This well-recognized disease occurs in Charolais cattle. The first onset of signs is at about 12 months of age when the gait is seen to be stiff and stumbling, especially in the hindlimbs, and the hindtoes are dragged. The ataxia may be asymmetric, and the animal cannot back up. The ataxia progresses over a period of 1 to 2 years. Affected animals tend to be down a lot and have difficulty in rising and posturing for urination. Urination is abnormal; it is a squirting but continuous flow that soils the tail. Some affected animals nod their heads from side to side when excited. Both males and females are affected. It has been described occurring in 2-year-old Charolais steer in New Zealand. Characteristic necropsy lesions are confined to the CNS and are histopathologic. The white matter of the cerebellum and internal capsule contains multiple foci of oligodendroglial dysplasia. The somatic lymph nodes contain nodules of hyperplastic lymphoid follicles, some catarrh of the medullae of the nodes, and an accumulation of eosinophils.

INHERITED SPINAL MYELINOPATHY

There is a progressive spinal myelinopathy of Murray Grey cattle, similar to that seen in Charolais cattle. It is possibly genetic in origin. Some calves are affected at birth; others do not become affected until 1 year old. The syndrome is one of a progressing paresis, without significant ataxia leading to paresis and permanent recumbency. There are degenerative lesions in spinal cord, midbrain, and cerebellum. The disease is conditioned by an autosomal recessive gene.

INHERITED PERIODIC SPASTICITY OF CATTLE

Inherited periodic spasticity has been observed in Holstein and Guernsey cattle and usually does not appear until the animals are adults. A recent report described it in a Canadian Hereford bull with an early onset between 1 and 2 years of age. It is a particular problem in mature bulls maintained in artificial insemination centers. In the early stages the signs are apparent only on rising; the hindlimbs are stretched out behind and the back depressed (Fig. 14-21). Marked tremor of the hindquarters may be noted. Initially the attacks persist only for a few seconds but are of longer duration as the disease progresses and may eventually last for up to 30 minutes. Movement is usually impossible during the attacks. The tetanic episodes fluctuate in their severity from time to time but there is never any abnormality of consciousness. Lesions of the vertebrae have been recorded but no lesions have been found in the nervous system. Idiopathic muscle

Fig. 14-21 Inherited periodic spasticity in a Holstein Friesian bull. The signs are apparent only on rising; the hindlimbs are stretched out behind and the back depressed.

cramps have been suggested as a cause. The disease is familial and the mode of inheritance appears to be by inheritance of a single recessive factor with incomplete penetrance.

Administration of the spinal cord depressant, mephenesin (3–4 g/100 kg BW given orally in three divided doses and repeated for 2–3 days) controls the more severe signs. A single course of treatment may be effective for some weeks.

NEURAXONAL DYSTROPHY

Neuraxonal dystrophy represents a heterogeneous group of degenerative diseases of genetic or acquired etiology that is characterized by spheroidal swellings of axons called spheroid bodies, which is the result of accumulation of axoplasmic organelles including neurofilaments. The change may be physiologic (caused by normal aging) or pathologic and are categorized as primary (familial) or secondary (acquired).[1] EDM is considered a more severe variant of neuraxonal dystrophy and is discussed separately.

NEURAXONAL DYSTROPHY OF SHEEP (SEGMENTED AXONOPATHY)

This is reported in Suffolk, Merino, Romney, Perendale, Coopworth, and crossbred sheep.[1] An inherited defect (autosomal recessive) is suspected in all cases. Abnormalities appear related to abnormal axonal transport and the inability to maintain integrity of the axon and their associated myelin sheaths.[2]

In **Coopworth sheep** the lambs are affected at birth but have a progressive syndrome in which cerebellar and proprioceptive signs predominate. Most die by 6 weeks of age. Large axonal spheroids are present in the spinal cord and midbrain, and there is a severe depletion of Purkinje cells in the cerebellum.

In **Suffolk** sheep the disease does not appear until 1 to 6 months; signs are a gradual onset of ataxia, followed by recumbency, leading to death or euthanasia. Spheroids in CNS axons are characteristic, mostly in the spinal cord and cerebellum, and contain large amounts of amyloid precursor protein.[1]

The disease in **Merinos** is in fine-wool sheep, is probably the same disease as that previously called **Murrurrundi disease**, and does not appear until 4 to 6 years of age. Most cases require euthanasia after about 2 months but some mild cases survive for up to 3 years. The clinical signs include a wide-based stance, dysmetria of all limb movements with a pronounced hypermetria of the forelimbs resulting in frequent falling, a fine intention tremor of the head, and a diminished menace reflex. A similar disease of medium-wool Merinos, characterized by progressive posterior ataxia and degeneration of sensory tracts in thoracic segments of spinal cord, commencing after 5 months of age and terminating fatally before 2 years of age, is also recorded in Australia. It is probably also an inherited defect

NEURAXONAL DYSTROPHY OF HORSES

In horses, neuraxonal dystrophy has been reported in **Quarter Horses, Haflingers, Morgans, Appaloosas, Paso Finos, and Standardbreds** with a familial occurrence present in a number of breeds.[3,4] The onset of clinical signs can be as early as a few months of age. Common neurologic abnormalities include ataxia, proprioceptive positioning deficits, dysmetria, a wide-based stance, obtundation, and an inconsistent menace response with no detectable visual impairment.[3] Clinical progression can be very slow over a few months to years, and in some cases stabilization of clinical signs may occur.[3] It can be difficult to clinically differentiate neuraxonal dystrophy from **EDM**; however, the latter is considered a more severe clinical variant of neuraxonal dystrophy.[5] Clinical signs of ocular disease are not detectable and the results of ERG and EEG are within the normal range.[6] Lesions at necropsy are only apparent microscopically and include specific tracts and nuclei in the caudal medulla and spinal cord, with occasional involvement of the cerebellum.

CAPRINE PROGRESSIVE SPASTICITY

A possibly inherited progressive paresis of Angora goats is recorded in Australia. Signs first appear at about 2 months of age, commencing with lethargy, followed by ataxia, then paresis progressing to sternal recumbency and eventual euthanasia. Tendon reflexes are normal but the kids have difficulty getting to their feet, especially in the hindlimbs. The gait is ataxic with frequent stumbles, and the kids are unwilling to run. At necropsy there are many large, clear vacuoles in many neurons of the spinal cord, posterior brainstem and midbrain, and degeneration of nerve fibers in the same areas and peripheral nerves.

INHERITED SPONTANEOUS LOWER MOTOR NEURON DISEASES

Motor neuron diseases involve selective degeneration of upper and/or motor neurons. Upper motor neurons originate in the cranial vault, where they stimulate contraction of muscles. In comparison, lower motor neurons connect the brainstem and spinal cord to the muscle fibers.[1] Effective treatments for motor neuron diseases have yet to be identified.

A lower motor neuron disease in newborn Romney lambs has been described.[1] Lambs are normal at birth but within 1 week they developed weakness and ataxia, which progressed until they were unable to stand. The principal histologic lesions were degeneration and loss of neurons in the ventral horns of the spinal cord and brainstem, wallerian degeneration of ventral rootlets and motor nerves, and associated denervation atrophy of skeletal muscle fibers. Large fibrillar spheroids were found in white and gray matter including nuclei in the brainstem. One missense mutation on the sheep called the ATP/GTP-binding protein 1 gene was identified in all affected animals, exhibiting recessive pattern of inheritance.[1] This binding protein plays a role in protein turnover by cleaving peptides into amino acids. A similar, though not identical, disease of newborn lambs has been recorded in a Dorset Down flock affecting about 20% of lambs. They lay with hindlimbs tucked under the body and forelimbs splayed sideways.

This progressive disease of Yorkshire piglets 5 to 10 weeks of age is presumed to be inherited. Clinical signs include hindlimb tremor, weakness, and ataxia appearing at 2 to 5 weeks of age. The gait includes fetlock knuckling, short choppy steps, and a tendency to collapse after a few steps. Segmental and postural reflexes are normal. By 10 weeks there is complete hindlimb paralysis, the pig is in sternal recumbency, and front limb paralysis has begun. The appetite is good and the pig is bright and alert. On necropsy there is symmetric degeneration and loss of motor neurons in the spinal cord in some ventral spinal nerve roots.

INHERITED SPINAL MUSCULAR ATROPHY

A progressive ataxia, weakness, muscle atrophy, and recumbency develops in young calves, mostly during the first 2 weeks of life.

Sensory functions are unimpaired. Some are already affected at birth and some may be stillborn. No new cases occur after 3 months of age. Conditioned by an autosomal recessive gene the defect occurs in Red Danish cattle, which originated from Brown Swiss, German Braunvieh, and American Brown Swiss. The primary lesion is degeneration of ventral horn cells of the spinal cord, without involvement of the brainstem or cerebellum. The visible lesion is the secondary atrophy of the denervated muscles.

INHERITED HYPOMYELINOGENESIS (CONGENITAL TREMOR OF PIGS)

Congenital tremor of pigs has a multiple etiology and some of the causes are not yet identified. The two inherited diseases are noted here: congenital tremor type A-IV of British Saddleback pigs and congenital tremor type A-III, a sex-linked inherited form of cerebrospinal hypomyelinogenesis of Landrace pigs. The A-IV disease is characterized by the presence of poorly myelinated axons in all parts of the CNS. The specific defect in A-IV is one of fatty acid metabolism. The structural abnormalities in the A-III disease have been identified; splayleg is a common accompaniment.

Both diseases are characterized by muscle tremor, incoordination, difficulty in standing, and some squealing. The A-III disease occurs only in males. Both are inherited as recessive characters.

PORCINE CONGENITAL PROGRESSIVE ATAXIA AND SPASTIC PARESIS

This is an autosomal recessive disorder of pigs in Switzerland with a yet to be identified gene defect. Clinical signs of a spastic gait with progressive ataxia become evident within 3 days of birth, and the condition is lethal. Male and female pigs are equally affected. Pedigree analysis has identified a boar born in 1978 that was used widely for artificial insemination as the originator of the genetic defect.

EQUINE DEGENERATIVE MYELOENCEPHALOPATHY (EQUINE NEURAXONAL DYSTROPHY)

EDM is characterized by **symmetric, slowly progressive spasticity and ataxia** in foals and horses less than 2 years of age. The disease occurs in most breeds in North America and Europe and is reported in captive zebra and Mongolian Wild Horses in North America. Neuronal dystrophy of the cuneate and gracilis nuclei is considered a form of EDM and is likely the underlying pathophysiologic process of EDM.[1]

The prevalence of the disease varies widely, with up to 40% of susceptible animals on a farm being affected, although the disease is usually sporadic. There is a familial predisposition to the disease apparently involving an increased requirement for vitamin E, although other factors, including housing, are contributory. Foals from dams that had an EDM-affected foal were at a significantly higher risk (relative risk = 25) of developing EDM than foals from other dams. The occurrence of clusters of cases involving related horses is supportive of a genetic component with inheritance as in an autosomal dominant with variable expression or polygenic manner, although this has not been confirmed in all breeds.[2-4] The disease in Quarter Horses is highly heritable and appears to be polygenic.[2,4]

EDM occurs in Standardbreds, Paso Finos, Quarter Horses, Mongolian horses, Appaloosas, Haflingers, Arabians, Morgans, Lusitanos, Thoroughbreds, Paint horses, Tennessee Walking Horses, Norwegian Fjord Horses, Welsh Pony, and various mixed breeds.[1] There is no sex predilection.

The pathogenesis of the disease is unknown. Abnormal expression of integral synaptic vesicle, synaptic vesicle-associated presynaptic plasma membrane, and cytosolic proteins was observed in two Arabian horses with equine degenerative myeloencephalopathy; however, abnormal α-tocopherol transfer protein does not appear to contribute to the disease.[4] These proteins have a role in trafficking, docking, and fusion of neuronal synaptic vesicles, and this finding suggests that there is disruption of axonal transport in equine degenerative myeloencephalopathy. A role for oxidative stress and damage to neurons is supported by documentation of markers of oxidative stress in nervous tissue and low serum and/or CSF vitamin E concentrations in two horses with EDM and not in healthy control horses.[5] Low vitamin E concentrations in serum are often associated with the disease, but in one small study only foals with a genetic predisposition to the disease, and having a low serum vitamin E concentration, developed the disease. Foals with low serum vitamin E concentrations that did not have the genetic predisposition to the disease did not develop EDM.[6] Loss of axons leads to defects in neurologic function and consequent gait abnormalities.

The clinical signs are those of a slowing progressive spinal ataxia that stabilizes when the animal is 2 to 3 years of age. Age of onset ranges from birth to 36 months, although most cases have clinical signs by 6 to 12 months of age. Affected foals and yearlings have symmetric signs that are most severe in the hindlimbs, of ataxia characterized by pivoting, circumduction, truncal sway, and difficulty performing complex movements such as backing or walking with the head elevated. At rest, severely affected horses may have an abnormal posture. The cutaneous trunci reflex may be absent. Spontaneous recovery does not occur, but progression to death is unusual. Radiography and myelography of the cervical spine does not reveal evidence of compression of the spinal cord. The disease is not associated with abnormalities detected on ocular examination, ERG or EEG.[7]

Serum vitamin E concentrations can be normal or low in affected horses, and this is not a reliable test for diagnosis of the disease.[1-3] The hemogram, serum biochemical profile, and CSF analysis are normal. There are no gross lesions on necropsy. Histologic lesions include neuronal atrophy, accumulation of lipofuscin-like pigment, and glial cell proliferation.

Differential diagnoses are listed in Table 14-20 later in the chapter, under the Equine Cervical Vertebral Compressive Myelopathy section. Diagnosis is achieved by exclusion of other causes, of abnormal gait without fever or disease in other body systems in horses, such as compressive myelopathy and equine protozoal myeloencephalopathy.

No treatment is curative, but vitamin E (6000 IU orally once daily) may prevent progression of signs. Supplementation of at-risk foals and yearlings with vitamin E can prevent the disease, although results are not equivocal.[1,6]

EQUINE CERVICAL VERTEBRAL COMPRESSIVE MYELOPATHY (WOBBLER, "WOBBLES," FOAL ATAXIA, EQUINE SENSORY ATAXIA, CERVICAL VERTEBRAL INSTABILITY)

SYNOPSIS

Etiology Unknown. The clinical signs are the result of cervical spinal cord compression as a result of abnormalities in the cervical spine.

Epidemiology Two predominant manifestations. Sporadic or endemic disease of young horses with young, rapidly growing male horses most commonly affected. Separate presentation in middle-aged and older horses in which it is sporadic.

Clinical signs Spinal ataxia evident as truncal sway, ataxia, and paresis usually more

Continued

severe in the hindlimbs. Radiographic evidence of narrow spinal canal.

Clinical pathology None.

Lesions Malacia and wallerian degeneration in the cervical spinal cord.

Differential diagnosis Equine degenerative myelopathy, equine protozoal myeloencephalitis, trauma, equine infectious anemia, cerebrospinal nematodiasis, West Nile encephalomyelitis, equine herpesvirus-1 myelopathy, osteomyelitis, cervical vertebral epidural hematoma, aortoiliac thrombosis, congenital vertebral malformation, diskospondylitis, and ryegrass staggers.

Diagnostic confirmation Radiography. Positive contrast myelography. Necropsy.

Treatment Antiinflammatory drugs. Surgical fusion of vertebrae.

Control None.

ETIOLOGY

The cause of neurologic disease is extradural compression of the cervical spinal cord, hence the term **compressive myelopathy.** The compression may be **static**, that is, the compression is present constantly with the neck in a neutral position, or **dynamic** and only present intermittently when the neck is either flexed or extended. The second situation is often referred to as cervical vertebral instability.

The etiology of CSM in most cases is not known. The disease in young horses is caused by malformation and malarticulation of the cervical vertebrae and could represent part of the osteochondritis dissecans spectrum of diseases.[1,2] There can be combinations of articular process osteophytosis, interarcuate ligament hypertrophy, dorsal laminal thickening, vertebral body end plate flaring, and synovial cysts. Importantly, changes in soft tissue associated with the bony lesions can contribute to the compressive myelopathy. Dynamic instability is associated with vertebral instability and subluxation and is most common in the cranial vertebrae (C3-C5).

Copper deficiency has been mooted as one cause of the bony lesions, as have high calorie rations and diets high in soluble carbohydrate.[2]

The disease in older horses is secondary to osteoarthritis of the articular processes. An inciting cause has not been identified.

Several basic syndromes of compressive myelopathy, based on age of occurrence, are recognized:

- CSM in immature horses (<3 years of age, depending on breed) that is often associated with developmental joint disease in the axial and appendicular skeleton. A fundamental underlying predisposing defect appears to be a narrow diameter of the cervical vertebral canal. Compression is a result of the lesions described earlier.
- Cervical vertebral instability is a disease of horses less than 1 year of age that is often associated with malformations of one or more of the cervical vertebrae.[3]
- Compressive myelopathy in mature horses, >4 years (usually >7 years) of age, associated with osteoarthritis of the articular facets of the caudal cervical vertebrae, with subsequent impingement of the vertebral canal by bony and soft tissue proliferative lesions.
- Miscellaneous causes of cervical cord compression by neoplasia (melanoma, sarcoma, lymphoma), trauma (cervical vertebral fractures), arachnoid or synovial cysts, epidural hematoma[4] or, rarely, discospondylitis.[5]

An alternative categorization is based on the nature of the bony lesion and not on the cause of compression of the spinal cord. **Type 1 cervical vertebral malformation** occur in horses <2 years of age that have vertebral changes that likely began in the first few months of life, including malformations causing stenosis of the vertebral canal, malformations at the articulations of the vertebrae including osteochondrosis, and enlarged physeal growth regions. **Type II cervical vertebral malformations** tend to occur in older horses with severe osteoarthritic lesions of the vertebral articulations.

EPIDEMIOLOGY

Occurrence

The disease in mature horses occurs sporadically throughout the world.

The disease in young horses is sometimes endemic on farms or studs and in particular lines of horses. There is a suggestion of a familial tendency for the disease, although this has not been well documented.

The **morbidity rate** can be as high as 25% of each foal crop on individual Thoroughbred farms, although the overall frequency of the disease in the general horse population is much lower. Among Thoroughbreds born on four stud farms in Europe and North America, the disease has an annual prevalence of diagnosis of 1.3% (range of 0.7%–2.1% over the study period) and annual prevalence on farms varying from 0% to 5.8%.[6]

Compressive myelopathy was detected in 83 of 4318 horses subject to necropsy examination in Normandy, France.[7] Fifteen percent of horses with a diagnosis of neurologic disease had cervical compressive myelopathy. There were more males affected than females.[7]

Risk Factors

Animal Risk Factors

Risk factors for CSM identified in a study of 1618 horses at 22 veterinary teaching hospitals in North America are summarized in Table 14-20.

The **disease in young horses** is commonly recognized in Thoroughbred, Standardbred, Warmblood, and Quarter horses, with Arabians and other breeds less likely to be diagnosed with the disease.[8] Ponies are rarely, if ever, affected. Horses less than 4 years of age are at greater risk of the disease, with most cases occurring in 1- to 3-year-old horses. Males, either intact or gelded, are more likely to be affected than are females.[8]

Table 14-20 Association of horse factors associated with a diagnosis of cervical stenotic myelopathy in 811 horses with cervical stenotic myelopathy and 805 control horses

Variable	Or (95% CI)	*P* value
Sex		
Gelding	2.0 (1.5–2.6)	<0.001

From Levine JM, et al. JAVMA 2008;233:1453

The **disease in older horses** is characterized by a slight predominance of male horses with overrepresentation of Warmbloods, which could represent a breed or use predisposition, and median age at diagnosis of 8 years.[1]

Horses with CSM have a narrower spinal canal than do unaffected animals and this condition, with degenerative joint disease of the articular facets and thickening of the ligamentum flavum, contributes to the greater likelihood that the horse will have spinal cord compression.

It is suspected that predisposition to the disease is heritable, but this has not been demonstrated by appropriate studies.

The disease in mature horses tends to be in horses used for athletic endeavors and is uncommon in broodmares or retired animals.

PATHOGENESIS

The disease is attributable to injury to the spinal cord as a result of compression by either soft tissue (joint capsule, intervertebral ligaments, or, rarely, intervertebral disk material) or cartilage and bone.

Constant or intermittent pressure on the spinal cord causes dysfunction or necrosis of white matter and neurons at the site of compression, degeneration of fibers of ascending tracts cranial to the site of compression, and of descending tracts caudal to the compression. The ascending tracts are those associated with general proprioception, whereas the descending tracts are upper motor neurons. These tracts are located superficially in the dorsolateral aspect of the cervical spinal cord and damage to them results in signs of ataxia and weakness. Tracts from the caudal limbs are more superficial, and therefore more easily injured, than tracts associated with the cranial limbs. Consequently, clinical signs are usually more severe in the hindlimbs. The spinal cord lesions are usually, but not always, bilaterally symmetric, as are the clinical signs. Proprioceptive pathways are disrupted, causing the signs of ataxia (incoordination) typical of the disease. Clinical signs vary depending on the site of the lesion (see later).

CLINICAL FINDINGS

The onset of clinical signs is sometimes acute in young horses with CSM and there can be a history of trauma, such as falling. However, the onset of clinical signs of CSM in both young and mature horses is usually gradual and insidious, and in mildly affected horses the nervous disease can be mistaken for lameness of musculoskeletal origin. Affected horses are bright and alert and have a normal appetite. There can be evidence of pain on manipulation of the neck or on firm pressure over the lateral facets, especially in mature horses with osteoarthritis of the caudal cervical vertebral facets.[1] There can be focal muscle atrophy adjacent to affected cervical vertebrae in older horses.

The severity of clinical signs varies from barely detectable to recumbency. There are no defects of al nerves, with the occasional exception of the cervicofacial reflex. The severity of signs of CSM are often graded according to the following:

Grade 0: no gait deficits at the walk
Grade 1: no gait deficits identified at the walk and deficits only identified during further testing (head elevation, backing, walking on a slope, stepping over obstacles, circling, tail pull at rest and while walking)
Grade 2: deficits noted at the walk
Grade 3: marked deficits noted at the walk
Grade 4: severe deficits noted at the walk and might fall or nearly fall at normal gaits
Grade 5: recumbent and unable rise without assistance

The **two primary defects in gait** in affected horses are related to defects in upper motor neuron function and general proprioception. These two primary deficiencies in neurologic function contribute to clinical signs characterized as ataxia, paresis, dysmetria, and spasticity. **Ataxia** is the incoordinated movement of limbs and is evident as interference of one limb with another (such as one foot stepping on another when the horse is tightly circled), knuckling of the fetlock joint (which can also be a sign of weakness), unusual placement of feet (excessively wide-based or narrow-based stance, incomplete or delayed return of the foot to its normal position after it is relocated to an abnormal position, excessive circumduction of the outside foot during tight circling), stumbling, and/or swaying of the trunk during walking in a straight line. **Paresis** is weakness and is evident in its most extreme form as inability of the horse to rise. In less extreme manifestations it is evident as knuckling of the fetlock joint, stumbling when walking downhill or over obstacles, and ease of pulling the horse to one side by the tail when it is walking. **Dysmetria** refers to uneven gait typified by undershoot or overshoot of the limb such that the hoof is in an incorrect position. **Spasticity** is a result of loss of inhibition of lower spinal reflexes by the upper motor neurons and results in a stilted or stiff gait.

Mildly affected horses may have deficits that are difficult to detect and only apparent under saddle or at high speed. The owner might complain of poor performance of a racehorse or dressage animal, of an animal that frequently changes leads, or that is poorly gaited. Careful examination can reveal excessive circumduction of the hindfeet, stumbling, and pacing when the head is elevated.

Moderately affected animals have truncal sway (the body of the horse and hindquarters swaying laterally when the horse is walked in a straight line) and excessive circumduction of the hindfeet. There can be a floating gait of the hindlimbs and scuffing of the toe. Having the horse move in a very tight circle about the examiner often causes the circumduction to become worse in the outside hindleg and the horse to place one foot on top of the other. Affected horses will sometimes pace when walked in a straight line with the head elevated. Blindfolding the horse does not exacerbate the signs. Affected horses will stumble when walked over low objects, such as a curb, and will knuckle at the fetlocks and stumble when walked down a steep hill.

Severely affected horses often fall easily when moved or are unable to stand. The horses are bright and alert, but anxious, and display marked truncal sway and ataxia. When standing, they will often have their legs in markedly abnormal positions.

Horses with lesions in the cervical spinal cord cranial to C6-C7 have signs in both forelimbs and hindlimbs. The hindlimbs are more severely affected and the signs are usually, but not always, bilaterally symmetric.[9] Approximately 43% of affected horses have asymmetric gait abnormalities.[9] Lesions of the cervical intumescence (C6 to T2) may cause signs that are more severe in the forelimbs than in the hindlimbs. Lesions at this site may also cause signs typical of brachial plexus injury. Focal muscle atrophy is not characteristic of CSM or cervical vertebral instability and there are never signs of CNC, cerebral, or cerebellar disease.

After initial progression the clinical signs usually stabilize or partially resolve. However, complete spontaneous recovery is very unusual. Death is unusual unless it is by misadventure, although many affected animals are killed for humane or economic reasons.[8]

Neurologic Examination

A tentative diagnosis of cervical compressive myelopathy is often made based on the clinical examination. Although this assessment is relatively straightforward for severely affected horses, the detection of neurologic abnormalities on physical examination is more challenging for horses with milder forms of the disease. This becomes important as additional diagnostic investigations might not be warranted in all cases of horses with clear-cut signs of cervical compressive myelopathy, but might be indicated in horses with less severe signs of the disease.

The reliability of the neurologic examination of horses has been investigated very little. The agreement between expert or trained observers for overall grade of neurologic abnormality was good (intraclass correlation coefficient of 0.74) when horses of all grades were considered (grades 0–4), but very poor for horses ≤ Grade 1 (intraclass coefficient (ICC) = 0.08) and only moderate (0.43) for horses ≥ Grade 2.[10] The higher ICC for the overall assessment was because observers could easily agree on differences

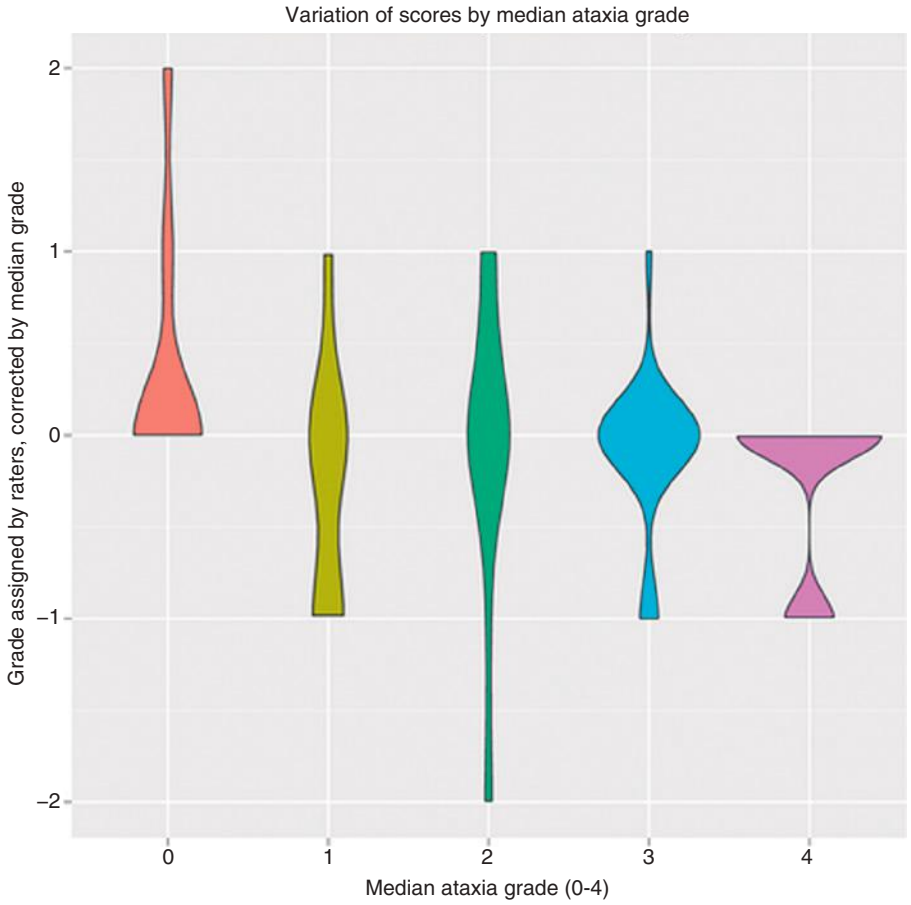

Fig. 14-22 Violin plot of the variation in individual ratings grouped by the median rating for each horse during live scoring only. To align the ratings around 0, each score was subtracted from the median score of the horse. A violin plot is similar to a boxplot, with the addition of the density of data points illustrated by an increase in width. This figure reveals that most grades have a fluctuation of 1 degree more or less than the median; however, grades 0 and 3 are condensed around the median illustrating better agreement, whereas grade 2 stretches from –2 to + 1 grades from the median. (From Olsen E, Dunkel B, Barker WHJ, et al. Rater Agreement on Gait Assessment During Neurologic Examination of Horses. *J Vet Int Med* 2014;28:630.)

between severely affected and unaffected horses. Greatest lack of agreement was for horses that had Grade 2 neurologic signs (Fig. 14-22).[10]

It is recommended in human medicine that an ICC must be >0.9 for it to be useful for decision making in individual patients,[11] and on this basis the current methods for neurologic examination for horses are not acceptable for clinical use.[10] It is the authors' opinion that the current neurologic grading system for examination of horses continue to be used because it provides a structured way of completing the examination. The results of the examination should be considered in light of its poor reliability, especially for horses with severity of median Grade 2, and interpreted with caution.

Ancillary Diagnostic Tests

The "slap test," in which the response of the arytenoid cartilages to a slap on the thorax is examined through an endoscope, has poorer sensitivity and specificity for detecting spinal cord disease than does a routine neurologic examination.

Acupuncture has no proven value in the diagnosis of cervical compressive myelopathy and should not be used for this purpose.

Radiographic Examination

Radiographic examination of the cervical vertebral column of potentially affected horses is often undertaken because there are frequently lesions of the bone associated with cervical compressive myelopathy. Radiographic examination includes plain radiographs taken from the lateral aspect with the horse standing or myelography using injection of radiopaque dye to allow visualization of the subarachnoid space and detection of extradural compression of this space.

Examination of both plain and contrast radiographs is potentially enhanced by use of one or more of a number of measures and ratios intended to detect and quantify extradural compression of the cord.

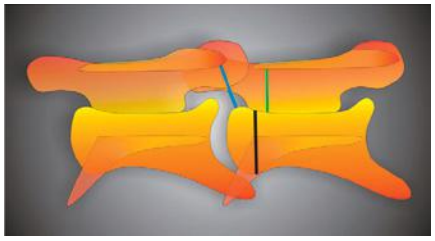

Fig. 14-23 Schematic drawing of the cervical vertebrae illustrating the sagittal ratios: the intravertebral sagittal ratio is calculated as the ratio of the minimum sagittal diameter of the spinal canal (green line) to the maximum sagittal diameter of the vertebral body, taken at the cranial aspect of the vertebra and perpendicular to the spinal canal (black line). The intervertebral sagittal ratio is the ratio of the minimal distance taken from the most cranial aspect of the vertebral body to the most caudal aspect of the vertebral arch of the more cranial vertebra (blue line) and the maximal sagittal diameter of the vertebral body (black line). (Reproduced with permission from Van Biervliet J. An evidence-based approach to clinical questions in the practice of equine neurology. *Vet Clin Nth Am Equine Pract* 2007;23(2):317-328.)

Radiographic signs detectable on plain radiographs of the cervical spine in horses with compressive myelopathy include the following:

- Encroachment of the caudal vertebral physis dorsally into the spinal canal ("ski jump lesion") caused by physeal enlargement
- Extension of the arch of the vertebra over the cranial physis of the next vertebra
- Sclerosis of the spinal canal
- Kyphosis, or subluxation, between adjacent vertebra
- Degenerative joint disease of the articular facets evident as osteoarthritis and bony proliferation

However, these signs are also common in normal horses and have poor predictive value. The overall agreement, relative sensitivity, and relative specificity, respectively, for identification of radiographic abnormalities (compared with the gold standard of necropsy examination) in affected horses is 66% (76/116 horses); 63% and 67% for identification of articular process osteophytosis; 61% (71/116), 42%, and 83% for vertebral canal stenosis; and 78% (91/116), 56%, and 85% for vertebral column subluxation.[9] Radiography appears to have useful specificity but limited sensitivity in the diagnosis of bony lesions associated with cervical compressive myelopathy. Use of additional views, such as oblique views of the caudal cervical vertebrae. can enhance the diagnostic value of radiography.[12]

Intervertebral and **intravertebral** ratios have been calculated to assist with diagnosis of CSM (Fig. 14-23). The ratios in and of

themselves have variable intraobserver and interobserver reliability with ratios varying by 5% to 10% within and between observers.[13,14] Interobserver agreement in measurements is poor and intraobserver agreement is good across the six most cranial sites but poor for caudal sites.[14] Intraobserver and interobserver variability is sufficient to affect clinical interpretation of radiographs and should be considered when interpreting radiographic examinations with suspected spinal cord disease.

An intravertebral sagittal ratio of the spinal canal to vertebral body diameter of less than 50% for C4-C6 is associated with a 26- to 41-fold increase in the probability of a compressive myelopathy for horse >320 kg; in a separate study all horses with a value of this ratio of less than 0.485 had at least one compressive lesion.[15] An intervertebral ratio can also be calculated and it has diagnostic utility that might be slightly greater than that of the intravertebral ratio.[2,15] The results of these tests are not definitive and a healthy horse can have ratios below this cutoff and affected horses can have normal ratios.[16,17] It is important to recognize that the utility of **intravertebral** (and other) ratios is dependent on the pretest likelihood that the horse has cervical compressive myelopathy. The ratios should therefore be considered in light of other clinical findings. Importantly, neither the intravertebral nor intervertebral ratios predict the site of compression, which can only be detected by myelographic examination.[2]

Myelography has been considered to provide the definitive antemortem confirmation of spinal cord compression, but recent studies demonstrate that it is not a perfect diagnostic test and that results should be interpreted cautiously.[2] The sensitivity of this technique, using a 50% reduction in the width of the dorsal dye column as a cutoff for diagnosis of the disease, is 53% (95% CI 34%–72%, $n = 22$) and the specificity is 89% (95% CI of 84%–93%, $n = 228$) (Fig. 14-24).[2] Others have found similar values for sensitivity and specificity with values of 47% and 78%, respectively, for older horses with compressive myelopathy at caudal cervical sites.[1] These values indicate a test with a relatively high false-negative rate but low false-positive rate for neutral views and indicate that a positive finding on myelography is highly suggestive of the disease, but that a negative finding does not eliminate the possibility of the disease. The **false-positive rate** is increased to 12% to 27% for compression at midcervical sites during neck flexion. Myelography is superior in diagnosing compressive lesions at C6-C7 than at more proximal sites. Occasionally the compression is lateral rather than dorsoventral and is not readily apparent on routine myelography.

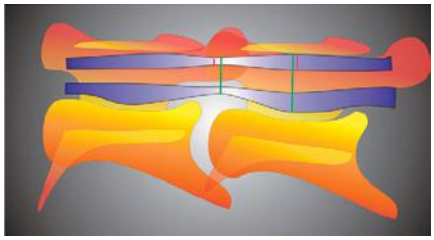

Fig. 14-24 Schematic drawing of cervical myelogram illustrating the dural diameter reduction (green lines) and the dorsal myelographic column reduction (pink lines). (Reproduced with permission from Van Biervliet J. An evidence-based approach to clinical questions in the practice of equine neurology. *Vet Clin Nth Am Equine Pract* 2007;23(2):317-328.)

Myelography has been described in standing, conscious horses, but this technique is not sufficiently well described to allow its recommendation at this time.[18]

Ex situ (postmortem) MRI examination of cervical vertebrae and spinal cord of normal and CSM-affected horses is more accurate than is interpretation of standing lateral radiographs.[17] However, both **CT and MRI** of horses with CSM are limited by the restricted views of the neck of adult horses. This prevents comprehensive examination of the cervical spine.[19,20]

Endoscopy of the epidural and subarachnoid spaces is reported in a horse with confirmed cervical compressive myelopathy.[21,22] The diagnostic or therapeutic value of this procedure is yet to be established.

The **prognosis** for horses with CSM is guarded. Sixty-four percent of affected horses were euthanized, presumably for economic or humane reasons.[9] However, the prognosis depends on the severity of clinical signs and the intended use of the horse. The criteria for euthanasia depend on the danger of the horse to itself (for instance, falling and injuring itself) or its attendants. Horses that are at high risk of self-injury or of injuring their attendants might qualify for humane euthanasia. However, horses with milder signs of disease compatible with their intended use, such as stallions or females with low-grade signs of the disease and reproductive potential, can be treated conservatively and live long lives.

It is imperative to consider the risk to riders or handlers associated with care or competing the horse when deciding on the fate of an affected horse.

The prognosis for horses intended for **athletic use** is less clear. Twenty-one of 70 Thoroughbred racehorses with cervical compressive myelopathy went on to race.[23] The likelihood of a horse racing was inversely related to the severity of its clinical signs.[23]

CLINICAL PATHOLOGY

Hematologic and serum biochemical values are usually within reference ranges in affected horses. CSF from affected horses can have increased protein concentration, but this finding is neither characteristic nor specific for compressive myelopathy. However, other causes of spinal ataxia can cause characteristic changes in the CSF and examination of the fluid might assist in ruling out these diseases.

Measurement of creatine kinase activity in CSF has no diagnostic value in horses.

NECROPSY FINDINGS

Gross examination reveals degeneration of the articular facets in many affected horses.

Impingement of soft tissues, especially the ligamentum flavum and joint structures, or cartilage and osteophytes into the spinal canal may be apparent. The spinal canal may be narrow. It may be indented and soft at the site or sites of compression. Histologically, there is nerve fiber swelling, widespread degeneration of myelin, and astrocytic gliosis. Cranial to the compressive lesion, wallerian degeneration is evident in the dorsal and lateral funiculi, although caudal to the compression these changes are most evident in the ventral and central lateral funiculi. Slight atrophy of cervical muscles is sometimes evident. There is histologic evidence of stretching and tearing of the ligamentum flavum and joint capsule at affected joints, especially C6 or C7.

DIFFERENTIAL DIAGNOSIS

Equine degenerative myelopathy, equine protozoal myeloencephalitis, trauma, equine infectious anemia, cerebrospinal nematodiasis (*Hypoderma* spp., *Setaria* sp., *Halicephalobus deletrix*), equine herpesvirus-1 myelopathy, aortoiliac thrombosis, West Nile encephalomyelitis, congenital vertebral malformation (especially in Arabian foals), discospondylitis, tumors involving the spinal canal (melanoma, lymphoreticular neoplasia, hemangiosarcoma),[5,24] extradural hematoma,[25] vertebral osteomyelitis, fibrocartilaginous embolic, postanesthetic myelopathy,[26] and ryegrass staggers (see Table 14-21).

