. bacteria, such as Procaine penicillin (22,000 U/kg BW, intramuscularly daily).

Effective control measures would appear to include good hygiene related to feeding utensils and equipment to prevent ingestion of *Clostridium* spp., minimizing ingestion of fecal material, and providing small meals frequently instead of large meals infrequently.

Diseases of the Intestines of Ruminants

SMALL AND LARGE INTESTINAL OBSTRUCTION IN CATTLE

Small and large intestinal obstructions in cattle include luminal blockages, intussusception, volvulus, and strangulation. The characteristic clinical findings are anorexia, abdominal pain, absence of feces, the passage of dark fecal blood and mucus, dehydration, and acid-base imbalance and death if physical obstructions are untreated.

SYNOPSIS

Etiology Physical obstruction of intestine caused by luminal blockages, intussusception, mesenteric volvulus, and strangulation.

Epidemiology Uncommon, but do occur.

Signs Abdominal pain (treading of hindlegs, stretching, and kicking at abdomen), scant or absence of feces, feces may be bloodstained, rumen stasis, distension of abdomen (later stages), distended loops of intestine, progressive dehydration, and toxemia leading to shock and recumbency.

Clinical pathology Hypochloremic, hypokalemic metabolic alkalosis, hemoconcentration.

Lesions Intussusception, volvulus, strangulation, and intraluminal obstruction.

Diagnostic confirmation Laparotomy.

Differential diagnosis
Adult cattle: diffuse peritonitis, acute local peritonitis, abomasal ulcers, right displaced abomasum, abomasal volvulus, grain overload, duodenal ileus, and urethral obstruction in male ruminants.
Calves under 2 months of age: abomasal dilatation: dietary in origin, abomasal volvulus, perforated abomasal ulcers, intussusception, volvulus at the root of the mesentery, acute diffuse peritonitis, and peracute to acute enteritis.

Treatment Surgical correction.

Control Nothing reliable.

ETIOLOGY AND EPIDEMIOLOGY

The most common causes are the intestinal accidents—volvulus, intussusception and strangulation—in which there is **physical occlusion of the intestinal lumen.** A **functional obstruction** occurs with local or general paralytic ileus; the lumen remains physically patent but there is no passage of ingesta.

There are three common groups of causes:

- Physical obstruction of the intestinal lumen along with infarction of the affected section of intestine (**intestinal accidents**)
- Physical obstruction of the intestinal lumen (**luminal blockages**)
- Functional obstructions with no passage of intestinal contents but with the lumen still patent (**paralytic ileus**).

Intestinal Accidents

Volvulus

Volvulus of the small intestine is rare and sporadic in cattle and is more common in dairy cattle than beef cattle. It is not more common in calves than in adults but there may be a decreased risk in cattle over 7 years

of age compared with calves under 2 months of age.

Mesenteric volvulus is most common in calves and young cattle, e.g., coiled colon on its mesentery. As in cecocolic volvulus, the colon may be dilated before volvulus develops. A case has been described in a mature cow, which recovered following surgery.

Volvulus of the duodenal sigmoid flexure has been recently reported in dairy cattle.[1] Most of the affected animals had a right flank omentopexy and pyloropexy performed 1 day to 2 years previously and it is likely that the omentopexy site altered the normal anatomic location of the cranial duodenum, predisposing this section of the duodenum to accumulation of ingesta and subsequent volvulus. Clinically the cattle resembled an RDA or AV. The common bile duct is included in the volvulus, causing obstruction to bile flow and an enlarged gallbladder that may be visible ultrasonographically.

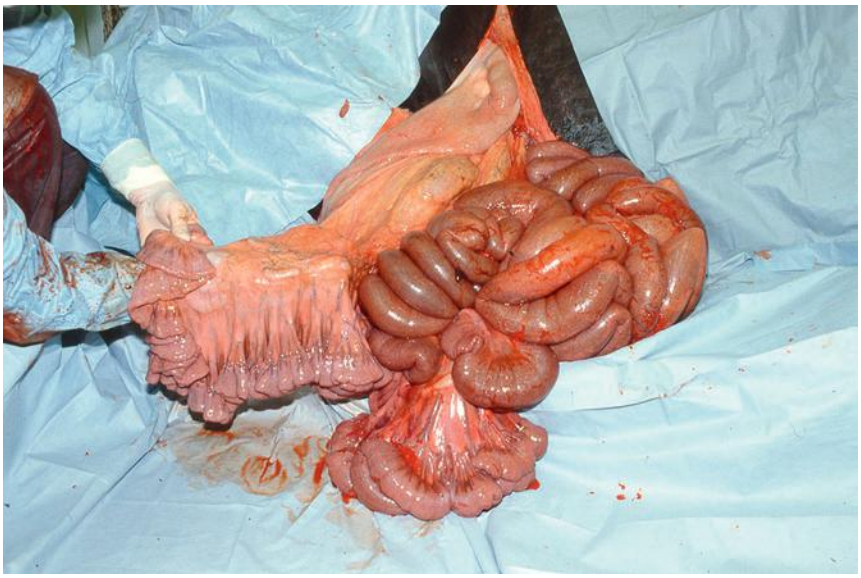

Fig. 8-20 Jejunal intussusception in an adult Holstein Friesian cow. The cow is in sternal recumbency with the head to the right. A right flank incision was made and much of the small intestine exteriorized. The surgeon is holding the jejunal flange, which is empty, as is the cecum *(top)*. Most of the jejunum is markedly distended with fluid, and the mesentery is tied up into a knot in the center of the picture, which is the location of a large intussusception.

Intussusception

Intussusceptions are rare in cattle and most common in calves under 2 months of age. The high prevalence of diarrhea caused by enteritis in calves suggests that enteritis may be a risk factor in this age group.

Four types of intussusception are recognized in cattle:

1. **Enteric:** this involves one segment of the small intestine, usually the distal jejunum or ileum, invaginating into another. It is most common in adults, with the distal jejunum most commonly affected because of the length and mobility of its mesenteric attachments. The high incidence of **jejunojejunal intussusception** in cattle has been attributed to the length and mobility of the jejunal mesenteric attachments, especially the distal third (Fig. 8-20). The presence of a mass in the intestinal wall may facilitate formation of intussusception, and there is one report of an intussusception associated with jejunal adenocarcinoma in a dairy cow.[2]
2. **Ileocecocolic:** with this type the ileum invaginates into the cecum or into the proximal colon at the cecocolic junction.
3. **Cecocolic:** this occurs with invagination of the cecal apex into the proximal colon.
4. **Colonic:** invagination of the proximal colon, or sometimes the spiral colon, occurs into a more distal segment. One report of spiral colon intussusception identified fibroserous granulation tissue as a likely predisposing cause.[3]

The latter three are not common in adult cattle, presumably because the mesenteric fat deposits and the ileocolic ligament stabilize the intestine. In calves, the incidence of intussusception is more uniformly distributed among the four types, presumably because of the thin, fragile nature of the mesentery, which may be more susceptible to tearing under tension and allowing increased movement of adjacent segments of intestine. A series is recorded in cows with intestinal polyposis: polyps in the mucosa dragged a section of intestine into an invagination in the next section. There is also intussusception of colon into spiral colon, and intussusception of the spiral colon has been described in an adult bull. One recorded intussusception has been associated with a transmural adenocarcinoma in an aged cow.

Strangulation

Strangulation may occur through a mesenteric tear or behind a persistent vitelloumbilical band, the ventral ligament of the bladder, through the lateral ligament of a bull's bladder, or via an adhesion, especially one between the omentum and an abscess of the umbilical artery in a young animal. Rupture of the small intestinal mesentery and strangulation of the intestine has been described in adult postparturient cows. A persistent urachus can also cause intestinal strangulation in mature cattle. Herniation of distal jejunum into a partially everted urinary bladder of a mature cow has been reported. Strangulation of the duodenum by the uterus during late pregnancy in cows has been described. The entire uterus had passed through a gap between the mesoduodenum and duodenum and with increasing weight had led to strangulation of the duodenum. The mesoduodenum and both walls of the greater omentum adjacent to its caudal edge were not connected with the duodenum, probably as a result of a congenital inhibitory malformation. Torsion of the descending sigmoid colon was identified in a 5-year-old Brown Swiss cow with no identifiable mesentery on the mesenteric border.[4]

Gut tie has been described in male cattle that have recently been castrated using the open method and traction of the spermatic cord. When the spermatic cord is pulled and broken during castration, it may recoil through the inguinal ring and become entangled around small intestine, causing a physical obstruction (Fig. 8-21). This is considered more likely if the right spermatic cord retracts into the abdomen after castration, but reports exist of bilateral abdominal adhesions.[5] It is also possible that traction of the spermatic cord may tear the peritoneal fold of the ductus deferens that attaches the ductus to the abdominal wall, permitting loops of intestine to pass through this hiatus and resulting in incarceration.

Compression Stenosis

Compression stenosis may arise from a blood clot from an expressed corpus luteum site on an ovary or traumatic duodenitis caused by migration of a metallic foreign body.

Cecal Dilatation

Cecal dilatation can be followed by cecocolic volvulus (see cecal dilatation and cecocolic volvulus in this chapter).

Luminal Blockages

External Pressure

External pressure by fat necrosis of mesenteries and omenta as well as lipomas may occur.

Fig. 8-21 Entrapment of the jejunum by a remnant of the ductus deferens ("gut tie") in an Angus steer (remnant being held by the surgeon). The steer was standing with its head to the right and a right flank laparotomy was performed. An incision was made in the right flank under regional analgesia and much of the jejunum was distended.

Ileal Impaction in Cows

Ileal impaction in Swiss Braunvieh cows in Switzerland has been described. The cause is uncertain but may be related to seasonal influences and winter feeding with a hay-based ration.

Fiber Balls or Phytobezoars

Fiber balls or phytobezoars may be common in areas in which fibrous feeds, e.g., *Romulea bulbocodium* or tree loppings, form a large part of the diet. The ability of *R. bulbocodium* to survive dry autumns and dominate the pasture ensures that many fiber balls develop in the abomasum in autumn. Obstructions do not occur until the next spring when pasture is lush. The disease is common in late pregnancy or the first 2 weeks of lactation or after a period of activity such as estrus. Bezoars pass at this time from the abomasum into the first part of the duodenum, where they stick fast.

Trichobezoars (Hairballs)

In cold climates a more common obstruction is by trichobezoars. Cattle confined outside have long shaggy hair coats and licking themselves and others probably leads to ingestion of the hair. Hairballs causing obstruction of the small intestine of young beef calves has been described.[3]

"Rectal Paralysis"

In cows near parturition, an apparent rectal paralysis leading to constipation may occur. The cause is unknown but is considered to be the result of pressure by the fetus or fetuses on pelvic nerves.

Duodenal Ileus

Duodenal ileus caused by obstruction or compression of the duodenum has been described in mature cows. The lumen may be obstructed by phytobezoars, blood clots, or compression from or adhesion to a liver abscess.

Functional Obstructions

Peritonitis and hypocalcemia are two common causes of functional obstruction in cattle.

PATHOGENESIS

Physical Obstruction

Physical obstruction of the small intestines of cattle results in an absence of feces, distension of the intestine cranial to the obstruction with fluid and gas, and acute abdominal pain. Luminal obstruction can be caused by trichobezoars or phytobezoars, ingestion of foreign objects such as a calf feeding nipple,[6] obstruction by a luminal blood clot (see section on hemorrhagic jejunitis in this chapter), dry feed impaction in the ileum,[7] or constriction and spasm of the jejunal lumen by a jejunal diverticulum.[8] Hypochloremic, hypokalemic metabolic alkalosis and dehydration are commonly present, particularly with obstructions to the proximal small intestine. The alkalosis results from small-intestinal and abomasal reflux into the rumen, with sequestration of hydrochloric acid in the abomasum. Ileus of the small intestines is one of the most common consequences of obstruction, resulting in distension and hypomotility cranial to the obstruction. The myoelectric activity patterns occurring during small intestinal obstruction are disorganized in the segment orad to the obstruction, characterized by rapidly migrating, prolonged, high-amplitude spikes that sometimes occur in clusters. This probably accounts for the intermittent abdominal pain.

Ileal impaction in Swiss Braunvieh cows in Switzerland is characterized clinically by anorexia, sudden drop in milk production, and some evidence of colic, including shifting of weight from leg to leg and occasional kicking at the abdomen.[7] The ventral aspect of the abdomen was enlarged and pear shaped, and a tense abdominal wall was present in some cows. A ping could be elicited over the right abdomen in most cows. The feces in the rectum may be reduced in amount or there may be none. On rectal palpation, dilated loops of small intestine are usually palpable. On laparotomy, the impaction was situated at the ileocecal valve, and the ileum proximal to ileocecal junction was impacted with ingesta for up to 15 cm in length. The color of the serosa of the ileum and distal part of the jejunum was normal. The cause of ileal impaction is attributed to seasonal influences and winter feeding with a hay-based ration.[8]

Volvulus and Intussusception

Volvulus of the small intestine is a rotation of the entire small intestine, with or without the cecum and spiral colon, or of only the distal third of the jejunum and the proximal portion of the ileum about its mesenteric axis (called a **flange volvulus**). The volvulus results in intestinal distension, vascular compromise, intestinal necrosis, and eventually death unless surgically corrected.

Intussusception is the invagination of one portion of the intestine into the lumen of an adjacent segment of intestine. Jejunojejunal intussusception is the most common form in cattle, although isolated cases of ileocecal, ileocolic, cecocolic, and colocolic intussusception also occur. In most cases the intussusception is single, but doubles do occur. There are reports of cattle surviving after sloughing of an intussusceptum, but these are rare and death usually occurs 5 to 8 days after the onset of clinical findings if surgical correction is not performed.

Generally, the effects of intestinal accidents in cattle are not as remarkable as in the horse. Neither the abdominal pain nor the cardiovascular collapse is as severe in adult cattle as in horses with similar lesions. The exception is in calves, in which the effects are more marked and more rapid. Distension of the abdomen occurs much more frequently in calves than in adult cattle. Involvement of large segments of intestine as in volvulus of the root of the mesentery may result in metabolic acidosis because of the rapid onset of shock. Ischemic necrosis of the intestinal wall results in various degrees of severity of peritonitis and abnormal peritoneal fluid containing erythrocytes, leukocytes, and increased serum proteins.

Hemorrhage into the intestinal tract at the level of the obstruction results in the passage of small quantities of dark blood, which may be almost black if the obstruction is high up in the small intestinal tract.

Distension of intestines with fluid and gas cranial to the obstruction may cause some mild distension of the abdomen but primarily if the large intestine is obstructed as in torsion of the coiled colon. The longer duration of the disease and the profound depression that develops suggest that endotoxemia, as in horses, may be the lethal agent, but the course is much slower than in the horse.

The effect of myoelectric activity of the cecum and proximal loop of the ascending colon on motility of this segment of intestine in experimental obstruction of the large intestine in cattle has been examined. Obstruction of the colon results in prestenotic hypermotility (colic motor complex) or prolonged propulsive peristaltic waves directed toward the obstruction site. This may represent an effort of the intestine to overcome the obstruction to reestablish the continuity of the passage of ingesta.

Patterns of myoelectric activity in the small and large intestine of cows orad and aborad to an obstruction site have been measured. Myoelectric activity in the ileum immediately orad to the occlusion was characterized by abolition of the migrating myoelectric complex and a constant pattern of strong bursts of long duration. Organized cyclic activity occurred in the large intestine despite complete disruption of the small-intestinal migrating myoelectric complexes, indicating the presence of mechanisms able to initiate and regulate coordinated myoelectric patterns in the large intestine independently of the small intestine.

Incarceration

The small intestine can be incarcerated in the epiploic foramen[7] or an acquired omental rent.[8-12] Incarceration may follow herniation of a gravid uterus into the omental bursa.[13] Definitive diagnosis is made during right flank laparotomy.

Duodenal Ileus

In **duodenal ileus** caused by obstruction of the lumen by phytobezoars or compression of the duodenum by a liver abscess associated with traumatic reticuloperitonitis in mature cows, there is abomasal and duodenal reflux into the rumen resulting in metabolic alkalosis with hypochloremia and increased ruminal chloride. The obstruction caused by phytobezoars and liver abscesses may occur at almost any segment of the duodenum. The ileus results in a marked reduction in gastrointestinal motility and distension of the forestomach and abomasum caused by the accumulation of excessive quantities of fluid, which results in dehydration. Abdominal pain is associated with the distension of the duodenum. The ileus results in marked decrease in movement of ingesta, and the feces are markedly reduced in quantity. Duodenal obstruction caused by malposition of the gallbladder in a heifer has been described.

Functional Obstruction

In **functional obstruction**, there is paralytic ileus and an increase in the transit time of ingesta and feces. The feces are scant and do not contain blood. Sequestration of fluids in the intestines may result in varying degrees of dehydration and a metabolic alkalosis with hypochloremia and hypokalemia.

CLINICAL FINDINGS

General Findings

There is an initial attack of acute abdominal pain in which the animal kicks at its abdomen, treads uneasily with the hindlegs, depresses the back, and may groan or bellow from pain. The pain occurs spasmodically and at short, regular intervals and may occasionally be accompanied by rolling. This stage of acute pain usually passes off within a few (8–12) hours and during this time there is anorexia and little or no feces are passed. In subacute abdominal pain the animal may assume a sawhorse stance and guard the abdomen (Fig. 8-22) The temperature and respiratory rates are relatively unaffected and the heart rate may be normal or elevated, depending on whether or not blood vessels are occluded. If there is infarction of a section of intestine there will be signs of endotoxic shock, including low blood pressure, very rapid heart rate, and muscle weakness and recumbency. These signs are absent in cases in which the blood supply of the intestine is not compromised. For example, in cecocolic volvulus the heart rate may be normal. In all cases, as the disease progresses and dehydration becomes serious, the heart rate rises and may reach as high as 100 beats/min just before death.

When the acute pain has subsided, the cow remains depressed, does not eat or ruminate, and passes no feces. The circulation, temperature, and respirations are usually within normal limits and ruminal

Fig. 8-22 Simmental cow exhibiting signs of subacute abdominal pain with ears forward, and alert expression, and a slight sawhorse stance **(A).** The jejunal mesentery contained multiple areas of hard fat, which occluded the intestinal lumen **(B).**

activity varies. In most cases there is complete ruminal stasis but, in exceptional cases, movements will continue, although they are usually greatly reduced. The rumen pack feels dry and firm on palpation through the abdominal wall.

Abdomen

The abdomen is slightly distended in all cases. Where there is distension of loops of intestine, as in ileus caused by dietary error, there may be some distension of the right abdomen. Fluid-splashing sounds can be elicited by ballottement and simultaneous auscultation over the right abdomen in most cases and in a minority of cases over the left abdomen. With obstruction of the pylorus the splashing sounds can be elicited only on the right side, just behind the costal arch and approximately halfway down its length. Regurgitation of fluid ingesta through the nose is common.

Feces

The character of the feces is highly variable. In the early stages they will be normal but passed frequently and in small amounts. It may be necessary to perform a rectal examination because the feces may not be passed from the anus. In some cases they will be hard lumps, usually covered with mucus. Blood is often present, not as melena but as altered red blood, in the form of a thick red slurry, leaving dried flakes of it around the anus, especially in intussusception. The last fecal material is more mucoid and may consist entirely of a plug of mucus (Fig. 8-23). In some cases of obstruction caused by fiber balls the fecal material is pasty, foul-smelling, and yellow-gray in color.

Palpation Per Rectum

When there is intussusception or volvulus of the small intestine, the affected segment is usually felt in the lower right abdomen, but the site varies with the nature of the obstruction. It is important to appreciate that not all intestinal obstructions can be palpated on rectal examination. It depends on the location of the affected segment of intestine: those in the anterior part of the abdomen are not palpable, and those in the caudal part of the abdomen may be palpable. In addition, the affected segment may or may not be palpable, and the adjacent segments cranial to the obstruction may be palpable as distended segments of intestine.