TREATMENT

Medical treatment of the acute disease consists of rest and administration of antiinflammatory drugs (dexamethasone 0.05–0.25 mg/kg intravenously or intramuscularly every 24 hours; flunixin meglumine 1 mg/kg intravenously every 8–12 hours; phenylbutazone 2.2–4.4 mg/kg orally every 12–24 hours; and/or dimethyl sulfoxide, 1 g/kg as a 10% solution in isotonic saline intravenously every 24 hours for three treatments).

Treatment of arthritis of the facets of mature horses can be achieved by injection of the articular facet joints with corticosteroids (40 mg of methylprednisolone acetate).[27] Injection of the joint is facilitated by ultrasonographic guidance. Injection of the joints with antiinflammatory drugs is assumed to result in reduction in inflammation and soft

Table 14-21 Differential diagnosis of disease causing spinal ataxia in adult horses

Disease	Etiology and epidemiology	Clinical signs and lesions	Treatment and prognosis
Cervical compressive myelopathy (cervical stenotic myelopathy, cervical vertebral instability)	Sporadic; young, rapidly growing males; more common in Thoroughbreds, Standardbreds, and Warmblood horses; syndrome in mature horses caused by arthritis or articular facets.	Symmetric ataxia often of sudden onset; may be associated with trauma; hindlimbs most severely affected; compression of cervical spinal cord demonstrated by myelography; CSF normal	Medical treatment of rest and antiinflammatory drugs; poor prognosis; surgical correction by ventral stabilization
Equine degenerative myelopathy	Young horses (<3 years); familial incidence of increased requirement for vitamin E	Gradual onset symmetric ataxia that stabilizes at about 3 years of age; no radiographic abnormalities in cervical spinal cord; CSF normal	Guarded prognosis; vitamin E 5–20 IU/kg per day in feed may prevent progression; no cure; death uncommon
Equine protozoal myeloencephalitis	*Sarcocystis neurona* or *Neospora hughesi* in spinal cord or brain; Americas only; infectious but not contagious	Any sign of central nervous system dysfunction; usually gradual onset of asymmetric spinal ataxia, focal muscle atrophy or weakness; CSF contains antibody to *S. neurona,* but also found in normal horses	Ponazuril 5–10 mg/kg orally daily for 28 days; older, but effective, treatment is pyrimethamine, 1 mg/kg orally and sulfadiazine, 20 mg/kg orally every 24 hours for 90–120 days; Nitazoxanide 25 mg/kg orally once daily for 2 days followed by 50 mg/kg orally for 26 days; Vaccination not recommended
Equine herpesvirus-1 myeloencephalopathy	EHV-1; infectious and contagious. Sporadic; outbreaks occur often preceded by fever or upper respiratory tract disease	Ascending paralysis with fecal and urinary incontinence, recumbency, normal mentation; CSF xanthochromic and increased protein concentration; lesion is vasculitis and malacia	Valacyclovir for prophylactic therapy at a dose of 30 mg/kg orally every 8 hours for 2 days, then 20 mg/kg every 12 hours for 1–2 weeks Corticosteroids controversial Nursing care; poor prognosis Vaccination potentially effective
West Nile encephalitis	West Nile virus; transmitted by bite of infected mosquito; horse is dead-end host and does not develop sustained viremia; enzootic to Mediterranean littoral and North America; Increased recognition in other areas (Australia, Kunjin); peak disease risk is late summer	Weakness, muscle fasciculations, altered mentation; recumbency	No specific treatment; nursing care; corticosteroids controversial; hyperimmune serum available in some areas; interferon has been used but efficacy uncertain
Trauma	Sudden onset; more common in young horses	Spinal ataxia, varying degrees of weakness and proprioceptive deficits; recumbency Radiographic lesions present occasionally CSF may contain red blood cells	Antiinflammatory drugs; rest
Ryegrass staggers	Intoxication by lolitrems produced by *Acremonium lolii* growing on perennial ryegrass; outbreaks of disease in horses on affected pasture	Ataxia, stiff gait, tremor, hypersensitivity, recumbency; no histologic lesions	Remove source of toxin; rapid recovery without other treatment
Parasite migration	Sporadic. *Strongylus* sp., *Hypoderma* sp., and filaroids (*Setaria* sp.).	Wide variety of clinical signs; progressive ataxia; CSF may contain eosinophils	Ivermectin 0.2 mg/kg orally Antiinflammatory drugs
Congenital anomalies	Sporadic; cause spinal cord compression or lack of neural tissue, e.g., spina bifida	Recumbency, ataxia present at birth	No treatment
Neoplasia	Melanoma, lymphosarcoma, hemangiosarcoma, metastatic neoplasia, multiple myeloma	Variable depending on site; usually extradural tumor although can be secondary to vertebral body involvement and pathologic fracture	No practicable treatment

tissue swelling with consequent reduced compression of the cervical spinal cord. There is no objective prospective assessment of the efficacy of this treatment

A "paced growth" program of slowed growth achieved by nutritional restriction of young horses (foals and weanlings) has been suggested as conservative treatment for immature horses with compressive myelopathy or at high risk of developing the disease.

Surgical fusion of cervical vertebrae is useful in the treatment of mild to moderately affected horses, although because of issues of safety of future riders there are concerns by some authorities about the advisability of this treatment.

CONTROL

Control measures are not usually used, although ensuring an appropriate diet and

growth rate of at-risk animals would be prudent.

EQUINE MOTOR NEURON DISEASE

Equine motor neuron disease is a **neurodegenerative disease** of horses in the United States, Canada, Europe, UK, and South America.[1-3] The disease is associated with low intake, and abnormally low serum concentrations, of vitamin E, possibly exacerbated by excessive intake of copper or iron.[4-6] The disease can be induced by feeding horses a diet with a low concentration of vitamin E, with development of clinical signs of the disease taking at least 18 months and up to 38 months.[5,7]

The disease affects horses of all breeds, with Quarter Horses most commonly affected, and the incidence of the disease increases with age (horses older than 2 years). The disease is associated with stabling and lack of access to pasture, and the risk of the disease increases with decreasing serum vitamin E concentration.

The pathogenesis of the disease is unknown but is suspected to be caused by oxidative injury to neurons subsequent to vitamin E deficiency. However, not all horses that develop the disease have a clear oxidant stress or decrease in antioxidant capacity.[8] The clinical signs are attributable to degeneration of motor neurons in the ventral horns of the spinal cord, with subsequent peripheral nerve degeneration and widespread neurogenic muscle atrophy.

The onset of **clinical signs** is usually gradual, but in a small proportion of affected horses the first sign is an acute onset of profound muscle weakness. Chronically affected horses have weight loss in spite of a normal or increased appetite, pronounced trembling and fasciculation of antigravity muscles, increased recumbency, and a short-strided gait. They often assume a posture with all feet under the body and a low head carriage, and frequently shift weight, which are all signs attributable to muscle weakness. The tail head is elevated in a large proportion of severely affected horses, which is likely a result of atrophy of the sacrocaudalis dorsalis medialis muscle. Profound flaccidity (weakness) of the tongue with lesions in the hypoglossal nuclei is reported and must be differentiated from botulism.[9] Retinal examination often reveals accumulation of lipofuscin-like pigment in the tapetal fundus.

EMG, under either general or regional anesthesia, is a useful diagnostic aid.[8] Characteristic findings include spontaneous fibrillation potentials and trains of positive sharp waves.

Lesions of redistribution of mitochondrial enzyme stain and anguloid atrophy of myofibers in sacrocaudalis dorsalis medialis muscle of adult horses with vitamin E–responsive muscle atrophy might represent a variant, or early stage, of equine motor neuron disease.[10]

The prognosis is poor for horses with advanced disease and most of these horses do not return to normal function and are destroyed, although the disease stabilizes in some cases that can then live for a number of years after diagnosis. Approximately 40% of cases will have stable clinical signs (no improvement) and 20% will continue to deteriorate after diagnosis and initiation of treatment. Early recognition and correction of diet with or without supplementation with vitamin E can result in recovery.

There is often a mild increase in serum creatine kinase activity. Horses with equine motor neuron disease have abnormal oral and intravenous glucose tolerance tests characterized by peak glucose concentrations that are lower than expected. The lower peak plasma glucose concentration is attributable to a 3× greater rate of glucose metabolism (removal from blood) in affected horses compared with normal horses. There is also evidence that horses with equine motor neuron disease are more sensitive to insulin than are normal horses.

Affected horses often have **serum vitamin E concentrations** that are below the reference range (<1.0–2.0 µg/dL, <1.0–2.0 µmol/L). Horses with equine motor neuron disease have higher spinal cord copper concentrations than do normal horses, but the diagnostic or clinical significance of this observation is unclear.

Examination of CSF is not useful in arriving at a diagnosis.

Examination of muscle from horses with equine motor neuron disease reveals a coordinated shift from characteristics of slow muscle to those of fast twitch muscle including contractile and metabolic functions of muscle. There is a lower percentage of myosin heavy chain type 1 fibers, higher percentages of hybrid IIAX and IIX fibers, atrophy of all fibers, and reduced oxidative capacity, increased glycolytic capacity, and diminished intramuscular glycogen concentrations, among other changes, in affected horses compared with normal horses.

The disease must be differentiated from botulism and other causes of weakness in adult horses. **Diagnostic confirmation** can be achieved by examination of a biopsy of the sacrocaudalis dorsalis medialis muscle or the spinal accessory nerve. The sacrocaudalis dorsalis medialis muscle is preferred because that muscle is predominantly composed of type 1 fibers and is severely affected by the disease. Examination of biopsy of this muscle has a sensitivity of approximately 90%.

Necropsy examination reveals moderate to severe diffuse muscle atrophy. Predominant histologic findings at necropsy examination include degeneration of neurons in ventral horns at all levels of the spinal cord. Muscle atrophy is evident because angular fibers, with predominantly type 1 fibers, or a combination of type 1 and type 2 fibers, are affected. There is accumulation of lipofuscin in the fundus and in capillary endothelium of the nervous tissue.

Treatment consists of administration of vitamin E. There are eight isoforms of vitamin E, and RRR-α-tocopherol, the naturally occurring form, is the most potent antioxidant. Synthetic vitamin E contains all isomers, whereas "natural" vitamin contains only one, the RRR isomer. Administration of lyophilized, water-soluble D-α-tocopherol (RRR-α-tocopherol) is apparently superior to administration of the DL-α-tocopherol acetate in increasing concentrations of vitamin E in blood of horses.[4] The usual dose is 4 IU of D-α-tocopherol (RRR-α-tocopherol) per kilogram BW orally once daily or 5000 to 7000 IU of α-tocopherol per 450-kg horse per day.[4] Supplementation results in improvement in 40% of affected horses within 6 weeks, with some appearing normal at 12 weeks.[4]

Control measures should ensure that horses have adequate access to pasture or are supplemented with good quality forage and/or vitamin E. Horses without access to green pasture should be supplemented with 1 U of vitamin E per kilogram BW per day.[4]

Diseases Primarily Affecting the Peripheral Nervous System

The **peripheral nervous system** consists of **cranial** and **spinal nerve** components. As such, the peripheral nervous system includes the dorsal and ventral nerve roots, spinal ganglia, spinal and specific peripheral nerves, CNs and their sensory ganglia, and the peripheral components of the autonomic nervous system.

ETIOLOGY

There are several different causes of peripheral nervous system disease.

Inflammatory

Polyneuritis equi, also known as **neuritis of the cauda equina** or **cauda equina syndrome**, is a rare and slowly progressive demyelinating granulomatous disease affecting peripheral nerves in the horse. Polyneuritis equi is characterized by signs of lower motor neuron lesions, primarily involving the perineal region but also affecting other peripheral nerves, especially CNs V and VI. CNs VIII, IX, X, and XII also may be involved. Clinical signs of perineal region paresis/paralysis predominate and manifest as varying degrees of hypotonia; hypalgesia; and hyporeflexia of the tail, anus, and perineal region. Degrees of urinary bladder paresis and rectal dilatation are also present. Differential diagnoses include sacral or coccygeal trauma, equine herpes myeloencephalopathy, equine protozoal myeloencephalitis, rabies, and equine motor neuron disease.

Cranial neuritis with guttural pouch mycosis and empyema in the horse may cause abnormalities of swallowing, laryngeal hemiplegia, and Horner's syndrome if the glossopharyngeal and vagal nerves are involved in the inflammatory process of the guttural pouch.

Acquired **myasthenia gravis** has been diagnosed in a 7-month-old Hereford heifer with a 5-day history of recumbency caused by symmetric generalized neuromuscular weakness.[1] The heifer stood with no assistance within 1 minute of edrophonium chloride (0.1 mg/kg intravenously) and was able to stand for 24 hours. Three additional episodes of prolonged recumbency responded to edrophonium, with an increasing period between episodes. Additional treatment was dexamethasone intramuscularly for 5 days. Acquired myasthenia gravis was diagnosed and attributed to an autoimmune disease directed against acetylcholine receptors at the neuromuscular junction. Congenital myasthenia gravis, caused by a homozygous mutation in the acetylcholine receptor gene, has been diagnosed in Braham calves in South Africa.[2]

Degenerative

Equine laryngeal hemiplegia, often called roaring, is a common disease of the horse in which there is paralysis of the left cricoarytenoid dorsalis muscle resulting in an inability to abduct the arytenoid cartilage and vocal fold, which causes an obstruction in the airway during inspiration. Endoscopic examination reveals asymmetry of the glottis. On exercise, inspiratory stridor develops as the airflow vibrates a slack and adducted vocal fold. The abnormality is caused by idiopathic distal degeneration of axons in the left recurrent laryngeal nerve, with the disease characterized as a bilateral mononeuropathy.[3] The left recurrent laryngeal nerve is more severely affected than the right because it is longer and is the longest nerve in the horse (see Chapter 12 for more details).

Diaphragmatic paralysis has been identified in 11 alpacas aged 2 to 12 months. Respiratory dysfunction was present, manifested as tachypnea, pronounced inspiratory effort, and arterial hypercapnia and hypoxemia.[4] The paralysis appeared bilateral in all seven alpacas imaged using fluoroscopy. Histologic examination revealed phrenic nerve degeneration in all six alpacas necropsied, with long nerves also demonstrating degeneration in two alpacas. The etiology was not identified.[4]

Traumatic

Injection injuries to peripheral nerves may result from needle puncture, the drug deposited, pressure from an abscess or hematoma, or fibrous tissue around the nerve. The sciatic nerve has been most commonly affected in cattle because historically most intramuscular injections were given deep in the hamstring muscles. Young calves were particularly susceptible because of their small muscle masses. Current recommendations in cattle are that intramuscular injections should be administered cranial to the shoulder.

Femoral nerve paralysis in calves occurs in large calves born to heifers with dystocia. The injury occurs when calves in anterior presentation fail to enter the birth canal because their stifle joints become engaged at the brim of the pelvis. Traction used to deliver these calves causes hyperextension of the femur and stretching of the quadriceps muscle and its neural and vascular supplies. In most cases the right femoral nerve is affected. Such calves are unable to bear weight on the affected leg within days after birth, the quadriceps muscle is atrophied, and the patella can be luxated easily. The patellar reflex is absent or markedly reduced in the affected limb because this reflex requires an intact femoral nerve and functional quadriceps muscle. Varying degrees of rear limb paresis result, accompanied by varying degrees of hindlimb gait abnormality. Skin analgesia maybe present over the proximal lateral to cranial to medial aspect of the tibia. At rest, the affected leg is slightly flexed and the hip on the affected side is held slightly lower. During walking, the animal has difficulty in advancing the limb normally because the limb collapses when weight bearing. In severe cases of muscle atrophy, the patella is easily luxated both medially and laterally. Injury to the femoral nerve is relatively easy to clinically identify, and there is usually no need to perform EMG studies of atrophied quadriceps muscle to document denervation.

Calving paralysis is common in heifers that have experienced a difficult calving. Affected animals are unable to stand without assistance; if they do stand, the hindlimbs are weak and there is marked abduction and inability to adduct. It has always been erroneously thought that traumatic injury of the obturator nerves during passage of the calf in the pelvic cavity was the cause of the paresis; however, detailed pathologic and experimental studies have demonstrated that most calving paresis/paralysis is caused by damage to the sciatic nerve. Experimental transection of the obturator nerves does not result in paresis. The term **obturator nerve paralysis** should only be used for postparturient cattle with an inability to adduct one or both hindlimbs, and calving paralysis in the preferred descriptive term for hindlimb paresis/paralysis occurring in the immediate postparturient period.

Damage to the sciatic nerve results in rear limb weakness and knuckling of the fetlocks; the latter clinical sign is an important means for differentiating sciatic nerve damage from obturator nerve damage (Fig. 14-25). The patellar reflex in ruminants with sciatic nerve damage is normal or increased, because the reflex contraction of the quadriceps muscle group by the femoral nerve is unopposed by the muscles of the hindlimb innervated by the sciatic nerve.

The peroneal nerve is most frequently damaged by local trauma to the lateral stifle where the peroneal nerve runs in a superficial location lateral to the head of the fibular bone. Damage to the peroneal nerve leads to knuckling over of the fetlock joint from damage to the extensor muscles of the distal limb, resulting in the dorsal aspect of the hoof resting on the ground when the animal is standing. Full weight can be borne on the

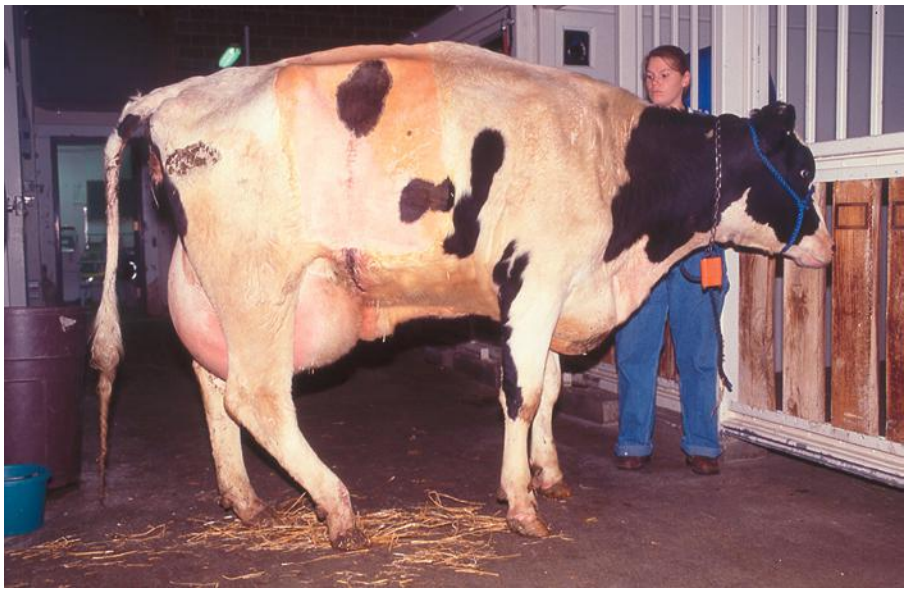

Fig. 14-25 Three-year-old Holstein Friesian cow with mild paresis of the right sciatic nerve. The hock is dropped relative to the normal unaffected left leg, and the fetlock has the characteristic knuckling. The cow has had a left displaced abomasum surgically corrected by a right flank incision and is being treated for concurrent mastitis.

affected limb when the digit is placed in its normal position, but immediately on walking the digit is dragged. There is a loss of skin sensation on the anterior aspect of the metatarsus and digit.

Damage to the tibial nerve causes mild hyperflexion of the hock and a forward knuckling of the fetlock joint. Tibial nerve damage is very rare, and most cases described as tibial nerve damage are actually sciatic nerve damage.

The radial nerve is most susceptible to traumatic damage because it courses distally and laterally over the later condyle of the humerus. Radial nerve paresis is most common when heavy adult cattle are placed in lateral recumbency, such as corrective foot trimming in bulls. Care must be taken in these animals to pad the area around the elbow and to ensure that the time spent in lateral recumbency is minimized. Clinical signs of radial nerve paresis include inability to advance the front limb with the ability to bear weight when the limb is placed directly under the animal in the normal position (Fig. 14-26). In advanced cases, the cranial aspect of the fetlock is dragged along the ground and the area needs to be protected from severe abrasion injury using a splint or cast.

Brachial plexus injury, including avulsion, is rare in large animals, because the muscle mass is usually sufficient to prevent overextension of the front limb. It is a rare outcome of correction of dystocia in goats, particularly when relatively excessive traction is applied to one front limb during delivery. Clinical signs of brachial plexus avulsion include a complete inability to bear weight

Fig. 14-26 Mild radial nerve paresis in a Holstein Friesian bull. Swelling is present over the lateral aspect of the elbow. Paresis was present immediately after taking the animal off a foot table for corrective foot trimming.

on the limb and a dropped elbow relative to the unaffected limb (Fig. 14-27).

Metabolic and Nutritional

PA deficiency may occur in pigs fed diets based solely on corn (maize). Affected animals develop a goose-stepping gait caused by degenerative changes in the primary sensory neurons of the peripheral nerves.

Toxic

Heavy metal poisoning including **lead and mercury poisoning in horses** has been

Fig. 14-27 One-week-old kid with brachial plexus avulsion of the right forelimb. The right limb "appears" longer than the unaffected left limb and the right elbow appears dropped. The right front leg cannot support weight and is not advanced in a normal manner during walking. The right leg received excessive traction during correction of a dystocia.

associated with clinical signs of degeneration of peripheral CNs, but these are not well documented.

Tumors

A multicentric schwannoma causing chronic ruminal tympany and forelimb paresis has been recorded in an aged cow. Neoplastic masses were present throughout the body, and both right and left brachial plexuses were involved. The peripheral nerves of each brachial plexus were enlarged. Large tumor masses were present on the serosal surfaces of the esophagus, pericardial sac and epicardium, and within the myocardium, endocardium, and the ventral branches of the first four thoracic spinal nerves. A large mass was present in the anterior mediastinum near the thoracic inlet.

Autonomic Nervous System

Equine grass sickness (equine dysautonomia, grass sickness, mal Seco) in the horse is a polyneuropathy involving both the peripheral nervous system (autonomic and enteric nervous systems) as well as the CNS.[5-7] Equine grass sickness occurs primarily in Scotland, although cases have been reported elsewhere in Europe, and in Patagonia and the Falkland Islands.[8] The disorder is characterized by a peracute to chronic alimentary tract disease of horses on pasture (hence the name). Gastrointestinal stasis is partial or complete. Peracute cases are in shock and in a state of collapse with gastric refluxing. Acute, subacute, and chronic cases also occur. Degenerative changes occur in the autonomic ganglia (especially the celiac–mesenteric, and stellate), thoracic sympathetic chain, ciliary, cranial and caudal cervical, the craniospinal sensory ganglia, and selected nuclei in the CNS. EMG reveals the presence of a neuropathy of skeletal muscles.[8] The etiology is unknown but neurotoxin involvement is suspected, possibly *Clostridium botulinum* type C/D.

TETANUS

ETIOLOGY

Tetanus is caused by *C. tetani,* a gram-positive, spore-forming obligate anaerobe bacillus. It is a ubiquitous organism and a commensal of the gastrointestinal tract of domestic animals and humans. The organism forms highly resistant spores that can persist in soil for many years. The spores survive many standard disinfection procedures, including steam heat at 100°C (212°F) for 20 minutes but can be destroyed by heating at 115°C (239°F) for 20 minutes. After a period of anaerobic incubation spores germinate to their vegetative form, which starts replicating and producing a complex of exotoxins causing the clinic signs characteristic for this condition. The toxins produced are **tetanolysin, tetanospasmin,** and **neurotoxin** or nonspasmolytic toxin.

SYNOPSIS

Etiology Muscle spasm from action of the exotoxin tetanospasmin produced by the vegetative stage of *Clostridium tetani.*

Epidemiology Marked difference in species susceptibility with horses being most and cattle being least susceptible. Usually a history of a wound or other tissue trauma. Occurs as isolated cases but also as outbreaks in young ruminants following castration and docking.

Clinical findings Generalized muscular rigidity and spasms, hyperesthesia, prolapse of third eyelid, trismus, ears pulled caudally, bloat in ruminants, convulsions, respiratory arrest, and death. High case fatality.

Necropsy findings None. May demonstrate the organism in necrotic tissue in some cases.

Diagnostic confirmation Diagnosis is based on characteristic clinical signs and wound history. No definitive antemortem test or pathognomonic postmortem lesion. A bioassay consisting of injecting mice with infectious material to induce characteristic clinical signs is used.

Treatment Objectives are to prevent further production of exotoxin, neutralize residual toxin, control muscle spasms until the toxin is eliminated or destroyed, maintain hydration and nutrition, provide supportive treatment.

Control Regular prophylactic vaccination with tetanus toxoid of susceptible animals, vaccination and administration of tetanus antitoxin to unvaccinated animals with fresh wounds, antibiotic therapy in animals with wounds that are contaminated or at risk to be contaminated.

EPIDEMIOLOGY

Occurrence

Tetanus occurs in all parts of the world and is most common in closely settled areas under intensive cultivation. It occurs in all farm animals, mainly as individual, sporadic cases, although outbreaks are occasionally observed in young cattle, young pigs, and lambs following wound management procedures.[1]

Case–Fatality Rate

In young ruminants the case–fatality rate is over 80%, but the recovery rate is high in adult cattle. In horses it varies widely between areas. In some areas almost all animals die acutely, and in others the mortality rate is consistently about 50%.[2,3]

Source of Infection

C. tetani organisms are commonly present in the feces of animals, especially horses, and in the soil contaminated by these feces. Surveys in different areas of the world show it is present in 30% to 42% of soil samples. The survival period of the organism in soil varies widely from soil to soil.

Transmission

The **portal of entry** is usually through deep puncture wounds, but the spores may lie dormant in the tissues for some time and produce clinical illness only when tissue conditions favor their proliferation. For this reason, the portal of entry is often difficult to identify. Puncture wounds of the hooves are common sites of entry in horses. Introduction to the genital tract at the time of parturition is the usual portal of entry in cattle. A high incidence of tetanus may occur in young pigs following castration and in lambs following castration, shearing, docking, vaccinations, or injections of pharmaceuticals, especially anthelmintics. Docking by the use of elastic band ligatures is reputed to be especially hazardous. **Neonatal tetanus** occurs when there is infection in the umbilical cord associated with unsanitary conditions at parturition. Cases of tetanus in ruminants after thermic dehorning and ear-tagging have been reported.[1]

Outbreaks of **"idiopathic tetanus"** occur occasionally in young cattle without a wound being apparent, usually in association with the grazing of rough, fibrous feed, and it is probable that toxin is produced in wounds in the mouth or gastrointestinal tract or is ingested preformed in the feed. Proliferation in the rumen may also result in toxin production.

Animal Risk Factors

The neurotoxin of *C. tetani* is exceedingly potent, but there is considerable variation in susceptibility between animal species, and horses are the most susceptible and cattle the least susceptible. The variation in prevalence of the disease in the different species is partly caused by this variation in susceptibility but is also because exposure and wound management practices are more likely to occur in some species than in others.

Importance

Tetanus is important because of its high case fatality and the very long convalescence in the survivors. In regions of the world where horses, donkeys, and mules still play an important role in the rural economy and where vaccination is uncommon, the economic impact of tetanus can be considerable.[2]

PATHOGENESIS

The tetanus spores remain **localized** at their site of introduction and do not invade surrounding tissues. Spores germinate to their vegetative form to proliferate and produce **tetanolysin, tetanospasmin,** and **neurotoxin** only if certain environmental conditions are attained, particularly a lowering of the local tissue oxygen tension. Toxin production may occur immediately after introduction if the accompanying trauma has been sufficiently severe, or if foreign material has also been introduced to the wound, or may be delayed for several months until subsequent trauma to the site causes tissue damage. The original injury may be inapparent by then. Of the three mentioned exotoxins, **tetanospasmin is the most relevant** for the pathophysiology of the condition. Although **tetanolysin** was found to promote local tissue necrosis, its role in the pathogenesis of tetanus remains doubtful. The role of the more recently identified neurotoxin, or nonspasmogenic toxin, which is a peripherally active for the pathophysiology of tetanus, is currently unknown.

Tetanospasmin diffuses to the systemic circulation, is bound to motor end plates, and travels up peripheral nerve trunks via retrograde intraaxonal transport to the CNS. The exact mechanisms by which the toxin exerts its effects on nervous tissue are not known, but it blocks the release of neurotransmitters such as GABA and glycine, which are essential for the synaptic inhibition of gamma motor neurons in the spinal cord. There it leads to an unmodulated spread of neural impulses produced

by normally innocuous stimuli, causing exaggerated responses and a state of constant muscular spasticity. No structural lesions are produced. Death occurs by asphyxiation caused by fixation of the muscles of respiration.

CLINICAL FINDINGS

The **incubation period** varies between 3 days and 4 weeks, with occasional cases occurring as long as several months after the infection is introduced. In sheep and lambs cases appear 3 to 10 days after shearing, docking, or castration.

Clinical findings are similar in all animal species. Initially, there is an increase in **muscle stiffness**, accompanied by muscle tremor. There is **trismus** with restriction of jaw movements; **prolapse of the third eyelid;** stiffness of the hindlimbs causing an unsteady, straddling gait; and the tail is held out stiffly, especially when backing or turning. Retraction of the eye and prolapse of the third eyelid (a rapid movement of the third eyelid across the cornea followed by a slow retraction) is one of the earliest and consistent signs (with the exception of sheep) and can be exaggerated by sharp lifting of the muzzle or tapping the face below the eye. Additional signs include an anxious and alert expression contributed to by an erect carriage of the ears, retraction of the eyelids and dilation of the nostrils, and hyperesthesia with exaggerated responses to normal stimuli (Fig. 14-28).

The animal may continue to eat and drink in the early stages but mastication is soon prevented by tetany of the masseter muscles and saliva may drool from the mouth. If food or water is taken, attempts at swallowing are followed by regurgitation from the nose. Constipation is usual and the urine is retained, partly as a result of the inability to assume the normal position for urination. The rectal temperature and pulse rate are within the normal range in the early stages but may rise later when muscular tone and activity are further increased. In cattle, particularly young animals, bloat is an early sign but is not usually severe and is accompanied by strong, frequent rumen contractions.

As the disease progresses, muscular tetany increases and the animal adopts a **sawhorse posture** (Figs. 14-29 and 14-30). Uneven muscular contractions may cause the development of a curve in the spine and deviation of the tail to one side. There is great difficulty in walking and the animal is inclined to fall, especially when startled. Falling occurs with the limbs still in a state of **tetany** and the animal can cause itself severe injury. Once down it is almost impossible to get a large animal to its feet again. Tetanic convulsions begin in which the tetany is still further exaggerated. Opisthotonus is marked, the hindlimbs are stuck out stiffly behind and the forelegs forward. Sweating may be profuse and the temperature rises, often to 42°C (107°F). The convulsions are at first only stimulated by sound or touch but soon occur spontaneously. In fatal cases there is often a transient period of improvement for several hours before a final, severe tetanic spasm during which respiration is arrested.

Fig. 14-28 Polled Hereford cow exhibiting early signs of tetanus with healthy calf. The tail is held slightly away from the perineum, the ears are back, the eyes have a surprised expressed with slight prolapse of the nictitating membrane, and saliva is drooling from the mouth. The cow calved 7 days previously and had a retained placenta and metritis.

Fig. 14-29 Suffolk lamb with tetanus after castration using a band. The lamb is exhibiting a sawhorse stance caused by generalized muscle rigidity and drooling of saliva.

The **course of the disease** and the **prognosis** vary both between and within species. The **duration** of a fatal illness in horses and cattle is usually 5 to 10 days, but sheep usually die on about the third or fourth day. A long incubation period is usually associated with a mild syndrome, a long course, and a favorable prognosis. **Mild cases** that recover usually do so slowly, with the stiffness disappearing gradually over a period of weeks or even months. The prognosis is poor when signs rapidly progress. Animals vaccinated in the past year have a better prognosis, as do horses that have received parenteral penicillin and tetanus antitoxin and in which the wound was aggressively cleaned when fresh.

CLINICAL PATHOLOGY

There are no specific abnormalities in blood or CSF and no antemortem test confirming

Fig. 14-30 Corriedale lamb with tetanus after tail docking. Note the ear and eyelid retraction and generalized stiffness.

the diagnosis. Blood levels of tetanus toxin are usually too low to be detected. Gram-stain of wound aspirates is considered of limited value because sporulated as well as vegetative forms of *C. tetani* resemble other anaerobic bacteria. Culturing the pathogen is difficult because of the low number of organisms normally present and the strict anaerobic conditions required for culture. Culture in combination with PCR has been used for identification of *C. tetani.*[1] A bioassay consisting of injecting infectious material into the tail base of mice and observing for onset of characteristic clinical signs is possible.[2]

NECROPSY FINDINGS

There are no gross or histologic findings by which a diagnosis can be confirmed, although a search should be made for the site of infection. Culture of the organism is difficult but should be attempted. If minimal autolysis has occurred by the time of necropsy, the identification of large gram-positive rods with terminal spores ("tennis-racket morphology") in smears prepared from the wound site or spleen is supportive of a diagnosis of tetanus.

Samples for Confirmation of Diagnosis

- Bacteriology: air-dried impression smears from spleen, wound site (cyto, Gram stain), culture swab from wound site in anaerobic transport media; spleen in sterile, leak-proof container (anaerobic CULT, bioassay).

DIFFERENTIAL DIAGNOSIS

Fully developed tetanus is so distinctive clinically that it is seldom confused with other diseases. The muscular spasms, the prolapse of the third eyelid, and a recent history of accidental injury or surgery are characteristic findings. However, in its early stages or mild forms, tetanus may be confused with other diseases.

All species
- Strychnine poisoning
- Meningitis

Horses
- Hypocalcemic tetany (eclampsia)
- Acute laminitis
- Hyperkalemic periodic paralysis
- Myositis, particularly after injection in the cervical region.

Ruminants
- Hypomagnesemia (cows, sheep and calves)
- White muscle disease
- Polioencephalomalacia
- Enterotoxemia.

TREATMENT

These are the main principles in the treatment of tetanus:
- Eliminate the causative bacteria
- Neutralize residual toxin
- Control muscle spasms until the toxin is eliminated or destroyed
- Maintain hydration and nutrition
- Provide supportive treatment

There are no structural changes in the nervous system, and the management of cases of tetanus depends largely on keeping the animal alive through the critical stages.

Elimination of the organism is usually attempted by the parenteral administration of penicillin in large doses (44,000 IU/kg), preferably by intravenous administration. Other antimicrobials that have been proposed include oxytetracycline (15 mg/kg), macrolides, and metronidazole. If the infection site is found, the wound should be aggressively cleaned and debrided but only after antitoxin has been administered, because debridement, irrigation with hydrogen peroxide, and the local application of penicillin may facilitate the absorption of the toxin.

The objective of administering **tetanus antitoxin** is to neutralize circulating toxin outside the CNS. The use of tetanus antitoxin is most appropriate in wounded animals that are susceptible to but unvaccinated against tetanus or with uncertain vaccination history. Because binding of tetanospasmin to neural cells is irreversible and because the tetanus antitoxin is unable to penetrate the blood-brain barrier, administration of antitoxin is of little value once signs have appeared. After the experimental administration of toxin, antitoxin is of limited value at 10 hours and ineffective by 48 hours. The recommended doses vary widely and range from 10,000 to over 300,000 IU per treatment, given intravenously, intramuscularly, or subcutaneously once or repeatedly, but reported treatment outcomes are inconsistent. Local injection of some of the antitoxin around the wound has also been proposed. There have been a number of attempts to justify the treatment of early cases of equine tetanus by intrathecal injection of antitoxin, but there is limited evidence of therapeutic value and the procedure carries risk.

The use of **tetanus toxoid** has also been recommended for patients with tetanus, but an antibody response may take 2 to 4 weeks and a booster vaccination is required in previously unvaccinated animals. The effectiveness of this treatment in previously unvaccinated animals is therefore doubtful. When combining tetanus toxoid and antitoxin, both compounds should be administered on different sites using different syringes.

Relaxation of the muscle tetany can be attempted with various drugs. Chlorpromazine (0.4–0.8 mg/kg BW intravenously, or 1.0 mg/kg BW intramuscularly, three or four times daily) and acepromazine (0.05 mg/kg BW three to four times daily) administered until severe signs subside, are widely used in horses. A combination of diazepam (0.1–0.4 mg/kg) and xylazine (0.5–1.0 mg/kg intravenously or intramuscularly) may be effective in horses refractory to phenothiazine tranquilizers.

Hydration can be maintained by intravenous or stomach-tube feeding during the critical stages when the animal cannot eat or drink. The use of an indwelling tube should be considered because of the disturbance caused each time the stomach tube is passed. Feed and water containers should be elevated, and the feed should be soft and moist.

Additional supportive treatment includes slinging of horses during the recovery period, when hyperesthesia is diminishing. Affected animals should be kept as quiet as possible and provided with dark, well-bedded quarters with nonslip flooring and plenty of room to avoid injury if convulsions occur. Administration of enemas and catheterization may relieve the animal's discomfort. This level of nursing, plus penicillin, ataractic drugs, and antitoxin for an average of 14 days, can deliver something like a 50% recovery by an average of 27 days, but the cost is high. A rumenostomy may be required in ruminant patients with recurrent bloat.

Horses that fall frequently sustain bone fractures and may need to be destroyed.

TREATMENT AND CONTROL

Treatment

Penicillin G (30,000 IU/kg IM or IV every 12–24 hours) (R-1)

Procaine penicillin (44,000 IU/kg IM every 12–24 hours) (R-1)

Oxytetracycline (15 mg/kg IV every 24 hours) (R-2)

Tetanus antitoxin (10,000–50, 000 IU per dose IM or IV once or repeatedly) (R-2)

Tetanus antitoxin (30,000–50,000 IU per dose intrathecal) (R-3)

Sedation horses

Chlorpromazine (0.4–0.8 mg/kg IV or IM every 6–8 hours) (R-1)

Acepromazine (0.05–0.1 mg/kg IV or IM every 6–8 hours) (R-1)

Diazepam (0.01–0.4 mg/kg IV or IM) (R-1)

Xylazine (0.5–1 mg/kg IV or IM) (R-1)

Sedation cattle

Diazepam (0.5–1.5 mg/kg IV or IM)

Xylazine (0.05–0.15 mg/kg IV or 0.1–0.3 mg/kg IM)

Sedation sheep

Acepromazine (0.05–0.1 mg/kg IV or IM every 6–8 hours) (R-1)

Diazepam (0.2–0.5 mg/kg IV or IM (every 6–8 hours) (R-1)

Control

Regular vaccination if tetanus toxoid (R-1)

Tetanus antitoxin (1500 IU per dose IM in unvaccinated animals with fresh wounds) (R-1)

IM, intramuscularly, IV, intravenously.

CONTROL

Many cases of tetanus could be avoided by proper skin and instrument disinfection at castrating, docking, and shearing time. These operations should be performed in clean surroundings; in the case of lambs docked in the field, temporary pens are preferred over permanent yards for catching and penning.

Passive Immunity

Short-term prophylaxis can be achieved by the injection of 1500 IU of tetanus antitoxin. The immunity is transient, persisting for only 10 to 14 days.

Tetanus Antitoxin

Tetanus antitoxin should be given to any horse with a penetrating wound or deep laceration, and the wound should also be cleaned aggressively. Tetanus toxoid can be administered at the same time as tetanus antitoxin, provided they are injected at different sites and using different syringes. Animals that suffer injury are usually given an injection of antitoxin and one of toxoid to ensure complete protection.

Tetanus antitoxin is often routinely given to **mares** following foaling and to newborn foals. In some areas the risk for tetanus in young foals is high and repeated doses of antitoxin at weekly intervals may be required for protection.

On farms where the incidence of tetanus in **lambs** is high, antitoxin is usually given at the time of docking or castration; 200 IU has been shown to be effective. The risk for tetanus in calves is lower than in lambs and tetanus antitoxin is not commonly given at the time of castration.

There is a risk for **serum hepatitis** in horses that have been given tetanus antitoxin and, while this risk is small, a policy of routine active immunization of the mare to provide the mare with active immunity and the foal with passive colostral immunity is preferred to one that relies on antitoxin. Provided foals get an adequate supply of colostrum they are protected during the first 10 weeks of life by active vaccination of the mare during the last weeks of pregnancy. Prevention of tetanus in newborn lambs is also best effected by vaccination of the ewe in late pregnancy.

Active Immunity

Available vaccines are formalin-inactivated adjuvanted toxoids; they induce long-lasting immunity. Primary vaccination requires two doses 3 to 6 weeks apart. Protective titers are obtained within 14 days of the second injection and last for at least a year and up to 5 years.

Traditionally **foals** have received primary vaccination at 3 to 4 months of age; however, there is evidence that maternal antibodies acquired by foals born to mares vaccinated shortly before parturition significantly inhibit the antibody response of the foal to primary vaccination until it is 6 months of age and that primary vaccination should be delayed until that age.

Although immunity lasts longer than 1 year, it is common to revaccinate horses yearly with a single booster injection. Pregnant mares should receive a booster injection 4 to 6 weeks before foaling to provide adequate colostral immunity to the foal.

Ewes are immunized with a similar schedule except that the primary doses are usually given at a managementally convenient time when the flock is yarded. A prelambing booster vaccination is given yearly. Commonly, commercial vaccines for sheep also contain antigens for other clostridial diseases for which sheep are at high risk.

Vaccination of **cattle** is usually not considered unless an outbreak of the disease has occurred in the immediate past and further cases may be anticipated.

BOTULISM

SYNOPSIS

Etiology Neurotoxin produced by *Clostridium botulinum* during vegetative growth. *C. botulinum* types B, C, and D and, on rare instances, type A are associated with disease in animals but the type prevalence varies geographically.

Epidemiology Ingestion of preformed toxin in which feed preparation or storage allows multiplication of the organism in the feed with toxin production. Contamination of feed with carrion containing toxin. Consumption of carrion on pasture by phosphorus-deficient animals. Risk factors often result in multiple cases. Toxicoinfections with toxin production from organisms in the intestine or wounds are more uncommon.

Clinical findings Early muscle tremor, progressive symmetric weakness, and motor paralysis leading to recumbency. Mydriasis, ptosis, weak tongue retraction; sensation and consciousness retained until death.

Necropsy findings None specific.

Diagnostic confirmation Demonstration of toxin in intestinal contents, serum, or feed. Demonstration of organisms in feed, intestinal contents, or wounds.

Treatment Type-specific antiserum and supportive treatment.

Control Avoidance of exposure by feed management. Vaccination.

ETIOLOGY

The causative organism *C. botulinum*, a spore-forming obligate anaerobe, produces neurotoxins during vegetative growth. Spores can survive in the environment for over 30 years. Under favorable conditions of warmth and moisture the spores germinate and vegetative cells multiply rapidly, elaborating a stable and highly lethal neurotoxin (BoTN) which, when ingested, or absorbed from tissues, causes the disease. The toxin is also capable of surviving for long periods, particularly in bones. Seven antigenically distinct **toxin types** (A-G), some with subtypes, have been identified. Farm animal disease is produced primarily by types B, C, D, and occasionally type A. Type A, B, E, and F toxins are generally related to human botulism.[1] Botulinum neurotoxin forming *C. botulinum* species are divided into groups I to IV depending on their physiologic properties.[1]

- **Group I**: proteolytic *C. botulinum* type A, B and F. These types degrade protein such as milk, serum, meat, and chicken protein
- **Group II**: nonproteolytic *C. botulinum*, includes nonproteolytic type B and F and all type E
- **Group III:** *C. botulinum* type C and D
- **Group IV:** *C. botulinum* type G.

The **geographic distribution** of these types varies considerably. In a study in the United States, type A was found in neutral or alkaline soils in the west, whereas types B

and E were in damp or wet soil all over, except that B was not found in the south. Type C was found in acid soils in the Gulf coast, and type D in alkaline soils in the west. Microorganisms capable of inhibiting *C. botulinum* were present, with or without the clostridia, in many soils. Type B is also common in soils in the UK and in Europe. Types C and D are more common in warm climates.

The organism is present in the **alimentary tract** of animals that have recently ingested contaminated material and may be introduced into new areas in this way, or by birds and blowflies. In healthy animals with normal intestinal fauna and motility *C. botulinum* does not multiply in the gastrointestinal tract

EPIDEMIOLOGY

Occurrence

Botulism has **no geographic limitations**, with isolated cases and sporadic outbreaks occurring in most countries. The source of exposure to toxin and the risk for disease differ between regions because of differences in food storage, feeding, and management practices. **Outbreaks** associated with ingestion of toxin in conserved feeds are more common in the northern states of the United States and in Europe, whereas outbreaks in animals on pasture are reported primarily from South Africa, Australia, and the Gulf coast area of the United States. The disease usually occurs in a number of animals at one time and has a high case–fatality rate.

Source of Infection

Most incidents of botulism are associated with the ingestion of preformed toxin (**forage botulism**). Toxin in feeds may result from the primary growth of *C. botulinum* in the feed or from the contamination of the feed with toxin-containing carrion (**carrion-associated botulism**). Less common sources are growth with toxin production in wounds (**wound botulism**) or growth and toxin production in the alimentary tract (**toxicoinfectious botulism**).

Forage Botulism

Forage botulism occurs when pH, moisture, and anaerobic conditions in the feedstuff allow the vegetative growth of *C. botulinum* and the production of toxin. This can occur in a number of spoiled stored forages. Cereal silages carry a risk in the United States. Silage and hay may spoil to a stage suitable for the growth of *C. botulinum*. This is most likely if the forage is very succulent or is wet by rain when it is made.

Big bale silage is a particular risk. The type of forage ensiled in big bales often has insufficient water-soluble carbohydrate for adequate lactic acid fermentation to achieve a stable low pH, and the higher dry matter content can also lead to a higher pH. Clostridial multiplication is inhibited below pH 4.5. Most non–carrion-associated botulism is caused by type B strains, and horses appear to be especially susceptible.

Proliferation of the organism can occur in **decaying vegetable material**. The disease has also occurred in horses fed on spoiled vegetables and potatoes contaminated by *C. botulinum* and on alfalfa haylage packed in airtight aluminum foil envelopes. Grass clippings allowed to accumulate and decay in a pile have poisoned horses, as has round bale hay that spoiled after rain. Decaying grass at the base of old tussocks and in trampled stubble are known to be suitable sites for growth of *C. botulinum*. Cases have occurred with brewers grains, and high-moisture grain has the potential for toxicity.

Carrion-Associated Botulism

This is almost always the cause of botulism in animals on pasture, and carrion is also a common cause of botulism in animals on conserved feeds. Carrion includes domestic and wild animals and birds. In endemic botulism areas, the carcasses of dead animals are invaded by *C. botulinum,* and high concentrations of toxin are produced such that very small amounts of flesh or bone have lethal concentrations. Most outbreaks of carrion-associated botulism are associated with **type C and D strains**; these strains produce much higher concentrations of toxin in carrion than type A and B strains. Toxin can persist in carrion for at least 1 year. Where the carcasses of rodents, cats, and birds contaminate hay or silage, toxin can leach out and contaminate surrounding hay or other feeds to cause multiple cases of botulism. In one instance a single mouse carcass is thought to have contaminated 200,000 tons of alfalfa cubes. A common source in Australia is hay made at the time of a mouse plague. At such times even good, fresh hay can contain a great deal of carrion. In another recorded incident 427 of 444 dairy cattle died after ingesting feed contaminated with BoTN type C from a cat carcass.

Poultry manure and ensiled **poultry litter** have caused outbreaks of botulism when used as fertilizers, as has poultry litter used for bedding cattle.[2] Outbreaks of botulism have occurred in cattle and sheep grazing pastures that have been fertilized with poultry manure or poultry litter. Cattle and sheep may eat poultry litter piled on a pasture before disposal. It is probable that the source of toxin in poultry litter is from poultry carcasses. Disease is usually caused by *C. botulinum* type D and occasionally type C.[2]

Direct carrion ingestion can occur where **cattle** subsist on a **chronically phosphorus-deficient diet** and manifest osteophagia, with subsequent ingestion of carrion. The disease is likely to occur in outbreak form. In **sheep**, pica is more usually associated with a dietary **deficiency of protein** or net energy. Occasional outbreaks occur that are caused by drinking of **water** contaminated by carcasses of dead animals. A not uncommon occurrence is livestock drinking lake water contaminated by the carcasses of ducks and other waterfowl that have died of botulism. Wetlands where outbreaks of avian botulism have occurred are likely to have repeated occurrences because of soil contamination.

Wound Botulism

Wound botulism is a **toxicoinfectious form of botulism** where the toxin is produced in wounds infected by *C. botulinum*.[3] Wound botulism is rare but is recorded in horses following castration, with omphalophlebitis, umbilical hernias treated with clamps, with an infected wound and in association with an injection abscess.

Toxicoinfectious Botulism

This results when toxin is produced by *C. botulinum* present in the intestine. Two conditions in horses, **equine grass sickness** (see Equine grass sickness in Chapter 7) and the **shaker foal syndrome,** are potential forms of toxicoinfectious botulism. The **shaker foal syndrome** is a disease of young foals up to 8 months of age with the highest prevalence in foals 3 to 8 weeks of age.

The disease occurs sporadically in the United States, Australia, and the UK but may occur repeatedly on some farms. *C. botulinum* type B has been isolated from the feces of naturally occurring cases of the disease, and the condition has been produced experimentally by the intravenous injection of *C. botulinum* toxin.

In cattle a toxicoinfection with *C. botulinum* is suspected to be the cause of a CWD reported to occur with increased incidence in northern and eastern Germany.[4,5] The condition was coined as **chronic or "visceral" botulism** and is thought to be caused by an enteral dysbiosis, allowing *C. botulinum* to grow in the ruminant intestinal tract and to expose the organism to subclinical doses of BoTN over a long time.[4,5] Symptoms associated with this condition are very unspecific including indigestion, lameness and ataxia, weight loss and drop in milk production, tucked-up abdomen, labored breathing, edema in brisket and legs, recumbency, and even death in advanced stages.[4] Although in many reported cases of herd outbreaks the diagnosis was solely based on clinical presentation and by ruling out other differential diagnosis, in several cases feces and intestinal content of affected or death animals were positively tested for *C. botulinum*.[4] The causative relationship is nonetheless under contentious debate because *C. botulinum* spores can routinely be isolated from feces of clinically healthy cattle.[6]

Experimental Reproduction

Cows challenged with type C botulinum toxin intravenously showed initial signs of

constipation and straining at defecation 48 hours after injection and weakness, decreased tail tone, decreased tongue tone, and muscle fasciculation of large-muscle groups between 76 and 92 hours. Weakness progressed to total posterior paresis between 80 and 140 hours in these cattle. On a weight-for-weight basis, cattle were considered to be 13 times more sensitive than mice to type C botulinum toxin.

Risk Factors

Animal Risk Factors

Botulism is most common in birds, particularly the domestic chicken and wild waterfowl. Cattle, sheep, and horses are susceptible but pigs, dogs, and cats appear to be resistant. The horse appears to be particularly susceptible to type B toxin. Cattle and sheep are usually affected by types C and D.

Environment Risk Factors

Botulism in range animals has a seasonal distribution. Outbreaks are most likely to occur during drought periods when feed is sparse, phosphorus intake is low, and carrion is plentiful. Silage-associated botulism is also seasonal with the feeding of silage. A key epidemiologic factor identified during recent botulism outbreaks in Europe and Great Britain was the proximity to broiler chicken litter.[2] The variation that occurs in the geographic distribution of the various types, and in carrion versus non–carrion-associated botulism is an important factor when considering prophylactic vaccination programs.

Importance

Severe outbreaks with high case–fatality rates can occur when contaminated feed is fed to large numbers of animals. Under extensive grazing conditions massive outbreaks of carrion-associated botulism also occur unless the animals are vaccinated.

Zoonotic Implications

BoTN is identified as a possible agent for bioterrorism. Furthermore an increasing number of large botulism outbreaks in cattle herds in the past decades have raised public health concerns associated with the consumption of meat or milk originating from affected herds.[1,7,8] In Germany, anecdotal reports of farmers having developed clinical signs resembling symptoms observed in their livestock suspected to suffer of a chronic form of botulism have contributed to these concerns.[9] Notwithstanding there is no evidence to support the assumption that there could be transmission between humans and animals.[1,7] Even the cases in which farm personnel and cattle were affected by a condition thought to be associated with *C. botulinum* different types of *C. botulinum* were isolated from people and cattle.[4,9]

The available evidence for the occurrence of human cases associated with meat and milk consumption has been reviewed.[7] No human cases of clinical botulism that were associated with the consumption of meat or milk derived from animals with botulism or healthy animals from herds affected by botulism were identified.[7] No cases of calves contracting clinical botulism from the consumption of raw milk in herds affected by botulism or cases of other species (dogs) contracting botulism from the consumption of fresh meat were available.[7]

Only one report of a cow affected by clinical botulism has been published in which BoTN was found in one mastitic quarter. The interpretation of this result is complicated by the fact that the BoTN affecting this animal was BoTN type C, whereas the BoNT type E was isolated in milk.[1] Furthermore the toxin was retrieved in a mastitic quarter but not the remaining three clinically healthy quarters. It has therefore been suggested that the BoNT retrieved in this quarter was either produced locally or is the result of contamination.[1] Cows are relatively sensitive to BoTN, whereas the toxin is rarely detectable in the blood of clinical cases. The excretion of BoTN in relevant amounts through the mammary gland is therefore considered to be unlikely. Nonetheless because of the mentioned uncertainties the meat and milk from cattle that have botulism should not be used for human consumption.

PATHOGENESIS

The toxins of *C. botulinum* are neurotoxins and produce functional paralysis without the development of histologic lesions. Botulinum toxins are absorbed from the intestinal tract or the wound and carried via the bloodstream to peripheral cholinergic nerve terminals including neuromuscular junctions, postganglionic parasympathetic nerve endings, and peripheral ganglia. The heavy chain of the toxin is responsible for binding to the receptors and translocation into the cell and the light chain of the toxin for resultant blockade of the release of acetylcholine at the neuromuscular junction. Flaccid paralysis develops and the animal may die of respiratory paralysis.

CLINICAL FINDINGS

Cattle and Horses

Signs usually appear 3 to 17 days after the animals gain access to the toxic material, but occasionally as soon as day 1, the incubation period is shorter as the amount of toxin available is increased. **Peracute cases** die without prior signs of illness, although a few fail to take water or food for a day beforehand. The disease is not accompanied by fever, and the characteristic clinical picture is one of progressive symmetric muscular paralysis affecting particularly the limb muscles and the muscles of the jaw, tongue, and throat. Muscle weakness and paralysis commence in the hindquarters and progress to the forequarters, head, and neck. The onset is marked by very obvious muscle tremor and fasciculation, often sufficient to make the whole limb tremble. Colic may be an initial sign in horses.

In most cases the disease is **subacute**. Restlessness, incoordination, stumbling, knuckling, and ataxia are followed by inability to rise or to lift the head. Mydriasis and ptosis occur early in the clinical course; mydriasis can be prominent in type C botulism in the horse. Skin sensation is retained. Affected animals lie in sternal recumbency with the head on the ground or turned into the flank, not unlike the posture of a cow with parturient paresis. Tongue tone is reduced, as is the strength of tongue retraction. In some cases the tongue becomes paralyzed and hangs from the mouth, the animal is unable to chew or swallow, and it drools saliva. In others there is no impairment of swallowing or mastication and the animal continues to eat until the end. This variation in signs is often a characteristic of an outbreak; either all the cases have tongue paralysis or all of them do not have it. Ruminal movements are depressed. Defecation and urination are usually unaffected, although cattle may be constipated. Paralysis of the chest muscles results in a terminal abdominal-type respiration. Sensation and consciousness are retained until the end, which usually occurs quietly, and with the animal in lateral recumbency, 1 to 4 days after the commencement of illness.

Occasional field cases and some experimental cases in cattle show **mild signs** and recover after an illness of 3 to 4 weeks. These chronic cases show restlessness and respiratory distress followed by knuckling, stumbling, and disinclination to rise. Anorexia and adipsia are important early signs but are often not observed in pastured animals. In some there is a pronounced roaring sound with each respiration. The roaring persists for up to 3 months. During the major part of the illness the animals spend most of their time in sternal recumbency. In some animals there is difficulty in prehending hay but concentrate and ensilage may be taken. This disability may persist for 3 weeks.

A syndrome ascribed to toxicosis with BoTN type B and manifested with anorexia, decline in milk production, dysphagia, a fetid diarrhea, regurgitation, and profuse salivation without myesthesia, paresis, and recumbency is reported in cattle in the Netherlands and Israel. In these cases death occurred as a result of aspiration pneumonia.

With **toxicoinfectious botulism** in foals, muscle tremor is often a prominent early sign. If the foal can walk, the gait is stiff and stilted and the toes are dragged. If the foal sucks, milk drools from the mouth; if it attempts to eat hay some of the material is regurgitated through the nostrils. Constipation occurs consistently. There is a rapid progression to severe muscular weakness and prostration, with the foal going down and

being unable to rise. If it is held up, there is a gross muscle tremor, which is not evident when the foal is lying down. Prostrate foals are bright and alert, have normal mentation and pain perception, and have dilatation of the pupils with a sluggish pupillary light reflex. During the latter period of the illness there is a complete cessation of peristalsis. The temperature varies from being slightly elevated to slightly depressed. Death occurs about 72 hours after the onset of signs and is caused by respiratory failure.

Sheep

Sheep do not show the typical flaccid paralysis of other species until the final stages of the disease. There is stiffness while walking and incoordination and some excitability in the early stages. The head may be held on one side or bobbed up and down while walking (**limber neck**). Lateral switching of the tail, salivation, and serous nasal discharge are also common. In the terminal stages there is abdominal respiration, limb paralysis, and rapid death.

Goats

Because of different feeding habits of sheep and goats the risk of exposure to BoTN of goats is considerably lower compared with sheep or cattle. Although goats look for bushes and shrubs on which to browse, cattle and sheep graze along the ground and are therefore more likely to ingest BoTN from contaminated waste spread over pasture.[8]

Pigs

Authentic reports in this species are rare. Clinical signs include staggering followed by recumbency, vomiting, and pupillary dilatation. The muscular paralysis is flaccid and affected animals do not eat or drink.

CLINICAL PATHOLOGY

There are no changes in hematologic values or serum biochemistry that are specific to botulism. In many cases under field conditions the diagnosis is solely based on clinical presentation and by ruling out potential differential diagnoses.

Laboratory diagnosis of botulism in the live or dead animal is difficult because of the lack of sensitive confirmatory laboratory tests. Laboratory confirmation is attempted by the following:

- Detection of preformed toxin in serum, intestinal tract contents, or feed
- Demonstration of spores of *C. botulinum* in the feed or gastrointestinal contents
- Detection of antibody in recovering or clinically normal at-risk animals.

Detection of toxin using bioassay in mice where mice are inoculated intraperitoneally coupled with toxin neutralization with polyvalent antitoxin is considered the most sensitive test currently available. Nonetheless the rate of positivity in clinical cases particularly when testing serum is low, which has been explained by the much higher sensitivity to BoNT of cattle and horse compared with mice and the rapid binding of BoNT in the neuromuscular junctions, leaving low to no amounts of free BoNT in blood. Currently gastrointestinal content or fecal material is preferred over fecal material for the detection of BoNT.[5,7]

In outbreaks of botulism it is not uncommon to have only a proportion of clinically affected animals, or none, test positive. Protection with monovalent antitoxin allows type identification. Toxin detection by an ELISA test appears less sensitive than mouse bioassay. Toxin production or carrion contamination can potentially occur in a number of feeds; however, the majority of outbreaks are associated with contamination in hay or silage and suspect feeds should be tested in mice for toxin. To get around the problem of lack of sensitivity with the mouse test, suspect feed has been fed to experimental cattle. Alternatively, one can make an infusion of the feed sample and use this as the sole drinking water supply for experimental animals. The problem with all feeding experiments is that the BoTN is likely to be very patchy in its distribution in the feed.

Failure to produce the disease in animals vaccinated against botulism, when deaths are occurring in the unvaccinated controls, has also been used as a diagnostic procedure.

Demonstration of spores of *C. botulinum* in the feed being fed or the feces of affected animals supports a diagnosis of botulism because botulism spores are rarely detected in the feces of normal foals and adult horses. Although the testing of gastrointestinal contents from clinically suspect cases in cattle is frequently used as diagnostic tool particularly when toxicoinfectious botulism is suspected, this approach is considered to lack specificity because the postmortem growth of environmental *C. botulinum* spores would result in false-positive results.[2,4,9] Furthermore *C. botulinum* can be isolated from the majority of fecal samples of healthy slaughter cows.

The detection of antibody in chronically affected animals and at-risk herdmates or as retrospective diagnosis by an ELISA test has been used to support a diagnosis in outbreaks of type C and type D botulism. Increased antibody prevalence over time or increased antibody prevalence in an affected group compared with a similar group nearby was reported by some authors.[10]

NECROPSY FINDINGS

There are no specific changes detectable at necropsy, although the presence of suspicious feedstuffs in the forestomachs or stomach may be suggestive. There may be nonspecific subendocardial and subepicardial hemorrhages and congestion of the intestines. Microscopic changes in the brain are also nonspecific, consisting mainly of perivascular hemorrhages in the corpus striatum, cerebellum, and cerebrum. Nonetheless, unless classic flaccid paralysis was observed clinically, the brain should be examined histologically to eliminate other causes of neurologic disease. The presence of *C. botulinum* in the alimentary tract is a further test. The presence of toxin in the gut contents is confirmatory if found but is often misleading, because the toxin may have already been absorbed. The presence of the toxin in the liver at postmortem examination is taken as evidence that the disease has occurred. In addition to traditional bioassays, such as the mouse protection test, newer methods for toxin detection include ELISA techniques, and a recently described immuno-PCR assay.

Samples for Confirmation of Diagnosis

- Bacteriology: suspected contaminated feed material, feces, rumen and intestinal contents, plus serum from clinically affected herdmates (bioassay, anaerobic CULT, ELISA)
- Histology: formalin-fixed brain.

DIFFERENTIAL DIAGNOSIS

A presumptive diagnosis is made on the clinical signs and history, occurrence in unvaccinated animals, and the ruling out of other diseases with a similar clinical presentation. The symmetric motor paralysis of botulism with muscle paralysis that progresses to recumbency in 1–4 days is a major differential for botulism from other causes of neurologic dysfunction in large animals.

Ruminants

- Periparturient hypocalcemia, characterized by low serum calcium concentrations and responsiveness to parenteral calcium administration
- Hypokalemia, characterized by marked hypokalemia
- Tick paralysis
- Paralytic rabies
- Poisoning by *Phalaris aquatica*
- Organophosphate/carbamate poisoning
- Louping-ill in sheep

Horses

- Equine encephalomyelitis
- Equine herpesvirus-1 myeloencephalopathy
- Atypical myopathy of unknown etiology; the condition that presents frequently fatal myopathy can be differentiated by the characteristic increase in serum creatine kinase activity and the presence of hemoglobinuria
- Equine motor neuron disease
- Hyperkalemic periodic paralysis
- Hepatic encephalopathy
- Paralytic rabies
- Ionophore toxicity
- Myasthenia gravis

TREATMENT

Recent studies report a survival rate in foals of 96% which was achieved by the early administration of antitoxin (before complete recumbency) coupled with a high quality of intensive care fluid therapy, enteral or parenteral feeding, nasal insufflation with oxygen, and mechanical ventilation if required. Duration of hospitalization was approximately 2 weeks. Antitoxin was considered essential to the high success rate in this report and this would limit the success of treatment geographically because antitoxin to the various BoTN types is not available universally. Specific or **polyvalent antiserum** is available in some countries and, if administered early in the course at a dose of 30,000 IU for a foal and 70,000 IU for adult horses, can improve the likelihood of survival. A single dose is sufficient, but it is expensive.

Animals should be confined to a stall with **supportive fluid therapy** and enteral feeding. Muzzling may be required to prevent aspiration pneumonia and frequent turning to prevent muscle necrosis and decubital ulcers. Bladder catheterization may be required in horses that do not urinate, and mechanical ventilation may be necessary for recumbent horses. Mineral oil is used to prevent constipation, and antimicrobial drugs are used to treat secondary complications such as aspiration pneumonia. Therapy should avoid the use of drugs that deplete the neuromuscular junction of acetylcholine, such as neostigmine, and those, such as procaine penicillin, tetracyclines, and aminoglycosides, that potentiate neuromuscular weakness.

A rapid progression of signs suggests a poor prognosis, and treatment should only be undertaken in subacute cases in which signs develop slowly and there is some chance of recovery. The prognosis in recumbent horses is grave.

Where groups of animals have had the same exposure factor, the remainder of the animals in the group should be vaccinated immediately.

Vaccination with either type-specific or combined BoNT toxoid in clinically affected animals is ineffective because binding of BoNT to neuromuscular junctions is irreversible.

TREATMENT AND CONTROL

Treatment

Polyvalent antiserum (30,000 IU for a foal and 70,000 IU for an adult horse, single dose) (R-2)

Control

Vaccinate with multivalent BoTN toxoid IM (R-2)

BoTN, botulin toxin, IM, intramuscularly.

CONTROL

In range animals, **correction of dietary deficiencies** by supplementation with phosphorus or protein should be implemented if conditions permit. Hygienic **disposal of carcasses** is advisable to prevent further pasture contamination but may not be practicable under range conditions. **Vaccination** with type-specific or combined (bivalent C and D) toxoid is practiced in enzootic areas in Australia and southern Africa. Type B and C vaccines would be more appropriate for prevention of disease in North America and Europe. The immunity engendered by vaccination is type specific. The number and interval of vaccinations required varies with the vaccine, and the manufacturer's directions should be followed. In horses, the disease is usually sporadic and caused by accidental contamination of feed or water; vaccination is seldom practiced in this species. Some local reactions are encountered after vaccination in horses but they are seldom serious. Vaccination of the mare may not prevent the occurrence of botulism in foals.

A common problem that arises when the disease appears to have resulted from feeding contaminated silage, hay, or other feed is what to do with the residue of the feed. In these circumstances the stock should be vigorously vaccinated with a toxoid on three occasions at 2-week intervals and then feeding of the same material can be recommenced.

TICK PARALYSIS

Infestations with a several species of ticks are associated with paralysis of animals. Dogs are most commonly affected but losses can occur in cattle, sheep, goats, llamas, horses, and a variety of wild animals. At least 31 species in seven genera of ixodid ticks and seven species in three genera of argasid ticks have been implicated in tick paralysis. The most important tick species for livestock are given in Table 14-22. *D. andersoni* is the most common cause of tick paralysis in livestock in North America; *D. occidentalis* is associated with paralysis in cattle, horses, and deer.[1] In Australia, *I. holocyclus* is the predominant tick associated with paralysis, whereas *I. rubicundus* and *Rhipecephalus evertsi* are common in Africa.[1] Animals in Europe and Asia have developed tick paralysis from *I. ricinus* and *Hyalomma punctata*.[1]

The toxin of *D. andersoni* interferes with liberation or synthesis of acetylcholine at the muscle fiber motor end plates.[2] The disturbance is functional and paralysis of the peripheral neurons is the basis for clinical

Table 14-22 Ticks reported to cause paralysis in livestock

Animal	Tick	Country
Sheep, calves, goats	*Dermacentor andersoni* *D. occidentalis*	United States, Canada United States
Calves, lambs, foals, goats	*Ixodes holocyclus*	Australia
Sheep, goats, calves	*I. pilosus*	South Africa

Lambs	*Rhipicephalus evertsi*	South Africa
Calves, sheep, goats	*Hyalomma punctata*	South Africa, Europe, Japan
Sheep	*H. aegyptium*	Yugoslavia
Sheep	*Ornithodorus lahorensis*	Central Asia
Cattle, sheep, goats	*Amblyomma cajannense*	Central, South America
Cattle	*R. evertsi*	Africa

signs. Continuous secretion of toxin by a large number (35–150) of partly engorged female ticks that have been attached for 5 to 8 days is necessary to produce paralysis, with complete recovery occurring within 24 hours when the ticks are removed. The disease is generally confined to calves and yearlings. Clinically, there is an ascending, flaccid paralysis commencing with incoordination of the hindlimbs, followed by paralysis of the forelimbs and chest muscles, causing lateral recumbency.[1] Respiration is grossly abnormal; there is a double expiratory effort and the rate is slow (12–15 breaths per minute) but deep. Death, caused by respiratory failure, may occur in 1 to 2 days, but the course is usually 4 to 5 days. The mortality rate may be as high as 50% in dogs, but is usually much lower in farm animals.

I. holocyclus have been shown to paralyze calves of 25 to 50 kg BW. Between 4 and 10 adult female ticks are required to produce this effect and paralysis occurs 6 to 13 days after infestation occurs. The ticks under natural conditions parasitize wild fauna, and infestations of other species occur accidentally. The disease is limited in its distribution by the ecology of the ticks and the natural host fauna. The paralysis characteristic of the disease is associated with a toxin secreted by the salivary glands of female ticks, which is present in much greater concentration in the glands of adults than in other stages. The severity of the paralysis is independent of the number of ticks involved; susceptible animals may be seriously affected by a few ticks.[1]

Hyperimmune serum is used in the treatment of dogs, but in farm animals removal of the ticks in the early stages is usually followed by rapid recovery. Control necessitates eradication of the ticks or host fauna. The general principles of tick control are outlined in Chapter 11. The use of appropriate insecticides is an effective preventive.

OVINE "KANGAROO GAIT" AND FENUGREEK STAGGERS

SYNOPSIS

Etiology Not known.

Epidemiology Seasonal occurrence involving only adult female sheep that are lactating, or in some cases, pregnant. Spontaneous recovery following cessation of lactation in most cases, but sometimes only 50%, but not always all affected sheep.

Clinical findings Bilateral forelimb locomotor disorder.

Lesions Edema of brain and spinal cord in early cases; axonal degeneration of the radial nerve followed by regeneration in more chronic cases (those greater than 6 weeks' duration).

Treatment Supportive.

Control None recognized.

ETIOLOGY

This is a neuropathy with no known cause. In Australia similar clinical and pathologic signs are associated with grazing mature plants or the stubble of fenugreek (*Trigonella foenum-graecum*), which is an annual winter-spring legume from which the seed is harvested as a condiment for human food.[1]

EPIDEMIOLOGY

Occurrence

This condition is recorded in Australia, New Zealand, and the UK. It is manifested by incoordination, including an acute onset of a high-stepping forelimb gait and bounding hindlimb gait.

Risk Factors

It occurs only in adult ewes with an onset in late pregnancy or early lactation. Spontaneous recovery occurs following cessation of lactation, and occasionally while ewes are still nursing lambs, although in Australia often only 50% of ewes recover completely.[1] The cumulative annual incidence varies between flocks but is usually less than 1%.

In the areas of northern England and southern Scotland the condition is significantly more common in upland and lowland flocks than in those hill grazing. Stocking density is higher in affected flocks than that in nonaffected flocks. Onset occurs while on pasture between March and June with a separate smaller peak in October. This seasonal occurrence could be a reflection of the parturition status of flocks or an effect of seasonal influences.

In Australia cases have been recorded in lactating ewes grazing improved pastures from June (winter) to February (summer) and the grazing of fenugreek crop or stubble in summer.

PATHOGENESIS

Clinical signs can be attributed to the generalized neuropathy affecting principally the radial nerves. Subsequent to the axonal degeneration a remyelination of the radial nerve occurs, explaining the clinical recovery. For cases not associated with ingestion of fenugreek, bilateral compression of the radial nerves is suggested as a cause, but there is no knowledge of how such an injury can occur. Despite the differences in diet, the similar clinical and pathologic presentation of kangaroo gait and fenugreek staggers has prompted the suggestion that these may be related entities.[1] Nevertheless there are some key differences; the initial acute stage of fenugreek staggers in Merino sheep is sometimes lethal and is later associated with weight loss, whereas kangaroo gait is not and seems to be restricted to larger meat breeds.

CLINICAL FINDINGS

These include incoordination, a high-stepping forelimb and bounding hindlimb gait, arched back, and proprioceptive deficits (knuckling of fore and occasionally hind fetlocks). There is bilateral forelimb paresis and palpable loss of muscle bulk in the forelimbs. The forelimbs and hindlimbs of affected sheep are positioned centrally under the body and so when they are pressed affected sheep move with a characteristic hopping or kangaroo gait. Affected ewes lie down more frequently and may graze on their knees but continue to eat and effectively suckle their lambs.

CLINICAL PATHOLOGY

There are no consistent abnormalities in hematology, blood biochemistry, or trace element analysis of affected sheep.

NECROPSY FINDINGS

In early cases there are signs of acute edema in the brain and spinal cord (wallerian degeneration of ventral motor tracts, spongy changes in the neuropil, and swollen astrocytes). This progresses to a peripheral neuropathy, with axonal degeneration of the myelinated fibers of the radial nerve fibers in longer standing cases (6 weeks or more), and then regeneration in recovering cases.

DIFFERENTIAL DIAGNOSIS

Romulosis, a condition associated with grazing fungus-infected onion grass (*Romulea rosea*), can cause incoordination and a similar hopping gait (bunny-hopping).

Foot rot or foot abscess involving the front feet can induce the same grazing behavior, but there is no problem in differentiation when the limbs and feet are examined.

Hypocalcemia in sheep occurs in late pregnancy or during lactation, and in the developing stages there is incoordination and muscle weakness. However, there is rapid progression to complete muscular paresis and a dramatic response to treatment.

Spinal abscess or fracture.

TREATMENT

Without the knowledge of etiology there is no specific treatment. Easy access to food and water should be provided.

POLYNEURITIS EQUI (CAUDA EQUINA SYNDROME)

Polyneuritis equi (formerly cauda equina neuritis) is a demyelinating, inflammatory disease of peripheral nerves of adult horses. The **etiology** of the disease is unknown although infectious (adenovirus, EHV-1), immune (autoimmune disease), and toxic etiologies have been suggested, without conclusive substantiation. Adenovirus was isolated from two of three horses with the disease, but this observation has not been repeated, and it appears unlikely at this time that adenovirus is the cause of polyneuritis equi. EHV-1 is not consistently isolated from affected horses.

The disease occurs in adult horses in Europe and North America but has not been reported from the Southern Hemisphere. The prevalence in a group of 4319 horses subject to postmortem examination in Normandy was 0.2% (one case).[1] The disease is usually sporadic with single animals on a farm or in a stable affected. However, outbreaks of the disease can affect multiple horses from the same farm over a number of years.

The **pathogenesis** of the disease involves nonsuppurative inflammation of the extradural nerves and demyelination of peripheral nerves. Initial inflammation of the nerves causes hyperesthesia, which is followed by loss of sensation as nerves are demyelinated. Both motor and sensory nerves are affected, with subsequent weakness, paresis, muscle atrophy, urinary and fecal retention and incontinence, and gait abnormalities.

The inflammatory response is characterized by an abundance of **T lymphocytes**, in addition to B lymphocytes, macrophages, giant cells, eosinophils, and neutrophils in the perineurium and endomeurium.[2] The T cells are CD8+ cytotoxic T lymphocytes with rare CD4+ helper T lymphocytes.[3] This, with electron microscopic imaging, evidence of "myelin stripping" by macrophages and the presence of antibodies to the myelin P2 protein has been interpreted as indicative of immune-mediated activity against myelin.[2,4] This immune response might be toward the myelin as a primary target or could be the result of bystander activity in which other agents, potentially viruses, induce an immune response that is directed against myelin.

The **acute disease** is evident as abrupt onset of hyperesthesia of the perineum and tail head, and perhaps the face, evident as avoidance of touching, and chewing or rubbing of the tail. The hyperesthesia progresses to hypalgesia or anesthesia of the affected regions.

The disease usually has a more **insidious onset** with loss of sensation and function occurring over days to weeks. The most common presentation is that of cauda equina syndrome with bilaterally symmetric signs of posterior weakness, tail paralysis, fecal and urinary incontinence and retention, and atrophy of the gluteal muscles. Tail tone is decreased or absent and the tail is easily raised by the examiner. The anus is usually atonic and dilated. There are signs of urinary incontinence with urine scalding of the escutcheon and hindlegs. Rectal examination reveals fecal retention and a distended bladder that is readily expressed. Male horses can have prolapse of the penis with maintained sensation in the prepuce, which is a finding consistent with the separate innervation of these anatomic regions. Affected horses can also have ataxia of the hindlimbs, but this is always combined with signs of cauda equina disease.

Signs of **CN dysfunction** occur as part of the disease, but not in all cases. CN dysfunction can be symmetric, but is usually asymmetric. Nerves prominently involved in the genesis of clinical signs are the trigeminal (CN V), facial (CN VII), and hypoglossal nerve (CN XII), although all CNs can be affected to some extent. Involvement of the CNs is evident as facial paralysis (CN VII), weakness of the tongue (CN XII), and loss of sensation in the skin of the face (CN V). There can be loss of movement of the pinnae (CN VII) and head tilt (CN VIII). Laryngeal paralysis can be present (CN X). The buccal branches of CN VII can be enlarged and palpable over the masseter muscles ventral to the facial crest.

Not all clinical signs occur in all horses and, depending on the stage and severity of the disease, some animals can have loss of sensation as the only abnormality, especially during the early stages of the disease.

EMG is consistent with denervation with prolonged insertion potentials, positive sharp waves, and fibrillation. Per rectal **ultrasound examination** of the extradural sacral nerve routes as they exit the ventral sacral foramina reveals enlargement and a diffusely mottled, hypoechoic appearance.[3]

Biopsy of the sacrocaudalis dorsalis lateralis muscle can provide antemortem diagnosis of the disease. Affected horses have intense lymphocytic and histiocytic infiltration around the terminal nerves within the muscle, often obliterating architecture of the nerves but sparing the myofibers.[3] There is neurogenic atrophy of the muscle fibers.

The disease is inexorably progressive, the prognosis for life is hopeless, and the course of the disease is usually less than 3 months.

Clinical pathologic abnormalities are not diagnostic. There is sometimes a mild neutrophilic leukocytosis and hypergammaglobulinemia. Serum vitamin E concentrations are usually normal. Analysis of CSF demonstrates mild mononuclear pleocytosis and increased protein concentrations, but these changes are not diagnostic of the disease. Horses with polyneuritis equi have antibodies to P2 myelin protein in serum, but the diagnostic value of this test has not been determined.