In intussusception the affected segment may be palpable in approximately 20% of cases, usually as an oblong, sausage-shaped mass of firm consistency, but if a long length of intestine is involved a spiral develops and is palpable as such. In volvulus the intestinal loop may be small, soft, and mobile. In many cases, it is possible to follow tightly stretched mesenteric bands coursing dorsoventrally in the middle part of the abdomen. Palpation of distended loops of intestine may cause distress, especially in the early stages, and distension of a number of loops may increase intraabdominal pressure to the point where entry of the hand beyond the pelvis is difficult. Within a few days, the rectum is empty except for tarry mucus and exudate and insertion of the arm usually causes pain and vigorous straining. Distension of loops of intestine is not nearly as obvious as in horses with intestinal obstruction and may not occur unless the colon or cecum is involved.

Fig. 8-23 Contents present in the rectum of a cow with acute intestinal obstruction caused by intussusception of the jejunum. There is very little fecal material evident, and the rectal contents are predominately mucus.

Duodenal Ileus

Duodenal ileus in mature cows is characterized by anorexia, depression, dehydration, abdominal pain (treading, kicking and stretching, and frequent lying down and standing up), rumen distension and hypotonicity, moderate bloat in some cases, scant feces, and the presence of fluid-splashing sounds on auscultation and ballottement of the right abdomen. Rectal examination may reveal no abnormal findings or an enlarged L-shaped rumen and distended loops of small intestine. Ultrasonography can be used to visualize the distended duodenum in the 10th to 12th intercostal spaces. If only one loop of intestine is visible, it indicates distension of the duodenum; when several loops of intestine are visible it indicates ileus of the jejunum or ileum. Duodenal obstruction caused by malposition of the gallbladder in cattle can be diagnosed using abdominal ultrasonography and laparotomy.

Volvulus of the Spiral Colon (Mesenteric Root Volvulus)

This can cause death in less than 24 hours. It is characterized by distension of the right abdomen, and a number of distended loops of intestine can be palpated. When there is cecal dilatation or cecocolic volvulus, there is usually one grossly distended intestinal loop extending horizontally across the abdomen just cranial to the pelvis and caudally or medially to the rumen. It may be possible to palpate the blind end of the cecum, and in cases that have been affected for several days the organ may be so distended with fluid and gas that it can be seen through the right flank, or fluid sounds can be produced by ballottement or simultaneous percussion and auscultation. Rarely, the distended cecum may be located in the left paralumbar fossa between the rumen and the abdominal wall, in a position reminiscent of an LDA. The disease is likely to recur in the same cow in subsequent years, and a case of chronic dilatation that persisted for 10 months is recorded.

Lipomas and Fat Necrosis

These abnormalities are usually easily palpable as firm, lobulated masses that can be moved manually. They may encircle the rectum. An obstructing phytobezoar may be palpable on rectal examination in the right anterior abdomen. It is usually 5 to 15 cm in diameter and so mobile that when touched it may immediately pass out of reach. Affected cattle may remain in this state for 6 to 8 days, but during this time there is a gradual development of a moderate, pendulous, abdominal enlargement; profound toxemia; and an increase in heart rate. The animal becomes recumbent and dies at the end of 3 to 8 days.

CLINICAL PATHOLOGY

Clinicopathologic findings are generally nonspecific and of limited assistance in making a diagnosis or assessing prognosis preoperatively; however, the more proximal and complete the intestinal obstruction, the more severe the magnitude of hypochloremia, hypokalemia, hyponatremia, and strong ion (metabolic) alkalosis.

Serum Biochemistry

Hypochloremia, hyponatremia, azotemia, and hyperglycemia are common.

Hemogram

Hemoconcentration, a mild left shift, and an inverted neutrophil to lymphocyte ratio are common in cases of intussusception.

NECROPSY FINDINGS

In small-intestinal volvulus, gross changes are consistent with vascular thrombosis and intestinal necrosis. Serosal, omental, and mesenteric hemorrhages of varying degrees of transmural necrosis are common. Intestinal contents include gas, ingesta, and various amounts of blood. In both intussusception and volvulus extensive intestinal necrosis and diffuse peritonitis are common.

TREATMENT

Surgical Correction

Surgical correction of physical obstructions of the intestine is the only method of treatment for animals in which survival and recovery are desirable. Right paralumbar fossa laparotomy is the most common approach. The methods for surgical correction are presented in textbooks dealing with large-animal surgery. Survival rates for correction of volvulus of the entire small

intestine have been 44%, with 86% for volvulus of the distal jejunum and ileum. Survival rates were much higher in dairy cattle (63%) than beef cattle (22%). Survival rates for intussusception in cattle were about 50%. Survival rates following surgical correction of a luminal obstruction of the small intestine by a trichobezoar are high (72%).[6] In ileal impaction in cattle, the postoperative outcome following laparotomy and massage of the contents of the impacted ileum into the cecum is excellent.[8]

Fluid Therapy

Fluid and electrolyte therapy given intravenously may be necessary preoperatively and always postoperatively (see Chapter 5). Multiple electrolyte solutions or 0.9% sodium chloride solution are effective even though metabolic alkalosis with hypochloremia and hypokalemia may be present.

Antimicrobials

Antimicrobials preoperatively and postoperatively are recommended for the control of peritonitis, which is inevitable.

DIFFERENTIAL DIAGNOSIS

- **Acute intestinal obstruction in mature cattle** is characterized by sudden onset of anorexia, reticulorumen atony, usually moderate abdominal pain, scant feces, fluid-splashing sounds over the right abdomen, possibly distended loops of intestine on palpation per rectum, and a progressively worsening course. It must be differentiated from other diseases of the forestomach and abomasum that result in scant feces, reduced reticulorumen activity, abdominal pain, and distended loops of intestine on rectal examination (see Table 8-2). Those diseases include vagus indigestion with or without abomasal impaction, diffuse peritonitis, right-displaced abomasum, abomasal ulcers, and duodenal ileus (see Table 8-2).
- **Hemorrhagic jejunitis syndrome** of dairy cattle is a sporadic disease characterized by sudden anorexia and loss of milk production, moderate abdominal distension, weakness leading to recumbency, bloody to dark feces (melena), fluid-splashing sounds on ballottement over the right abdomen, tachycardia, and distended firm loops of small intestine palpable on rectal examination. The case–fatality rate is high. At necropsy there is severe necrohemorrhagic enteritis or jejunitis with intraluminal hemorrhage or blood clots. This topic is addressed in detail elsewhere in this chapter.
- **Cecal dilatation and cecocolic volvulus** are characterized by gastrointestinal atony with inappetence, possibly distension of the right abdomen, and a high-pitched ping on auscultation and percussion of the right paralumbar fossa, and the cecum is easily identifiable by palpation per rectum.
- **Renal and ureteric colic** may simulate intestinal obstruction but occur rarely. Acute involvement of individual renal papillae in pyelonephritis in cattle is also thought to cause some of these attacks of colic.
- **Urethral obstruction in male ruminants** causes abdominal pain, but there are additional signs of grunting, straining, distension of the urinary bladder, and tenderness of the urethra. Defecation is not affected.
- **Photosensitive dermatitis** in cattle is also accompanied by kicking at the belly, but the skin lesions are obvious and there are no other alimentary tract signs.
- **Acute intestinal obstruction in calves** under 2 months of age must be differentiated from abomasal dilatation—dietary in origin, abomasal volvulus, perforated abomasal ulcers, intussusception, volvulus of the root of mesentery, acute diffuse peritonitis, peracute to acute enteritis, and gastrointestinal tympany. The salient features of each of these diseases is summarized in Table 8-7.

Nonsteroidal Antiinflammatory Drugs

NSAIDs have been routinely administered in the perioperative period for their antiinflammatory and analgesic effects. Because prostaglandins are critical for the recovery of barrier function in ischemic intestine, concern has been raised about whether the routine administration of NSAIDs may have negative effects on intestinal repair and recovery in animals with damaged intestine.[14] Studies that have been conducted suggest that NSAIDs vary in their effect on the recovery of ischemic-injured jejunum,[14,15] but current knowledge is incomplete regarding a preferred NSAID in ruminants following surgical correction of an intestinal lesion.

INTESTINAL OBSTRUCTION IN SHEEP

Intestinal obstructions are not commonly observed in sheep unless a series of them causes a noticeable mortality. Some notable occurrences are the following:

- Heavy infestation with nodular worm (*Oesophagostomum columbianum*) leading to high prevalence of intussusception occlusion by adhesion.
- High incidence of intussusception in traveling sheep for no apparent reason.
- Cecocolic volvulus (red-gut) is seen in sheep grazing lush pastures of alfalfa or clover in New Zealand. Affected lambs survive only a few hours, and up to 20% of a flock are affected. The outstanding postmortem lesion is a distended, reddened cecum and/or colon that has undergone volvulus. The rumen is smaller and the large intestine larger than normal because of the high digestibility of the diet. All ages, except sucking lambs, are affected and the mortality rate may be as high as 20%. Sheep that are seen alive have a distended abdomen, show abdominal pain, and have tinkling sounds on auscultation of the right flank.

TERMINAL ILEITIS OF LAMBS

This disease causes poor growth in lambs 4 to 6 months old. The circumstances usually suggest parasitism or coccidiosis. The terminal 50 to 75 cm of the ileum is thickened and resembles the classical lesion of Johne's disease. Chronic inflammation is evident and there are some shallow ulcers in the epithelium. The terminal mesenteric lymph node is enlarged. Histopathological examination of affected ileal wall shows mucosa thickened by epithelial hyperplasia, leukocytic infiltration, and connective tissue infiltration. The cause is unknown, and the course of the disease has not been identified because most affected lambs are likely to be culled for ill-thrift.