Necropsy findings are definitive for the disease. Gross findings include thickening of the epidural nerve roots that is most severe in the cauda equina. The bladder and rectum can be distended. There can be evidence of fecal and urine scalding and self-trauma of the perineum. There can be thickening of the facial nerves. Microscopic changes are characterized by a granulomatous inflammation of the extradural nerves, although radiculoganglioneuritis and myelitis can also occur. There is loss of axons with demyelination and signs of remyelination. There is profound infiltration of nerves by macrophages, moderate to marked infiltration of cytotoxic T lymphocytes, and lesser infiltration of B lymphocytes.[3] Inflammatory cells are initially lymphocytes, plasma cells, and macrophages. As the inflammation becomes more severe or chronic there is extensive proliferation of fibroblasts and fibrocytes in addition to infiltration of lymphocytes and macrophages. There is axonal degeneration with proliferation of the perineurium. The chronic inflammatory changes result in loss of peripheral neural architecture. Lesions are present in many regions of the spinal cord, but are most severe in the sacral division and cauda equina. Lysosomal accumulations are present in the semilunar, geniculate, and sympathetic chains and granulomatous lesions in the celiac-mesenteric ganglion. Lesions of the CNs similarly involve infiltration with lymphocytes and histiocytes, and the inflammation can extend to the terminal branches of the nerves.

The **diagnosis** of polyneuritis equi is based on the presence of clinical signs of the disease, ruling out other diseases causing similar clinical signs, and necropsy examination. Diseases with manifestations similar to polyneuritis equi include the following:

- EHV-1 myeloencephalopathy
- Migrating parasites (Table 14-21, **differential diagnosis of disease causing spinal ataxia in horses**)
- Sorghum-Sudan grass neuropathy
- Equine protozoal myeloencephalitis
- Ryegrass staggers (*A. lolii*)
- Dourine
- Trauma to the sacral vertebral column
- Abscess or neoplasia involving the sacral or caudal lumbar vertebral column
- Meningitis
- Intentional alcohol sclerosis of tail head nerves in Quarter Horses.

There is no definitive **treatment** for polyneuritis equi. Administration of antiinflammatory agents, including corticosteroids, appears to be without sustained benefit.

Supportive care includes evacuation of the rectum and bladder and maintenance of hydration and provision of adequate nutrition. Feeding a diet that softens feces, or administration of fecal softeners or lubricants, can be beneficial. Bethanecol (0.05–0.1 mg/kg every 8–12 hours, orally) might increase bladder tone. Topical administration of petroleum jelly or similar products can protect the skin of the perineum and escutcheon from fecal and urine scalding.

SCANDINAVIAN KNUCKLING SYNDROME (ACQUIRED EQUINE POLYNEUROPATHY)

This is a recently recognized syndrome of metatarsophalangeal joint extensor paresis in horses in Scandinavia.[1-3] The disease appears to be widespread in Sweden, Norway, and Finland occurring as clusters of disease outbreaks on farms.[1] The etiology is uncertain, although preserved feed is considered the source of an unidentified toxin.

A report described the risk factors and outcome of 42 cases distributed over 13 farms in Scandinavia from 2007 to 2009. Cases occurred between December and May with an overall prevalence of 27% and on-farm prevalence of 11% to 71% (for farms with >6 horses) although the number of cases, and affected farms, varies markedly from year to year.[2,4] The case–fatality rate was 29% in the epidemiology study[1] and 53% (40 of 75) in a case series.[2] The disease was less prevalent in horses >12 years of age, and younger horses had a greater chance of surviving the disease.

Clinical signs were typified by bilateral knuckling of the hindlimbs, which was most apparent on circling. Mild to moderate pelvic limb weakness was detected in 16 of 42 horses.[1] A small proportion of cases (3/42) had mild forelimb signs of weakness and knuckling. There was focal muscle atrophy of hindlimb musculature in seven cases. Mentation and vital signs (temperature, pulse, and respiratory rate) were within normal limits. The disease usually has a slow onset, but some affected horses developed severe signs with hours.[2] The median duration of clinical signs in affected horses that recover is 4.4 months (range 1–17 months) and survivors can recover completely.

Routine hematology and serum biochemical analysis do not reveal consistent abnormalities, apart from increased creatine kinase and AST activity in recumbent horses.[2]

Lesions are restricted to the peripheral nervous system and are evident in sciatic, peroneal, radial, and plantar digital nerves.[2,3] Lesions include areas of thick, swollen axons with subperineural accumulation of mucoid material. There is lymphohistiocytic infiltration of nerves and mild to moderate loss of myelinated nerve fibers.[3] Swollen axons and large vacuoles were present in sections of the lumbar tumescence. There are no lesions detected in the brain.[2]

Treatment consists of supportive and nursing care. Control measures are not reported.

PERIPHERAL NERVE SHEATH TUMORS

PNSTs are most commonly benign tumors of the peripheral nervous system with a rare occurrence in veterinary medicine.[1] Most commonly affected species are dogs and cattle.[1] Tumors are composed of components of the peripheral nerve, including Schwann cells, perineural cells, fibroblasts and collagen. While in human medicine PNSTs are subdivided into **neurofibromas** and **schwannomas**, dependent on the predominant cell type and other histologic characteristics, this distinction is less clearly defined in veterinary medicine.[2,3] The existence of true neurofibromas as described in humans has been questioned.[1,2] PNSTs that can occur on any location of the peripheral nervous system most commonly originate from autonomic nerves such as cardiac and intercostal nerves or the brachial plexus.

CLINICAL FINDINGS

In cattle, PNSTs are generally asymptomatic and found incidentally during physical examination or slaughter. Clinical signs are uncommon but can include limb paresis or paralysis, recurrent bloat and vagal indigestion, cardiac insufficiency, and chronic wasting.[1,3,4] The cutaneous presentation is rare but can present as single or multiple indolent cutaneous masses between 1 and over 15 cm in diameter that are well demarcated. In some instances PMSTs may infiltrate surrounding tissue, immobilizing the mass and complicating surgical excision.

CLINICAL PATHOLOGY

Diagnosis must be confirmed histologically. Important features included the concurrent presence of highly and poorly cellular areas of Schwann cells. Nerve fibers are absent in schwannomas but may be found in neurofibromas. Immunohistostaining is used to confirm the presence of Schwann cells and to differentiate between schwannomas and neurofibromas.[1,2]

TREATMENT

Treatment of accessible masses (cutaneous form) is rarely required but may be indicated either for cosmetic reasons as an excisional biopsy or to remove the mass integrally. Although the prognosis in most cases is excellent, tumors with infiltrative growth may recur because of incomplete excision of abnormal c ells.

Diseases of the Musculoskeletal System

15

Diseases of the organs of support, including muscles, bones, and joints, have much in common in that the major clinical manifestations of diseases that affect them are lameness, failure of support (weakness), insufficiency of movement, and deformity. Insufficiency of movement affects all voluntary muscles, including those responsible for respiratory movement and mastication, but lameness and failure of support are manifestations of involvement of the limbs.

Various classifications of the diseases of the musculoskeletal system, based on clinical, pathologic, and etiologic differences, are in use, but the simplest is that which divides the diseases into **degenerative** and **inflammatory** types. This classification system is used in this chapter.

- The degenerative diseases of muscles, bones and joints are distinguished as myopathy, osteodystrophy, and arthropathy, respectively.
- The inflammatory diseases are myositis, osteitis and osteomyelitis, and arthritis, respectively.

Principal Manifestations of Musculoskeletal Disease

LAMENESS

Lameness is an abnormal gait or locomotion characterized by limping or not bearing full weight on a leg, usually associated with localized pain in the musculoskeletal system. Lameness must be distinguished from **ataxia**, which is an abnormal gait characterized by lack of coordination of muscular action, usually because of a lesion of the central or peripheral nervous system.

Weakness (paresis) is the inability to maintain a normal posture and gait, usually because of a lesion of muscle or generalized weakness as a result of an abnormal systemic state (e.g., shock), a metabolic abnormality (e.g., hypocalcemia or hypokalemia), or starvation. Weakness can also be caused by a lesion in the spinal cord or peripheral nerves.

The incidence and severity of lameness in livestock populations varies tremendously because of differences in management systems (grazing versus confinement, concrete versus slatted floors, free stall design and use by dairy cattle, frequency of foot trimming, etc.), nutrition, genetics, age, body weight, and many other factors. For example, certain breeds may be more susceptible to diseases of the feet and legs than others. Osteoarthritis occurs most commonly in old animals. Diseases of the legs of dairy cattle occur most commonly at the time of parturition and during the first 50 days of lactation. Diseases of the feet of dairy cattle occur most commonly in days 50 to 150 of the lactation period. Often the etiology is complex, and a definitive etiologic diagnosis cannot be made. This makes clinical management difficult and often unrewarding. The direct monetary costs for the treatment of lame animals are not high, but the actual treatment of either individual animals or groups of animals is time-consuming and laborious. The condemnation of animals to slaughter because of lesions of the musculoskeletal system also contributes to the total economic loss.

When lameness is a herd problem, not only are the economic losses increased, but clinical management becomes very difficult. The epidemiologic factors that contribute to lameness include the following:

- Injuries as a result of floor surfaces
- Persistently wet, unhygienic ground conditions
- Overcrowding and trampling during transportation and handling
- Nutritional inadequacies
- Undesirable skeletal conformation
- Failure to provide regular foot trimming

Because of the difficulty inherent in the differentiation of diseases causing lameness, and other abnormalities of gait and posture, a summary is presented in Table 15-1. It does not include lameness in racing horses, which is described in textbooks on lameness in horses, or diseases of the nervous system that interfere with normal movement and posture. These are discussed in Chapter 14.

ABNORMAL POSTURE AND MOVEMENT

As a group, diseases of the musculoskeletal system are characterized by reduced activity in standing up and moving and by the adoption of unusual postures.[1] Abnormal movements include weakness (limpness) or stiffness and lack of flexion. Abnormal postures include persistent recumbency, including lateral recumbency. There may be signs of pain on standing, moving, or palpation. There is an absence of signs specifically referable to the nervous system. Differentiation from diseases of the nervous system and from each other may be aided by specific biochemical, radiologic, or hematologic findings that indicate the system involved. Specific epidemiologic findings may indicate the location of the lesion (which may be secondary) in muscle, bones, or joints, as set out in Table 15-1.

DEFORMITY

Atypical disposition, shape, or size of a part of the musculoskeletal system constitutes a deformity. This may occur in a number of ways, and be caused by the following defects.

Muscle and Tendon Defects

- Congenital hypermobility of joints, inherited and sporadic
- Congenital flexed or stretched tendons of limbs causing contracture of joints or hyperextension
- Inherited congenital splayleg of pigs
- Muscle hypertrophy (doppelender, culard) of cattle
- Acquired asymmetric hindquarters of pigs

Defects of the Skeleton

- Dwarfism—inherited miniature calves, achondroplastic dwarves; short legs of inherited congenital osteopetrosis; nutritional deficiency of manganese; acorn calves
- Giant stature—inherited prolonged gestation, not really giantism, only large at birth
- Asymmetry—normal wither height, low pelvis height of hyena disease of cattle
- Limbs—complete or partial absence, inherited or sporadic amputates; curvature of limbs in rickets; bowie or bentleg of sheep poisoned by *Trachymene* spp.
- Head—inherited and sporadic cyclopean deformity; inherited probatocephaly (sheep's head) of calves; inherited moles,

Table 15-1 Differential diagnosis of diseases of the musculoskeletal system

Disease and clinical findings	Epidemiologic findings	Clinical pathology	Necropsy findings	Examples
Myasthenia				
Paresis, paralysis, and incoordination	Ischemia or reduced supply of energy or electrolytes.	Hypoglycemia, hypocalcemia, hypokalemia, hypomagnesemia	Reversible malfunction	Iliac thrombosis, toxemia, milk fever, lactic acidosis, some poisonous plants
Myopathy				
Either stiff gait, disinclination to move, board-like muscles *or* weakness, pseudoparesis or paralysis, difficulty rising, staggery gait, flabby muscles. Always bilateral, mostly hindlimbs.	Often precipitated by sudden increase in muscular work. Usually diet-dependent and related to: (1) high carbohydrate intake (2) deficiency in selenium/vitamin E intake (3) Ingestion of myopathic agents (e.g., in poisonous plants, cod liver oil)	Marked elevations in serum activity of CPK and AST. Myoglobinemia and possibly myoglobinuria.	White, waxy, swollen, "fish flesh" muscle.	*Horses:* Azoturia (equine paralytic myoglobinuria, tying up, equine rhabdomyolysis, equine atypical myopathy); postanesthetic myositis. *Pigs:* Porcine stress syndrome, selenium deficiency, inherited splaylegs. *Cattle:* Selenium/vitamin E deficiency (enzootic muscular dystrophy), poisoning by *Cassia occidentalis, Karwinskia humboldtiana,* ischemic necrosis of recumbency. *Sheep:* Approximately the same; exertional rhabdomyolysis.
Myositis				
Acute inflammation, swelling, pain; may be associated with systemic signs if infectious. Chronic manifested by atrophy, contracture of joint, incomplete extension.	Related to trauma or specific infectious disease. Atrophy, pallor in chronic.	As for myopathy, plus hematologic response when infection present.	Bruising, edema, and hemorrhage in acute.	Blackleg, false blackleg (malignant edema). Eosinophilic myositis in beef cattle. Traumatic injury by strain of muscle or forceful impact.
Osteodystrophy				
Stiff gait, moderate lameness often shifting from leg to leg, arched back, crackling sounds in joints while walking. Disinclination to move; horses affected early race very poorly.	Absolute deficiency and/or relative imbalance of dietary calcium, phosphorus, and vitamin D. Most apparent in rapidly growing, working, and heavy milk-producing animals.	Radiographic evidence of osteoporosis, deformed epiphyseal lines, broadness of epiphyses. Subperiosteal unossified osteoid.	Osteoporosis, subepiphyseal collapse of bone at pressure points. Fracture of soft bones. Bone ash determinations of Ca, P, and Mg content of bones.	*Cattle:* Phosphorus deficiency, Marie's disease. Hypovitaminosis D. Calcium deficiency. Poisoning by *Trachymene glaucifolia* (bowie or bentleg).
Severely affected animals disinclined to stand, recumbent much of time. Fractures common. Bones soft (e.g., frontal bones) to digital pressure. Deformities of bones (e.g., bowing, pelvic collapse). Ready detachment of tendons and ligaments.				*Horses:* Osteodystrophia fibrosa as a result of low calcium diet, or to poisonous plants containing large amounts of oxalate (see under oxalate poisoning). *Pigs:* Osteodystrophia fibrosa attributable to low Ca and high P in diet.
Osteomyelitis				
Pain, swelling (little), toxemia, fever; may be discharge through sinus.	Only of specific disease.	Radiographic evidence of rarefaction, new bone growth.	Osteomyelitis.	Actinomycosis, brucellosis in pigs and cattle. Necrotic and atrophic rhinitis disease in pigs.
Arthropathy (osteoarthritis)				
Lameness with pain on walking, standing, palpation. Some enlargement but not gross.	(1) Inherited predisposition in cattle (2) Dietary excess of phosphorus, relative deficiency of calcium	Excessive sterile brownish fluid with floccules. Radiologic evidence of joint erosion, epiphyseal deformity, new bone growth peripherally.	Erosion of cartilage and bone, ligament rupture, new bone growth (epiphytes) around edge of joint.	*Cattle:* Degenerative joint disease (of young beef bulls), inherited osteoarthritis. *Horses:* As early part of osteodystrophy syndrome.

Continued

Table 15-1 Differential diagnosis of diseases of the musculoskeletal system—cont'd

Disease and clinical findings	Epidemiologic findings	Clinical pathology	Necropsy findings	Examples
Slackness in joints, may be ligament rupture, crepitus.	(3) Very rapid increase in body weight in young (4) Heavy milk production during many lactations		Excess brownish sterile clear fluid containing floccules.	*Pigs:* Epiphysiolysis of femurs of young breeding boars. Osteochondrosis.
Arthritis				
Acute: Sudden onset, severe pain, very lame, sore to touch, swelling and heat in joint.	Most commonly in young via navel infection and bacteremia, or residual from septicemia of neonate.	Aspiration of fluid under very sterile conditions shows leukocytes and somatic cells in large numbers. Culture may be positive but often negative.	*Acute:* Inflammation or suppuration, increased fluid content. *Chronic:* Thickened synovial membrane.	*Cattle: Mycoplasma* spp., *Erysipelothrix rhusiopathiae Streptococcus* and *Staphylococcus* spp., *Escherichia coli,*
Chronic: Continuous pain, recumbency, may be toxemia if infectious. Joint may be visibly swollen but may be normal in appearance. Pain may be evident only when animal stands on joint.		Joint fluid may appear normal in chronic case	Increased amount of clear fluid. Erosion of articular cartilage	*Salmonella* spp. in newborn. *Brucella abortus,* *Mycoplasma* spp. and *Chlamydophila* spp. *Pigs: E. Erysipelothria rhusiopathiae, Mycoplasma* spp. *Sheep: Corynebacterium pseudotuberculosis, E. rhusiopathiae, Histophilus somni, Mannheimia haemolytica, Actinobacillus seminis, Chlamydophila* spp., *Mycoplasma* spp. *Horses:* Foal septicemias.
Tenosynovitis, cellulitis, lymphangitis, bursitis				
Inflammation of other supporting tissues. Visible, painful enlargements.	Sporadic as a result of trauma or localization of systemic infection.	Culture of aspirate from local lesion.	Inflammation of affected part. Acute hemorrhagic or chronic, suppurative.	*Horses and cattle:* Bursitis—*B. abortus.* Tenosynovitis—*Histophilus somni,* cattle, *Streptococcus equi* horse, *Histophilus somni,* sheep.
Interdigital dermatitis (footrot)				
Severe foot lameness. Visible local lesion at skin–horn junction, necrotic smell, horn underrun. Allied similar conditions have less severe lesions.	Severe epidemics in wet, warm weather in sheep. Infection soil-borne. Some farms have disease persistently.	Culture of infectious agent, swab from depth of lesion.	Necrosis of soft tissue.	*Sheep:* Footrot—*Bacteroides nodosus;* foot scald—avirulent *B. nodosus;* foot abscess—*F. necrophorus;* *Trueperella pyogenes;* interdigital dermatitis—*F. necrophorum.* *Cattle:* Footrot—*F. necrophorum, B. nodosus.*
Laminitis				
Severe foot pain, separation of horn from sensitive laminae, rotation of the pedal bone. Metabolic, traumatic, or infectious types.	Sporadic except infectious type in sheep related to dipping. Possibly inherited susceptibility to metabolic laminitis in cattle.	Very high blood pressure. Radiologic demonstration of P_3 rotation.	Infection or hemorrhage/ edema, sensitive laminae.	*Sheep: Erysipelothrix rhusiopathiae*—postdipping laminitis. *Horses*—traumatic as a result of continuous pawing. *All species:* Metabolic associated with heavy grain feeding—in mares with retained placenta and metritis.
Damage to horn of hoof				
Severe foot pain if sensitive laminae affected. Horn damage obvious.	Related to hard, abrasive surfaces—pigs and dairy cattle; soft underfoot—cows indoors on wet bedding.	None.	Foot-horn lesion only.	*Cattle:* Stable footrot on soft footing; sole wear on rough concrete. *Pigs:* Sole wear on rough concrete, predisposed by biotin deficiency in diet. *Horses:* Thrush and canker on soft wet underfoot.

Table 15-1 Differential diagnosis of diseases of the musculoskeletal system—cont'd

Disease and clinical findings	Epidemiologic findings	Clinical pathology	Necropsy findings	Examples
Traumatic injuries of feet of newborn piglets				
Severe lameness in piglets 1–8 days of age. Bruising of sole, congestion, and swelling followed by peeling, erosion, and cracking of horn of sole; both claws and accessory digits injured more often on medial aspect, and incidence in hindfeet twice that of forefeet; abrasions of skin of carpal joints common; accessory digits involved too. Ascending secondary bacterial infection resulting in tenosynovitis and septic arthritis. Most piglets recover following antibacterial therapy.	Newborn piglets raised on concrete or slatted floors. Distribution of lesions related to sucking behavior of piglets, the backward, outward, and downward thrusting movements of the hindlegs while sucking.	None.	Erosion, necrosis, congestion, fissures, and hemorrhage of horn of sole and sensitive laminae of digit. Secondary tenosynovitis and arthritis.	*Piglets:* Newborn piglets raised on concrete, expanded metal, or plastic slatted floors.
Coronitis dermatitis at coronet				
Lesions vary from granuloma through vesicles, erosions. Lameness in all, but severity varies with type of lesion. Essential to examine oral mucosa.	Acute outbreaks of lameness as a result of coronitis in any species raises specter of food-and-mouth disease.	Microbiology of material from local lesion.	Local lesions only.	*Sheep:* Bluetongue, foot-and-mouth disease, vesicular stomatitis, ecthyma, strawberry footrot, ulcerative dermatosis, heel dermatitis (*B. nodosus*), strongyloidosis. *Cattle:* Foot-and-mouth disease, vesicular stomatitis, bovine virus diarrhea, bovine malignant catarrh, epitheliogenesis imperfecta. *Pigs:* Foot-and-mouth disease, vesicular exanthema of swine, swine vesicular disease, vesicular stomatitis. *Horses:* Vesicular stomatitis, greasy heel, chorioptic mange.

AST, aspartate aminotransferase; CPK, creatine phosphokinase.

bulldog calves; acquired atrophic rhinitis of pigs

Joint Defects

- Inherited congenital ankylosis of cattle causing fixation of flexion
- Joint enlargement of rickets and chronic arthritis

SPONTANEOUS FRACTURES

Spontaneous fractures occur uncommonly in farm animals, with the exception of physeal fractures of the metacarpus and metatarsus in young ruminants, and preexisting diseases are usually present in fractures not associated with a traumatic incident, such as the following:

- Nutritional excess of phosphorus causing osteodystrophia in horses
- Nutritional deficiency of calcium causing osteodystrophia in pigs
- Nutritional deficiency of phosphorus or vitamin D in ruminants causing rickets and/or osteomalacia; hypervitaminosis A may contribute
- Nutritional deficiency of copper
- Chronic fluorine intoxication

PAINFUL ASPECTS OF LAMENESS

Musculoskeletal pain can be caused by lacerations and hematomas of muscle, myositis, and space-occupying lesions of muscle. Osteomyelitis, fractures, arthritis, joint dislocations, and sprains of ligaments and tendons are also obvious causes of severe pain. Among the most painful of injuries are swollen, inflammatory lesions of the limbs caused by deep penetrating injury or in cattle by extension from footrot. Amputation of a claw, laminitis, and septic arthritis are in the same category. Ischemia of muscle and generalized muscle tetany, as occurs in electroimmobilization, also appear to cause pain.

Research on the pathophysiology and pharmacology of pain associated with lameness in animals indicates that the thresholds to painful stimuli change in response to pain (wind-up), and this change is seen as an indication of an alteration in nerve function or in nociceptive processing at higher levels. In flocks of sheep with severe lameness as a result of footrot, affected sheep had a lower threshold to a mechanical nociceptive stimulus than matched controls, and their thresholds remained low when tested 3 months later, after the apparent resolution of the foot lesions. Thus hyperalgesia persisted in severely lame sheep for at least 3 months. It is suggested that *N*-methyl-D-aspartate receptors are involved in the development of this long-term hypersensitivity. Similar findings have been reported in dairy heifers affected with claw lesions during the peripartum period.

Relief of Musculoskeletal Pain

Several aspects of relieving pain in agricultural animals are important. Cost has always been a deterrent to the use of local anesthetics and analgesics, but with changing attitudes, the need to control pain is more apparent. Treatment of the causative lesion is a major priority, but the lesion may be painful for varying lengths of time.[2] Relief and the control of pain should be a major consideration. Details on the use of analgesics are presented in Chapter 4.

EXAMINATION OF THE MUSCULOSKELETAL SYSTEM

The clinical examination of the musculoskeletal system and the feet of farm animals includes the following special examinations.

Analysis of Gait and Conformation

Inspection of the gait of the animal is necessary to localize the site of lameness. Evaluation of its conformation may provide clues about factors that may contribute to lameness. Information related to gait and abnormalities of the nervous system is presented in Chapter 15. Details on the examination of farm animals for lameness are available in textbooks on lameness in horses and cattle. Computer-assisted analysis of gait (kinematics) and hoof loading (via force plates) are commonly used in equine practice and are increasingly being used in research studies related to lameness in cattle and pigs.[1]

Close Physical Examination

A close detailed physical examination of the affected area is necessary to localize the lesion. This includes passive movements of limbs to identify fractures, dislocations, and pain on movement. Muscles can be palpated for evidence of enlargement, pain, or atrophy.

Radiography

Radiography remains an extremely useful diagnostic method for diseases of bones and joints and soft tissue swelling of limbs, which cannot be easily defined by physical examination. Detailed radiographic information about the joint capsule, joint cavity, or articular cartilage can be obtained using negative (air), positive, or double-contrast arthrography.

The widespread availability of digital imaging systems (direct radiography [DR]) now permits radiographs to be immediately examined on-site, rather than following development in the clinic. This ensures that good-quality images are obtained in all views, and the information is used in real time to direct treatment.[2] The price of digital radiography systems continues to decrease but is still significant relative to ultrasonography.

Ultrasonography

Most large animal veterinary practices have an ultrasound machine that is used for transrectal pregnancy diagnosis in cattle and horses and transabdominal pregnancy diagnosis in sheep and goats. Use of these machines with a 5.0- or 7.5-MHz linear transducer provides a rapid on-farm method for evaluating musculoskeletal, tendon, and joint diseases. Ultrasonography is cheaper and provides different information than that provided by radiography; it is also less invasive than joint fluid aspiration and analysis. Detailed information about the use of ultrasonography to diagnose bovine musculoskeletal disorders is available.[3,4] Recent advances in ultrasound technology, including harmonic imaging, compound imaging, three-dimensional (3D) imaging, elastography, and fusion imaging will increase the clinical utility of ultrasonography in ambulatory practice.[5,6]

Ultrasonographic examination of the stifle region in cattle has successfully imaged homogeneously echogenic patellar and collateral ligaments, the combined tendon of the long digital extensor and peroneus tertius muscles, the popliteal tendon, the anechoic articular cartilage of femoral trochlea, the echogenic menisci, and the hyperechoic bone surfaces were imaged successfully. The boundaries of the joint pouches became partially identifiable only when small amounts of anechoic fluid were present in the medial and lateral femorotibial joint pouches. The main indication for ultrasonography of the bovine stifle is evaluation of acute septic and traumatic disorders of the region, when specific radiographic signs are often nonspecific or absent. The cruciate ligaments could not be imaged in live cattle. The cruciate ligaments are identifiable using ultrasonography in the horse, in which flexion of the hindlimb is a routine procedure necessary for identification of these structures.

The main indication for ultrasonographic examination of the carpal region in cattle is the evaluation of septic and traumatic disorders of the carpal joints and tendon sheaths. Each tendon and tendon sheath in the carpal region must be scanned separately. The use of a stand-off pad is recommended because it permits adaptation of the rigid transducer to the contours of the carpus. The carpal joint pouches and tendon sheath lumina are not clearly defined in healthy cattle. Thus the ability to image these structures indicates the presence of synovial effusion. Ultrasonographic imaging can be used to differentiate the pathologic changes in the soft tissue structures of digital flexor tendon sheaths of cattle.

Ultrasonography is a valuable diagnostic aid for septic arthritis. Joint effusion, which is one of the earliest signs of septic arthritis; the accurate location of soft tissue swelling; the extent and character of joint effusion; and involvement of concurrent periarticular synovial cavities or other soft tissue structures can be imaged by ultrasonography. The ultrasonogram can image the presence of small hyperechogenic fragments within the joint, which appear very heterogeneous. Normal synovial fluid is anechoic and appears black on the sonogram. A cloudy appearance is usually associated with the presence of pus.

Ultrasonography has been used to evaluate the anatomy of the elbow, carpal, fetlock, and stifle joints of clinically normal sheep using a 7.5-MHz linear transducer with a stand-off pad. The anatomic structures that could be consistently identified in normal ovine joints included bone, articular cartilage, ligaments, and tendons. In sheep with chronic arthritis/synovitis, the gross thickening of the joint capsule is visible as a hyperechoic band up to 20 mm thick.

Arthrocentesis and Synovial Fluid Interpretation

Joint fluid is collected by needle puncture of the joint cavity (arthrocentesis) and examined for the presence of cells, biochemical changes in the joint fluid, and the presence of infectious agents.

Analysis of synovial fluid is a fundamental requirement for differentiating septic arthritis from degenerative arthritis, and fluid parameters are summarized in Table 15-3 later in this chapter. A number of inflammatory biomarkers in synovial fluid have been evaluated in research studies, but the leukocyte count and differential, erythrocyte count, total protein concentration, and an index of viscosity usually provide sufficient information for clinical use.

Arthrocentesis can result in joint contamination with hair when a 20-g needle is inserted. Angled needle insertion reduces joint contamination relative to perpendicular insertion.[6] Insertion of a spinal needle with the stylet in place also reduces joint contamination with hair, relative to insertion without the stylet. A larger-diameter needle (19 g) had a higher risk of hair contamination after arthrocentesis than a 20-g needle.[7]

Arthroscopy

Special endoscopes are available for inspection of the joint cavity and articular surfaces (arthroscopy). Diagnostic and surgical arthroscopy are now commonplace in specialized equine practice. Surgical arthroscopy is rapidly replacing conventional arthrotomy for the correction of several common surgical conditions of the musculoskeletal system of the horse. Accurate quantification of equine carpal lesions is possible when the procedure is performed by an experienced arthroscopist. Convalescent time following surgery is decreased and the cosmetic appearance

improved compared with arthrotomy. A synovial membrane biopsy can be examined histologically and for infectious agents and may yield useful diagnostic information. Surgical arthroscopy is being increasingly used in referral cattle practice.[8]

Serum Biochemistry and Enzymology

When disease of bone or muscle is suspected, the serum concentration of calcium and phosphorus, the serum alkaline phosphatase activity, and the serum activity of two muscle-derived enzymes, creatinine kinase (CK) and aspartate aminotransferase (AST), also known as serum glutamic oxaloacetic transaminase (SGOT), may be useful. Both CK and AST are sensitive indicators of muscle cell damage, with CK also being specific. Equations have been developed that relate the change in serum CK activity to grams of skeletal muscle tissue damaged; this methodology should be widely applied in the clinical management of livestock with musculoskeletal injury because it is sufficiently sensitive to pick up skeletal muscle damage as a result of an intramuscular (IM) antibiotic injection.[9]

Other serum biochemical indicators of muscle damage that have been used in experimental studies include myoglobin, a low-molecular-weight protein that is an early marker of muscle damage, and two indices of muscle damage: myosin, a high-molecular-weight protein, and 3-methylhistidine, a posttranslationally modified amino acid released after myosin or actin degradation.[9] In normally hydrated animals with normal renal function, it is important to understand that serum creatinine concentration provides a useful index of skeletal muscle mass. This is covered in more detail in Chapter 13.

The serum concentrations of calcium and phosphorus and the serum alkaline phosphatase activity are much less sensitive indicators of osteodystrophy.

Muscle Biopsy

A muscle biopsy may be useful for microscopic and histochemical evaluations.

Infrared Thermography

Infrared thermography has been increasingly applied to the diagnosis of inflammatory conditions of muscles and tendons, in that acute inflammation is associated with localized heat that can be detected by using a camera capable of imaging the infrared spectrum.[10,11,12]

Nuclear Scintigraphy

Technetium-labeled bone scanning has been available for decades at major referral institutions, but the use of nuclear scintigraphy has declined with the increased availability and resolution of ultrasonographic and magnetic resonance imaging (MRI) units. Nevertheless, scintigraphy is still a valuable diagnostic method for bone diseases such as osteomyelitis of the vertebral column in adult horses and cattle when the lesion is surrounded by a large mass of superimposing muscle.[13]

Magnetic Resonance Imaging

MRI is increasingly being used for the diagnosis of musculoskeletal disease and related research studies.[14,15] As a cross-sectional imaging modality, it provides outstanding tissue contrast and multiple views of the region of interest. Because of the high cost of purchasing and maintaining MRI equipment, this modality is only available at large referral centers, and even then, specially constructed tables have to be made to permit imaging of adult horses and cattle under general anesthesia. High-quality images can usually be obtained from the carpus and hock to the hoof or foot. It is anticipated that rapid advances will be made in the clinical application of MRI to the diagnosis of specific musculoskeletal injuries, such as evaluating cartilage damage and navicular disease in horses.[14,15]

Computed Tomography

Computed tomography (CT) has not been used much for the clinical analysis of musculoskeletal tissue. It is anticipated that continued advances in MRI technology will continue to make this the preferred anatomic technology, despite the development of CT units in Europe that can accommodate the standing horse.[16]

Nutritional History

Because the most important osteodystrophies and myopathies are nutritional in origin, a complete nutritional history must be obtained. This should include an analysis of the feed and determination of the total amount of intake of each nutrient, including the ratio of one nutrient to another in the diet.

Environment and Housing

When outbreaks of lameness occur in housed cattle, sheep, goats, and pigs, the quality of the floor must be examined to evaluate the possibility of floor-related injuries.

Diseases of Muscles

MYASTHENIA (SKELETAL MUSCLE ASTHENIA)

The differential diagnosis of paresis, paralysis, and incoordination should include a consideration of skeletal muscle weakness unrelated to primary neurogenic hypotonia or to permanent muscle injury, including myopathy and myositis. Most of the syndromes that fall into this group of myasthenia have been described in detail elsewhere in this book and are referred to briefly here only to complete the list of abnormalities of skeletal muscle that affect gait and posture. Unlike myopathy and myositis, they are reversible states.

The common causes of myasthenia in farm animals are as follows:

- **Ischemia** in iliac thrombosis in the horse and neonatal calf and after recumbency in cows with parturient paresis. The end stage is myonecrosis and is not reversible.
- **Metabolic effect on muscle fibers**—causes include hypokalemia, hypocalcemia, and possibly hypophosphatemia (in parturient paresis of dairy cows), hypomagnesemia (in lactation tetany), hypoglycemia of newborn pigs, and lactic acidemia after engorgement on grain.
- **Toxins**—general toxemia is a cause. Also, many plant toxins exert an effect on skeletal muscle activity. Although in most cases the mode of the action of the toxin is unknown (hypoglycin A is a notable exception), the toxins have been listed as neurotoxins.

MYOPATHY

The term *myopathy* describes the noninflammatory degeneration of skeletal muscle that is characterized clinically by muscle weakness and pathologically by hyaline degeneration of the muscle fibers. The serum activities of some muscle enzymes are elevated, and myoglobinuria is a common accompaniment.

ETIOLOGY AND EPIDEMIOLOGY

The most important myopathies in farm animals are a result of nutritional deficiencies of vitamin E and selenium and the effects of unaccustomed exercise. In humans, in contrast, the muscular dystrophies occur as inherited defects of muscle or degenerative lesions caused by interruption of their nerve supply. The skeletal myopathies can be classified into primary and secondary myopathies.

A retrospective analysis of the case records in a veterinary teaching hospital over a 9-year period revealed that the most common myopathy in horses was exercise-associated muscle disorder (69%). The remainder consisted of postexhaustion syndrome (9%), infectious myopathies (11%), immunologic myopathy (6%), nutritional myopathy (5%), and hyperkalemic periodic paralysis (2%).

The major causes of myopathy in farm animals and their epidemiologic determinants are as follows.

Enzootic Nutritional Muscular Dystrophy

A nutritional deficiency of vitamin E and/or selenium is a common cause of enzootic nutritional muscular dystrophy in young calves, lambs, foals, and piglets. Factors enhancing or precipitating onset include rapid growth, highly unsaturated fatty acids in the diet, and unaccustomed exercise. The disease also occurs in adult horses.

Exertional or Postexercise Rhabdomyolysis

Exertional or postexercise rhabdomyolysis is not known to be conditioned by vitamin E (selenium) deficiency and occurs as equine paralytic myoglobinuria (tying-up syndrome, azoturia) in horses after unaccustomed exercise or insufficient training. It also occurs in sheep chased by dogs, in cattle after running wildly for several minutes, and as capture myopathy during capture of wildlife.

Equine Atypical Myopathy (Seasonal Pasture Myopathy)

Equine atypical myopathy was originally referred to as *atypical myoglobinuria*, but was renamed to *atypical myopathy* to reflect the underlying pathologic process rather than a possible clinical sign. The first reports were in the United Kingdom, and following a large outbreak in northern Germany in fall 1995, the disease has now been recognized in most of Europe. A similar disease has been reported in the United States and named *seasonal pasture myopathy*. Cases have also been reported from Australia and New Zealand.

Affected horses at pasture have a sudden onset of clinical signs consistent with an acute, non–exercised-related myopathic process. The causative toxin appears to be **hypoglycin A,** which is found in the seeds of maple trees.

Equine Polysaccharide Storage Myopathy

Equine polysaccharide storage myopathy is a metabolic disease being recognized with increasing frequency in many breeds of horse. It occurs in Quarter horses, Appaloosa, and Paint-related breeds. The disease represents a group of diseases with similar clinical signs and pathology but different etiology. Some horses have a mutation in the glycogen synthase 1 (*GYS1*) gene that affects carbohydrate metabolism, including Percheron and Belgian draught horses.

Metabolic

Hyperkalemic periodic paralysis occurs in certain pedigree lines of North American show Quarter horses.

Degenerative Myopathy

Degenerative myopathy occurs in newborn calves, sheep, and goats infected by Akabane virus in utero.

Inherited Myopathies

Porcine stress syndrome, which is discussed under that heading, now includes pale, soft, exudative pork encountered at slaughter and malignant hyperthermia following halothane anesthesia. Certain blood types in pigs have been used as predictors of stress susceptibility, and malignant hyperthermia in Pietrain pigs is genetically predetermined. Most of these myopathies of pigs thus have an inherited basis, and the stress of transportation, overcrowding, and handling at slaughter precipitates the lesion and rapid death.

Congenital myopathy of Braunvieh–Brown Swiss calves is thought to be inherited. Affected calves become progressively weak and recumbent within 2 weeks of birth.

Doubling-muscling in cattle and **splay-legs of newborn pigs** are also considered to be inherited. A **dystrophy-like myopathy** in a foal has been described and is similar to human muscular dystrophy. **Dystrophy of the diaphragmatic muscles** in adult Meuse–Rhine–Yessel cattle is thought to be inherited. **Xanthosis** occurs in the skeletal and cardiac muscles of cattle and is characterized grossly by a green iridescence.

Toxic Agents

Certain myopathies are caused by poisonous plants, including *Cassia occidentalis, Karwinskia humboldtiana, Ixioloena* spp., *Geigeria* spp., and lupins. A special case is enzootic calcinosis of all tissues, especially muscle, and the principal signs are muscular. It is caused by poisoning by *Solanum malacoxylon, Tricetum* spp., and *Cestrum* spp. Another special case is equine atypical myopathy.

Ischemia

Ischemic myonecrosis occurs in the thigh muscles of cattle recumbent for approximately 48 hours or more and is discussed in detail under the heading "Downer Cow Syndrome." Iliac thrombosis in horses is an important cause of ischemic myopathy and has been reported in neonatal calves.

Neurogenic

Neurogenic muscular atrophy occurs sporadically as a result of traumatic injury and subsequent degeneration or complete severance of the nerve supply to skeletal muscle. The myopathy in arthrogryposis associated with the Akabane virus is thought to be a result of lesions of the lower motor neurons supplying the affected muscles. It has been suggested that cattle with muscular hypertrophy may be more susceptible to the effects of exercise and the occurrence of acute muscular dystrophy. Suprascapular nerve paralysis in the horse (sweeney) is a traumatic neuropathy resulting from compression of the nerve against the cranial edge of the scapula.