CECAL DILATATION AND CECOCOLIC VOLVULUS IN CATTLE

Cecal dilatation occurs primarily in dairy cattle in the first few months of lactation. The cecum may be dilated with gas or distended with ingesta, and volvulus may occur. Cecocolic volvulus is characterized by the rotation of the cecum, terminal ileum, and proximal loop of the ascending colon around their mesenteric axis. Clinically, both cecal dilatation and cecocolic volvulus are characterized by inappetence; drop in milk production; decreased amount of feces; a ping over the right upper flank; and a distended, easily recognizable viscus (or more than one in the case of cecocolic volvulus) on rectal

palpation. The prognosis is excellent with cecal dilatation and usually good with cecocolic volvulus if the diagnosis is made early.

ETIOLOGY

The etiology is uncertain. Experimentally, an increase in the concentration of volatile fatty acids in the cecum can result in cecal atony. Dietary carbohydrates not completely fermented in the rumen are fermented in the cecum, resulting in an increase in the concentration of volatile fatty acids, a drop in pH, and cecal atony. Butyric acid has the greatest depressant effect on cecal motility and acetic acid has the least. Inhibition of cecal motility may lead to accumulation of ingesta and gas in the organ and consequently dilatation, displacement, and possible volvulus.

The concentrations of absolute and undissociated acetic, propionic, butyric, i-valerianic, and n-valerianic acids, as well as total volatile fatty acids, are higher in samples collected from the cecum and proximal loop of the ascending colon of cows with cecal dilatation or dislocation compared with concentrations in control cows. However, the role of increased concentrations of volatile fatty acids in the etiology and pathogenesis of cecal dilatation or dislocation is uncertain. The results of more recent studies have highlighted the potential role that decreased spiral colon motility plays in the development of cecal dilatation and cecocolic volvulus.[1]

EPIDEMIOLOGY

Dilatation of the cecum and volvulus of the cecum and ascending colon occurs in well-fed, high-producing dairy cows 3 to 5 years of age during the first 12 weeks after parturition. Brown Swiss cattle appear overrepresented in most case series. The disease occurs throughout the year but is most common during the calving season in North America and Europe. There is a record of five cases occurring in lactating dairy cows on one farm within 9 days. The cows were pastured day and night on grass dominated by white clover and received a 22% crude protein concentrate in the milk parlor twice daily in addition to silage. Cecocolic volvulus has also been described in sheep.

Atony or hypomotility of the spiral colon is thought to initiate the disease, leading to dilatation and displacement, including volvulus.[1]

PATHOGENESIS

The pathogenesis of cecal dilatation, displacement, and volvulus is thought to be similar to that which occurs in dilatation and displacement of the abomasum, except that the primary defect appears to be downstream in the spiral colon. The combination of intestinal gas and decreased cecal emptying into the proximal loop of the ascending colon results in accumulation of fluid and gas in the cecum followed by dilatation and displacement of the cecum into the pelvic inlet. This results in a mild indigestion, or the dilatation may be subclinical and may be detected incidentally when the cow is examined for other purposes.

The myoelectrical activity of the cecum is well coordinated with the ileum and the proximal loop of the ascending colon and spiral colon. The patterns of myoelectrical activity observed in cattle with cecal dilatation following surgical correction are more consistent with that of an obstructive pattern; as a consequence, the main area of hypomotility appears to be the spiral colon.[1] This hypothesis is consistent with alterations in mRNA expression for adrenergic,[2] muscarinic,[3] and seritonergic[4] receptors in cattle with cecal dilatation; the changes in expression appear to be greatest in the spiral colon.

In cecocolic volvulus, the apex of the cecum is rotated cranially and the cecal body becomes distended. The viscus and the first few segments of the proximal loop of the ascending colon twist about the mesentery, causing incarceration and eventually strangulation obstruction of the affected portions of the intestine. The term cecocolic volvulus is a more accurate description of this condition because cecal torsion indicates a twist of the cecum along its longitudinal axis, which is extremely rare. Translocation of the cecum may occur to the left or right and in each case involves the proximal loop of the ascending colon. The net effect is partial or total obstruction of the intestinal tract, accumulation of gas or ingesta in the cecum and ascending colon, varying degrees of paralytic ileus, reduced amount of feces, and necrosis of the cecum because of ischemia. **Cecal impaction** is rare and characterized by gross distension of the viscus with dry ingesta, and in a mature cow the cecum may measure 90 cm in length by 20 cm in diameter. The severity of the disease depends primarily on the degree of twisting of the cecum and its adjacent spiral colon, which results in ischemic necrosis. Rarely, a prolapse of the small intestine through a tear in the mesentery of the small intestine near its root may also pull the cecum cranially by the ileocecal fold and cause an anticlockwise volvulus, as viewed from the right side of the animal.

It has been postulated that hypomotility of the cecum and proximal loop of the ascending colon may be responsible for the delayed recovery from and recurrence of cecal dilatation and displacement that occur following surgical evacuation of the cecum. However, the myoelectric activity of the cecum and proximal loop of the ascending colon in cows after spontaneous dilatation and displacement of the cecum indicates that delayed recovery is not caused by hypomotility; instead, hypomotility of the spiral colon appears to be the primary factor.

CLINICAL FINDINGS

In **cecal dilatation without volvulus**, there are varying degrees of anorexia, mild abdominal discomfort, a decline of milk production over a period of a few days, and a decreased amount of feces. In some cases, there are no clinical signs and the dilated cecum is found coincidentally on rectal examination. In simple dilatation, the temperature, heart rate, and respirations are usually within normal ranges. A distinct ping is detectable on percussion and simultaneous auscultation in the right paralumbar fossa, extending forward to the 10th intercostal space; however, the ping usually changes in quality over time. Simultaneous ballottement and auscultation of the right flank may elicit fluid-splashing sounds. There may be slight distension of the upper right flank, but in some cases the contour of the flank is normal.

In **cecocolic volvulus**, anorexia, ruminal stasis, reduced amount or complete absence of feces, distension of the right flank, dehydration, and tachycardia are evident, depending on the severity of the volvulus and the degree of ischemic necrosis. There may be some evidence of mild abdominal pain characterized by treading of the pelvic limbs and kicking at the abdomen. The ping is centered over the right paralumbar fossa and may extend to the 10th and 12th intercostal spaces. Fluid-splashing sounds are usually audible on ballottement and auscultation of the right flank.

On palpation per rectum the distended cecum can usually be palpated as a long, cylindrical, movable organ measuring up to 20 cm in diameter and 90 cm in length. Palpation and identification of the blind end of the cecum directed toward the pelvic cavity is diagnostic. In **simple dilatation**, with minimal quantities of ingesta, the cecum is enlarged and easily compressible on rectal palpation. **In cecocolic volvulus**, the viscus is usually distended with ingesta and feels enlarged and tense on rectal palpation. The blind end of the cecum may be displaced cranially and laterally or medially, and the body of the cecum is then felt in the pelvic cavity. Varying degrees of distension of the colon and ileum may occur, depending on the degree of displacement or volvulus present (Fig. 8-24). Rupture of the distended cecum may occur following rectal palpation or transportation of the animal. This is followed by shock and death within a few hours.

Ultrasonographic Examination of the Cecum

The cecum and proximal and spiral ansa of the colon can be visualized ultrasonographically using a 3.5-MHz linear transducer in mature cows. The cecum can be visualized from the middle region of the abdominal wall. It extends caudocranially, varies in diameter from 5.2 to 18.0 cm, and is situated immediately adjacent to the abdominal wall. The lateral wall of the cecum appears as a thick, echogenic, crescent-shaped line. The cecum can be visualized as far cranially as

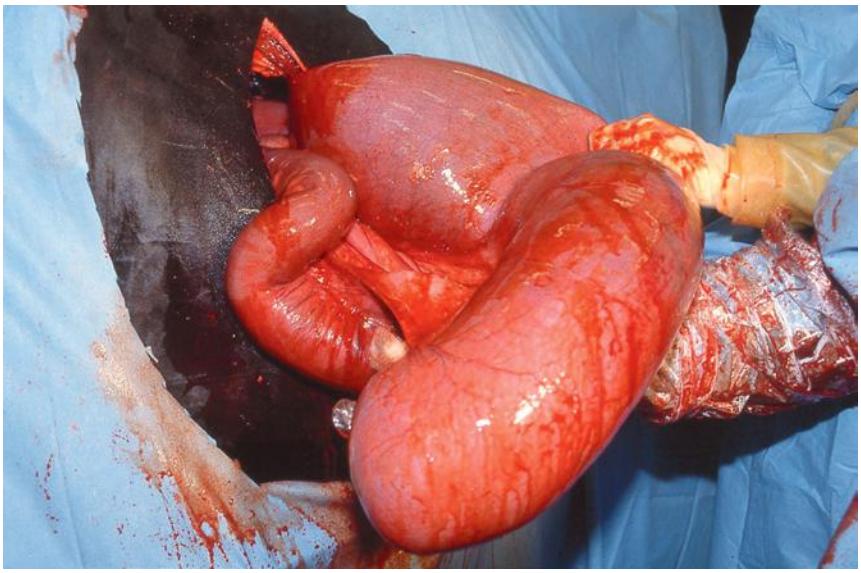

Fig. 8-24 Cecocolic volvulus in a Holstein Friesian cow. The cows head is to the right and a right flank laparotomy is being performed with the cow standing. The cecum is markedly distended and has a bluish color suggestive of ischemia. The ileum is also markedly distended (smaller luminal structure caudal to the cecum.

the 12th intercostal space. Although its junction cannot be identified, the proximal ansa of the colon is recognizable on the basis of its anatomic position and its diameter, which is smaller than that of the cecum. The spiral ansa of the colon and the descending colon are situated dorsal to the cecum and can be identified by moving the transducer horizontally along the abdominal wall to the last rib. The spiral ansa of the colon is situated ventral to the descending colon, and its walls appear as thick echogenic lines. In a contracted state, the spiral colon has the appearance of a garland.

The ultrasonographic findings in cows with dilatation, volvulus, and retroflexion of the cecum have been described and compared with the findings on laparotomy. The wall of the proximal ansa of the colon and of the dilated cecum closest to the abdominal wall is visible in all cows and appears as an echogenic semicircular line immediately adjacent to the peritoneum. The contents of the cecum and of the proximal and spiral ansa of the colon are not always visible because of gas. In some cows, the contents are hypoechogenic to echogenic in appearance. The dilated cecum can be imaged from the right abdominal wall at the level of the tuber coxae. The cecum can be imaged from the 12th, 11th, and 10th intercostal spaces in some cows, and in other cows the cecum and proximal ansa of the colon are situated immediately adjacent to the right abdominal wall by the liver and/or gallbladder. The diameter of the cecum, measured at various sites, varies from 7.0 to 25.0 cm. Cecal dilatation can be diagnosed on the basis of the results of rectal examination in most cows but in all cows ultrasonographically. Dilatation and caudal displacement of the cecum and dilatation and craniodorsal retroflexion of the cecum can be visualized. In some cows, the direction of the retroflexed cecum cannot be determined.

CLINICAL PATHOLOGY

A mild degree of dehydration may be present and a compensated hypochloremia and hypokalemia occur. Hypocalcemia is present in 85% of cases.[5] Hematological values are normal in most affected cattle unless there is necrosis of the cecum accompanied by peritonitis.

DIFFERENTIAL DIAGNOSIS

- **Cecal dilatation and cecocolic volvulus** must be differentiated from right-side dilatation and volvulus of the abomasum. The ping in cecal dilatation and volvulus is usually centered in the paralumbar fossa; in abomasal dilatation and volvulus it is usually centered over the last few ribs and lower in the middle third of the right abdomen. The distended cecum is usually easily palpable rectally in the upper part of the abdomen and is readily identified as the cecum because it is movable. In dilatation and volvulus of the abomasum, the distended viscus is usually palpable in the right lower quadrant of the abdomen much further forward than a dilated cecum and not movable. In many cases, the distended abomasum can barely be touched with the tips of the fingers, whereas the distended cecum can be palpated easily.
- **Intestinal obstruction** of the small intestines or other parts of the large intestine are characterized by subacute abdominal pain, absence of feces, more marked systemic signs such as dehydration and tachycardia, and perhaps the presence of distended loops of intestine on rectal examination.

TREATMENT

The method of treatment depends on the severity of the case and whether there is uncomplicated dilatation and displacement caudally or if volvulus is present.

Medical Therapy

Mild cases of uncomplicated gaseous dilatation of the cecum may be treated conservatively by feeding good-quality hay, and recovery can occur in 2 to 4 days. The use of parasympathomimetic drugs such as neostigmine 0.02 mg/kg BW given subcutaneously every hour for 2 to 3 days has been recommended, but controlled trials demonstrating efficacy have not been performed. Xylazine is contraindicated for the abdominal pain associated with cecal dilatation because it reduces the myoelectrical activity of the cecum and proximal loop of the ascending colon. Cisapride at 0.08 mg/kg BW orally shows some promise. Bethanechol at 0.07 mg/kg BW subcutaneously and neostigmine at 0.02 mg/kg BW subcutaneously increased the frequency of cecocolic spike activity, the duration of cecocolic spike activity, and the number of cecocolic propagated spike sequences every 10 minutes. Bethanechol is considered superior to neostigmine because it induces more pronounced coordinated and aborally propagated spike activity.

Surgical Correction

For volvulus with the accumulation of ingesta and the possibility of necrosis of the cecum and ascending colon, the treatment of choice is surgical correction, and the prognosis is usually good. The recurrence rate of cecal dilatation and displacement ranges from 11% to 13% within the first week after surgery, whereas the long-term recurrence rate is about 25%. In severe cases with necrosis of the cecum, partial resection or total typhlectomy may be necessary. Extensive cecal necrosis requires total typhlectomy, which can be successful and lactating dairy cows may thrive and their milk production may be excellent in the current lactation.

Bacterial Diseases of the Ruminant Alimentary Tract

ACTINOMYCOSIS (LUMPY JAW)

SYNOPSIS

Etiology *Actinomyces bovis,* normal inhabitant of the ruminant oral cavity.

Epidemiology Common but sporadic disease from infection through wounds to the buccal mucosa by feed or through dental alveoli.

Clinical findings Initially painless, hard, immovable bony swelling on mandible or maxilla. Eventually discharge of small amounts of pus through one or more openings in skin.

Clinical pathology Presence of "club" colonies containing gram-positive filaments.

Diagnostic confirmation Isolation of organism.

Treatment and control Surgical debridement. Iodides and/or antimicrobial orally or parenterally.

ETIOLOGY

Actinomyces bovis is the primary cause, but other bacteria may be present in extensive lesions including non-*bovis Actinomyces* spp.

EPIDEMIOLOGY

The disease is sporadic but common in cattle. Occasional cases occur in pigs, horses, goats, dogs, and humans. Although actinomycosis occurs only sporadically, it is important because of its widespread occurrence and poor response to treatment. It is recorded in most countries of the world.

A. bovis is a common inhabitant of the bovine mouth and infection is presumed to occur through wounds to the **buccal mucosa** caused by sharp pieces of feed or foreign material. Infection may also occur through **dental alveoli** and may account for the more common occurrence of the disease in young cattle when the teeth are erupting. Infection of the **alimentary tract** wall is probably related to laceration by sharp foreign bodies.

PATHOGENESIS

An initial trauma of the oral mucosa or gingiva caused by small but sharp penetrating feed particles creates a portal of entry for the causative agent. The ensuing infection causes periostitis and osteomyelitis.[1] In the jawbones a rarefying **pyelogranulomatous osteomyelitis** is produced.

The effects on the animal are purely physical. Involvement of the jaw causes interference with prehension and mastication, and when the alimentary tract is involved there is physical interference with ruminal movement and digestion, both resulting in partial starvation. Rarely, localization occurs in other organs, caused apparently by hematogenous spread from these primary lesions.

CLINICAL FINDINGS

Cattle

Actinomycosis of the **jaw** commences as a painless, **bony swelling** that appears on the mandible or maxilla, usually at the level of the **central molar teeth**. The enlargement may be diffuse or discrete and in the case of the mandible may appear only as a thickening of the lower edge of the bone with most of the enlargement in the intermandibular space. Such lesions are often not detected until they are too extensive for treatment to be effective.

The more common, discrete lesions on the lateral surfaces of the bones are more readily observed. Some lesions enlarge rapidly within a few weeks, others slowly over a period of months. The swellings are very **hard, immovable** and, in the later stages, painful to the touch. They usually break through the skin and discharge through one or more openings (Fig. 8-25).

The discharge of pus is small in amount and consists of sticky, honey-like fluid containing minute, hard, yellow-white granules. There is a tendency for the sinuses to heal and for fresh ones to develop periodically. Teeth embedded in the affected bone become malaligned and painful and cause difficult mastication with consequent loss of condition. In severe cases, spread to contiguous soft tissues may be extensive and involve the muscles and fascia of the throat. Excessive swelling of the **maxilla** may cause dyspnea. Involvement of the local lymph nodes does not occur. Eventually the animal becomes so emaciated that destruction is necessary, although the time required to reach this stage varies from several months to a year or more.

The most common form of actinomycosis of soft tissues is involvement of the **esophageal groove** region, with spread to the lower esophagus and the anterior wall of the reticulum. The syndrome is one of **impaired digestion**. There is periodic diarrhea with the passage of undigested food material, chronic bloat, and allotriophagia. Less common lesions of soft tissue include **orchitis** in bulls, the **trachea** causing partial obstruction, and abscess in the brain or lungs.

Pigs

Rare cases of wasting occur because of visceral actinomycosis but extensive granulomatous lesions on the skin, particularly over the **udder**, are more common.

CLINICAL PATHOLOGY

Smears of the discharging pus stained with Gram stain provide an effective simple method of confirming the diagnosis. In nondraining lesions tissue core biopsies or fluid aspirates provide suitable material to identify the causative agent. Gram-positive filamentous rods can be identified by staining the crushed yellow granules found in pus.

Fig. 8-25 **A,** Polled Hereford cow with actinomycosis of the left mandible. **B,** Brown Swiss cow with actinomycosis of the left mandible with a draining tract.

NECROPSY FINDINGS

Rarefaction of the bone and the presence of loculi and sinuses containing thin, whey-like pus with small, gritty granules are usual. An extensive fibrous tissue reaction around the lesion is constant, and there may be contiguous spread to surrounding soft tissues. The

presence of **"club" colonies** containing the typical, thread-like bacteria is characteristic of the disease. These formations may be seen on microscopic examination of smears made from crushed granules in pus or on histologic examination of section.

Granulomatous lesions containing pockets of pus may be found in the esophageal groove, the lower esophagus, and the anterior wall of the reticulum. Spread from these lesions may cause a chronic, local peritonitis. There may be evidence of deranged digestion with the rumen contents sloppier than usual, an empty abomasum, and a mild abomasitis and enteritis. Involvement of local lymph nodes does not occur, irrespective of the site of the primary lesion.

DIFFERENTIAL DIAGNOSIS

Abscesses of the cheek muscles and throat region are quite common when spiny grass awns occur in the diet. They are characterized by their movability and localization in soft tissues compared with the immovability of an actinomycotic lesion. Pus may be thin, fetid, or caseous depending on the duration of the abscess. Prompt recovery follows opening and drainage.

Foreign bodies or accumulations of dry feed jammed between the teeth and cheek commonly cause a clinical picture that resembles actinomycosis, and the inside of the mouth should be inspected if the enlargement has occurred suddenly.

The syndrome of indigestion caused by **visceral actinomycotic lesions** resembles that caused by chronic peritonitis.