Neoplasms

Neoplasms of striated muscle are uncommon in animals. Rhabdomyosarcomas are reported in the horse, affecting the diaphragm and causing loss of body weight, anorexia, and respiratory distress.

PATHOGENESIS

Primary Myopathy

The characteristic change in most cases of primary myopathy varies from hyaline degeneration to coagulative necrosis, affecting particularly the heavy thigh muscles and the muscles of the diaphragm. Myocardial lesions are also commonly associated with the degeneration of skeletal muscle and when severe will cause rapid death within a few hours or days. The visible effects of the lesions are varying degrees of muscle weakness, muscle pain, recumbency, stiff gait, inability to move the limbs, and the development of respiratory and circulatory insufficiency.

In primary nutritional muscular dystrophy associated with a deficiency of vitamin E and/or selenium there is lipoperoxidation of the cellular membranes of muscle fibers, resulting in degeneration and necrosis. The lesion is present only in muscle fibers, and the histologic and biochemical changes that occur in the muscle are remarkably similar irrespective of the cause. Variations in the histologic lesion occur but indicate variation in the severity and rapidity of onset of the change rather than different causes.

Myoglobinuria

Because of the necrosis of muscle, myoglobin is excreted in the urine, and **myoglobinuric nephrosis** is an important complication, particularly of acute primary myopathy. The degree of myoglobinuria depends on the severity of the lesion, with acute cases resulting in marked myoglobinuria, and on the age and species of animal affected. Adult horses with myopathy may liberate large quantities of myoglobin, resulting in dark-brown urine. Yearling cattle with myopathy release moderate amounts, and the urine may or may not be colored; calves with severe enzootic nutritional muscular dystrophy may have grossly normal urine. In all species the renal threshold of myoglobin is so low that discoloration of the serum does not occur.

Muscle Enzymes

An important biochemical manifestation of myopathy is the increased release of muscle cell enzymes that occurs during muscle cell destruction. Creatine kinase (CK) and serum glutamic oxaloacetate transaminase are both elevated in myopathy; CK, particularly, is a more specific and reliable indication of acute muscle damage. Increased amounts of creatinine are also released into the urine following myopathy.

Exertional Rhabdomyolysis

In exertional rhabdomyolysis in horses there is enhanced glycolysis with depletion of muscle glycogen, the accumulation of large amounts of lactate in muscle and blood, and the development of hyaline degeneration of myofibers. Affected muscle fibers are richer in glycogen in the acute stage of "tying-up" than in the late stages, suggesting increased glycogen storage in the early phase of the disease compared with normal healthy horses. During enforced exercise there is local muscle hypoxia and anaerobic oxidation, resulting in the accumulation of lactate and myofibrillar degeneration. The pathogenesis of postanesthetic myositis in horses is uncertain. A significant postischemic hyperemia occurs in horses that develop postanesthetic myopathy. Postanesthetic recumbency can occur in the horse with polysaccharide storage myopathy.

Types of Muscle Fiber Affected

In most animals, skeletal muscle is composed of a mixture of fibers with different contractile and metabolic characteristics. Fibers with slow contraction times have been called slow-twitch or type I fibers, and those with fast contraction time are fast-twitch or type II fibers. Histochemically, type I and II fibers can be differentiated by staining for myofibrillar ATPase. Type II fibers can be subgrouped into type IIA and IIB on the basis of acid preincubations. Several different characteristics of these muscle fibers have been studied in the horse. There are variations in the percentage of each type of fiber present and in composition of muscle fibers dependent on genetic background, age, and stage of training. There are also variations in the muscle fibers within one muscle and between different muscles. The histochemical characteristics of equine muscle fibers have been examined:

- Type I fibers are characterized by strong aerobic capacity, compared with type IIA.
- Type IIA fibers are more glycolytic and have strong aerobic and moderate to strong anaerobic capacities.
- Type IIB fibers are characterized by a relatively low aerobic and a relatively high anaerobic capacity and are glycolytic.

The histochemical staining characteristics of normal equine skeletal muscle have been examined and serve as a standard for comparison with data obtained from skeletal muscles with lesions.

Secondary Myopathy Resulting From Ischemia

In secondary myopathy resulting from ischemia there may be multiple focal areas of necrosis, which causes muscle weakness and results in an increase of muscle enzymes in the serum. The degree of regeneration with myofibers depends on the severity of the lesion. Some regeneration occurs, but there is considerable tissue replacement. In aortic and iliac thrombosis in calves under 6 months of age the thrombosis results in acute to chronic segmental necrosis of some skeletal muscles and coagulation necrosis in others.

Neurogenic Atrophy of Muscle

In neurogenic atrophy there is flaccid paralysis, a marked decrease in total muscle mass, and degeneration of myofibers, with failure to regenerate unless the nerve supply is at least partially restored.

CLINICAL FINDINGS

The nutritional myopathies associated with a deficiency of vitamin E and/or selenium occur most commonly in young, rapidly growing animals and may occur in outbreak form, particularly in calves and lambs. The details are presented under the heading "Vitamin E and Selenium Deficiency."

Primary Myopathy

In general terms, in acute primary myopathy there is a sudden onset of weakness and pseudoparalysis of the affected muscles, causing paresis and recumbency and, in many cases, accompanying respiratory and circulatory insufficiency. The affected animals will usually remain bright and alert but may appear to be in pain. The temperature is usually normal but may be slightly elevated in severe cases of primary myopathy. Cardiac irregularity and tachycardia may be evident, and myoglobinuria occurs in adult horses and yearling cattle. The affected skeletal muscles in acute cases may feel swollen, hard, and rubbery, but in most cases it is difficult to detect significant abnormality by palpation. Animals with acute cases of primary myopathy may die within 24 hours after the onset of signs.

Acute Nutritional Myopathy

Although acute nutritional myopathy in horses occurs most commonly in foals from birth to 7 months of age, acute dystrophic myodegeneration also occurs in adult horses. There is muscle stiffness and pain, myoglobinuria, edema of the head and neck, recumbency, and death in a few days. A special occurrence of myopathy has been recorded in suckling Thoroughbred foals up to 5 months of age. The disease occurs in the spring and summer in foals running at pasture with their dams and is unassociated with excessive exercise. In peracute cases there is a sudden onset of dejection, stiffness, disinclination to move, and prostration, with death occurring 3 to 7 days later. Lethargy and stiffness of gait are characteristic of less acute cases. There is also a pronounced swelling and firmness of the subcutaneous tissue at the base of the mane and over the gluteal muscles. There may be excessive salivation, desquamation of lingual epithelium, and board-like firmness of the masseter muscles. The foals are unable to suck because of inability to bend their necks. Spontaneous recovery occurs in mild cases, but most severely affected foals die.

Severe nutritional myopathy of the masseter muscles in a 6-year-old Quarter horse stallion has been reported. The masseter muscles were swollen and painful, and there was exophthalmos and severe chemosis with protrusion of the third eyelids. The mouth could be opened only slightly, and masticatory efforts were weak. Serum enzymology supported a diagnosis of nutritional muscular dystrophy, and the concentrations of vitamin E and selenium in the blood and feed were lower than normal.

Tying-Up

In tying-up in horses there is a very sudden onset of muscle soreness 10 to 20 minutes following exercise. There is profuse sweating and the degree of soreness varies from mild, in which the horse moves with a short, shuffling gait, to acute, in which there is a great disinclination to move at all. In severe cases, horses are unable to move their hindlegs, and swelling and rigidity of the croup muscles develops. Myoglobinuria is common.

Postanesthetic Myositis

Horses with postanesthetic myositis experience considerable difficulty during recovery from anesthesia. Recovery is prolonged, and when initial attempts are made to stand, there is lumbar rigidity, pain, and reluctance to bear weight. Some affected horses will be able to stand within several hours if supported in a sling. The limbs may be rigid and the muscles firm on palpation. In severe cases the temperature begins to rise—reminiscent of malignant hyperthermia. Other clinical findings include anxiety, tachycardia, profuse sweating, myoglobinuria, and tachypnea. Death may occur in 6 to 12 hours. Euthanasia is the only course for some horses. In the milder form of the syndrome, affected horses are able to stand but are stiff and in severe pain for a few days.

Exertional Rhabdomyolysis

In horses, the clinical findings are **variable** and range from poor performance to recumbency and death. Signs may be mild and resolve spontaneously within 24 hours or severe and progressive.

The **usual presentation** is a young (2- to 5-year-old) female racehorse with recurrent episodes of stiff gait after exercise. The horse does not perform to expectation and displays a **short-stepping gait** that may be mistaken for lower leg lameness. The horse may be reluctant to move when placed in its stall, be apprehensive and anorexic, and frequently shift its weight. More severely affected horses may be unable to continue to exercise, have **hard and painful muscles** (usually gluteal muscles), sweat excessively, be apprehensive, refuse to walk, and be tachycardic and tachypneic. Affected horses may be hyperthermic. Signs consistent with abdominal pain are present in many severely affected horses. Deep-red urine (myoglobinuria) occurs but is not a consistent finding. Severely affected horses may be recumbent and unable to rise.

Many different manifestations of equine polysaccharide storage myopathy occur. All manifestations are related to dysfunction, which results in pain, weakness, segmental fiber necrosis, stiffness, spasm, atrophy, or any combination of these. The muscles most severely affected are the powerful rump, thigh, and back muscles, including the gluteals, semimembranosus, semitendinosus, and longissimus.

In exertional rhabdomyolysis in sheep chased by dogs, affected animals are recumbent, cannot stand, and appear exhausted, and myoglobinuria is common. Death usually follows. A similar clinical picture occurs in cattle that have run wildly for several minutes.

Hyperkalemic Periodic Paralysis

Initially there is a brief period of myotonia with prolapse of the third eyelid. In severe cases, the horse becomes recumbent and the myotonia is replaced by flaccidity. Sweating occurs, and generalized muscle fasciculations are apparent, with large groups of muscle fibers contracting simultaneously at random. The animal remains bright and alert and responds to noise and painful stimuli. In milder cases, affected horses remain standing, and generalized muscle fasciculations are prominent over the neck, shoulder, and flank. There is a tendency to stand base-wide. When the horse is asked to move, the limbs may buckle, and the animal appears weak. The horse is unable to lift its head, usually will not eat, and may yawn repeatedly early in the course of an episode. The serum potassium levels are elevated above normal during the episodes.

Secondary Myopathy Resulting From Ischemia

In secondary myopathy resulting from ischemia (e.g., downer cow syndrome), the affected animal is unable to rise, and the affected hindlegs are commonly directed behind the cow in the frogleg attitude. The appetite and mental attitude are usually normal. No abnormality of the muscles can be palpated. With supportive therapy, good bedding, and the prevention of further ischemia by frequent rolling of the animal, most cows will recover in a few days.

In calves with aortic and iliac artery thrombosis there is an acute onset of paresis or flaccid paralysis of one or both pelvic limbs. Affected limbs are hypothermic and have diminished spinal reflexes and arterial pulse pressures. The diagnosis can be defined using angiography. Affected calves die or are euthanized because treatment is not undertaken.

Neurogenic Atrophy

With neurogenic atrophy there is marked loss of total mass of muscle, flaccid paralysis, loss of tendon reflexes, and failure of regeneration. When large muscle masses are affected (e.g., quadriceps femoris in femoral nerve paralysis in calves at birth), the animal is unable to bear normal weight on the affected leg.

Dystrophy of the Diaphragmatic Muscles

In dystrophy of the diaphragmatic muscles in adult Meuse–Rhine–Yessel cattle there is loss of appetite, decreased rumination, decreased eructation, and recurrent bloat. The respiratory rate is increased, with forced abdominal respirations, forced movement of the nostrils, and death from asphyxia in a few weeks.

Severe diaphragmatic necrosis in a horse with degenerative myopathy as a result of polysaccharide storage myopathy has been described. Affected horses may have severe respiratory distress and respiratory acidosis, and they do not respond to supportive therapy.

DIAGNOSIS

Muscle-Derived Serum Enzymes

The serum activity of the muscle enzymes is characteristically elevated following myopathy as a result of release of the enzymes from altered muscle cell membranes. CK is a highly specific indicator of both myocardial and skeletal muscle degeneration. Plasma CK activity is related to three factors: the amount and rate of CK released from an injured muscle into plasma, its volume of distribution, and its rate of elimination. CK has a half-life of about 4 to 6 hours; following an initial episode of acute myopathy, serum activity of the enzyme may return to normal within 3 to 4 days if no further muscle degeneration has occurred. Levels of AST are also increased following myopathy; however, because the enzyme is present in other tissues, such as the liver, it is not a reliable indicator of primary muscle tissue degeneration.

Because AST has a longer half-life than CK, the levels of AST may remain elevated for several days following acute myopathy. The daily monitoring of both CK and AST levels should provide an indication of whether active muscle degeneration is occurring. A marked drop in serum CK activity and a slow decline in serum AST activity suggest that no further degeneration is occurring, whereas a constant elevation of CK suggests active degeneration.

In acute nutritional muscular dystrophy in calves, lambs, and foals the serum CK activity will increase from normal values of below 100 IU/L to levels ranging from 1,000 to 5,000 IU/L and even higher. The levels of CK in calves will increase from a normal of 50 IU/L to approximately 5,000 IU/L within a few days after being placed outdoors followed by unconditioned exercise. The amount of skeletal muscle damaged can be estimated based on the change in the amount of CK activity over time (specifically, the area under the serum CK activity–time relationship) and species-specific pharmacokinetic values related to CK clearance.[1]

The measurement of serum activity of glutathione peroxidase is a useful aid in the diagnosis of myopathy as a result of selenium deficiency.

In downer cows with ischemic necrosis of the thigh muscles, the serum CK and AST activities will be markedly elevated and will remain elevated if muscle necrosis is progressive in cows that are not well bedded and rolled from side to side several times daily to minimize the degree and extent of ischemic necrosis.

High serum activities of CK (1000 IU/L and greater) usually indicate acute primary myopathy. Levels from 500 to 1000 IU/L may be difficult to interpret in animals recumbent for reasons other than primary myopathy. This will necessitate a careful reassessment of the clinical findings, history, and epidemiology.

In horses with acute exertional rhabdomyolysis (paralytic myoglobinuria) the serum CK activity will range from 5000 to 10,000 IU/L. Following vigorous exercise in unconditioned horses, the serum CK and AST activity will rise as a result of increased cell membrane permeability associated with the hypoxia of muscles subjected to excessive exercise. Lactate dehydrogenase (LDH) activity has also been used as a biochemical measurement of the degree of physical work done by horses in training. With progressive training in previously unconditioned horses there is no significant change between rest and exercise in the serum CK, AST, and LDH activities. In horses with postanesthetic myositis the serum CK activity may exceed 100,000 IU/L, the serum calcium is decreased, and the serum inorganic phosphorus is increased. In naturally occurring cases of exertional rhabdomyolysis in horses the most consistent acid–base abnormality may be hypochloremia rather than metabolic acidosis as has been assumed.

Muscle Biopsy

Investigation of the structural and biochemical alterations of muscle tissue in myopathy include biopsy techniques. Needle biopsies require specialized Bergstrom muscle biopsy needles, which are expensive, and most practitioners do not have them on hand. Open biopsy is recommended to obtain a strip of muscle. Biopsy of either the semimembranosus or semitendinosus muscles, at a site between the base of the tail and the tuber ischium, provides an adequate sample. Muscle biopsy samples can be processed for either frozen section or routine formalin-fixed, paraffin-embedded sections. The frozen section is considered the gold standard.

Inclusions of periodic acid–Schiff (PAS)-positive, amylase-resistant complex polysaccharide are abnormal and characteristic findings in muscle of equine polysaccharide storage myopathy.

Histochemical techniques can be used on muscle biopsies of horses with muscular disease and animals with congenital and inherited myopathies.

Myoglobinuria

Myoglobinuria is a common finding in adult horses with acute paralytic myoglobinuria but is not a common finding in acute nutritional muscular dystrophy in young farm animals, except perhaps in yearling cattle with acute muscular dystrophy. The myoglobinuria may be clinically detectable as a red-brown or chocolate-brown discoloration of the urine. This discoloration can be differentiated from that caused by hemoglobin by spectrographic examination or with the use of orthotoluidine paper strips. Urine becomes dark when myoglobin levels exceed 40 mg/dL of urine. Discoloration of the plasma suggests hemoglobinuria. Both myoglobin and hemoglobin give positive results for the presence of protein in urine. Porphyria causes a similar discoloration, although this may not be evident until the urine has been exposed to light for some minutes. The coloration is lighter, pink to red rather than brown, and the urine is negative to the guaiac test and fluoresces with ultraviolet light. Creatinuria accompanies acute myopathy but has not been used routinely as a diagnostic aid.

Electromyography is a special technique for the evaluation of the degree of neurogenic atrophy.

NECROPSY FINDINGS

Affected areas of skeletal muscle have a white, waxy, swollen appearance like fish flesh. Commonly only linear strips of large muscle masses are affected, and the distribution of lesions is characteristically bilaterally symmetric. Histologically, the lesion varies from a hyaline degeneration to a severe myonecrosis, with subsequently the disappearance of large groups of muscle fibers and replacement by connective tissue. Calcification of the affected tissue may be present to a mild degree in these cases.

The lesions in exertional rhabdomyolysis in the horse are of a focal distribution and consist of hyaline degeneration with insignificant inflammatory reaction and slight calcification. The degenerative changes affect primarily the fast-twitch fibers, which have a low oxidative capacity and are used when the horse runs at very close to its maximum speed.

DIFFERENTIAL DIAGNOSIS

Most myopathies in farm animals occur in rapidly growing, young animals and are characterized clinically by a sudden onset of acute muscular weakness and pain, often precipitated by unaccustomed exercise. There may be evidence of a dietary deficiency of vitamin and selenium in the case of nutritional muscular dystrophy. A sudden onset of recumbency or stiffness in young farm animals that are bright and alert should arouse suspicion of acute muscular dystrophy. Primary myopathies are not common in adult cattle, sheep, or pigs, but myopathy secondary to recumbency for other reasons does occur.

Secondary myopathy as a result of aortic and iliac thrombosis in calves must be differentiated from other common causes of hindlimb paresis, including traumatic injury to the spinal cord, spinal cord compression as a result of vertebral body abscess, nutritional muscular dystrophy, myositis and nerve damage as a result of trauma of intramuscular injections, and clostridial myositis.

The exertional myopathies in the horse in training are usually readily obvious. Creatine kinase (CK) is a valuable aid to diagnosis. In special circumstances, such as neurogenic myopathy, muscle biopsy and electromyography may be useful additional diagnostic aids. The histologic and histochemical staining characteristics of equine muscle have been described and serve as a standard for comparison with abnormal muscle.

Myositis may present a similar syndrome but is usually present as a secondary lesion in a clinically distinguishable primary disease or is accompanied by obvious trauma or toxemia.

TREATMENT

Vitamin E and selenium are indicated for the treatment of nutritional muscular dystrophy, and the details are provided under that heading. The treatment of exertional rhabdomyolysis in horses has not been well defined because of the uncertain etiology, but enforced rest and the relief of pain, if necessary, seem logical. Supportive therapy for any case of myopathy, particularly severe cases in which there is persistent recumbency, consists of the following:

- Liberal quantities of thick bedding, such as at least 6″ (15 cm) of straw hay
- Removal from solid floors to softer ground
- Frequent turning from side to side to minimize secondary myopathy
- Provision of fluid therapy to prevent myoglobinuric nephrosis
- A palatable, nutritious diet

With the exception of the sporadically occurring congenital and inherited myopathies of farm animals, all the nutritional and exertional myopathies are amenable to treatment if it is begun early and if adequate supportive therapy is provided.

In myopathies associated with systemic acidosis, the use of a solution of sodium bicarbonate may be indicated. Dietary sodium bicarbonate at the rate of 2% of total dry matter intake has been used for the treatment of exertional rhabdomyolysis in a horse. Horses with postanesthetic myositis must be considered as critical care patients for 18 to 24 hours. Maintenance of adequate renal perfusion is vital. Large quantities of intravenous polyionic balanced electrolyte fluids (50 to 100 L) must be given over a 24-hour period. Dantrolene sodium at 4 mg/kg body weight (BW) given orally immediately upon recognition of clinical signs is efficacious.

CONTROL

The nutritional myopathies in farm animals can be satisfactorily prevented by the provision of adequate quantities of dietary vitamin E and selenium in the maternal diet during pregnancy or at the strategic times in postnatal life. The prevention of exertional myopathy in the horse depends on a progressive training program and avoidance of sudden unaccustomed exercise in animals that are in good body condition and have been inactive. Similarly, in general terms, the prevention of porcine stress syndrome will depend on careful handling and transportation techniques combined with genetic selection of resistant pigs.

MYOPATHY OF HORSES

Diseases of the muscles of horses include conditions that induce rhabdomyolysis (literally, dissolution or liquefaction of muscle) and, less commonly, conditions in which function of the muscle is impaired but there is not rhabdomyolysis. Rhabdomyolysis is characterized biochemically by marked

increases in the activity in serum of muscle-derived enzymes, such as creatine kinase (CK) and aspartate aminotransferase (AST). The diagnosis of rhabdomyolysis presents no great challenge, but determining the underlying disease condition usually requires a more sophisticated approach than just measuring CK and AST activity in serum.

ETIOLOGY

Horses are affected by a number of diseases of muscle (Table 15-2), and diagnosis of the particular disease based solely on clinical signs might not be possible because of the limited range of manifestations of muscle disease. A useful differentiator is whether development of clinical signs is associated only with exercise or also occurs at rest. Classical exercise-induced rhabdomyolysis presents as signs of muscle disease during or soon after the completion of exercise, whereas signs of some inherited defects or intoxications are evident without the stimulus of exercise. Other muscle diseases can be apparent at rest and are exacerbated by exercise.

Myopathies of equids can be grouped according to their etiopathogenesis:

- **Genetic anomalies**—polysaccharide storage myopathy (type I), malignant hyperthermia, glycogen branching enzyme deficiency, hyperkalemic periodic paralysis, recurrent exertional rhabdomyolysis of Thoroughbreds (suspect), mitochondrial myopathy (specific genetic anomaly not identified), and myotonia in foals. More will be discovered with advent of access to the equine genome and ready access to advanced molecular technologies
- **Environmental or management—** unaccustomed exercise, heat stress or stroke, inconsistent exercise
- **Nutritional—**vitamin E/selenium deficiency (white-muscle disease, masseter myonecrosis), diet high in nonstructural (soluble) carbohydrates
- **Intoxications**—ingestion of hypoglycin A in *Acer negundo* or *Acer pseudoplantanus* seeds, inophores (monensin, salinomycin), tremetone (white snake root, rayless goldenrod [*Isocoma pluriflor*]), or *Cassia occidentalis,* or snake bite (*Notechis scutatus* and likely other elapid and crotalid snakes)
- **Infectious**—localized infections (clostridial myositis), *Streptococcus equi* myositis, *Salmonella* spp. myositis, associated with *Anaplasma phagocytophila* infection
- **Inflammatory or infarctive**—as part of purpura hemorrhagica (infarctive) or immune myositis (inflammatory)
- **Metabolic**—sarcopenia with pituitary pars intermedia dysfunction
- **Unknown**—sporadic exercise-induced rhabdomyolysis, recurrent exercise-induced rhabdomyolysis, polysaccharide storage myopathy type II

PATHOGENESIS

Exercise-induced rhabdomyolysis occurs because of abnormal responses of the muscle to contractions during exercise. Although the exact pathogenesis of exercise-induced muscle damage has not been demonstrated in horses, it likely involves accumulation of normal metabolites to excessive levels in all or part of the cell, formation of abnormal metabolites, or inadequate provision of energy to maintain homeostasis of myocytes during sustained or repetitive contractions. The critical common event is likely accumulation of calcium in the cytosol as a consequence of damage to the sarcolemma and sarcoplasmic reticulum and impaired function of calcium channels and pumps. Reduction of the cytosolic calcium concentration is achieved by the sarcoplasmic reticulum calcium-ATPase pump and calcium transport across the sarcolemma by the Na^+/K^+ pump and the Ca^+/Na^+ exchanger. Abnormal cytosolic calcium concentrations result in activation of intracellular proteases and other enzymes, leading to damage to cell constituents, including the cell membrane, with subsequent leakage of cell contents into interstitial fluid and blood. This is evident clinically as increases in activity in blood (serum, plasma) of muscle-derived enzymes (CK, AST, lactate dehydrogenase [LDH]) and concentration of myoglobin in blood and urine.

DIAGNOSIS

Diagnosis of muscle diseases of horses is made using combinations of history and clinical signs, hematologic or biochemical examination of blood or urine, electromyography, exercise challenge tests, muscle biopsy, and genetic testing.

Clinical signs common to most muscle disease are varying degrees of exercise intolerance, gait abnormalities characterized by short strides or a stilted gait, pain on palpation of affected muscles, muscle fasciculation, myoglobinuria, and muscle atrophy. Not all signs are present in every disease of muscle, and horses can be clinically normal between episodes. Clinical signs of particular diseases are discussed under those topics elsewhere in this text.

There are no changes in routine hematology that are characteristic of all diseases of muscle or are discriminatory among muscle diseases. Most muscle diseases are associated with elevations in serum activity of **muscle-derived enzymes** (CK, AST, LDH). The most commonly measured enzymes are CK and AST. Serum concentrations of CK increase within minutes to hours of injury to the muscle and decline to baseline concentrations within 1 to 2 days of muscle cell membranes regaining their integrity. CK has an elimination half-life of approximately 2 hours in the plasma of horses, which accounts for the rapid reduction in activity in serum. Conversely, AST has a longer elimination half-life, and activity both increases and declines more slowly than that of CK. Horses with injury to muscle that resolved several days previously can therefore have normal activity of CK and elevated activity of AST in serum.

Plasma concentrations of **vitamin E and selenium**, or red cell glutathione peroxidase activity, are usually within the reference interval for healthy animals, with the exception of foals with white-muscle disease and adults with masseter myonecrosis.

Urinalysis of samples collected during the active phase of the disease can contain myoglobin. **Myoglobinuria** should be distinguished from hematuria (by centrifugation of the sample) or hemoglobinuria (by measurement of hemoglobin or myoglobin concentrations). Myoglobinuria kidney injury can cause the presence of granular casts in urine sediment. Urine and serum collected when the horse does not have clinical signs of muscle disease have been proposed to be useful in detecting abnormalities in body content of sodium, potassium, chloride, calcium, and phosphate. Calculation of **fractional excretion of electrolytes** have limited, if any, utility in the diagnosis of causes of exertional rhabdomyolysis.

Muscle biopsy is useful in providing a histologic diagnosis and is diagnostic in a number of diseases of muscle of horses. For muscle biopsy to be useful, the disease being considered must affect the muscle biopsied, the sample should be collected and transported to the laboratory in way that ensures that it is diagnostic, and the sample should be processed and examined in a laboratory accustomed to handling muscle biopsies. Open biopsies, as opposed to collection using a Bergstrom needle, are preferred for clinical samples.

Genetic testing is available for several diseases, and more tests will become available with advances in the field. Demonstration of mutations documented to cause muscle disease in a horse with compatible clinical signs can be considered diagnostic of the disease.

Additional testing can include imaging (ultrasonographic examination, scintigraphy), exercise testing, electromyography, analysis of targeted compounds in body fluids (e.g., methylenecyclopropyl acetic acid in horses with suspect hypoglycin A intoxication), and necropsy.

A rational diagnostic approach combining clinical signs, historical information, genetic testing, and muscle biopsy has been described (Fig. 15-1).[1]

TREATMENT

Treatment should be directed at the underlying disease, and specifics are provided under each disease topic.

Table 15-2 Common or well-characterized myopathies of equids*

Disease	Etiology	Risk factors	Clinical signs	Diagnosis	Treatment	Control
Exertional myopathy						
Sporadic exertional rhabdomyolysis	Unknown.	Unaccustomed exercise, heat stress or stroke, electrolyte imbalances.	Signs of acute rhabdomyolysis (see text).	Elevated serum activity of muscle-derived enzymes.	Supportive. Pain relief. Ensure adequate hydration.	Avoid known risk factors.
Recurrent exertional rhabdomyolysis (RER)	Idiopathic, presumed inherited in Thoroughbreds and Standardbreds.	Breed and diet in some instances.	Recurrent episodes of acute rhabdomyolysis.	Elevated serum activity of muscle-derived enzymes. Genetic testing. Muscle biopsy.	Supportive during acute episodes.	High-fat diet—for RER in Thoroughbreds and other light horse breeds. Dietary modification for PSSM (see following entry). Regular and consistent exercise. Turn out to pasture. Dantrolene (1–3 mg/kg PO q24h).
Polysaccharide storage myopathy type I (PSSM1)	Mutation in glycogen synthase gene (GYS1) leading to higher activity of glycogen synthase in muscle.	Quarter horse and related breeds, draft breeds (Belgians and Percherons), particularly in Europe, and Warmbloods. Many breeds affected. Intermittent exercise.	Exertional rhabdomyolysis (clinical or subclinical). Stiff gait, myalgia, and exercise intolerance. Some horses with histologic lesions are clinically normal. Homozygotes more severely affected than heterozygotes.	Genetic testing. Muscle biopsy.	Supportive.	Dietary control. High-fat, high-fiber diet with low content of soluble nonstructural carbohydrates. Regular, consistent exercise.
Polysaccharide storage myopathy type II (PSSM2)	No demonstrated abnormality in GSY1 gene or glycogen synthase activity. Unknown cause.	Disease documented in many breeds.	Exertional rhabdomyolysis (clinical or subclinical). Stiff gait, myalgia and exercise intolerance. Some horses with histologic lesions are clinically normal.	Examination of muscle biopsy. Rule out PSSM1 by genetic testing.	Supportive.	Dietary control. High fat, high fiber diet with low content of soluble nonstructural carbohydrates. Regular, consistent exercise.
Muscle sprains	Associated with exercise.	Exercise.	Localized muscle pain, stiff gait, ultrasonographic or scintigraphic abnormalities.	Clinical signs, response to treatment, results of imaging. Muscle-derived enzymes minimally elevated.	Rest. Nonsteroidal antiinflammatory drugs.	Prudent exercise and training schedules.
Mitochondrial myopathy	Deficiency of Complex I enzymes in respiratory chain of mitochondria. Other causes likely to be identified.	Exercise. Arabian breed.	*No rhabdomyolysis.* Severe exercise intolerance with signs of discomfort (sweating, short-strided gait).	Muscle-derived enzymes in serum not elevated. Accumulation of lactate out of proportion to exercise intensity or duration. Electron microscopy of muscle tissue.	Rest.	None. Consider wisdom of breeding affected horses.
Nonexertional myopathy						
Glycogen-branching enzyme deficiency	Fatal autosomal recessive mutation of glycogen branching enzyme (GBE1).	Foals of Quarter horse and related breeds.	Abortion and stillbirth. Neonates are hypoglycemic, weak, recumbent; die soon after birth.	Hypoglycemia. Minimal elevations in muscle derived enzymes. Accumulation of abnormal polysaccharide in muscle.	None.	Breeding programs.

Continued

Table 15-2 Common or well-characterized myopathies of equids*—cont'd

Disease	Etiology	Risk factors	Clinical signs	Diagnosis	Treatment	Control
Malignant hyperthermia	Heterozygous, nonsynonymous polymorphism attributable to mutation in RyR1 gene (ryanodine receptor 1).	Quarter horse breed. Anesthesia.	Clinically normal until anesthetized, then hyperthermia, tachycardia, arrhythmias, rhabdomyolysis, and death.	Clinical signs. Elevated serum creatine kinase activity (but not in peracute cases). Detection of mutation by genetic analysis.	Supportive.	Detection of genetic abnormality before anesthesia.
Hyperkalemic periodic paralysis	Autosomal-dominant trait attributable to missense mutation in sodium channel gene (SCN4A).	Quarter horse or related breed. Familial and congenital.	Asymptomatic through episodic disease with occasional death. Muscle fasciculation and tremor. Episodic collapse with myotonia, prolapse of third eyelid, sweating, recumbency.	Measurement of serum potassium concentration (elevated) during episode. Genetic analysis.	Measure to reduce serum potassium concentration (dextrose, fluids, insulin).	Acetazolamide. Low-potassium diet. Prudent breeding program.
Myotonia	Hereditary. Genetic basis has not been identified.	Quarter horse, Thoroughbred, Anglo-Arabian foals.	Disease evident in foals. Generalized muscle stiffness. Dimpling of muscle on pressure (percussion). Weakness.	Classic electromyography of myotonic discharges (dive bomber).	None.	Prudent breeding programs.
Purpura hemorrhagica myopathy	Purpura hemorrhagica. Infarction of muscles.	As for purpura hemorrhagica.	Usually 2–4 weeks after respiratory infection. Acute-onset muscle pain, swelling, abnormal gait, plus signs of purpura hemorrhagica. High case-fatality rate.	Clinical signs. Increased serum activity of muscle-derived enzymes. Muscle biopsy.	Treatment of purpura hemorrhagica. Supportive. Pain relief.	Prevention of respiratory disease.
Immune myositis	Idiopathic.	More common in Quarter horses, but can affect any breed.	Severe muscle atrophy. No rhabdomyolysis at time of detection of atrophy.	Muscle biopsy—histiocytic lymphocytic myositis.	Administration of corticosteroids. Expect full recovery with or without treatment.	None.
Streptococcal myositis	Infection by *Streptococcus equi.*	Risk factors for infection by *S. equi*.	Acute- to peracute-onset myalgia, stiff gait, swelling and pitting edema of epaxial muscles.	Demonstration of muscle disease and rhabdomyolysis with *S. equi* infection.	Aggressive support care, antibiotic administration, NSAIDs.	Prevention of infection by *S. equi.*
Clostridia myositis	Infection by *Clostridium septicum* or other clostridia.	Trauma, intramuscular injections.	Acute-onset fever, tachycardia, localized pain over previous injection site or site of trauma.	Demonstration of clostridia in wound fluids.	Aggressive supportive care, administration of antimicrobials that block protein synthesis (tetracycline).	First aid of wounds, use of hygienic injection technique.
Masseter myonecrosis	Likely selenium deficiency. Role for vitamin E unclear.	Horses on selenium-deficient diet.	Swelling and pain of masseter muscles, trismus; some horses have stilted gait and evidence of myocardial disease.	Clinical signs. Ultrasonographic examination of muscle and heart. Measurement of serum selenium concentration or red cell glutathione peroxidase activity.	Support. Administration of selenium with or without vitamin E	Ensure diet contains adequate selenium.

Table 15-2 Common or well-characterized myopathies of equids*—cont'd

Disease	Etiology	Risk factors	Clinical signs	Diagnosis	Treatment	Control
White-muscle disease	Selenium deficiency.	Foals in regions with low selenium in fodder.	Acute-onset weakness, stiff gait, recumbency, myoglobinuria.	Measurement of serum selenium concentration or red cell glutathione peroxidase activity. Increase serum activity of muscle-derived enzymes.	Supportive. Administration of selenium with or without vitamin E.	Ensure adequate selenium status of mares and foals.
Atypical, pasture-associated myopathy	Ingestion of hypoglycin A in seeds of maple trees, *Acer negundo* (USA) or *Acer pseudoplantanus* (Europe).	Access to seeds of *A. negundo* or *A. pseudoplantanus,* usually by horses at pasture.	Acute onset of weakness, muscle fasciculations, myoglobinuria, recumbency, and death.	Increased concentrations of methylenecyclopropyl acetic acid in serum of affected horses.	Supportive.	Avoid exposure to seeds of *A. negundo* or *A. pseudoplantanu.*
Tremetone toxicosis	Rayless goldenrod (*Isocoma pluriflora*), white snakeroot.	Ingestion of plant.	Weakness, muscle fasciculation, tachycardia, arrhythmia, death over 5–7 days.	Increased serum CK and AST activity and troponin-I concentration. Necropsy with degeneration of myocardium and skeletal muscle.	Supportive.	Prevent access to the plants.
Envenomation by snakes	Documented as a consequence of envenomation by Australian tiger snake (*Notechis scutatus*).	Exposure to habitat of snakes.	Acute-onset anxiety, weakness, muscle fasciculations, myoglobinuria, death.	Demonstration of toxin in blood, body tissue, fluids, or urine. Elevated serum activity of muscle-derived enzymes.	Antivenom. Supportive care.	Avoid exposure to snakes.
Ionophore intoxication	Ingestion of ionophores such as salinomycin, monensin, lasalocid, maduramicin, or narasin.	None.	Anorexia, weakness, stiff gait, colic, recumbency, tachycardia, sudden death, myoglobinuria.	Historical exposure. Necropsy. Detection of ionophore in stomach contents.	Supportive. No specific antidote.	Ensure that horses do not have access to feed containing ionophores.
Fibrotic myopathy	Injury to hamstring muscles (semimembranosus and others).	Exercise. Congenital forms exist.	Foot-slapping gait. Firmness on palpation of hamstring region. Not painful. No response of gait to analgesics.	Differentiate from stringhalt. Palpation of affected muscles. Ultrasound examination.	Surgery.	None.

**Not all myopathies are associated with rhabdomyolysis, and some are evident at rest. Details of each disease can be found under that topic.*
AST, aspartate aminotransferase; CK, creatine kinase; NSAIDs, nonsteroidal antiinflammatory drugs.

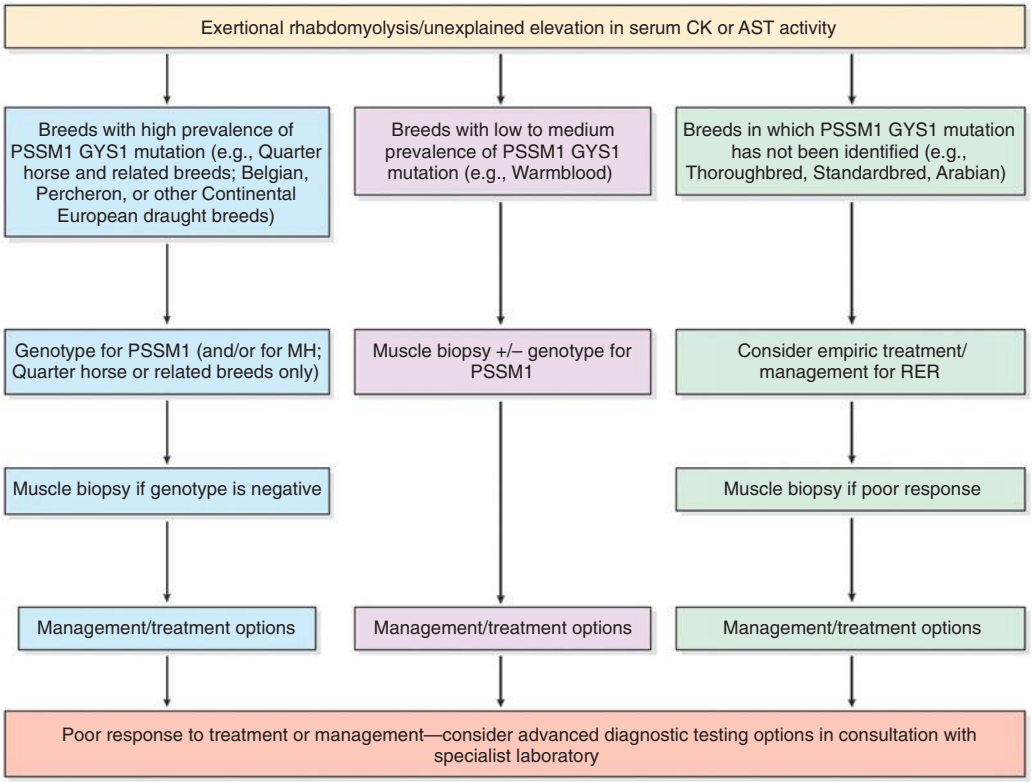

Fig. 15-1 Diagnostic approach to horses with exertional myopathy or persistent increases in serum activity of creatine kinase and aspartate aminotransferase. The approach differs depending on the breed of horse (and hence pretest probability of disease and documented genetic abnormalities). MH, malignant hyperthermia; RER, recurrent exertional rhabdomyolysis (Reproduced with permission from Piercy RJ and Rivero J. Muscle disorders of equine athletes. In Hinchcliff KW, Kaneps AJ, and Geor RJ (eds): Equine Sports Medicine and Surgery: Basic and clinical sciences of the equine athlete, 2nd edition. W.B. Saunders. London. 2014:109.)