Cutaneous and mammary lesions in sows closely resemble necrotic ulcers associated with *Borrelia suilla.*

TREATMENT AND CONTROL

Treatment is with surgical debridement and antibacterial therapy, particularly iodides. Oral or intravenous administration of iodides is the most common treatment approach, although less effective in cases of actinobacillosis. For intravenous treatment a 10% or 20% sodium-iodide solution is administered slowly intravenously at a dose of 70 mg/kg. This treatment may be repeated after 1 to 2 weeks. Oral treatment with potassium iodide at a dose of 6 to 10 g per animal daily for at least 10 days has also been proposed; reports of treatment efficiency are anecdotal. Another treatment recorded as being effective consists of isoniazid given orally at the rate of 10 to 20 mg/kg BW daily for about 30 days. Cessation of the growth of the lesion should occur, but response in advanced cases is poor. Repeated cryotherapy with liquid nitrogen is reported to be effective. For control, isolation or disposal of animals with discharging lesions may be advisable, although the disease does not spread readily unless predisposing environmental factors cause a high incidence of oral lacerations. In severe cases and cases unresponsive to iodide treatment, parenteral antimicrobial therapy using penicillin, ampicillin, tetracyclines, or florfenicol have been suggested.

TREATMENT AND CONTROL

Treatment

Sodium-iodide (as 10% or 20% solution) (70 mg/kg IV, may be repeated after 7–10 days) (R-2)

Potassium-iodide (6–10 g per animal orally every 24 h for 10 days) (R-2)

Isoniazid (2.5–5 mg/kg orally every 24 h for 30 days) (R-2)

Procaine penicillin (44,000 IU/kg IM every 24 h for 7 days) (R-2)

Florfenicol (20 mg/kg every 48 h IM) (R-2)

Oxytetracycline (10 mg/kg IM every 24 h for at least 7 days (R-2)

Oxytetracycline long-acting formulation (20 mg/kg IM every 72 h) (R-2)

Control

Isolation and disposal of cattle with discharging lesions (R-2)

IM, intramuscularly; IV, intravenously.

ACTINOBACILLOSIS (WOODEN TONGUE)

SYNOPSIS

Etiology *Actinobacillus lignieresii.*

Epidemiology Organism is normal inhabitant of alimentary tract. Infection through abrasion of oral mucosa or skin. Site difference in sheep and cattle reflects differences in risk associated with prehension of food. Sporadic disease but outbreaks in which herd/flock predisposing factors are present.

Clinical findings Difficulty in prehension of food. Inflammation and abscessation of tongue and draining lymph nodes in cattle and of lips in sheep; Nodulary/proliferative skin lesions most common on head, neck, or lower limbs.

Clinical pathology and diagnostic confirmation Demonstration of organism.

Treatment and control Iodides, antibiotics, and hygiene. Avoidance of abrasive pastures.

Actinobacillosis refers to a sporadically occurring inflammatory process of soft tissue usually occurring in cattle, sheep, goats, and buffaloes. A similar condition has also been reported n horses and humans, where it was associated with animal bites. The condition manifests as a chronic pyogranulomatous inflammatory condition involving the tongue (wooden tongue), skin (skin actinomycosis), lymph nodes, and more rarely parts of the upper digestive tract including esophagus, rumen, and reticulum.

ETIOLOGY

The causative agent of actinobacillosis is *A. lignieresii,* a normal inhabitant of the upper digestive tract of ruminants that becomes an opportunistic pathogen once having penetrated into deeper soft tissue through an integumental or mucosal break. *A. lignieresii* may be recovered in pure culture from the lesions, but other pyogenic organisms may also be present. Recent investigations have shown that bacteria with phenotypic similarity to *A. lignieresii* isolated from horses are genotypically distinct from those isolated from ruminants and they have been designated as *Actinobacillus* genomospecies 1.

EPIDEMIOLOGY

Occurrence

The disease in **cattle** has a worldwide distribution and is usually of sporadic occurrence on individual farms. In **sheep**, the disease is recorded in most sheep-raising countries and is common in Scotland. In most instances, only occasional cases occur but in some flocks a morbidity rate of up to 25% may be encountered. Actinobacillosis also occurs, but is rare, in horses.

Source of Infection and Transmission

A. lignieresii is a normal inhabitant of the oral cavity and rumen of ruminants. The organism is susceptible to ordinary environmental influences and does not survive for more than 5 days on hay or straw. Infection in soft tissue results from damage to the oral mucosa or skin.

In **cattle**, infection most often occurs through ulcerating or penetrating lesions to the sulcus of the tongue, penetrating lesions in the apex, and lacerations to the side of the body of the tongue caused by the teeth. Abattoir surveys suggest that subclinical infections are common and have found small actinobacillary granulomas in the draining lymph nodes of the head and approximately 3% of tongues in slaughter cattle. Recently reports of outbreaks of **skin actinomycosis** in young beef cattle that were associated with skin lesions on lower limbs have been published. The underlying cause could not be determined but was assumed to be increased occurrence of skin lesions e.g., though abrasive surfaces that would have created portals of entry for this environmental pathogen.[1] An incidental report of a postoperative complication of a C-section in which actinobacillosis occurred in the wound is available.[2]

In **sheep**, the different nature of prehension of food leads to lesions predominantly in the lips and cheeks with occasional extension to the mucous membranes of the turbinates and the soft tissue of the head and neck.

Risk Factors

The disease is usually sporadic, but multiple cases in a herd and apparent outbreaks of the disease can occur when animals graze **abrasive pasture** species or pastures with **spiny awns** and transmission may be enhanced by infected discharges contaminating these pastures or feeds. A high prevalence is recorded in cattle grazing "burnt-over" peat pastures in New Zealand. These pastures contain a great deal of gravel and ash likely to cause oral injury. A similar high incidence has been observed in sheep fed prickly pear (*Opuntia* spp.). A severe outbreak has also been reported in heifers fed on very dry, stemmy, tough haylage and in cattle fed wheat straw from a specific thresher that produced straw with sharp edges. There is a higher prevalence of this disease in cattle in areas of copper deficiency.

Actinobacillosis granulomas may also occur at **atypical sites** in cattle, such as the external nares or the jugular furrow following infection of surgery wounds or **traumatic lesions** caused by nose grips or jugular venipuncture.[2] Reports of skin actinomycosis affecting several to many animals in a herd have been reported in recent years.[1,3] Infection of the cheeks resulting in bilateral facial enlargement is also recorded.

Zoonotic Implications

A. lignieresii is rarely associated with human disease but has been isolated from bite wounds inflicted by horses and ruminants.

PATHOGENESIS

Local infection by the organism causes an acute inflammatory reaction and the subsequent development of granulomatous lesions in which necrosis and suppuration occur, often with the discharge of pus to the exterior. Spread to regional lymph nodes with **ensuing lymphadenitis** is usual. Lingual involvement in cattle causes interference with prehension and mastication because of acute inflammation in the early stages and distortion of the tongue at a later stage. Visceral involvement is recorded and is identical with that described under actinomycosis.

CLINICAL FINDINGS

Cattle

The onset of **glossal actinobacillosis** is usually acute, and the affected animal is unable to eat for a period of about 48 hours. There is excessive **salivation** and **gentle chewing** of the tongue as though a foreign body were present in the mouth. On **palpation** the tongue is swollen and hard, particularly at the base, with the tip often appearing to be normal. Manipulation of the tongue causes pain and resentment. Nodules and ulcers are present on the side of the tongue, and there may be an ulcer at the anterior edge of the dorsum. In the later stages in which the acute inflammation is replaced by fibrous tissue, the tongue becomes shrunken and immobile and there is considerable interference with prehension.

Lymphadenitis is common and is often independent of lesions in the tongue. There may be visible and palpable enlargement of the submaxillary and parotid nodes. Local, firm swellings develop and often rupture with the discharge of thin, nonodorous pus. Healing is slow and relapse is common. Enlargement of the retropharyngeal nodes causes loud snoring respiration and interferes with **swallowing**.

Cutaneous actinobacillosis is also recorded with actinobacillosis granulomas occurring on atypical but visible areas such as the external nares, cheeks, skin or eyelid, and limbs. External trauma from abrasive materials in the environment is the usual initiating cause. Lesions are several centimeters in diameter and are pliable or firm and painful on palpation, red, and can bleed easily. Caseated small foci may be evident in the mass when it is debulked.

Sheep

In sheep the tongue is not usually affected. Lesions up to 8 cm in diameter occur on the **lower jaw, face, and nose**, or in the skin folds from the lower jaw to the sternum. They may be superficial or deep and usually extend to the cranial or cervical lymph nodes. Viscid, yellow-green pus containing granules is discharged through a number of small openings. Extensive lesions cause the formation of much fibrous tissue, which may physically impede prehension or respiration. Thickening and scabbiness of the lips may also be observed. Involvement of the nasal cavities may cause persistent bilateral nasal discharge. Affected sheep have difficulty in eating and many die of starvation. *A. lignieresii* is also an occasional cause of **mastitis** in ewes.

A similar involvement of the lips with abscessation in the area of the mandibular lymph nodes is recorded in camels. Incidental cases as well as outbreaks reported in **buffaloes** all were associated with cutaneous but not with glossal involvement.[4] In **horses** the disease is uncommon but intermandibular phlegmon, or infection of the tongue or of the muzzle can occur as well as infection at other body sites.

CLINICAL PATHOLOGY

Purulent discharges commonly contain "sulfur" bodies, which are granular in nature and, on microscopic examination, consist of **club-like rosettes** with a central mass of bacteria. These are not pathognomonic for *A. lignieresii* but can also be found in purulent exudate from granulomas associated with *A. bovis, Pseudomonas aeruginosa,* and *S. aureus.* Definitive diagnosis depends on the recovery of the organism from the lesion; therefore examination of smears or culture of pus for the presence of *A. lignieresii* is advisable. Isolation of the pathogen has been reported to be difficult from chronic lesions particularly when antimicrobials have been used. Full-thickness incision biopsies used for histopathological examination can be of value in diagnosis and show multiple pyelogranulomas in the deep dermis with distinct eosinophilic club rosettes surrounding gram-negative bacterial rods.