There are some general principles and treatments for management of acute rhabdomyolysis regardless of its underlying cause. The treatment chosen depends on the severity of the disease. The **general principles** are rest; correction of dehydration and electrolyte abnormalities; prevention of complications, including nephrosis and laminitis; and provision of analgesia.

Mildly affected horses (heart rate < 60 bpm, normal rectal temperature and respiratory rate, no dehydration) can be treated with rest and phenylbutazone (2.2 mg/kg, orally or intravenously [IV] every 12 hours for 2 to 4 days). Horses should be given mild exercise with incremental increases in workload as soon as they no longer have signs of muscle pain. Access to water should be unrestricted.

Severely affected horses (heart rate > 60 bpm, rectal temperature > 39° C [102° F], 8% to 10% dehydrated, reluctant or unable to walk) should not be exercised, including walking back to their stable, unless it is unavoidable. Isotonic, polyionic **fluids**, such as lactated Ringer's solution, should be administered IV to severely affected horses to correct any hypovolemia and to ensure a mild diuresis to prevent myoglobinuric nephropathy. Less severely affected horses can be treated by administration of fluids by nasogastric intubation (4 to 6 L every 2 to 3 hours). Although it has been recommended that urine should be alkalinized by administration of mannitol and sodium bicarbonate (1.3% solution IV, or 50 to 100 g of sodium bicarbonate orally every 12 hours) to minimize the nephrotoxicity of myoglobin, this therapy is not effective in humans at risk of myoglobinuric nephrosis. Affected horses should not be given diuretics (e.g., furosemide) unless they are anuric or oliguric after restoration of normal hydration.

Phenylbutazone (2.2 to 4.4 mg/kg, IV or orally, every 12 to 24 hours), **flunixin meglumine** (1 mg/kg IV every 8 hours), or **ketoprofen** (2.2 mg/kg IV every 12 hours) should be given to provide **analgesia**. **Mild sedation** (acepromazine 0.02 to 0.04 mg/kg IM, or xylazine 0.1 mg/kg IM, both with butorphanol, 0.01 to 0.02 mg/kg) can decrease muscle pain and anxiety. Tranquilizers with vasodilatory activity, such as acepromazine, should only be given to horses that are well hydrated. **Muscle relaxants**, such as methocarbamol, are often used but have no demonstrated efficacy. Dantrolene is used for prevention and does not have demonstrated efficacy in treatment of acute disease.

Recumbent horses should be deeply bedded and repositioned by rolling every 2 to 4 hours. Severely affected horses should not be forced to stand.

CONTROL

Control measures should be specific for the particular disease wherever possible (see discussion of the specific diseases elsewhere in this text).

Prevention of the sporadic, idiopathic disease centers on ensuring that horses are fed a balanced ration with adequate levels of vitamin E, selenium, and electrolytes and have a regular and consistent program of exercise. Despite lack of clear evidence for a widespread role for **vitamin E or selenium deficiency** in exertional rhabdomyolysis, horses are often supplemented with 1 IU/kg vitamin E and 2.5 µg/kg selenium daily in the feed. Care should be taken not to induce selenium toxicosis.

Sodium bicarbonate (up to 0.5 to 1.0 g/kg body weight [BW] daily in the ration) and other electrolytes are often added to the feed of affected horses, but their efficacy is not documented. **Phenytoin** has proven useful in the treatment of recurrent rhabdomyolysis. It is administered at a dose rate of 6 to 8 mg/kg, orally, every 12 hours, and the dose is adjusted depending on the degree of sedation produced (a reduced dose should be used if the horse becomes sedated) or lack of effect on serum CK or AST activity. Phenytoin can be administered to horses for months. **Dimethylglycine, altrenogest, and progesterone** are all used on occasion in

horses with recurrent rhabdomyolysis, but again without demonstrated efficacy. **Dantrolene** might be effective in treatment of recurrent exertional rhabdomyolysis in Thoroughbred horses (see section on Recurrent Exertional Rhabdomyolysis later in this chapter).

The feeding of high-fat, low-soluble-carbohydrate diets is useful in the prevention of recurrent exertional rhabdomyolysis in Thoroughbred horses and polysaccharide storage myopathy in Quarter horses. The usefulness of this practice in preventing sporadic, idiopathic exertional rhabdomyolysis has not been demonstrated.

MYOSITIS

Myositis may arise from direct or indirect trauma to muscle and occurs as part of a syndrome in a number of specific diseases, including blackleg, foot-and-mouth disease, bluetongue, ephemeral fever, swine influenza, sarcosporidiosis, and trichinosis, although clinical signs of myositis are not usually evident in the latter. Sporadic cases of a localized infectious myositis of skeletal muscles, associated with *Escherichia coli,* may occur in calves. An asymptomatic eosinophilic myositis is not uncommon in beef cattle and may cause economic loss through carcass condemnation. The cause has not been determined.

Acute Myositis of Limb Muscles

Acute myositis is accompanied by severe lameness, swelling, heat, and pain on palpation (Fig. 15-2). There may be accompanying toxemia and fever. In chronic myositis there is much wasting of the affected muscles, and this is difficult to differentiate clinically from atrophy as a result of other causes. Biopsy of the muscles may be necessary to confirm the diagnosis.

Injury to the gracilis muscle can cause acute, severe lameness in performance Quarter horses. Horses competing in barrel racing may be susceptible to gracilis muscle injury because the muscle functions to adduct the hindlimb. The prognosis is good for returning to athletic use after an adequate period of muscle healing and mild exercise. However, fibrotic myopathy or muscle atrophy can be a complication of the injury resulting in persistent gait deficits.

In horses, traumatic myositis of the posterior thigh muscles may be followed by the formation of fibrous adhesions between the muscles (fibrotic myopathy) and by subsequent calcification of the adhesions (ossifying myopathy). External trauma can result in fibrotic myopathy, but it may also be associated with excessive exercise or secondary to intramuscular injections. Occasionally similar lesions may be seen in the foreleg. The lesions cause a characteristic abnormality of the gait in that the stride is short in extension and the foot is suddenly withdrawn as it is about to reach the ground. The affected area is abnormal on palpation.

Generalized myositis ossificans, an inherited disease of pigs, is also characterized by deposition of bone in soft tissues. In traumatic injuries caused by penetration of foreign bodies into muscle masses, ultrasonography may be used to detect fistulous tracts and the foreign bodies.

Extensive damage to or loss of muscle occurs in screwworm and sometimes blowfly infestation, although the latter is more of a cutaneous lesion, and by the injection of necrotizing agents. For example, massive cavities can be induced in the cervical muscles of horses by the intramuscular injection of escharotic iron preparations intended only for slow IV injection. Similarly, necrotic lesions can result from the IM injection of infected or irritant substances. Horses are particularly sensitive to tissue injury, or are at least most commonly affected. Some common causes are chloral hydrate, antimicrobials suspended in propylene glycol, and even antimicrobials alone in some horses.

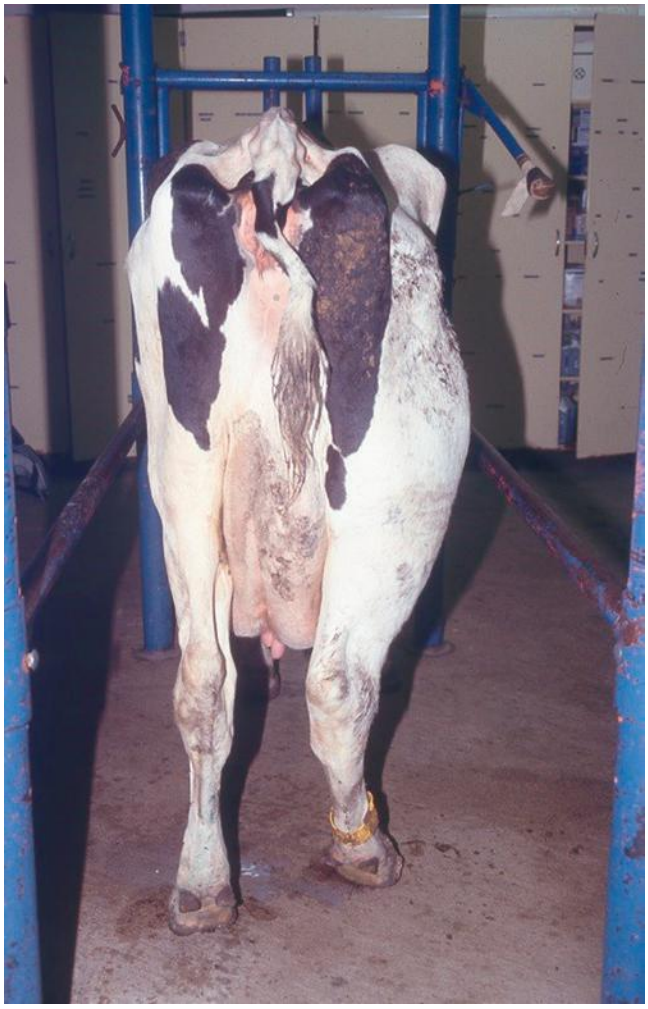

Fig. 15-2 Myositis centered in the right lateral distal femur region of a lactating dairy cow as a result of a penetrating wound. The cow also has a fractured and shortened tail as a result of a traumatic injury when a calf.

Injection-Site Lesions in Cattle

Muscle lesions associated with injection sites in the cattle industry are a source of major economic loss because of the amount of trim required at slaughter. The presence of injection-site lesions in whole muscle cuts, such as the top sirloin and outside round, limits their use and value. The occurrence of injection-site lesions in muscle remains among the top five quality challenges for both beef and dairy market cows and bulls. Because injection-site lesions are concealed in muscles and/or are under subcutaneous fat, they are seldom found during fabrication at the packing plant and appear instead

during wholesale/retail fabrication or at the consumer level.

Historically, most IM injections were given in the gluteals and the biceps femoris muscles, which are prime cuts of beef. Surveys of injection sites in beef cattle in North America have found lesions in a significant percentage of prime cuts of beef. Lesions consisting of clear scars and woody calluses are mature and probably originated in calfhood; scars with nodules or cysts are less mature, occurring later in the feeding period. It is now recommended that all **IM injections be given in the cervical muscles** (in front of the shoulder). Reducing the incidence of injection-site lesions requires that manufacturers of biological and antibiotic preparations develop less irritating formulations. Products should be formulated for subcutaneous use whenever possible and administered in the neck muscles, which are not prime cuts of beef.

The outcome of an IM injection depends on the nature of the lesion produced. Myodegeneration following IM injections of antibiotics in sheep results in full muscle regeneration within less than 3 weeks. Necrosis following the injection results in scar formation with encapsulated debris, which persists for more than a month and leaves persistent scar tissue.

An outbreak of myositis, lameness, and recumbency occurred following the injection of water-in adjuvanted vaccines into the muscles of the left and right hips of near-term pregnant beef cattle. Within 24 hours, some cattle were recumbent, some had non-weight-bearing lameness, and, within 10 days, 50% of the herd developed firm swellings up to 24 cm in vaccination sites. Histologically, granulomatous myositis with intralesional oil was present. The swellings resolved over a period of 6 months. The acute transient lameness was attributed to the use of two irritating biological vaccines in the hip muscles of cows near parturition.

Injection-Site Clostridial Infections in Horses

Clostridial myositis, myonecrosis, cellulitis, and malignant edema are terms used to describe a syndrome of severe necrotizing soft tissue infection associated with *Clostridium* spp. Affected horses typically develop peracute emphysematous soft tissue swelling in the region of an injection or wound within hours of the inciting cause.

Myositis can occur following the IM or inadvertent perivascular administration of a wide variety of commonly administered drugs. In a series of 37 cases, the lesion occurred in most cases within 6 to 72 hours of a soft tissue injection, and most lesions were in the neck musculature.

Aggressive treatment of clostridial myositis can be associated with a survival rate of up to 81% for cases resulting from *Clostridium perfringens* alone; survival rates for other *Clostridium* spp. are lower. A combination of a high dose of IV antibiotic therapy, surgical fenestration and aggressive debridement, antiinflammatory and analgesic therapy, and general supportive care is recommended.[1]

Diseases of Bones

OSTEODYSTROPHY

Osteodystrophy is a general term used to describe those diseases of bones in which there is a failure of normal bone development or abnormal metabolism of bone that is already mature. The major clinical manifestations include distortion and enlargement of the bones, susceptibility to fractures, and interference with gait and posture.

ETIOLOGY

The common causes of osteodystrophy in farm animals include the following.

Nutritional Causes

Calcium, Phosphorus, and Vitamin D

Absolute deficiencies or imbalances in calcium–phosphorus ratios in diets cause the following conditions:

- Rickets in young animals (e.g., growing lambs fed a diet rich in wheat bran)
- Absolute deficiencies of calcium in beef calves on intensive rations with inadequate supplementation
- Osteomalacia in adult ruminants

Osteodystrophia fibrosa in the horse occurs most commonly in animals receiving a diet low in calcium and high in phosphorus.

Osteodystrophia fibrosa in pigs occurs as a sequela to rickets and osteomalacia, which may occur together in young, rapidly growing pigs that are placed on rations deficient in calcium, phosphorus, and vitamin D following weaning.

Copper Deficiency

- Osteoporosis in lambs
- Epiphysitis in young cattle

Other Nutritional Causes

- Inadequate dietary protein and general undernutrition of cattle and sheep can result in severe osteoporosis and a great increase in ease of fracture.
- Chronic parasitism can lead to osteodystrophy in young, rapidly growing ruminants.
- Hypovitaminosis A and hypervitaminosis A can cause osteodystrophic changes in cattle and pigs.
- Prolonged feeding of a diet high in calcium to bulls (such as high-quality alfalfa) can cause nutritional hypercalcitoninism, replacement of trabecular bone in the vertebrae and long bones with compact bone, and neoplasms of the ultimobranchial gland.
- Multiple vitamin and mineral deficiencies are recorded as causing osteodystrophy in cattle. The mineral demands of lactation in cattle can result in a decrease in bone mineral content during lactation with a subsequent increase during the dry period.

Chemical Agents

- Chronic lead poisoning is reputed to cause osteoporosis in lambs and foals.
- Chronic fluorine poisoning causes the characteristic lesions of osteofluorosis, including osteoporosis and exostoses.
- Grazing the poisonous plants *Setaria sphaceleta, Cenchrus ciliaris,* and *Panicum maximum* var. *trichoglume* causes osteodystrophia in horses.
- Enzootic calcinosis of muscles and other tissues is caused by the ingestion of *Solanum malacoxylon, Solanum torvum, Trisetum flavescens* (yellow oatgrass), and *Cestrum diurnum,* which exert a vitamin D–like activity.
- Bowie or bentleg, a disease caused by poisoning with *Trachymene glaucifolia,* is characterized by extreme outward bowing of the bones of the front limbs.

Inherited and Congenital Causes

There are many inherited and congenital defects of bones of newborn farm animals, which are described and discussed later in this chapter. In summary, these include:

- Achondroplasia and chondrodystrophy in dwarf calves and some cases of prolonged gestation
- Osteogenesis imperfecta in lambs and Charolais cattle. There is marked bone fragility and characteristic changes on radiologic examination.
- Osteopetrosis in Hereford and Angus calves
- Congenital chondrodystrophy of unknown origin ("acorn" calves)
- Inherited exostoses in horses; inherited thicklegs and inherited rickets of pigs, which are well-established entities

Angular deformities of joints of long bones as a result of asymmetric growth-plate activity are common in foals and are commonly repaired surgically. The distal radius and distal metacarpus are most often affected, the distal tibia and metatarsal less commonly. Physiologically immature foals subjected to exercise may develop compression-type fractures of the central or third tarsal bones. Some of these foals are born prematurely or are from a twin pregnancy. Retained cartilage in the distal radial physis of foals 3 to 70 days of age presents without apparent clinical signs.

Physitis is dysplasia of the growth plate, characterized by an irregular border between

the cartilage and the metaphyseal zone of ossification, an increase in the lateromedial diameter of the physis, and distoproximally oriented fissures at the medial aspect of the metaphysis, which originate at the physis. In some cases, these may result in bilateral tibial metaphyseal stress fractures in foals.

Abnormal modeling of trabecular bone has been recognized in prenatal and neonatal calves. Abnormalities included growth retardation lines and lattices, focal retention of primary spongiosa, and the persistence of secondary spongiosa. Intrauterine infection with viruses such as bovine virus diarrhea (BVD) may be a causative factor.

Physical and Environmental Causes

Moderate osteodystrophy and arthropathy may occur in rapidly growing pigs and cattle raised indoors and fed diets that contain adequate amounts of calcium, phosphorus, and vitamin D. Those animals raised on slatted floors or concrete floors are most commonly affected, and it is thought that traumatic injury of the epiphyses and condyles of long bones may be predisposing factors in osteochondrosis and arthrosis in the pig (leg weakness) and epiphysitis in cattle. Experimentally raising young calves on metal slatted floors may result in more severe and more numerous lesions of the epiphysis than occurs in calves raised on clay floors. Total confinement rearing of lambs can result in the development of epiphysiolysis and limb deformities. However, the importance of weight-bearing injury as a cause of osteodystrophy in farm animals is still uncertain. In most reports of such osteodystrophy, all other known causes have not been eliminated.

Chronic osteodystrophy and arthropathy have been associated with undesirable conformation in the horse.

Vertebral exostoses are not uncommon in old bulls and usually affect the thoracic vertebrae (T2 and T12) and the lumbar vertebrae (L2 to L3), which are subjected to increased pressure during the bending of the vertebral columns while copulating. The exostoses occur mainly on the ventral aspects of the vertebrae, fusing them to cause immobility of the region. Fracture of the ossification may occur, resulting in partial displacement of the vertebral column and spinal cord compression. The disease is commonly referred to as spondylitis or vertebral osteochondrosis and also occurs less commonly in adult cows and in pigs. It is suggested that the annulus fibrosus degenerates and that the resulting malfunctioning of the disk allows excessive mobility of the vertebral bodies, resulting in stimulation of new bone formation. A similar lesion occurs commonly in horses and may affect performance, particularly in hurdle races and cross-country events. The initial lesion may be a degeneration of the intervertebral disk.

Some types of growth-plate defects occur in young, rapidly growing foals, and these are considered to be traumatic in origin. Failure of chondrogenesis of the growth plate may be the result of crush injuries in heavy, rapidly growing foals with interruption of the vascular supply to the germinal cells of the growth plate. Asymmetric pressures as a result of abnormal muscle pull or joint laxity may slow growth on the affected side and result in limb angulation.

Femoral fractures occur in newborn calves during the process of assisted traction during birth. Laboratory compression of isolated femurs from calves revealed that the fracture configurations and locations are similar to those found in clinical cases associated with forced extraction. The breaking strength of all femurs fell within the magnitude of forces calculated to be created when mechanical devices are used to assist delivery during dystocia. It is suggested that the wedging of the femur in the maternal pelvis and resulting compression during forced extraction accounts for the occurrence of supracondylar fractures of the femur of calves delivered in anterior presentation using mechanical devices in a manner commonly used by veterinarians and farmers.

Tumors

Osteosarcomas are highly malignant tumors of skeletoblastic mesenchyme in which the tumor cells produce osteoid or bone. Osteosarcomas are the most common type of primary bone tumor in animals such as dogs and cats but are rare in horses and cattle. Most tumors of bone in large animals occur in the skull. A periosteal sarcoma on the scapula has been recorded in the horse and an osteosarcoma of the mandible in a cow.

PATHOGENESIS

Osteodystrophy is a general term used to describe those diseases of bones in which there is a failure of normal bone development or abnormal metabolism of bone that is already mature. There are some species differences in the osteodystrophies that occur with dietary deficiencies of calcium, phosphorus, and vitamin D. Rickets and osteomalacia have a similar pathogenesis, with the end result being decreased or defective bone mineralization. In broad terms, rickets is the failure of endochondral ossification in growing bone, whereas osteomalacia is disrupted remodeling in mature bone. Rickets and osteomalacia occur primarily in ruminants fed a deficient diet, osteodystrophia fibrosa occurs in horses, and all three may occur in pigs.[1]

Rickets

Rickets is a disease of young, rapidly growing animals in which there is a **failure of provisional calcification of the osteoid** plus a **failure of mineralization of the cartilaginous matrix of developing bone**. There is also failure of degeneration of growing cartilage and formation of osteoid on persistent cartilage, with irregularity of osteochondral junctions and overgrowth of fibrous tissue in the osteochondral zone. Rickets is most commonly caused in ruminants by a deficiency of vitamin D or phosphorus.[2] Genetic causes of rickets exist, one of which is a simple autosomal-recessive inheritance in Corriedale sheep in New Zealand.[3,4]

Failure of provisional calcification of cartilage results in an increased depth and width of the epiphyseal plates, particularly of the long bones (humerus, radius, ulna and tibia) and the costal cartilages of the ribs. The uncalcified, and therefore soft, tissues of the metaphyses and epiphyses become distorted under the pressure of weight-bearing, which also causes medial or lateral deviation of the shafts of long bones. There is a decreased rate of longitudinal growth of long bones and enlargement of the ends of long bones as a result of the effects of weight, causing flaring of the diaphysis adjacent to the epiphyseal plate. Within the thickened and widened epiphyseal plate, there may be hemorrhages and minute fractures of adjacent trabecular bone of the metaphysis, and in chronic cases the hemorrhagic zone may be largely replaced by fibrous tissue. These changes can be seen radiographically as "epiphysitis" and clinically as enlargements of the ends of long bones and costochondral junctions of the ribs. These changes at the epiphyses may result in separation of the epiphysis, which commonly affects the femoral head. The articular cartilages may remain normal, or there may be subarticular collapse resulting in grooving and folding of the articular cartilage and ultimately degenerative arthropathy and osteochondrosis. Eruption of the teeth in rickets is irregular, and dental attrition is rapid. Growth of the mandibles is retarded and is combined with abnormal dentition. There may be marked malocclusion of the teeth.

Osteomalacia

Osteomalacia is a **softening of mature bone as a result of extensive resorption of mineral deposits** in bone and failure of mineralization of newly formed matrix. There is no enlargement of the ends of long bones or distortions of long bones, but spontaneous fractures of any bone subjected to weight-bearing are common.

Osteodystrophia Fibrosa

Osteodystrophia fibrosa may be superimposed on rickets or osteomalacia and occurs in secondary hyperparathyroidism. Diets low in calcium or that contain a relative excess of phosphorus cause secondary hyperparathyroidism. There is extensive resorption of bone and replacement by connective tissue. The disease is best known in the horse and results in swelling of the mandibles, maxillae, and frontal bones (the "**bighead**" syndrome). Spontaneous fracture of long bones and ribs occurs commonly.

Radiographically there is extreme porosity of the entire skeleton.

Osteoporosis

Osteoporosis is defined as a systemic skeletal disease characterized by low bone mass and microarchitectural deterioration of bone tissue, with a consequent increase in bone fragility and increased susceptibility to fractures.[5] In osteoporosis, the bone becomes porous, light, and fragile, and it fractures easily. Osteoporosis is uncommon in farm animals and is usually associated with general undernutrition and intestinal parasitism rather than specifically a deficiency of calcium, phosphorus, or vitamin D.[6] Copper deficiency in lambs may result in osteoporosis as a result of impaired osteoblastic activity. Chronic lead poisoning in lambs also results in osteoporosis as a result of deficient production of osteoid. In a series of 19 lactating or recently weaned sows with a history of lameness, weakness, or paralysis, 10 had osteoporosis and pathologic fractures, and six had lumbar vertebral osteomyelitis. Bone ash, specific gravity of bone, and the ratio of cortical to total bone were significantly reduced in sows with osteoporosis and pathologic fractures.

Ovariectomized sheep that are fed an acidogenic (calcium-wasting) diet and administered corticosteroids develop osteoporosis, which is being used as a model to study the disease in humans.[6,7]

Osteodystrophy of Chronic Fluorosis

Osteodystrophy of chronic fluorosis is characterized by the development of exostoses on the shafts of long bones as a result of periosteal hyperostosis. The articular surfaces remain essentially normal, but there is severe lameness because of the involvement of the periosteum and encroachment of the osteophytes on the tendons and ligaments.

Congenital Defects of Bone

Congenital defects of bone include complete (**achondroplasia**) and partial (**chondrodystrophy**) failure of normal development of cartilage. Growth of the cartilage is restricted and disorganized, and mineralization is reduced. The affected bones fail to grow, leading to gross deformity, particularly of the bones of the head.

CLINICAL FINDINGS

In general terms there is weakening of the bones as a result of defective mineralization and osteoporosis, which results in the **bending of bones**, which probably causes pain and shifting lameness—one of the earliest clinical signs of acquired osteodystrophy. The normal weight and tension stresses cause distortion of the normal axial relationships of the bones, which results in the bowing of long bones. The distortions occur most commonly in young, growing animals. The distal ends of the long bones are commonly enlarged at the level of the epiphyseal plate, and circumscribed swellings of the soft tissue around the epiphyses may be prominent and painful on palpation.

The effects of osteodystrophy on appetite and body weight will depend on the severity of the lesions and their distribution. In the early stages of rickets in calves and pigs the appetite and growth rate may not be grossly affected until the disease is advanced and causes considerable pain. Persistent recumbency as a result of pain will indirectly affect feed intake unless animals are hand-fed.

Spontaneous fractures occur commonly and usually in mature animals. Common sites for fractures include the long bones of the limbs, pelvic girdle, femoral head, vertebrae, ribs, and transverse processes of the vertebrae. Ordinary hand pressure or moderate restraint of animals with osteomalacia and osteodystrophia fibrosa is often sufficient to cause a fracture. The rib cage tends to become flattened, and in the late stages affected animals have a slab-sided appearance of the thorax and abdomen. Separations of tendons from their bony insertions also occur more frequently and cause severe lameness. The osteoporotic state of the bone makes such separations easy. Any muscle group may be affected, but in young cattle in feedlots, separations of the gastrocnemius are the most common. Thickening of the bones may be detectable clinically if the deposition of osteoid or fibrous tissue is excessive or if exostoses develop, as in fluorosis. Compression of the spinal cord or spinal nerves may lead to paresthesia, paresis, or paralysis, which may be localized in distribution. Details of the clinical findings in the osteodystrophies caused by nutritional deficiencies are provided later in this chapter.

Calcinosis of cattle is characterized clinically by chronic wasting; lameness; ectopic calcifications of the cardiovascular system, lungs, and kidneys; ulceration of joint cartilage; and extensive calcification of bones.

DIAGNOSIS

The **laboratory analyses** that are indicated include the following:

- Serum calcium and phosphorus concentration
- Serum alkaline phosphatase activity
- Feed analysis for calcium, phosphorus, vitamin D, and other minerals when indicated (such as copper, molybdenum, and fluorine)
- Bone ash chemical analysis
- Histopathology of bone biopsy
- Radiographic examination of the skeleton
- Single-photon absorptiometry, a safe and noninvasive method for the measurement of bone mineral content, is now available.

Radiographic examination of the affected bones and comparative radiographs of normal bones are indicated when osteodystrophy is suspected. Radiographic examination of slab sections of bone is a sensitive method for detecting abnormalities of trabecular bone in aborted and young calves.

Serum calcium and **phosphorus** concentrations in nutritional osteodystrophies may remain within the normal range for long periods, and not until the lesions are well advanced will abnormal levels be found. Several successive samplings may be necessary to identify an abnormal trend.

Serum alkaline phosphatase activity may be increased in the presence of increased bone resorption, but this is not a reliable indicator of osteodystrophy. Increased serum levels of alkaline phosphatase may originate from osseous tissues, intestine, or the liver, but osseous tissue appears to be the major source of activity.

Nutritional history and **feed analysis** results will often provide the best circumstantial evidence of osteodystrophy. In vitamin D–dependent rickets, serum 25(OH)D_3 concentrations will be decreased. In phosphorus-dependent rickets, serum 25(OH)D_3 will be normal or increased with normal to decreased parathyroid (PTH) concentrations. Urine calcium-to-phosphorus ratios below 0.05 suggest a calcium or vitamin D deficiency, whereas ratios above 1 reflect phosphorus deficiency.[1]

The definitive diagnosis is best made by a combination of chemical analysis of bone, histopathologic examination of bone, and radiography. The details for each of the common osteodystrophies are discussed under the appropriate headings.

NECROPSY FINDINGS

The pathologic findings vary with the cause, and the details are described under each of the osteodystrophies elsewhere in the book. In general terms, the nutritional osteodystrophies are characterized by bone deformities, bones that may be cut easily with a knife and that bend or break easily with hand pressure, and in prolonged cases the presence of degenerative joint disease. In young growing animals the ends of long bones may be enlarged, and the epiphyses may be prominent and circumscribed by periosteal and fibrous tissue thickening. On longitudinal cut sections the cortices may appear thinner than normal, and the trabecular bone might have been resorbed, leaving an enlarged marrow cavity. The epiphyseal plate may be increased in depth and width and appear grossly irregular, and small fractures involving the epiphyseal plate and adjacent metaphysis may be present. Separation of epiphyses is common, particularly of the femoral head. The calluses of healed fractures of long bones, ribs, vertebrae, and the pelvic girdle are common in pigs with osteodystrophy. On histologic examination there are varying degrees of severity of rickets in young, rapidly growing animals

and osteomalacia in adult animals, and osteodystrophia fibrosa is possible in both young and adult animals.

DIFFERENTIAL DIAGNOSIS

In both congenital and acquired osteodystrophy the clinical findings are usually suggestive. There are varying degrees of lameness, stiff gait, long periods of recumbency and failure to perform physical work normally, and progressive loss of body weight in some cases, and there may be obvious contortions of long bones, ribs, head, and vertebral column. The most common cause of osteodystrophy in young, rapidly growing animals is a dietary deficiency or imbalance of calcium, phosphorus, and vitamin D. If the details of the nutritional history are available and if a representative sample of the feed given is analyzed, a clinical diagnosis can be made on the basis of clinical findings, nutritional history, and response to treatment. In some cases, osteodystrophy may be attributable to overfeeding, such as might occur in rapidly growing, large foals.

However, often the nutritional history may indicate that the animals have been receiving adequate quantities of calcium, phosphorus, and vitamin D, which necessitates that other, less common causes of osteodystrophy be considered. Often the first clue is an unfavorable response to treatment with calcium, phosphorus, and vitamin D. Examples include copper deficiency in cattle, leg weakness in swine of uncertain etiology—but perhaps there is weight-bearing trauma and a relative lack of exercise because of confinement—or chemical poisoning such as enzootic calcinosis or fluorosis. These will require laboratory evaluation of serum biochemistry, radiography of affected bones, and pathologic examination. The presence of bony deformities at birth suggests congenital chondrodystrophy, some cases of which appear to be inherited, whereas some are attributable to environmental influences.

TREATMENT

The common nutritional osteodystrophies attributable to a dietary deficiency or imbalance of calcium, phosphorus, and vitamin D will usually respond favorably following the oral administration of a suitable source of calcium and phosphorus combined with parenteral injections of vitamin D. The oral administration of dicalcium phosphate, at the rate of 3 to 4 times the daily requirement, daily for 6 days, followed by a reduction to the daily requirement by the 10th day, combined with one injection of vitamin D at the rate of 10,000 IU/kg BW, is recommended. Affected animals are placed on a diet that contains the required levels and ratios of calcium, phosphorus, and vitamin D. The oral administration of the calcium and phosphorus will result in increased absorption of the minerals, which will restore depleted skeletal reserves. Calcium absorption is increased in adult animals following a period of calcium deficiency; young animals with high growth requirements absorb and retain calcium in direct relation to intake. General supportive measures include adequate bedding for animals that are recumbent.

The treatment of the osteodystrophies resulting from causes other than calcium and phosphorus deficiencies depends on the cause. Copper deficiency will respond gradually to copper supplementation. There is no specific treatment for the osteodystrophy associated with leg weakness in pigs, and slaughter for salvage is often necessary. Overnutrition in young, rapidly growing foals may require a marked reduction in the total amount of feed made available daily.

Oxytetracycline has been used for the treatment of flexural deformities of the distal interphalangeal joints of young foals. It is postulated that oxytetracycline chelates calcium, rendering it unavailable for use for striated muscle contraction. It is considered effective for obtaining a short-term moderate decrease in metacarpophalangeal joint angle in newborn foals.

Hemicircumferential periosteal transection and elevation has gained wide acceptance for correction of angular limb deformities in young foals.

HYPERTROPHIC OSTEOPATHY (MARIE'S DISEASE)

Although hypertrophic osteopathy is more common in dogs than in the other domestic animals it has been observed in horses,[1-4] cattle,[5] sheep, New World camelids, and captive cervids.[6] The term *hypertrophic osteoarthropathy* is used in humans where there is joint involvement, but the term *hypertrophic osteopathy* is preferred in large animals because the joints are never affected.

Hypertrophic osteopathy is characterized by proliferation of the periosteum, leading to the formation of periosteal bone, and bilateral symmetric enlargement of bones, usually the long bones of limbs and in advanced cases in the horse, the ventral mandible.[1,4] The enlargement is quite obvious and in the early stages is usually painful and often accompanied by local edema. On radiographic examination there is a shaggy periostitis and evidence of periosteal exostosis. The pathogenesis is obscure, but the lesion appears to be neurogenic in origin associated with an increased blood flow to the limbs, with unilateral vagotomy causing regression of the bony changes. Stiffness of gait and reluctance to move are usually present, and there may be clinical evidence of the pulmonary lesion with which the disease is frequently, but not always, associated (the condition was called *hypertrophic pulmonary osteopathy* for many years). Such pulmonary lesions are usually chronic, neoplastic, or suppurative processes such as tuberculosis. Cases of hypertrophic osteopathy have been diagnosed in horses without evidence of intrathoracic disease.[1] In one mare with a large granulosa thecal cell tumor, clinical signs of hypertrophic osteopathy decreased after surgical excision of the tumor.[2]

The majority of reports in large animals are in horses, where the lesions are found more commonly around but not involving the joints of distal limbs.[1] Radiographs of the distal limbs reveal periosteal new bone involving the metaphysis or diaphysis or both. The new bone appears smooth and speculated or has a palisade–like appearance perpendicular to the cortex, with chronic cases having other and less active bony changes.[1]

The disease is considered to be incurable, unless the thoracic lesion can be removed, but there are occasional reports of clinical improvement following prolonged administration of antiinflammatory agents[1] or antibiotics.[3] Affected animals are usually euthanized. At necropsy the periostitis and exostosis are evident, and most, but not all, have gross evidence of chronic intrathoracic disease.[1,2] There is no involvement of the joints.

OSTEOMYELITIS

ETIOLOGY AND PATHOGENESIS

Inflammation of bone (**osteitis**) or bone and bone marrow (**osteomyelitis**) is uncommon in large animals except when infection is introduced by traumatic injury or by the hematogenous route. **Bacteria can reach bone by any of three routes:**

- Hematogenously
- By extension from an adjacent focus of infection
- By direct inoculation through trauma or surgery

Focal metaphyseal osteomyelitis can occur following open fractures in the horse. Specific diseases that may be accompanied by osteomyelitis include actinomycosis of cattle and brucellosis, atrophic rhinitis, and necrotic rhinitis of pigs. Nonspecific, hematogenous infection with other bacteria occurs sporadically and is often associated with omphalitis, abscesses from tail-biting in

pigs, or infection of castration or docking wounds in lambs.

Foals and calves under 1 month of age and growing cattle 6 to 12 months of age may be affected by osteomyelitis in one or more bones. The majority of foals with suppurative polyarthritis have a polyosteomyelitis of the bones adjacent to the affected joints. In a series of cases of tarsal osteomyelitis in foals there was usually evidence of infectious arthritis. Osteomyelitis of the pubic symphysis associated with *Rhodococcus equi* in a 2-year-old horse has been described. The lameness was localized to the pelvis and was associated with a fever and an inflammatory leukogram.

The infections occur commonly in the metaphysis, physis, and epiphysis, which are sites of bony growth and thus susceptible to blood-borne infections. The metaphyseal blood vessels loop toward the physis and ramify into sinusoids that spread throughout the metaphyseal region. Blood flow through the sinusoids is sluggish and presents an ideal environment for propagation of bacteria. Lesions occur on both sides of the physis in both the metaphysis and the epiphysis. Multiple lesions are common and support the explanation that septic emboli are released from a central focus.

In a series of 445 cattle with bone infection of the appendicular skeleton, a distinction was made between hematogenous and posttraumatic origin (wound/fracture). Bone infection was classified into four types according to the site of infection: Type 1 is metaphyseal and/or epiphyseal osteomyelitis close to the growth plate; type 2 is primary subchondral osteomyelitis, mostly accompanied by septic arthritis; type 3 is infectious osteoarthritis with subchondral osteomyelitis, implying that infection in the subchondral bone originates from the infection. Type 4 includes bone infections that cannot be categorized in the other groups. Hematogenous osteomyelitis was 3.2 times more frequent than posttraumatic osteomyelitis. *Trueperella* (*Arcanobacterium* or *Corynebacterium*) *pyogenes* was the most common etiologic agent. Approximately 55% of the affected animals with osseous sequestration had physical evidence of lacerations, contusions, abrasions, or puncture wounds from a previous traumatic event.

Hematogenous osteomyelitis in cattle can be of two types:

- Physeal type, in which an infection generally of metaphyseal bone originates at or near the growth plate, usually affecting the distal metacarpus, metatarsus, radius, or tibia
- Epiphyseal type, in which an infection originates near the junction of the subchondral bone and the immature epiphyseal joint cartilage, most often affecting the distal femoral condyle epiphysis, the patellar, and the distal radius

Epiphyseal osteomyelitis is usually a result of infection with *Salmonella* spp. and is most common in calves under 12 weeks of age. The physeal infections are usually caused by *T. pyogenes* and occur most commonly in cattle over 6 months of age.

Osseous Sequestration in Cattle

Osseous sequestration is a common orthopedic abnormality in cattle and horses. In most cases, the lesions develop in the bones of the distal portion of the limbs (Figs. 15-3 and 15-4). Sequestration is associated with trauma that results in localized cortical ischemia and bacterial invasion secondary to loss of adjacent periosteal and soft tissue integrity and viability. The soft tissues covering the bones that comprise the distal portions of the limbs fail to provide adequate protection and collateral blood supply to the bone.