NECROPSY FINDINGS

Necropsy examination is not usually performed in cattle affected by the disease. In sheep, lymphangitis and abscesses containing thick, tenacious, yellow-green pus occur around the local lesion. Typical club colonies are visible on staining sections of affected tissue. Culture of material from lesions usually detects the presence of *A. lignieresii.*

DIFFERENTIAL DIAGNOSIS

- Foreign bodies in the mouth
- Rabies
- Esophageal obstruction
- Tuberculosis
- Cutaneous lymphosarcoma

TREATMENT

Iodides are still a standard treatment for both actinomycosis and actinobacillosis. In the former, the results are relatively inefficient, but in actinobacillosis, response is usually dramatic and permanent. Laboratory studies suggest that iodides have little bactericidal effect against *A. lignieresii.* It is probable that iodides exert their effect by reducing the severity of the fibrous tissue reaction.

Oral or intravenous dosing of iodides may be used. Potassium iodide, 6 to 10 g/day for 7 to 10 days, given orally to cattle, is effective. Treatment must be discontinued when symptoms of iodism develop. Lacrimation, anorexia, coughing, and the appearance of dandruff indicate that maximum systemic levels of iodine have been reached. Sodium iodide (70 mg/kg) can be given intravenously as a 10% or 20 % solution in one dose to both cattle and sheep. One course of potassium iodide or one injection of sodium iodide is usually sufficient for soft-tissue lesions, with the acute signs in actinobacillosis disappearing in 24 to 48 hours after treatment. At least one or preferably two further treatments at 10- to 14-day intervals are required for bony lesions.

Occasionally animals show distress, including restlessness, dyspnea, tachycardia, and staggering during injections of sodium iodide. Abortion occasionally occurs following the treatment of heavily pregnant cows with sodium iodide. This has not been reproduced in an experimental study; however, although uncommon, it is wise to advise the owner of this risk. Subcutaneous injections of sodium iodide cause severe irritation and local swelling immediately. The irritation

disappears within an hour or two but the swelling persists for some days. Subcutaneous injection is the standard route of administration for sheep, with the dose rate of sodium iodide being 20 mL of a 10% solution weekly for 4 to 5 weeks.

Sulfonamides, penicillin, streptomycin, and broad-spectrum antibiotics are also used. Streptomycin, given by intramuscular injection and repeated if necessary, has given good results in actinomycosis in cattle when combined with iodides and local surgical treatment. Isoniazid has been used as a treatment for actinomycotic infections in humans, and it has been reported on favorably as an adjunct to antibiotic or iodide therapy in cattle. The daily dose rate recommended is 10 mg/kg BW orally or intramuscularly, continued for 3 to 4 weeks.

Cutaneous actinobacillosis may require an extended course of treatment with streptomycin and/or dihydrostreptomycin for 2 to 4 weeks to achieve resolution.

TREATMENT AND CONTROL

Treatment

Sodium-iodide (as 10% or 20% solution) (70 mg/kg IV, may be repeated after 7–10 days) (R-2)

Potassium-iodide (6–10 g per animal orally every 24 h for 10 days) (R-2)

Isoniazid (2.5–5 mg/kg orally every 24 h for 30 days) (R-2)

Procaine penicillin (44,000 IU/kg IM every 24 h for 7 days) (R-2)

Florfenicol (20 mg/kg every 48 h IM) (R-2)

Oxytetracycline (10 mg/kg IM every 24 h for at least 7 days (R-2)

Oxytetracycline long-acting formulation (20 mg/kg every 72 h IM) (R-2)

Dihydrostreptomycin 10 mg/kg IM for at least 7 days) (R-2)

Control

Isolation or disposal of animals with discharging lesions (R-1)

IM, intramuscularly; IV, intravenously.

CONTROL

Restriction of the spread of disease is best implemented by quick treatment of affected animals and the prevention of contamination of pasture and feed troughs. Isolation or disposal of animals with discharging lesions is essential, although the disease does not spread readily unless predisposing environmental factors cause a high incidence of oral or skin lacerations.

ORAL AND LARYNGEAL NECROBACILLOSIS

SYNOPSIS

Etiology *Fusobacterium necrophorum*.

Epidemiology Oral infection of calves less than 3 months old; laryngeal involvement in older animals up to 18 months of age.

Clinical findings

Necrotic stomatitis: Fetid breath and necrotic ulceration of mucosa of cheek.

Laryngeal necrobacillosis: Fetid breath. Inspiratory dyspnea and stridor, necrotic lesions on arytenoid cartilages.

Lesions: Necrosis at site of lesion.

Treatment Antimicrobials. Surgical debridement of necrotic lesions and arytenoidectomy in unresponsive cases. Tracheostomy may be required to allow breathing with necrotic laryngitis.

Control None specific.

The term "necrobacillosis" commonly refers to infections associated with necrotizing lesions caused by *F. necrophorum*.[1] Although oral necrobacillosis refers to an inflammatory process affecting tissue of the oral cavity of calves, laryngeal necrobacillosis refers to an infection of the more caudal pharyngeal and laryngeal region. **Calf diphtheria** is a common synonym for necrobacillosis of the pharynx and larynx, and **necrotic stomatitis** is a synonym for the oral form. They are considered together because the essential lesion and infection are the same in both instances.

ETIOLOGY

F. necrophorum is a gram-negative, non–spore-forming, rod-shaped anaerobic but aerotolerant organism. It is a normal inhabitant of the ruminant oral cavity and upper digestive and respiratory tract and an opportunistic pathogen generally associated with abscesses and various necrotic infections.[2] Along with the oral/laryngeal necrobacillosis, *F. necrophorum* is also the causative agent of digital necrobacillosis (foot rot) and liver necrobacillosis (liver abscesses) in cattle.

Historically a subdivision of *F. necrophorum* divided into four different biotypes (A, B, AB, and C) was used. Biotypes A and B, which are considered to be most relevant in the etiology of *F. necrophorum*–associated diseases in cattle have been renamed as *F. necrophorum* subsp. *necrophorum* (formerly biotype A) and *F. necrophorum* subsp. *funduliforme* (formerly type B). The subspecies necrophorum is the more prevalent subspecies in necrobacillotic processes in animals. *F. necrophorum* subsp. *funduliforme* tends to occur more frequently in mixed infections.[2] Both *F. necrophorum* subsp. *necrophorum* and *F. necrophorum* subsp. *funduliforme* are associated with the disease.

F. necrophorum possesses a number of virulence factors such as endotoxic LPS, leukotoxin (LT) hemolysin, and hemagglutinin as well as others that are considered to be of critical importance for the anaerobic pathogen to penetrate, colonize, and proliferate in nonsuperficial tissue.[2] The pathogen is considered incapable of penetrating the intact mucosa or skin. Therefore other factors causing a primary tissue trauma, and thereby a portal of entry, are probably required. In the case of laryngeal disease, the point of entry is thought to be contact ulcers in the mucosa caused by repeated closure of the larynx.

EPIDEMIOLOGY

Occurrence

The disease has no geographic limitations but is more common in countries in which animals are housed in winter or maintained in feedlots. In the United States infections involving the pharynx and larynx appear to be more prevalent in the western states than in other sections of the country. It is a common disease in feedlots in yearling cattle, often in company with papillomatosis of the larynx. Laryngeal necrobacillosis is one of the most common infectious upper airway diseases associated with severe respiratory distress in calves observed in Belgium, the Netherlands, and parts of France. The condition in this region primarily affects **double-muscled Belgian Blue calves**, which are considered to be genetically predisposed to the condition.[3]

The disease is seen incidentally in sheep and goats. Laryngeal chondritis has been described in Texel sheep, which may be predisposed to the disease because of anatomic factors, namely the short head of the breed. This may affect the shape of the larynx or its relationship to adjacent tissues.

Transmission

Oral/laryngeal necrobacillosis is an infectious but noncontagious disease. The causative bacterium is a common inhabitant of the environment and upper digestive tract of cattle. It has been proposed that the infection may be spread through dirty milk pails and feeding troughs. Entry through the mucosa is probably affected through abrasions caused by rough feed and erupting teeth. The difficulty of reproducing the disease and the irregularity of its occurrence, even when *F. necrophorum* is known to be present, suggests the possibility of etiologic factors presently unknown.

Risk Factors

Host Risk Factors

Animals suffering from intercurrent disease or nutritional deficiency are most susceptible, but there is also an obvious **age predisposition** to the condition. Necrotic stomatitis is predominantly seen in weaned and unweaned calves 2 weeks to 3 months of age. Laryngeal infections commonly affect older calves up to 1 year of age and rarely occur in older animals up to 3 years of age.

An unusually high disease incidence has been observed in double-muscled Belgian Blue calves, a breed that is common in Belgium, the Netherlands, and some parts of France.[3]

Pathogen Risk Factors

A number of pathogen risk factors have been identified for *F. necrophorum,* of which LT and LPS are considered most important for the pathogenesis of necrobacillotic infections. Several investigations have reported that subtypes and strains of the bacterium vary in the amount of LT produced, which may contribute to the virulence of a specific strain. A correlation between LT production and the ability to induce abscesses has been reported in laboratory rats.[1]

Environmental Risk Factors

Necrobacillosis is highest in groups kept in confined quarters. Cases in pastured animals have been reported but are rare. Unsanitary conditions have been incriminated in facilitating the spread of the condition through contaminated nipples or pails.

PATHOGENESIS

F. necrophorum is a normal inhabitant of the oral cavity and causes inflammation and necrosis once it is able to penetrate tissue, e.g., through an injury of the mucosa of the oral cavity, pharynx, and larynx. Edema and inflammation of the mucosa of the larynx results in varying degrees of closure of the rima glottidis and inspiratory dyspnea and stridor. The presence of the lesion causes discomfort, painful swallowing, and toxemia. Extension of the lesion to the arytenoid cartilages will result in laryngeal chondritis. Involvement of the cartilage will usually result in delayed healing or failure to recover completely.