Osteomyelitis Secondary to Trauma

In horses, osteomyelitis is a frequent sequela to wounds of the metacarpal and metatarsal bones and the calcaneus. These bones have limited soft tissue covering, which may predispose them to osteomyelitis following traumatic injury. Similarly, a portion of the lateral aspect of the proximal end of the radius has limited soft tissue covering. Penetrating and nonpenetrating wounds in this region therefore may result in serious consequences even though they may initially appear to be minor. Because lesions may be an extension of septic arthritis, a thorough examination of the wound area is necessary.

Inflammation of Bone Marrow

Acute inflammation of the bone marrow commonly accompanies bacterial sepsis, resulting in either multifocal microabscesses or perivascular infiltrates of neutrophils, fibrin, edema, and hemorrhage. The most common abnormality associated with fibrinous inflammation is disseminated intravascular coagulopathy. Discrete granulomas may occur in the marrow of animals with systemic mycotic disease, idiopathic granulomatous disease, and serous atrophy of fat.

Fig. 15-3 **Holstein–Friesian heifer with a sequestrum of the left distal third metacarpal bone with draining tract associated with a hard swelling.**

Fig. 15-4 **Palmar-dorsal radiograph of the limb of the heifer in Figure 15-3 showing involucrum laterally and medially (thick sheath of periosteal new bone surrounding a sequestrum) and marked bone proliferation on the cortical surface.**

CLINICAL FINDINGS

The common clinical findings of osteomyelitis include the following:

- Lameness
- Generalized soft tissue swelling and inflammation
- Pain on palpation of the affected area
- Chronic persistent drainage
- Secondary muscle atrophy of the affected limb

Erosion of bone occurs, and pus discharges into surrounding tissues, causing cellulitis or phlegmon, and to the exterior through sinuses, which persist for long periods. The affected bone is often swollen and may fracture easily because of weakening of its structure. When the bones of the jaw are involved, the teeth are often shed, and this, together with pain and the distortion of the jaw, interferes with prehension and mastication. Involvement of vertebral bodies may lead to the secondary involvement of the meninges and the development of paralysis. Lameness and local swelling are the major manifestations of involvement of the limb bones.

Most osseous sequestra in cattle are associated with the bones of the extremities, most commonly the third metacarpal or metatarsal bone. Cattle 6 months to 2 years of age are most likely to have a sequestrum compared with animals less than 6 months of age.

The lesions are typically destructive of bone and cause severe pain and lameness. Those associated with *Salmonella* spp. are characteristic radiographically in foals and calves. *T. pyogenes, Corynebacterium* spp., and *E. coli* may also be causative agents. Affected animals are very lame, and the origin of the lameness may not be obvious. A painful, discrete soft tissue swelling over the ends of the long bones is often the first indication. The lameness characteristically persists in spite of medical therapy, and the animal may become lame in two or more limbs and spend long periods recumbent.

Osteomyelitis affecting the cervical vertebrae, usually the fourth to sixth vertebra, causes a typical syndrome of abnormal posture and difficulty with ambulation. Initially there is a stumbling gait, which then becomes stiff and restricted and with a reluctance to bend the neck. Soon the animal has difficulty eating off the ground and must kneel to graze pasture. At this stage there is obvious atrophy of the cervical muscles, and pain can be elicited by deep, forceful compression of the vertebrae with the fists. There is no response to treatment, and at necropsy there is irreparable osteomyelitis of the vertebral body and compression of the cervical spinal cord. Radiologic examination is usually confirmatory.

Cervicothoracic vertebral osteomyelitis in calves between 2 and 9 weeks of age is characterized by difficulty in rising with a tendency to knuckle or kneel on the forelimbs, which are hypotonic and hyporeflexic. Pain can be elicited on manipulation of the neck. The lesion usually involves one or more of the vertebrae from C6 to T1. *Salmonella dublin* is commonly isolated from the vertebral lesion.

DIAGNOSIS

Radiographs are an essential part of the diagnosis. **Radiographic changes** include the following:

- Necrotic sequestrum initially
- New bone formation
- Loss of bone density

Radiographic lesions are characteristically centered at the growth and extend into both metaphysis and epiphysis.

Nuclear scintigraphy, which is only available at large referral centers, can be useful in identifying osteomyelitis in areas of bone surrounded by a large amount of muscle, which minimizes the ability to detect subtle radiographic lesions.

Culture of the inflammatory exudate and necrotic sequestra removed surgically is necessary to determine the species of bacteria and their antimicrobial susceptibility. Samples of bone obtained at surgery provide the most accurate culture results compared with specimens obtained from the draining sinuses, which may yield a mixed flora. Specimens should consist of sequestra and soft tissues immediately adjacent to bone thought to be infected. Special transport media are desirable for optimum culture results. Anaerobic bacteria are frequently associated with osteomyelitis and should be considered when submitting samples for culture.

NECROPSY FINDINGS

At necropsy the osteomyelitis may not be obvious unless the bones are opened longitudinally and the cut surfaces of the metaphysis and epiphysis are examined.

DIFFERENTIAL DIAGNOSIS

A differential diagnosis for a destructive lesion in the end of a long bone of a foal or calf would include the following: a healing fracture, traumatic periostitis or osteitis, bone tumor, nutritional osteodystrophy and infection of the bone as a result of external trauma, fracture, extension from adjacent infection or hematogenous spread. The absence of equal pathologic involvement in the comparable parts of long bones and the young age of the animal will usually suggest infection of bone. The pathologic features of multiple-bone infection in foals are described.

TREATMENT

Despite advances in antimicrobial therapy and refined diagnostic techniques, the clinical management of osteomyelitis is difficult. Medical therapy alone is rarely completely successful because of the poor vascularity of the affected solid bone, the inaccessibility of the infection, and the potential for development of a biofilm slime layer by bacteria. In cases of long-term infection or those with extensive bone necrosis, surgery is generally recommended to remove sequestra, devitalized tissue, and sinus tracts that are harboring large numbers of bacteria. Good results are obtained when the affected bone is removed and standard wound management practices are implemented.[1] A retrospective case series of 108 thoroughbred foals with septic osteomyelitis secondary to bacteremia indicated that 81% were discharged from the hospital, and 48% successfully raced.[2]

In septic physitis, the implantation of homologous cancellous bone grafts following debridement of necrotic bone, the application of a walking cast for 4 to 5 weeks, and antimicrobial therapy for 2 weeks is usually a successful approach. Absolute asepsis is a fundamental requirement for successful application of a bone graft; after debridement of the necrotic bone, the cavity is flushed with saline and aqueous ampicillin or a combination of penicillin G potassium and ceftiofur.

Antimicrobials are an integral part of the treatment, and selection of the most appropriate drug should be based on identification and susceptibility testing of the organism. Initial treatment may be based on the most common isolates, and a combination of penicillin G and gentamicin or amikacin provides an excellent initial treatment in horses until culture and susceptibility results are available. Aminoglycosides such as gentamicin or amikacin do not provide an ideal initial treatment option in food-producing animals because of the extensive slaughter withdrawals associated with their use. Ideally, parenteral antimicrobial therapy should be continued for a minimum of 10 days and ideally 4 to 6 weeks following surgical curettage. However, in a series of osteomyelitis of the calcaneus of adult horses, there was no difference in the survival rate of animals between those treated surgically and those treated medically. Likewise, a retrospective study of 108 Thoroughbred foals with osteomyelitis secondary to septicemia did not demonstrate an improved success rate with surgical debridement.[2]

Most anaerobic bacteria associated with osteomyelitis are sensitive to penicillin and the cephalosporins, but some species of *Bacteroides fragilis* and *Bacteroides asaccharolyticus* and other species of *Bacteroides* are known to produce beta-lactamases, which can inactivate penicillin and cephalosporin. Metronidazole and clindamycin will penetrate bone and can be considered for use in the horse, but metronidazole is not permitted to be used in food-producing animals in some countries.

Regional perfusion of the distal limb may be helpful as part of the initial treatment by providing higher antimicrobial concentrations at the site of infection. A tourniquet made of latex tubing is placed at a suitable location on the limb proximal to the site of infection. In regional intravenous perfusion, a large superficial vein is identified, and the overlying skin is disinfected. A butterfly catheter is inserted into the vein and a water-soluble antimicrobial agent that is minimally cytotoxic, such as penicillin G potassium or ceftiofur, is infused intravenously and the tourniquet left in place for 30 minutes to facilitate diffusion into infected tissues.

In regional osseous perfusion, an intraosseous infusion screw is inserted using aseptic technique into the medullary cavity, and appropriate water-soluble antimicrobial agents are periodically infused without the use of a tourniquet. The intraosseous screw is left in place under a sterile wrap in between infusions.

TAIL-TIP NECROSIS IN BEEF CATTLE

Tail-tip necrosis occurs in cattle housed in confinement on slatted floors. The disease has occurred in steers, heifers, and bulls being fed for beef production, and less frequently in dairy cattle.

The lesion is most commonly caused by a traumatic injury of the tail caused by tramping of the tail by other animals.[1] The tail tip of a lying bull usually is away from the animal's body and therefore accessible for tramping by herdmates. Focal damage is more severe when the tail tip is tramped on slatted floors. Tail-tip necrosis is rare in dairy cattle confined in free stalls because most cows lie down in free stalls and their tails are thereby relatively protected from being tramped. Less frequently, the lesion starts as a ball of manure on the tail switch of animals with loose feces; the manure accumulates until a large dry fecal mass (up to 15 cm in diameter) is present on the tip of the tail. The presence of the hard fecal mass increases the likelihood of damage to the tail tip, particularly when animals are confined.

The lesion begins at the tip of tail followed by varying degrees of extension proximally. Initially, the tip of the tail is swollen, followed by inflammation and infection with *Trueperella pyogenes*. Histopathologic changes are compatible with cutaneous ischemia as a pathogenic mechanism. Extension of the infection can result in metastases to other parts of the body, resulting in abscesses and osteomyelitis. Affected cattle do not grow normally, and deaths from pyemia may occur. The morbidity is about 5%. Approximately 10% of affected animals may be condemned for osteomyelitis and abscessation.

Risk Factors

Risk factors include slatted concrete floors, close confinement, warm seasons, and a body weight above 200 kg. The risk increases as the space allotment, expressed as kg animal per m^2 pen, increases from approximately 165 kg/m^2. Tail tramping is more frequent in slatted-floor pens with lower space allotment (1.5 m^2 per head) than in similar pens with higher space allotment (2.4 m^2 per pen head). In an Ontario study, no case of tail-tip necrosis was diagnosed in solid-floor barns, whereas 1.36% of cattle in slatted-floor barns were either treated or slaughtered for tail-tip necrosis. In a mail survey of feedlots in Ontario, 96% of 71 feedlots with slatted floors, but only 5% of 184 feedlots with solid floors, reported a problem with tail-tip necrosis from 1982 to 1986. Of 441 tails inspected at slaughter plants, 35% were affected, with 3% involving skin lacerations and infection, and 4% were amputated before slaughter. Most cases occur from May to September when the temperature is above 18° C (64 F). This may be associated with increased contamination as a result of increased humidity and temperature under confinement conditions.

In slatted-floor barns, abnormal locomotor patterns occur in 20% to 25% of the times when animals get up and lie down. When animals get up abnormally, they first rise from the front, then consequently assume a dog-like sitting posture. To obtain momentum to rise in the rear, they then start to sway back and forth. The tail may become pinched between the hock of the rocking animal and the floor, resulting in blunt trauma to the tip of the tail.

TREATMENT

Treatment consists of early amputation combined with intensive antimicrobial therapy. Early detection is important. During warm months, cattle confined on slatted floors and weighing more than 200 kg should be closely inspected at least 2 or 3 times weekly. This includes palpation of all tail tips because early lesions are difficult to see.

CONTROL

Control is dependent on providing sufficient space for housed cattle on slatted floors.

LAMINITIS OF HORSES

SYNOPSIS

Etiology Degeneration of the sensitive lamellae of the hoof. Syndromes of endocrinopathic, sepsis-associated, supporting limb and concussive laminitis are recognized. Pasture-associated laminitis is considered a form of endocrinopathic laminitis.

Epidemiology Disease involving single animals. As a sequela to severe systemic disease induced by colic, enterocolitis, metritis, and grain engorgement. Horses worked on hard surfaces. Horses or ponies at pasture, and especially obese horses and ponies and those with hyperinsulinemia as a result of insulin resistance or equine metabolic syndrome. Horses with pituitary pars intermedia dysfunction. Horses with unilateral lameness often develop laminitis in the contralateral, supporting limb.

Clinical signs Lameness, ranging from mild to sufficiently severe to cause the horse to be recumbent, involving both front feet, and occasionally all four feet.

Clinical pathology None characteristic of the disease.

Diagnostic confirmation Physical examination. Radiography.

Treatment There is no single effective treatment. Control of pain by administration of nonsteroidal antiinflammatory drugs is important. Administration of vasodilatory agents, anticoagulants, frog and sole support, and corrective hoof trimming and shoeing are all used with variable success. Chilling of the limb (cryotherapy) in horses at high risk (e.g., diarrhea, metritis) during the prodromal or acute phase is promising but unproven as yet in prospective clinical trials.

Control Prophylaxis for acute, severe diseases. Aggressive treatment of systemic disease associated with metritis, colic, and enterocolitis, including digital cryotherapy. Prevent unrestricted access to feeds rich in soluble carbohydrates. Maintain optimal body condition. Treat existing equine metabolic syndrome (insulin resistance) or pituitary pars intermedia dysfunction.

Laminitis refers to a spectrum of processes and clinical signs related to breakdown of the connection between of the basement membrane of the secondary dermal lamellae and the basal cells of the secondary epidermal lamellae, with subsequent disruption of the anatomic relationship between the hoof and the distal phalanx. Understanding of the condition is dependent on a specialized vocabulary and jargon, including the following:[1,2]

- **Hoof**—the layers of integument of the foot from the secondary epidermal lamella distally (outward, toward the hoof surface). The keratinized portion of the hoof is the hoof capsule.
- **Distal phalanx**—the most distal of the bones in the limb of the horse (synonyms of pedal bone, P3, or third phalanx)
- **Lamellae** (colloquially, "laminae")—primary and secondary lamellae originate from the inside of the hoof and from the surface of the distal phalanx. Primary lamellae give rise to secondary lamellae. The basal cells of the primary and secondary epidermal lamellae attach the hoof to the basement membrane of the primary and secondary lamellae of the distal phalanx through numerous anchoring points, the hemidesmosomes (Fig. 15-5).[3] Hemidesmosomes are composed of multiple anchoring filaments that connect to laminin-5, a unique glycoprotein that attaches to type IV collagen in the lamina densa of the basement membrane. Type VII collagen connects the lamina densa to the distal phalanx. laminin-5 in the basement membrane is connected through the hemidesmosomes by integrin (which crosses the cell wall) and plectin to the cytoskeleton of the basal cell. Protein BP-180 is associated with the hemidesmosomes and might be involved in anchoring. Basal cells are connected to one another by desmosomes (containing cadherins, a group of compounds responsible for cell–cell adhesion).[3]
- **Parietal integument** (incorrectly, "lamellar integument")—that part of the space between the hoof capsule and distal phalanx occupied by the lamellae, parts of the dermis, and all subcutaneous tissue.

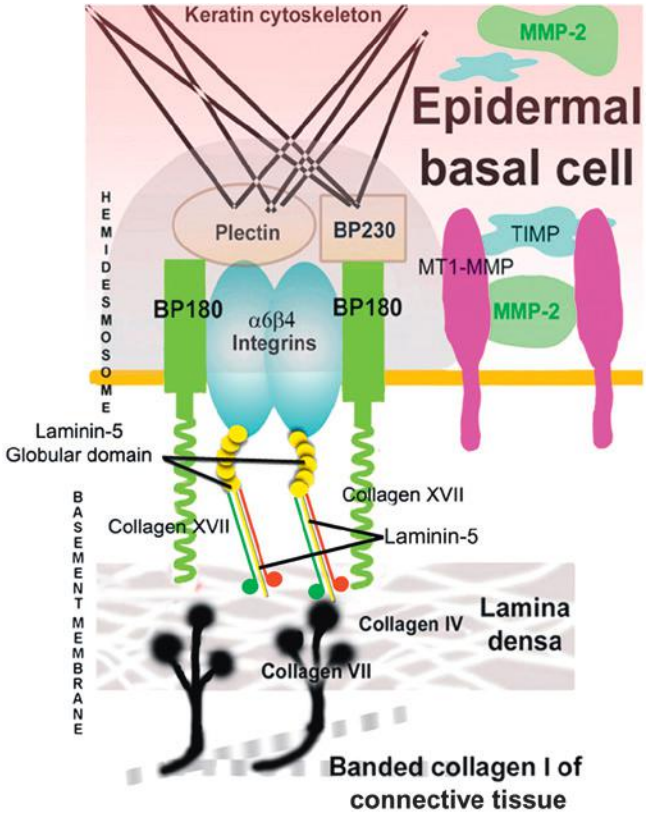

Fig. 15-5 Depiction of the structure of a hemidesmosome and lamina densa, which provide the connection between the basal cell and basement membrane. Note the variety of proteins, including glycoproteins and collagen, that provide tight attachment of the distal phalanx to the hoof. (Reproduced with permission from Pollit C. The anatomy and physiology of the suspensory apparatus of the distal phalanx. *Vet Clin North Am Equine* 2010; 26:29–49.)

- **Laminitis**—the conventional definition is that of a clinical syndrome of foot pain, usually in an acute setting, in horses resulting from separation of the dermal and epidermal lamellae. Laminitis implies an inflammatory component or etiopathogenesis, which does not appear to always be present in all phases of the disease.
- **Prodromal laminitis** (developmental laminitis)—that phase between initiation of the disease process in the foot and appearance of clinical signs.
- **Acute laminitis—**that phase between first development of signs of foot pain and displacement of the distal phalanx (often 72 hours but variable and displacement does not occur in all cases).
- **Chronic laminitis—**phase of the disease after displacement has occurred. It can be further divided into early chronic laminitis, chronic active laminitis, and chronic stable laminitis.
- **Acute founder**—clinical signs of laminitis (strong digital pulses, toe relieving stance, and frequent weight shifting) plus signs of disruption of the normal gross anatomy of the foot evident as supracoronary depressions or radiographic evidence of rotation or distal displacement of the distal phalanx within the hoof ("sinking").
- **Chronic founder**—clinical signs of concave dorsal hoof wall, abnormally wide dorsal white lines, and divergent growth rings in the hoof wall. Sometimes referred to as "chronic laminitis," this syndrome is not characterized by continued disruption of the lamellae but rather represents the sequelae to laminitis or acute founder. If there is ongoing disruption of the epidermal-dermal connection, then this would be laminitis or acute founder.
- **Prolapse of the sole—**a consequence of distal displacement of the distal phalanx resulting in loss of concavity of the sole.
- **Penetration of the sole—**progression of prolapse of the sole to the point where the dermis or pedal bone protrudes through the sole.

ETIOLOGY

The proximate cause of laminitis is acute degeneration of the connections between the basal cells of the primary and secondary epidermal lamellae and the basement membrane of the primary and secondary dermal lamellae. Loss of these connections can lead to microscopic and macroscopic disruption of the normal architecture of the foot and development of clinical signs of foot pain. The factors inciting or leading to breakdown of the epidermal-dermal connections within the hoof are uncertain and the subject of much active investigation.

Laminitis is recognized in a number of settings, which could have differing inciting causes:

- **Endocrinopathic** laminitis—laminitis associated with hormonal influences favoring hyperinsulinemia and often associated with insulin resistance as part of equine metabolic syndrome (EMS) or pasture associated laminitis.[4] Hyperinsulinemia is an experimental model for inducing laminitis.[5,6] Endocrinopathic laminitis, associated with either EMS or pituitary pars intermedia dysfunction, is responsible for most cases of laminitis, with estimates ranging from 71% to 89% of cases.[4,7]
- **Sepsis-related** laminitis—horses with septic illness characterized by signs of a systemic inflammatory response (fever, tachycardia, depression), such as horses with enterocolitis, pneumonia and/or pleuritis, and postpartum septic metritis, or after ingestion of large quantities of soluble carbohydrate, are at increased risk of laminitis.
- **Weight-bearing** laminitis—horses that chronically bear more weight on one limb, such as animals with severe persistent unilateral lameness, often develop laminitis in the weight-bearing limb.
- **Concussive** laminitis—associated with prolonged or unaccustomed exercise on a hard surface.
- **Toxic** laminitis—exposure to shavings of black walnut (*Juglans nigra*) causes laminitis. The mechanism involves a severe systemic inflammatory response, and this category of laminitis could share basic mechanisms with that caused by sepsis. Black walnut has been used as an experimental model of laminitis but is now considered less clinically relevant.[8]
- Sustained (lasting 48 hours) digital hyperthermia does not cause laminitis.[9]

EPIDEMIOLOGY

For such a common and important disease, the epidemiology of laminitis is poorly documented.[10] Quantitative analysis and identification of putative risk factors is available from few studies, and in many instances such studies do not have clear case definitions or rely on lay reporting of the diagnosis and presence of potential risk factors, with the result that conclusions are unreliable and conflicting. There is a pressing need for well-designed, comprehensive studies that address the prevalence, risk factors, and outcome of spontaneously occurring laminitis in non-hospital settings.

A recent systematic review of the scientific literature reporting on risk factors for laminitis concluded that there is limited evidence to support a role for many of the putative risk factors for laminitis.[10] Based on the reporting in the 6 highest-quality reports of 17 reviewed, the following conclusions were made:[10]

- Age—good evidence that increasing age is a risk factor for laminitis, although some studies did not find this association for acute laminitis
- Sex (gender)—inconsistent evidence; most studies did not find an association
- Breed—inconsistent evidence; most studies did not find an association
- Height—no evidence of an association
- Bodyweight—inconsistent evidence
- General obesity—no evidence
- Cresty neck—weak evidence
- Health variables—no evidence
- Exercise—weak evidence that reduced exercise level is a risk factor
- Endotoxemia—weak evidence, noting that experimental endotoxemia does not cause laminitis
- Pituitary pars intermedia dysfunction—no evidence
- Seasonality—inconsistent evidence
- Weather—weak evidence

Some of these results are surprising and likely will be revised as additional studies are conducted. As noted in the following discussion, there is consensus on several risk factors for development of laminitis that are not reflected in the results of the systematic review cited previously. In the absence of multiple high-quality epidemiologic studies, the results of the systematic review should be considered in light of other knowledge.

Occurrence

Single sporadic cases are the rule for **horses,** in which the disease is usually related to individual risk factors such as obesity, systemic illness, or lameness. An estimated 13% of horse operations in the United States have a horse with laminitis at any one time, and laminitis accounts for 7.5% to 15.7% of all lameness in horses.[11] A study of 1000 horses on a single farm in East Anglia (UK) found annual that annual incidence rates for laminitis varied from 7.9% to 17.1%, that 33% of animals diagnosed once with laminitis has a repeat episode of the disease, and that 24% of animals with laminitis had a repeat episode in the same year.[12] Laminitis accounts for up to 40% of hoof problems in horses, depending on the use of the horse. Approximately 5% of horses with laminitis die or are euthanized. Among cases occurring in the field (as opposed to veterinary hospitals), approximately 74% recover and become sound, with 8% improving but continuing to be lame.[11] However, approximately 10% of horses that developed laminitis had a permanent change in their primary use as a result of having developed laminitis.

Within the United Kingdom, 30% of all cases of laminitis are speculated to be caused by grazing lush pasture, 21% as a result of pituitary pars intermedia dysfunction, 13% by obesity, and 9% attributable to equine

metabolic syndrome (cited in[4]). Laminitis accounts for approximately 4.4% of reported diseases in equids in the United Kingdom.[13]

Risk Factors

Animal Risk Factors

There are few studies that provide quantitative estimates of risk factors for equids developing laminitis.

Phenotype

There is a consensus that ponies and horses at increased risk of developing pasture-associated laminitis have a particular phenotype characterized by regional and generalized obesity.[14] Although not borne out by the systematic review, there appears to be considerable diverse evidence that ponies, and especially obese ponies, are at high risk of developing pasture-associated laminitis.[14,15] This risk also applies to obese horses and especially those of "easy keeper" or "thrifty" breeds such as Andalusians, Quarter horses, Morgan, and Arabians. The risk of laminitis is associated with insulin resistance, and not all obese horses or ponies are insulin resistant. Ponies at increased risk might be identified by a variety of means, including measurement of plasma or serum insulin concentration 2 hours after ingestion of glucose (1 g/kg orally).[16] Ponies with exaggerated insulin response are at increased risk of developing laminitis.

Hyperinsulinemia

Available evidence clearly indicates a propensity for ponies and horses at risk of insulin resistance (obesity, equine metabolic syndrome) to have a higher incidence of laminitis, especially if they are kept on pasture. These equids are considered to develop endocrinopathic laminitis.[15-20] A unifying feature of these horses and ponies is the presence, or presumed presence, of hyperinsulinemia.[14] Reports indicate that between 10% to 22% of obese horses and 28% of ponies in Australia have hyperinsulinemia. Insulin concentrations are higher (138 vs. 315 ρmol/L) in ponies with a history of laminitis than in younger ponies of similar body condition that have never had laminitis,[15,21] and are higher in previously laminitic ponies that have a higher body-condition score than unaffected ponies.[14] The affected ponies are also insulin resistant based on a higher insulin : glucose ratio or the reciprocal of the square root of plasma insulin concentration (RISQI).[15,21] Similarly, hyperinsulinemia is common in horses presenting to veterinary hospitals with a complaint of laminitis—from 21 of 36 (58%) to 13 of 30 (43%).[7,22]

Horses or ponies with documented hyperinsulinemia or pituitary pars intermedia dysfunction (PPID) are at increased risk of having laminitis.[7] Horses of 15 years of age or older in Queensland with PPID diagnosed by seasonally adjusted plasma adrenocorticotropic hormone (ACTH) concentrations were 4.7 times as likely to have laminitis compared with similarly aged horses without PPID.[23] Aged horses with hyperinsulinemia (>20 μU/mL) were 10 times more likely to have laminitis than were horses without documented hyperinsulinemia.[23] Laminitis in horses with PPID is associated with hyperinsulinemia but not at a greater rate than for horses that do not have PPID,[23] suggesting that the hyperinsulinemia present in some horses with PPID might be coincidental in the horse has both EMS and PPID and that it is the EMS that predisposes to hyperinsulinemia and laminitis. Although not supported by the systematic review, clinical evidence clearly supports a link between insulin resistance (hyperinsulinemia) or PPID and risk of laminitis.

The disease is more common in the United States during spring and summer (1.3% in spring and 0.4% in winter in the central United States) and during May in the United Kingdom.[12] Increasing number of hours of sunlight has been linked to the risk of laminitis in horses at pasture—a reflection of the effect of sunlight to increase the content of nonstructural carbohydrate in pasture and not of a biological effect of sunlight on the horses.[12]

The disease is very uncommon in foals and horses less than 8 months of age, then increases in frequency with increasing age such that horses greater than 20 years of age have an incidence of the disease roughly 3 times that of horses between 5 and 20 years of age. This apparent age distribution could represent, among other factors, an increase in prevalence of PPID as horses and ponies age.

Trauma and other physical factors such as excessive work on hard surfaces, increased weight-bearing on one limb, and persistent pawing can contribute to the development of the disease in horses. Standing for periods of days during transport can predispose to laminitis.

Laminitis is associated with many **systemic illnesses** of horses. Horses with illness attributable to colic, diarrhea, pleuropneumonia, and metritis are prone to develop laminitis. **Potomac horse fever** (equine neorickettsiosis) is frequently a cause of laminitis in horses, and laminitis is the major cause of death from this disease. Approximately 28% of horses with **anterior enteritis** (duodenitis/proximal jejunitis) develop laminitis, usually within 2 days of developing enteritis. There are anecdotal reports that suggest that administration of **corticosteroids** (dexamethasone, triamcinolone) causes or exacerbates laminitis, but this association has not been proved.[24-26] Laminitis is common in horses that engorge on grain or similar feeds containing a high concentration of soluble carbohydrates. Ingestion of large quantities of lush pasture has been anecdotally associated with increased risk of laminitis, especially among ponies. It is thought that the presence of a high concentration of soluble carbohydrates in the grass is responsible for the increased risk of laminitis.

Supporting Limb Laminitis

Development of laminitis in a limb bearing a disproportionate amount of the horse's weight for prolonged periods of time is a frequent occurrence among horses treated for severe chronic unilateral lameness or subject to fracture repair requiring casting of the limb. Of 113 horses that received half-limb or full-limb casts, 14 (12%) developed confirmed supporting limb laminitis.[27] Risk factors significantly associated with development of laminitis included body weight of the horse and duration of casting in weeks, with horses requiring full-limb casts or transfixion pin casts more likely to develop this complication than horses requiring half-limb casts. Supporting hindlimbs (for the contralateral hindlimb) were as likely to be affected as supporting forelimbs.

Horses hospitalized for treatment of laminitis, or those that develop laminitis during hospitalization for other diseases, have risk factors that differ from those of horses with pasture-associated laminitis. Endotoxemia (defined clinically, not by measurement of blood endotoxin concentration, and therefore more appropriately referred to as toxemia) was the only factor associated with development of laminitis.[28] This study provides evidence that severe systemic inflammation increases the risk of laminitis, but it provides no evidence of the effect of endotoxemia.

Importance

Death is unusual in horses with laminitis that do not have other severe systemic illness, but the severe lameness can cause a great deal of inconvenience, and affected horses can develop permanent deformities of the feet. Some have to be euthanized on humane grounds.

Of 107 horses with pasture-associated laminitis, 77 had a "good" outcome as assessed by a panel of veterinarians, and 47 of 79 animals used for riding before developing laminitis were being ridden 8 weeks later. Five of the initial 107 animals were euthanized by 8 weeks after development of the disease, and those that were more severely affected (based on Obel grade of lameness) were more likely to have been euthanized.[29]

Among 247 hospitalized horses that died or were euthanized because of laminitis and 344 horses that developed laminitis but did not die, factors increasing the risk of death because of laminitis were being Thoroughbred (odds ratio [OR] = 1.57) or a racehorse (OR = 1.76), treatment with flunixin meglumine (OR = 1.76), distal displacement of the third phalanx (OR = 2.68), pneumonia (OR

= 2.87), and lameness of Obel grade II (OR = 2.99), grade III (OR = 9.63), or grade IV (OR = 20.48) compared with Obel grade I.[30]

PATHOGENESIS

The pathogenesis of laminitis is complex and in most cases involves systemic disease that is at least partially expressed in the foot. Evidence for laminitis being part of a systemic disease and not only a localized disease of the foot includes observations that analysis of a panel of tissue samples from horses with experimentally induced laminitis revealed that degradation of laminin-332 and collagen type IV, both proteins found in the basement membrane of the hoof, occurs in the skin and stomach in addition to the hoof lamellae.[31] Additionally, systemic inflammatory responses, including infiltration of neutrophils, are noted in lung, skin, liver, and gastrointestinal tract of horses with black walnut–induced laminitis.[32-34] These findings suggest that systemic inflammation and degradation of proteins common to a wide range of tissues, and including the basement membrane, are common to many epithelial tissues during equine laminitis, suggesting a systemic pathogenesis for at least some forms of this disease.

The local pathogenic process common to all forms of laminitis is disruption of the connective tissue (involving laminin-5 and collagen types IV and VII) providing connections between the lamellar basal cells and the basement membrane of the third phalanx.[35] Carbohydrate overload is associated with up-regulation of genes expressing MMP-13 (matrix metalloproteinase 13) and localized loss of collagen I, fibronectin, chondroitin, and keratin sulfate glycosaminoglycans in secondary lamellae.[36]

It is possible, indeed likely, that a more than one type of insult to basal cells or basement membrane can result in loss of adhesion between the basal cell and the basement membrane—sometimes referred to as dyshesion—or degeneration of the basement membrane. As a consequence of the loss of these connections, the weight of the horse is no longer transmitted through the numerous lamellae to the hoof wall but is instead transmitted toward the sole of the foot.

Loss of the connection between the third phalanx and hoof allows the third phalanx to **rotate** within the hoof capsule, likely in response to the torque applied by the deep digital flexor tendon, and/or to displace ventrally (**sink**) within the hoof as a result of weight transmitted through the third phalanx; or there can be a combination of these changes. Rotation of the third phalanx causes the sole to be pushed downward or "dropped," and the point of the toe of the third phalanx may actually penetrate the sole. Serum accumulates in the space created by degeneration of the laminae and displacement of the third phalanx, and there is breakdown of the white line.

Exactly what the mechanism is that links the risk factors listed previously to the laminar degeneration, the basis of the separation, is unknown. There are differences in the microscopic lesions induced by either **hyperinsulinemia or models of sepsis-induced laminitis** (carbohydrate overload, oligofructose [OF] administration), suggesting that the inciting mechanisms in each from of laminitis could differ,[37] with subsequent common events resulting in the clinical signs of laminitis.[38] Calprotectin, a marker of the presence or activation of neutrophils, expression in lamellae was absent in control horses, moderate in hyperinsulinemic horses, and marked in OF-treated horses, indicating that hyperinsulinemia induces less leukocyte emigration than carbohydrate overload at 48 hours after initiation of the inciting cause.[37] Laminitis induced by administration of black walnut is characterized by early (1.5 hours) marked infiltration of neutrophils and expression of neutrophil adhesion molecules in lamellar endothelial cells and cytokines favoring extravasation of neutrophils into lamellae.[39-42] There are similar changes during carbohydrate overload laminitis but with a somewhat delayed time frame with some extravasation of leukocytes, which are predominantly monocytes and macrophages (compare with neutrophils in black walnut laminitis), during the prodromal phase but maximal accumulation in lamellar tissues at the onset of clinical signs.[43-46] Similarly, there is increased mRNA concentrations for IL-1 beta, IL-6, IL-12p35, COX-2, E-selectin, and ICAM-1 in laminae from horses with Obel grade I lameness but not during the prodromal phase in horses with carbohydrate-induced laminitis.[43]

The majority of laminar inflammatory events appear to occur at or near the onset of lameness in the carbohydrate-overload (CHO) model, whereas many of these events peak earlier in the prodromal (developmental) stages in the black walnut extract–model. This suggests that, in addition to circulating inflammatory molecules, there may be a local phenomenon in the CHO model resulting in the simultaneous onset of multiple laminar events, including endothelial activation, leukocyte emigration, and proinflammatory cytokine expression.[43] CHO laminitis is associated with increases in mRNA of various CXC and CC chemokines during either the prodromal or clinical phase, or both, and in the increase in expression of a wide range of proinflammatory genes.[45,47] CHO-induced laminitis is associated with marked changes in fecal microbiota, including overgrowth of gram-negative bacteria.[48] Inflammatory signaling is a consistent entity in the pathophysiology of laminitis, although there is evidence that leukocyte appearance in lamellar tissues is not the first event in the pathogenesis of laminitis but has a key early role in the development of lesions and progression of the disease.

Hyperinsulinemia (with euglycemia) induced by prolonged (up to 72 hours) infusion of insulin and glucose results in development of clinical and histologic signs of laminitis in insulin-sensitive horses and in ponies.[5,49-51] The concentrations of insulin required to induce laminitis in insulin-sensitive horses are very high (>1000 μU/mL), although lesions, but not clinical signs, have been detected in horses in which insulin concentrations approximated 200 μU/mL as a result of infusion of glucose.[6] Microscopic lesions induced by infusion of insulin during the prodromal (development) phase of laminitis have been well characterized and contrasted with those of carbohydrate overload.[51-53] There is no detectable calprotectin present before 48 hours (about the time of onset of clinical signs of laminitis), whereas secondary epidermal lamellar width decreases, and there is histomorphological evidence of epidermal basal (and suprabasal) cell death after 6 hours of hyperinsulinemia.[50,53] Increased cellular proliferation in the secondary epidermal lamellae, infiltration of the dermis with small numbers of leukocytes, and basement membrane (BM) damage occurred later at 24 and 48 hours. Narrowing of the secondary epidermal lamellae was progressive over the 6- to 48-hour period.[50] There were signs of apoptosis of basal cells. Cellular lesions preceded leukocyte infiltration and BM lesions, indicating that the latter changes may be secondary or downstream events in hyperinsulinemic laminitis to initial insults to basal cells.[50]

A role for insulin-like growth factor (IGF) has been proposed, with insulin acting as an agonist for the IGF receptor. Cell proliferation occurs in the lamellae during insulin-induced laminitis, and in other species high concentrations of insulin can activate receptors for the powerful cell mitogen IGF-1.[54] It is speculated that stimulation of the IGF-1 receptor by insulin could lead to inappropriate lamellar epidermal cell proliferation and lamellar weakening, a potential mechanism for hyperinsulinemic laminitis.[54]

Hyperinsulinemia causes increases in plasma concentrations of pentosidine, an advanced glycoxidation end product indicative of inflammation, which could indicate a role for glucose toxicity in the genesis of endocrinopathic laminitis.[21] However, the failure to detect advance glycoxidation products in the lamellae of horses during the prodromal phase of laminitis induced by hyperinsulinemic–hyperglycemic clamp, although these products were detected when clinical signs of laminitis had developed, and the lack of evidence of oxidative stress do not lend support to oxidative stress and protein glycosylation playing a central role in the pathogenesis of acute, insulin-induced laminitis.[55] The insulin-independent glucose transporter GLUT-1 was increased in lamellar tissue in the developmental stages of

insulin-induced laminitis compared with control horses, although the importance of this observation is unclear.[55] There does not appear to be a role for toll-like receptor 4 (TLR4) in the development of hyperinsulinemic laminitis in otherwise healthy horses.[56]

Hyperinsulinemia in isolated (ex vivo) hooves of healthy horses increases vascular resistance and lamellar endothelin-1 expression and perfusion of isolated lamellar veins with cortisol and insulin.[57] Exposure of isolated lamellar veins to cortisol increases maximum contractility to the vasoconstrictors (noradrenaline and 5-hydroxytryptamine) and decreases the maximal contraction to endothelin-1, whereas exposure to insulin decreases contractility of vessels to phenylephrine and endothelin-1 (ET-1).[58] It is possible that short-term cortisol excess could enhance venoconstrictor responses to 5-hydroxytryptamine and noradrenalin in laminar veins in vivo, thereby predisposing to laminitis.[58] The authors conclude that a reduction in the ability of insulin to counteract alpha-adrenoreceptor and ET-1-mediated contraction, likely to occur in subjects with insulin resistance, could further exacerbate venoconstriction in animals prone to laminitis. These mechanisms could also predispose horses with PPID or EMS to laminitis.[58] Others have demonstrated that insulin resistance, which is associated with hyperinsulinemia, increases vascular reactivity and response to various vasoconstrictors and has, in the absence of direct experimental evidence in horses or ponies, been speculated to contribute to excessive vasoconstriction in the dermis of susceptible horses.[20] Short-term hyperinsulinemia increases vascular resistance in the equine digit and increases expression of ET-1 in the laminar tissue, providing a possible explanation for a role for insulin in perfusion of the digit.[57] Furthermore, laminitis induced by IV infusion of insulin is associated with warmth of the hoof, which is considered evidence of vasodilatation in the foot. It is plausible that there is a combination of these mechanisms, beginning with digital venoconstriction and ending in arteriovenous shunting, that could lead to hypoxemia of lamella and loss of integrity of the basal cells or basement membrane.