CLINICAL FINDINGS

In describing the clinical findings, a distinction must be made between calf diphtheria, which is characterized by the involvement of the larynx and necrotic stomatitis. In the former, a moist painful cough accompanied by severe inspiratory dyspnea that cause a roaring inspiratory sound ("honker calf" or "hard breather"), salivation, painful swallowing movements, complete anorexia, and severe depression are the characteristic signs. The temperature is high at 41°C (106°F), the pharyngeal region may be swollen and painful on external palpation, and there is salivation and nasal discharge. The breath has a foul rancid smell.

In cases of laryngeal necrobacillosis examination of the pharynx and larynx by visual inspection through the oral cavity with the aid of a speculum positioned over the base of the tongue will often reveal the lesions. The larynx can be viewed directly and illuminated with a strong source of light. A flexible endoscope is also useful when available and is necessary for examination of the larynx and cranial part of the trachea. The mucosa of the larynx and glottis are usually edematous and inflamed and a necrotic lesion is usually present and visible on one or both arytenoid cartilages. The opening of the larynx is often reduced because of the edema and inflammation. Careful visual inspection of the larynx during inspiration may reveal that the lesion extends into one or both vocal cords. The examination usually causes considerable discomfort, anxiety, and the production of purulent or bloodstained saliva.

Death is likely to occur from toxemia or obstruction to the respiratory passages on days 2 to 7. Most affected calves die without treatment, but only a small proportion of calves in a group are usually affected. Spread to the lungs may cause a severe, suppurative aspiration bronchopneumonia.

In calves affected with necrotic stomatitis, there is usually a moderate increase in temperature (39.5°C–40°C; 103°F–104°F), depression, and anorexia. The breath is foul and saliva, often mixed with straw, hangs from the mouth. A characteristic swelling of the cheeks may be observed posterior to the lip commissures, which, on opening the mouth this, is found to be caused by a deep ulcer in the mucosa of the cheek. The ulcer is usually filled with a mixture of necrotic material and food particles. An ulcer may also be present on the adjacent side of the tongue and cause severe swelling and protrusion of the tongue. In severe cases the lesions may spread to the tissues of the face and throat and into the orbital cavity. Similar lesions may be present on the vulva and around the coronets, and a spread to the lungs may cause fatal pneumonia. In other cases death appears to be caused by toxemia.

CLINICAL PATHOLOGY

Bacteriologic examination of swabs from lesions may assist in confirming the diagnosis.

NECROPSY FINDINGS

Severe swelling, caused by edema and inflammation of the tissues surrounding the ulcer, is accompanied by the presence of large masses of caseous material. Occasionally, lesions similar to those in the mouth, pharynx, and larynx may be found in the lungs and in the abomasum. Microscopically, areas of coagulation necrosis are bordered by large numbers of neutrophils and filamentous bacteria.

Samples for Confirmation of Diagnosis

- **Bacteriology:** anaerobic culture swab from deep within lesion (ANAEROBIC CULT)
- **Histology:** formalin-fixed sample of interface between ulcer site and normal tissue (light microscopy).

DIFFERENTIAL DIAGNOSIS

Necrotic laryngitis is characterized by inspiratory dyspnea and stridor, toxemia, fever, edema, (inflammation), and necrotic lesions of the laryngeal mucosa.

- **Neoplasms of the larynx** Occur only rarely, usually in mature cattle, and cause chronic inspiratory dyspnea.
- **Traumatic pharyngitis** May resemble laryngitis, but the lesions are obvious on visual inspection of the pharynx. In chronic cases of traumatic pharyngitis there may be periesophageal cavities containing rumen contents
- **Foreign bodies** Pieces of wire and small wooden sticks, for example, may become lodged in the mucosa of the arytenoid cartilages and cause clinical signs similar to necrotic laryngitis.

TREATMENT

The lesions of necrotic stomatitis will usually heal in a few days following debridement of the ulcers, application of a solution of tincture of iodine, and oral administration of sulfamethazine at a dose of 150 mg/kg BW daily for 3 to 5 days as labeled for use in food animals, or parenteral penicillin or broad-spectrum antimicrobials. Therapy should be at least for 5 days, and therapy for up to 3 weeks may be necessary.

Successful treatment of necrotic laryngitis is dependent on early recognition and prompt therapy with antimicrobials daily for several days. A broad range of antimicrobials have been proposed for the treatment of oral/laryngeal necrobacillosis. *F. necrophorum* is susceptible in vitro to β-lactam antibiotics, tetracyclines, macrolides, and lincomycins but is resistant to aminoglycosides and ionophore antibiotics.[2] The apparent sensitivity of this gram-negative pathogen to penicillins and cephalosporins is peculiar even based on its cell wall structure.[2] Although third- and fourth-generation cephalosporins (e.g., ceftiofur and cefquinome) are highly effective against *F. necrophorum,* these antimicrobials that have been classified as critically important for human and veterinary medicine are only indicated as second choice for cases that have poorly responded to other antimicrobials. Corticosteroids may be a beneficial adjunctive therapy, especially to reduce the edema. Tracheostomy may be necessary in some cases to relieve dyspnea. Failure to respond is usually associated with chronic suppurative chondritis, which requires subtotal arytenoidectomy.

TREATMENT AND CONTROL

Treatment

Procaine penicillin (22,000 IU/kg IM every 12 h or 44,000 IU/kg IM every 24 h for at least 7 days) (R-2)

Continued

Oxytetracycline (10 mg/kg IM every 24h for at least 7 days or long-acting formulation 20 mg/kg every 72 h) (R-2)

Ampicillin trihydrate (10 mg/kg SC or IM every 24 h for at least 7 days) (R-2)

Ceftiofur hydrochloride (2.2 mg/kg SC or IM every 24 h for at least 7 days) (R-2)

Dexamethasone (0.2–0.5 mg/kg IV or IM as a single dose) (R-2)

IM, intramuscularly; IV, intravenously; SC, subcutaneously.

CONTROL

Proper hygienic precautions in calf pens or feeding and drinking places together with avoidance of rough feed should prevent the spread of the disease. When the incidence is high, prophylactic antibiotic feeding may keep the disease in check.

ENTEROHEMORRHAGIC *ESCHERICHIA COLI* IN FARM ANIMALS AND ZOONOTIC IMPLICATIONS

Enterohemorrhagic *Escherichia coli* (EHEC), particularly *E. coli* serogroup O157:H7, have been recognized as food-borne pathogens causing potentially fatal human illness since the 1980s and have since then become a worldwide public health concern of increasing relevance. First outbreaks of human EHEC infections were recorded in 1982 in Oregon and Michigan and have been associated to the consumption of undercooked hamburger patties.[1] Since then, *E. coli* O157:H7, and in more recent years also a number of other serotypes, have caused major human illness outbreaks worldwide with considerable morbidity and mortality. Clinical signs can range from mild diarrhea, bloody diarrhea, and hemorrhagic colitis to the hemolytic uremic syndrome (HUS).[1]

Ruminants, and cattle in particular, are the main reservoir of EHEC but do not typically develop clinical disease. Human infection is acquired through consumption of contaminated food or water, direct contact with EHEC-carrying animals, or via person-to-person transmission.[1]

ETIOLOGY

EHEC comprise a subgroup of so-called Shiga-toxin–producing serotypes of *E. coli* that have been implicated in severe human disease. Shiga-toxin–producing *E. coli* strains produce toxins similar to the one produced by *Shigella dysenteriae,* the so-called Shiga toxins (Stx), and are therefore also denoted as **Shiga-toxin–producing *E. coli* (STEC)**. The presence of Shiga-toxin is determined by the Vero cell toxicity test, so STEC are also called **verotoxin** or **verocytotoxin-producing *E.coli* (VTEC)**.[2] The only consistent difference between pathogenic STEC serovars and apathogenic *E. coli* strains is indeed the possession of Stx genes.[3]

The large majority of outbreaks and sporadic cases of severe disease in humans are associated with a very limited number of EHEC serotypes.[1] By far the most prevalent single serotype of *E. coli* associated with human illness is ***E. coli* O157:H7**. However, in recent years a number of other EHEC serotypes have been linked to human illness and are on the rise worldwide; EHEC strains have therefore been classified into *E. coli* O157:H7 and non-O157:H7 *E.coli* recently. The six most prevalent non-O157 STEC serogroups associated with clinical disease in humans are in descending order: O26, O111, O103, O121, O45, and O145.[4]

EPIDEMIOLOGY

The predominant carriers and shedders of EHEC are healthy domesticated ruminants, cattle in particular, and to a lesser extent sheep and possibly goats.[5] EHEC strains associated with clinical disease in humans constitute only a minor fraction of the STEC isolates that are routinely recovered from healthy cattle, whereas the large majority of bovine STEC isolates either do not occur at all or are greatly underrepresented in people.[5] Although the majority of STEC isolates carried by healthy ruminants are not transmitted to humans there is no doubt that cattle are the main source of human EHEC infection.[5] The highest recovery rates of STEC among non-ruminant farm animal species was reported for turkeys, whereas other species such as pigs or chicken are only incidental carriers.[5] Rodents, domestic animals, and flies have been identified as incidental carriers.

It is estimated that between 20% and 50% of human EHEC infections are attributable to non-O157 *E. coli* strains, but estimates vary greatly from country to country and within one country from region to region.[4] In North America, Japan, and the UK *E. coli* O157:H7 is the serotype most commonly associated with clinical disease in people, whereas in Europe, Australia, Argentina, or South Africa infections with non-O157 serotypes have been estimated to be at least as prevalent as infections with the O157:H7 serotype in people.[4] Human cases of HUS are in most cases associated with infections from the serotype O157:H7. Estimates of sporadic cases of HUS in people associated with non-O157 STEC are less than 10% in North America and between 10% and 30% in Germany, Italy, and Great Britain.[4]

Occurrence and Prevalence of Infection

Cattle

Ruminants, and cattle in particular, are the most important nonclinical natural reservoirs of STEC. Generally, cattle remain asymptomatic because intestinal mucosal cells lack the Stx-specific globotriaosylceramide receptor.[4]