Other theories for the etiopathogenesis of laminitis include the following:

- Ischemia of the laminae with subsequent dysfunction or death of basal cells or degeneration of the basement membrane—proposed causes of ischemia include vasoconstriction, development of arteriovenous shunts, interstitial edema, and presence of microthrombi in digital vessels. Ischemia as a result of microthrombus formation is no longer considered a potential cause of laminitis. However, there is evidence from experimental laminitis, both black walnut and carbohydrate models, that there are changes to the microvasculature of the dermis, possibly secondary to changes in circulating concentrations of vasoactive amines or contractile activity of vessels in the hoof.[57,59-63] Alternatively, increases in capillary filtration pressure, resulting from venoconstriction, might cause edema and increased interstitial pressure with subsequent ischemia of the laminae.[11]
- Enzymatic digestion of connective tissues of the lamella by matrix metalloproteins (MMPs) induced by circulating factors including products of *Streptococcus bovis* infection has been proposed as a cause of the loss of integrity of the basal cell–basement membrane junction. Recent evidence indicates that MMP-9 is not involved in this process because it remains in the inactive proenzyme form during the prodromal (developmental) phase of oligofructose-induced laminitis, although MMP-13 might be.[36,64,65] However, other proteinases, such as ADAMT-4, and metalloproteinases might be involved in affecting basal cell or basement membrane function. Interesting, ADAMT-4 is located primarily in the basal cells and not in the matrix, calling into question its role in basement membrane integrity or disruption of adhesion between basal cells and the basement membrane.[66,67] Alternatively, elevated ADAMT-4 expression and versican depletion could be associated with abnormal basal cell function and disruption of adhesion.[68]
- Infusion of endotoxin does not induce laminitis in healthy horses or ponies, nor does the systemic inflammatory response induced by administration of endotoxin manifest as expression of genes of proinflammatory cytokines in the lamellae.[69] Many of the inciting causes of laminitis are diseases that are associated with **endotoxemia** or, more generally, toxemia, and in experimental models endotoxin was detectable in the blood of horses that developed laminitis, suggesting that endotoxin could contribute to the development of the disease. However, infusions of endotoxin do not cause laminitis, although endotoxin does impair endothelium-dependent relaxation and augments adrenergic contraction of palmar digital arteries.
- Theories for development of laminitis in a supporting limb include loss of intermittent weight-bearing with a reduction in vascular perfusion of the hoof and ischemia of the lamellae.[70]
- There is no evidence that laminitis is an autoimmune disease.[71]

The disease occurs in three distinct phases: (1) a developmental stage in which lesions are detectable in the sensitive laminae but during which there are no clinical signs, (2) the acute phase from the development of the first clinical signs through to rapid resolution or to rotation or ventral displacement of the third phalanx, and (3) the chronic stage evidenced by rotation of the third phalanx with or without ventral displacement and characterized by variable but persistent pain.

CLINICAL FINDINGS

The disease presents as both an acute disease and as a chronic disease. The severity of the acute disease varies considerably from very mild with rapid (5 to 7 days) recovery, to severe with progression to the chronic, refractory stage.

Severity of lameness attributable to laminitis can be graded according to a scale proposed by Obel in 1948:

Grade 0—normal
Grade 1—horse alternately and intermittently lifts its feet; lameness is not evident at a walk but the gait is short and stilted at a trot.
Grade 2—there is a stilted gait at the walk, but the horse moves willingly; a foot may be lifted by a handler without the horse resisting.
Grade 3—the horse moves reluctantly and resists attempts by a handler to lift a foot.
Grade 4—the horse refuses to move and does so only if forced.

The reliability of this system has been assessed, and it has reasonable intraobserver reliability (weighted kappa statistic of 0.54) when using all four (five) grades, which increases to 0.69 when reduced to three categories (sound, grades I and II combined, and grades III and IV combined).[72] Interobserver agreement (58 veterinarians in primary opinion equine practice) was 0.43 (moderate agreement) for the unweighted kappa statistic and 0.65 (substantial agreement) for the weighted kappa statistic when all four (five) grades were used. When grades were lumped into the three categories, the interobserver agreement increased to 0.52 and 054 for unweighted and weighted kappa statistics, respectively. Importantly, there was 83% agreement on detection of severely affected animals (of the three lumped grades).[72] These results are similar to those of a study comparing use of a visual analog scale, Obel grade, and clinical grading system. All methods of assessing severity of laminitis had acceptable intra- and interobserver agreement, with more experienced observers having greater reliability.[73] These studies demonstrate that the Obel grading system is useful for clinical description of laminitis and therefore assessment of the response to therapy.

The **acute disease** develops rapidly; apparently normal horses can founder within hours. Signs of the disease are entirely attributable to pain in the feet. All hooves can be affected, but more commonly the forefeet are affected and the hindfeet are spared. The disease is rarely unilateral except in cases in which the disease develops because of severe lameness in the contralateral limb or repeated pawing. Mild, or early, disease is apparent as a resistance to movement and repetitive and frequent shifting of weight from one foot to the other. There is a characteristic shuffling gait.

More severe disease is apparent as refusal to move or to lift a hoof. At this stage the horse has an anxious expression that can be accompanied by muscle fasciculation, sweating, a marked increase in heart rate to as high as 75/min, and rapid and shallow respiration. There is a characteristic posture with all four feet being placed forward of their normal position, the head held low, and the back arched. There is usually a great deal of difficulty in getting the animal to move, and when it does so the gait is shuffling and stumbling, and the animal evidences great pain when the foot is put to the ground. The act of lying down is accomplished only with difficulty, often after a number of preliminary attempts. There is also difficulty in getting the animals to rise, and some horses may be recumbent for long periods. It is not unusual for horses to lie flat on their sides. In occasional cases, the separation of the wall from the laminae is acute, and the hoof is shed. There may be exudation of serum at the coronet, and this is considered a sign of impending sloughing of the hoof and a poor prognosis.

Clinical signs in laminitis include pain on palpation around the coronet and a marked withdrawal response when hoof testers are applied to the hoof. The intensity of the pulse in the palmar digital artery, palpable over the abaxial aspects of the proximal sesamoid, of affected feet is markedly increased over normal. In horses in which the third phalanx is displaced distally (sinks), a concavity can be palpable at the coronary band. Infiltration of the palmar digital nerves at the level of the proximal sesamoid with local anesthetic agents provides marked, but not complete, relief.

In the **chronic stages** of the disease, there is separation of the wall from the sensitive laminae and a consequent dropping of the sole. The hoof wall spreads and develops marked horizontal ridges, and the slope of the anterior surface of the wall becomes accentuated and concave. Horses with chronic or refractory laminitis may continue to feel much pain, lose weight, and develop decubitus ulcers over pressure points because of prolonged recumbency. Loss of integrity of the sole and disruption of the white line can allow infection to develop in the degenerate lamellae. The infection can spread to involve the pedal bone, causing a septic pedal osteitis. The lameness might abate, but the animal becomes lame easily with exercise and can suffer repeated, mild attacks of laminitis.

Fig. 15-6 Radiograph of a horse demonstrating rotation of the distal phalanx with likely penetration of the sole. The coronary band is indented, and there is no evidence of sinking. There is not osteolysis of the distal phalanx. (Reproduced with permission.[75])

Radiographic examination of the feet is an essential component in evaluation of horses with laminitis. The standard radiographic views that should be obtained to aid assessment of horses with laminitis are the lateromedial, horizontal dorsopalmar, and dorsal 45 degrees proximal palmarodistal oblique views.[74] A variety of objective measures have been developed to aid in the interpretation of radiographic examinations of the feet of laminitic horses (Figs. 15-6 and 15-7), and these are discussed in detail elsewhere.[74]

Initially and in mild cases, changes in the position of the distal phalanx are not evident. Radiographs of more severe or advanced cases will demonstrate rotation of the distal phalanx within the hoof, evident as a tilting of the most distal aspect of the third phalanx toward the sole. The space created by rotation of the pedal bone can fill with gas or serum and be evident as a radiolucent line between the pedal bone and the dorsal hoof wall. Displacement of the pedal bone toward the sole will be evident in approximately 25% of cases as a thickening of the dorsal hoof wall and reduction of the distance between the sole and solar aspect of the distal phalanx. Chronic or refractory cases can have osteopenia of the pedal bone with proliferation of bone at the toe.

Prognosis

The radiographic examination provides information of prognostic value, although because of differing radiographic techniques and interpretations the value of combining separate research studies to develop firm guidelines is difficult.[74] Horses that return to their previous level of athletic function after a bout of laminitis have pedal bone rotation of less than 5.5 degrees, whereas horses that can no longer perform as athletes usually have more than 11.5 degrees of rotation, although there are exceptions to this rule and the prognosis should be developed through a holistic assessment of the horse (level of pain, number of feet involved, sole penetration).[74] Therefore, these values should only be used as rough guidelines. The general rule is that the greater the degree of rotation or extent of displacement of the distal phalanx, the worse the prognosis for return to function and pain-free living.

Objective radiographic variables include the distance between the proximal aspect of the hoof wall (marked on the radiographic image by a piece of wire or strip of metal stuck to the dorsal hoof wall) and the

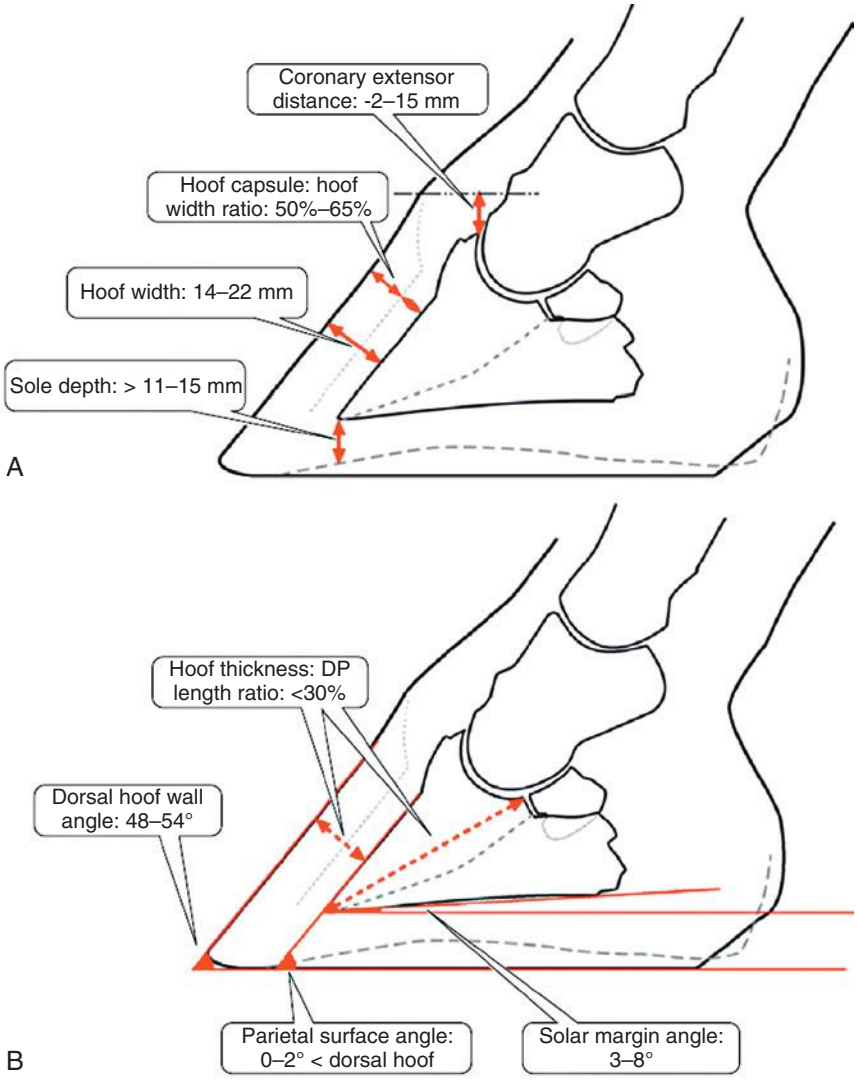

Fig. 15-7 Diagrams showing the normal radiologic distances and proportions in the front feet of sound horses. Care must be taken in interpretation of these values because there is marked individual (breed and size) variability, and many can also be altered by farriery; the measurements in these diagrams do not represent the absolute minimum and maximum of normal values; rather. they are representative of the center of the range. (Reproduced with permission.[74])

proximal limit of the extensor process of the distal phalanx (the "founder" distance), and the distance between the dorsal hoof wall and the dorsal cortex of the distal phalanx. Although values for these measures vary among breeds and with the size of the horse, most normal horses will have a "founder" distance of 4.1 ± 2.2 (standard deviation) mm and a wall thickness of 16.3 ± 2.4 mm. Intensively managed horses with signs of sinking (medial, lateral, or vertical) had an overall success rate of 18% (17/95), whereas nonsinkers (horses with or without apparent rotation) with laminitis had a 71% (107/150) success rate.[75]

CLINICAL PATHOLOGY

There are no changes that are characteristic of the disease.

NECROPSY FINDINGS

The disease is not usually fatal, but severely affected animals are often euthanized. In acute cases, there may be evidence of colitis, grain overload, or retained placenta and metritis in mares. No reliable gross findings are visible on the feet, but a midsagittal section of the hoof may reveal congestion, hemorrhage, and slight separation of the dorsal surface of P3 from the epidermal laminae of the inner surface of the horny hoof wall in severe cases. The separation of P3 becomes more obvious in subacute and chronic cases, leading to a ventral rotation of the phalanx. In some cases the degree of rotation of P3 results in perforation of the sole.

Histologic examination is required only in acute cases, and confirmation of the diagnosis in such instances demands that the foot be cut into slab sections and fixed shortly after the death of the animal, before even moderate autolysis can ensue. Microscopically, the lesions are degeneration and necrosis of epithelial cells of the laminae, separation of epithelial cells from the basement membrane, and loss of the basement membrane.

DIFFERENTIAL DIAGNOSIS

Horses

Rhabdomyolysis, tetanus, colic, and spinal ataxia may all mimic the immobility and pain of laminitis, but there is no pain in the feet in these diseases, and other distinguishing characteristics are apparent on careful clinical examination.

TREATMENT

The adage "where facts are few experts are many" (Donald R. Gannon) applies well to the treatment of laminitis. There are few well-designed studies of the treatment of naturally occurring laminitis, and thus the choice of treatment is based on personal experience, extrapolation from our imperfect understanding of the pathogenesis of the disease, the availability of certain drugs, and current fashion. Indeed, the treatment of laminitis might one day be chronicled to demonstrate the power of "expert" opinion to determine treatments, many of which are now recognized as useless. A fascinating example is that of the application of nitroglycerin patches to the pasterns of horses with laminitis or at increased risk of laminitis. A multitude of horses were treated in this way, some to the extent that they were rendered hypotensive, at considerable direct cost and opportunity cost, and all for naught. Although not intended to discount the opinion of experts in the treatment of laminitis, it is a salutary tale demonstrating the strength of fashion and fad in promoting ineffective treatments of this important disease.

In general, the treatments can be grouped into several classes, based on the intended intervention. These are as follows:

- Removal of the causative agent or treatment of the inciting disease
- Pain relief and minimization of inflammation
- Prevention of further damage to lamellae and rotation or distal displacement of the pedal bone
- Promotion of keratinization and hoof growth

The efficacy of administration of analgesic, antiinflammatory, anticoagulant, and vasodilatory drugs and mechanical support of the hoof has never been demonstrated in appropriate clinical trials. There is evidence that local cryotherapy (cooling of the distal limb) is effective in reducing the clinical signs and severity of lesions of

oligofructose-induced experimental laminitis,[76] with limited although supportive clinical evidence.[77]

Acute laminitis is an emergency, and treatment should be started without delay because early and aggressive therapy might enhance the chances of recovery.

Treatment of Inciting Process or Disease

The inciting disease should be treated aggressively and every attempt made to remove any causative agent.

Horses with systemic inflammatory disease (colitis, metritis, etc.) should be treated aggressively to reduce the likelihood that they will develop laminitis. Treatment of colitis, metritis, pleuropneumonia, colic, and other diseases is dealt with under those topics.

Horses with laminitis should be rested and housed in stalls that are well bedded with sand or soft shavings. Horses suspected of having PPID, insulin resistance, or EMS[17] should have the diagnosis confirmed and appropriate therapy instituted.

Cryotherapy or Digital Cooling

There is experimental, and some clinical, evidence that chilling of the feet is effective in preventing development of laminitis and in attenuating the effects of established (acute) laminitis induced experimentally.[77,78]

Progression of experimental laminitis (CHO model) can be prevented by cooling (chilling) of the feet of horses during the prodromal and acute phases of the disease.[76,78] Cooling of the distal limbs of horses administered 10 g/kg body weight of oligofructose markedly reduced the clinical signs of laminitis and development of histologic lesions in the feet of treated horses. Cooling in the experimental model began at the time of administration of oligofructose and continued for 72 hours. Horses treated by immersion of the limbs in cold water (0.5 to 2.0° C; 33–36 F) had only mild signs of lameness (grade I or less) at all times up until euthanasia at 72 hours.[76] Furthermore, chilling of the limbs significantly reduced expression of a range of genes of proinflammatory proteins and increased expression of an antiinflammatory protein during both the prodromal and clinical phases of disease.[79]

Chilling of limbs after the onset of laminitis induced by oligofructose prevents lamellar structural failure and reduces the severity of damage to lamellae.[80] Chilling (cryotherapy) of feet was initiated as soon as Obel grade II lameness was detected (horses were examined every 4 hours) and continued until euthanasia 36 hours after onset of lameness. Horses were also administered phenylbutazone (8 mg/kg IV—a high dose) and had continuous peripheral nerve block to alleviate foot pain. The frequency of weight shifting was significantly reduced in chilled feet, as assessed by pedometer, which was inferred as indicating less pain in chilled feet. It is important to consider that model was one of experimental laminitis, chilling was initiated less than 4 hours after onset of lameness, and chilling was maintained continuously for the duration of the study (36 hours). Whether the treatment would be as effective for other forms of laminitis or if initiated later in the development of lameness, and the optimal duration of chilling, are not known.

A **retrospective case-control study** identified that horses at risk of developing laminitis secondary to colitis were 0.14 (95% confidence interval [CI] 0.04 to 0.51) times less likely to develop laminitis if treated with digital cryotherapy.[77]

It has been practice for some time by both laypeople and veterinarians to cool the feet of acutely laminitic horses. With evidence that chilling reduces clinical and biochemical/genetic signs of inflammation in the feet of horses with induced laminitis, there is justification for clinical trials to determine the usefulness of this treatment in horses with acute or ongoing (chronic, active) laminitis. Prophylactic chilling of the feet of horses at high risk of developing laminitis, such as those with colitis, pleuropneumonia, metritis, and grain engorgement, could be considered, recognizing that there is a history of proposed treatments for laminitis that have not lived up to their promise. Protocols for chilling of limbs in a clinical setting have not been developed or demonstrated to be effective and without important adverse effects. It is important that any such protocols address issues such as the optimal time for starting cooling of limbs in horses with acute laminitis, duration of treatment, how to rewarm the limb, whether all limbs or only the forelimbs should be cooled, efficacy in differing forms of laminitis (endocrinopathic, sepsis-associated, supporting limb, concussive), and long-term outcome. Techniques have been developed to assist in monitoring the distal limb temperatures of horses during limb chilling.[81]

Analgesics and Antiinflammatory Drugs

A mainstay of the treatment of both acute and chronic laminitis is the use of nonsteroidal antiinflammatory drugs (NSAIDs). These are administered to provide pain relief, and there is no evidence that they delay progression of the disease.

Phenylbutazone, at doses of 2.2 to 4.4 mg/kg IV or orally every 12 to 24 hours, is an effective analgesic in cases of mild to moderate laminitis. Higher doses (6.6 mg/kg every 12 to 24 hours) can be required in severe cases. However, the potential for phenylbutazone toxicosis, evident as colic, gastrointestinal ulceration, nephrosis, hypoproteinemia, leukopenia, and hyponatremia, is dose related, and high doses of phenylbutazone should only be used for at most several days and only in horses experiencing severe pain. **Flunixin meglumine** (1.1 mg/kg, IM or IV every 8 to 12 hours) or **ketoprofen** (2.2 mg/kg, IM every 12 to 24 hours) are also effective analgesics. Their concurrent use with phenylbutazone can enhance pain relief but also increases the risk of NSAID toxicosis. A number of other NSAIDs are available for use in horses (meloxicam, firocoxib) and might be useful for management of pain in some horses. The use of aspirin is dealt with under "Anticoagulants."

Narcotic analgesics such as butorphanol, morphine, and meperidine (pethidine) provide effective pain relief; α-2 agonists such as **xylazine and detomidine** provide only brief respite from the pain.

Horses with severe lameness (Obel grade III or IV) might benefit from administration of drug cocktails including tramadol and subanesthetic doses of ketamine (0.6 mg/kg per hour IV)[82] or constant-rate infusions of a mixture of an α-2 agonist, a narcotic, and ketamine.[83] The use of objective assessment tools to assess the severity of pain and response to administration of analgesics is preferred over unstructured assessment of pain.[83]

Local analgesia of the foot with agents such as lidocaine or bupivacaine provides marked pain relief. However, analgesia is usually only brief, depending on the agent used, and has the disadvantage of causing the horse to bear more weight on the affected limbs. Local analgesia can be useful in facilitating relocation of the horse, hoof trimming, corrective shoeing, or application of sole and frog support, but not as a routine treatment.

Lidocaine, administered intravenously as a constant-rate infusion, has been advocated as an antiinflammatory drug for the treatment of laminitis. However, evidence from the black-walnut model of laminitis does not indicate efficacy in reducing markers of inflammation.[84]

Because of suspicion that **corticosteroids** induce or exacerbate laminitis, at this time their use is contraindicated in the treatment of laminitis.[24-26,85,86]

Vasodilatory Drugs

Vasodilatory drugs are used on the premise that vasoconstriction is an important mechanism underlying the development or progression of acute laminitis. Several classes of drugs have been used, including α-adrenergic antagonists such as phenoxybenzamine and phentolamine, drugs with multiple mechanisms of action such as acepromazine and isoxsuprine, and nitric oxide donors such as glyceryl trinitrate (nitroglycerine) and L-arginine. None of the vasodilatory drugs should be used in horses with compromised cardiovascular function or dehydration.

Phenoxybenzamine and phentolamine are not readily available and have limited use. Phenoxybenzamine causes sedation. **Acepromazine** is a potent vasodilator,

principally because of its α-adrenergic antagonist activity, that is currently used occasionally in the treatment of acute laminitis.[12] Acepromazine increases blood flow to the digit, but its effect on nutritive flow to the lamellae is unknown, as is the case for all the vasodilators. The effect of Acepromazine persists for approximately 90 minutes after IV administration. Acepromazine can be administered at dose rates ranging from 0.01 to 0.05 mg/kg, IM, every 6 to 12 hours. Sedation may be considerable at the higher doses and/or with more frequent administration and might be a desired effect in reducing movement (and hence potential for further damage to lamellae) and anxiety. **Isoxsuprine** is a combined α-antagonist and β-agonist that increases blood flow to the leg but not to the foot in normal horses. It has been used at doses of 1 to 1.5 mg/kg orally every 12 hours. Pentoxifylline (4.4 mg/kg orally q8h), which increases red blood cell deformability, does not increase digital blood flow in normal horses.

Application of **nitroglycerine** a nitric oxide donor, to the palmar digital arteries of affected horses has been reported to increase or not affect blood flow to the dorsal hoof wall. However, the effect of these substances on the course of the disease is unknown. In spontaneous cases of acute laminitis, nitroglycerine has been applied to the skin over both palmar digital arteries of affected feet at a dose of 15 to 30 mg per artery, once daily. However, because of lack of evidence of efficacy and the potential for systemic hypotension secondary to systemic absorption of the drug, its use is no longer recommended.

Anticoagulants

Anticoagulant drugs are administered to prevent the development of microthrombi within the hoof. Current evidence does not support an important role for microthrombi in the development of laminitis. However, activated platelets do accumulate in lamellar vessels and release vasoactive compounds.[59] Aspirin is a very poor analgesic in horses but is used because it reduces platelet aggregation in normal horses by blocking formation of thromboxane A_2. However, thromboxane may not be an important cause of platelet aggregation in horses. Aspirin is administered at a dose of 10 mg/kg orally every 48 hours. The efficacy of aspirin in the treatment of laminitis has not been determined.

Heparin in sufficient doses prolongs blood clotting, provided that there is adequate antithrombin III in the patient's blood. Heparin has been reported to prevent or to have no effect on the development of laminitis in horses with anterior enteritis or colic, respectively. Heparin can be administered at 40 to 80 IU/kg IV or subcutaneously (SC) every 8 to 12 hours for 3 to 5 days. Anemia can develop during heparin administration but resolves rapidly when administration of the drug is stopped.

Administration of low-molecular-weight heparin is proposed as prophylaxis for laminitis in horses at high risk of the disease. A study of horses admitted for colic surgery included 304 horses treated with low-molecular-weight heparin between 1995 and 2007 and 56 horses, admitted before 1995, that were not treated with the compound found that the prevalence of horses developing laminitis in the treatment group (3.3%; 95% CI, 1.7% to 6.2%) was significantly lower than in the control group (10.7%; 95% CI, 4.4% to 22.6%).[87] However, horses in the control group were a historical control, and there might well be other factors that contributed to the reduction in incidence of laminitis, such as improved preoperative, intraoperative, and postoperative care. This one study cannot be considered to provide proof of efficacy.

Mechanical Support

Mechanical support to provide pain relief, minimize further damage to lamellae, and in an attempt to prevent rotation or distal displacement of the pedal bone is an important part of the care of horses with acute laminitis.

Support of the frog and/or sole can be achieved using packing material such as dental acrylic or firm plastic or silicone that is molded to conform to the shape of the sole. Some clinicians prefer to use **wedge pads** to elevate the heel and reduce tension in the deep digital flexor tendon, with the aim of preventing rotation of the distal phalanx by reducing "break-over" forces. Trimming of the toe could achieve the same effect.

Housing the horse on sand or other soft bedding is frequently recommended.

Corrective shoeing of horses with chronic laminitis is widely practiced, and there are proponents of a wide variety of shoe types (fullered egg-bar, heart-bar, glue-on shoes). Appropriate hoof care, which might include shoeing, is important in managing horses with chronic laminitis. Interestingly, there was not a difference among shoe types in efficacy for pain relief in horses with chronic laminitis.

Promotion of Healing

Methionine has been given to both acute and chronic laminitis cases on the known requirement for methionine in the chondroitin complex of collagen. There is some rationale for the treatment, but it seems more appropriate as a supportive than as a principal treatment. The oral dose rate is 10 g/day for 3 days followed by 5 g/day for 10 days.

Antibiotics might be indicated to treat secondary infection of the degenerate lamellae.

Rest is important in the convalescent phase. Horses with no rotation or sinking of the pedal bone should be rested after resolution of the clinical signs. Return to work should be gradual. Horses that develop rotation or sinking of the pedal bone should be monitored both by physical examination and radiographic examination. It will be many months before horses with even mild rotation can be returned to work. Horses with severe rotation or sinking will likely never resume active work, although they may become pasture sound.

TREATMENT

Summary of treatment of acute laminitis

Depending on the cause, treatment of acute laminitis should include:

- Chilling of the limb (cryotherapy) (R-1)
- Administration of nonsteroidal antiinflammatory drugs (R-1)
- Administration of vasodilators (acepromazine) (R-2)
- Support of the frog and/or sole (R-1)
- Application of nitroglycerin (R-4)
- Aggressive treatment of the inciting disease (R-1)
- Trimming the hoof, distal phalanx realignment, and corrective shoeing (R-1)

Chronic Laminitis

The **prognosis** for return to normal of horses with chronic or refractory laminitis (laminitis of more than 1 week's duration) is poor (see previous discussion for the use of radiography to determine prognosis).

Treatment includes NSAIDs for pain relief, corrective shoeing (egg-bar or heart-bar shoes), trimming of the hoof (shortening the toe or complete removal of the dorsal hoof wall), and realignment of the distal phalanx.[88] Rehabilitating rotational displacement usually involves shoeing changes that move the center of pressure of the foot caudally from its normal position under the toes, decrease tension on the deep digital flexor tendon to reduce rotational forces on the distal phalanx that act to increase the distance between the distal phalanx and dorsal hoof wall, provide axial support of load structures within the perimeter of the wall (sole, frog, bars), and ease break-over in all directions (medial, lateral, and dorsally) in an effort to reduce distraction forces on the lamellae during movement.[75] Methods to move the center of pressure caudally and decrease tension on the deep digital flexor tendon using bar shoes and a heel elevation are recommended.[75] Use of a wedge to counteract rotational forces might be beneficial.[75]

Tenotomy of the deep digital flexor can provide relief, but the efficacy of this procedure in affecting long-term outcome has not been well demonstrated.[11,75]

CONTROL

The disease is not readily subject to control because of its sporadic nature, with the exception of management of diseases that increase risk of laminitis, such as PPID, insulin resistance, and EMS. Details of the

management of these conditions is provided elsewhere.

Moderate exercise by nonobese ponies previously affected with laminitis reduced serum amyloid A concentrations and haptoglobin concentrations and led to reductions in exercise-induced increases in postexercise serum insulin concentrations.[89] These results suggest a beneficial role for relatively low-intensity exercise (10 minutes enforced walking followed by 5 minutes of trotting) on inflammation in ponies at risk of laminitis.

LAMINITIS IN RUMINANTS AND SWINE

SYNOPSIS

Etiology Degeneration of the sensitive laminellae of the hoof.

Epidemiology

Cattle: An endemic disease of some herds of high-producing dairy cattle, and in feedlots. Associated with ruminal acidosis, either clinical or subclinical.

Clinical signs

Cattle: Inapparent to severe lameness, most common in the hindfeet. Predisposition to other infectious or traumatic diseases of the foot.

Clinical pathology None characteristic of the disease.

Diagnostic confirmation Physical examination. Radiography.

Treatment

Cattle: Nonsteroidal antiinflammatory drugs. Corrective hoof care.

Control

Cattle: Dietary control to prevent ruminal acidosis. Correction of housing and flooring problems.

ETIOLOGY

Laminitis is caused by acute degeneration of the sensitive primary and secondary lamellae of the hoof. The cause of this degeneration is unknown, although the disease can be induced by administration of oligofructose (17 g/kg, orally) to dairy heifers.[1,2] The disease is less well characterized than that of horses, and several conditions are often classified as laminitis. Laminitis in dairy cattle occurs as part of a spectrum of foot diseases.[3,4] There is a detailed description of the radiographic (CT) anatomy of the digit of cattle.[5]

EPIDEMIOLOGY

Occurrence

In **cattle** the disease can occur as clusters in herds and on farms where a predisposition appears to be inherited or where access to large quantities of soluble carbohydrate are available, such as for high-producing dairy cows or feedlot cattle. On farms of high-producing dairy cattle the prevalence may be as high as 78%. The prevalence of laminitis-related hoof lesions in Norwegian dairy cattle is 18%,[6] although the prevalence is lower in Switzerland.[7] Among Swiss cattle, 5.4% had signs of subclinical laminitis, and 3.3% had signs of chronic laminitis.[7] A recent study of 1352 dairy cows in Israel detected lameness in 387 (28.6%).[8] Of these lame cows, 320 (82.7%) had 591 lesions that could be associated with subclinical laminitis.[8]

Risk Factors

Cattle and Sheep

Subclinical laminitis that predisposes to the development of other diseases of the hoof occurs in calves and first-calf heifers and is common in intensively fed feedlot cattle. Laminitis, conditioned by the inheritance of an autosomal-recessive gene, is recorded in Jersey heifers.[9] There may be an association between the disease in feedlot ruminants and **ruminal acidosis**. Administration of oligofructose to dairy heifers induced ruminal acidosis, with clinical signs of laminitis (hoof pain and abnormal gait) occurring by 30

hours after administration and being most severe at 3 to 5 days.[1]

Beef cattle being prepared for shows are often grossly overfed on high-grain rations and become affected with a chronic form of the disease that markedly affects their gait and may cause permanent foot deformity. The disease occurs in dairy cattle fed improper rations, especially first-calf heifers and cattle of herds attempting to increase milk production, and it is not uncommon for the disease to present as a herd problem.

Among **dairy cattle,** the heifers are usually the most affected, and the disease usually develops soon after calving, with more than 50% of cases occurring in the period 30 days before and 30 days after calving. There may be a relationship between being introduced to the herd, with the frequent harassment by dominant cows, when heavily pregnant, and when the surface of the yards is rough. Housing can be important, including standing in slurry or having to twist and turn in narrow passageways and races, and there is an association between the prevalence of the disease and rough concrete floors.

Diet is an important risk factor for development of laminitis in heifers. Diets of wet, fermented grass silage are associated with a greater risk of laminitis than are diets rich in dry unfermented straw and a concentrate. Furthermore, transition from a low-net-energy diet to a high-net-energy diet immediately after calving increases the risk of subclinical mastitis in Holstein dairy cows.

The disease is also reported to occur after metritis, retained placenta, mastitis, and mammary edema, but the incidence is not usually very high.

Pigs

Laminitis has been recorded in pigs, but the disease is difficult to diagnose in this species, and many cases secondary to other diseases (e.g., postparturient fever) can be missed. The disease is also recorded when pigs are fed very heavy concentrate diets.

Importance

Subclinical laminitis of dairy cattle predisposes to other hoof disease that decrease milk production.[10]

PATHOGENESIS

The pathogenesis of laminitis in cattle, sheep, and pigs is unclear but likely has some similarity to that in horses (see "Laminitis in Horses"), with increased expression of genes coding inflammatory or proinflammatory products in corium of cattle with induced laminitis.[11] The links between nutrition and lameness in cattle have been reviewed.[12] Chronic laminitis leads to a low resistance of claw horn to mechanical insults in the dorsal wall, abaxial wall, and sole,[13] which could explain why laminitis predisposes cattle to other foot lesions.

CLINICAL FINDINGS

Cattle and Sheep

In cattle and sheep the clinical picture is similar to but less marked than that observed in the horse.

In **calves 4 to 6 months** of age, and in heifers, an acute syndrome similar to that seen in the horse has been described. Affected animals lie down much of the time and are reluctant to rise. When they attempt to rise, they remain kneeling for long periods. Their standing posture is with all four feet bunched together with the back arched; they shift their weight from foot to foot frequently and walk with a shuffling, painful gait. The feet are painful when squeezed and later become flattened and enlarged and look as though slippers are being worn. There is severe ventral rotation of the third phalanx.

In **adult cows** some cases have acute signs, whereas others show only local lesions. These include sole ulcers and patchy changes in the horn, including softening, waxy yellow discoloration, and red–brown patches suggestive of previous hemorrhage. The cow is chronically lame.

Young bulls are very susceptible to laminitis and may develop abnormalities of gait and posture, such as a stilted gait and frequent knuckling of the fetlocks, which may mislead the diagnostician.

Chronic laminitis in adult cows is characterized by a smaller anterior hoof wall-sole angle, down from 55 degrees to 35 degrees, a concave anterior wall, and the appearance of horizontal grooves (growth arrest lines) around the entire claw. The sole is usually dropped a little, and bruising and sole ulcers may be present. Overgrowth of the sole of the lateral claw may reach the point of creating a false or double sole. The white line is greatly widened and disrupted, and stones and other debris may be impacted in it.

Chronic, traumatic laminitis is most common in heifers when they are first introduced into the milking or dry herds. Housing them on concrete and exposing them to frequent confrontations with bossy cows lead to the development of sole hemorrhages and inflammation of the laminae.

Radiographic signs in cattle include rarefaction of the pedal bone, particularly the toe, and the development of osteophytes at the heel and on the pyramidal process.

Pigs

In sows the clinical signs are similar and include arching of the back, bunching of the feet, awkwardness of movement, increased pulsation in the digital arteries, and pain when pressure is applied to the feet.

CLINICAL PATHOLOGY

There are no changes that are characteristic of the disease.

NECROPSY FINDINGS

Histologic examination of claws from heifers killed 72 hours after overload showed changes consistent with acute laminitis, including stretched lamellae, wider basal cells with low chromatin density, and a thick, wavy, and blurry appearance of the basement membrane.[2,14]

DIFFERENTIAL DIAGNOSIS

Cattle

- White-muscle disease, epiphysitis, other primary diseases of the foot

TREATMENT

Although similar principles to those used to determine treatment of laminitis in horses are likely to apply to cattle, treatment in cattle is usually limited to administration of NSAIDs (aspirin 20 mg/kg, orally every 12 hours, phenylbutazone 4.4 mg/kg orally every 48 hours, or flunixin meglumine 1.0 mg/kg IV every 12 hours). The inciting cause (metritis, ruminal acidosis) should be treated aggressively.

CONTROL

Cattle and lambs that are brought into feedlots should be gradually introduced to grain feeds and a higher forage:grain ratio provided in the feed. Calves should not be fed intensively on grain until they are 14 months old because of the high frequency of internal hoof lesions at the earlier ages. Some protection against laminitis in dairy cattle in intensive units is gained by careful planning of housing cubicles to make them more comfortable and less damaging to the feet and by providing more straw in the cubicles. Exercise should be provided around calving time. Vaccination with a gram-negative bacterin-endotoxoid combination vaccine has provided some protection against laminitis induced by grain overload. Dietary supplementation of biotin (20 mg per head per day) improves hoof health of primiparous dairy cows and may be beneficial in reducing the incidence or severity of lameness in a herd. This treatment might not improve objective indicators of hoof health, but it does improve production.

Selection of traits for foot and leg conformation in Norwegian Red cattle is not associated with a reduced risk of disease of the claws.[15]

Diseases of Joints

DEGENERATIVE JOINT DISEASE (OSTEOARTHROPATHY) AND OSTEOCHONDROSIS

There are two common noninfectious conditions of the joint, degenerative joint disease and osteochondrosis. The terms *degenerative joint disease* and *osteoarthropathy* are used here to describe noninfectious lesions of the articular surfaces of joints characterized by the following:

- Degeneration and erosion of articular cartilage
- Eburnation of subchondral bones
- Hypertrophy of bone surrounding the articular cartilage, resulting in lipping and spur formation at the joint margins

In contrast, a separate condition is **osteochondrosis** (dyschondroplasia), which is a degeneration of both the deep layers of the articular cartilage and the epiphyseal plate—**a defect in endochondral ossification**—that occurs most commonly in pigs and horses but also occurs in cattle. Osteochondrosis in horses is one of a number of conditions included in **developmental orthopedic disease**, which is a catch phrase that includes a number of skeletal conditions of the rapidly growing horse.[1]

ETIOLOGY AND EPIDEMIOLOGY

The etiology of degenerative joint disease and osteochondrosis is not clear in some cases. In most of the commonly occurring cases, the lesions are considered to have a genetic basis and to be multifactorial and perhaps secondary to conformational defects resulting in excessive joint laxity, acute traumatic injury of a joint, the normal aging process, and nutritional deficiencies. The etiologic information is primarily circumstantial, and some of the epidemiologic observations that have been associated with degenerative joint disease and osteochondrosis of farm animals are outlined here.

Nutritional Causes

- Secondary to, or associated with, rickets, osteomalacia, bowie, and osteodystrophia fibrosa
- Coxofemoral arthropathy in dairy cattle associated with aphosphorosis
- Experimental diets deficient in manganese or magnesium, causing arthropathy and joint deformity in some calves—magnesium supplementation of foals decreased the prevalence of osteochondrosis.[2]
- Copper deficiency is thought to be related to osteochondrosis and enlargement of limb joints in foals on pasture and pigs fed experimental copper-deficient diets, and deficiency appears to impair the repair of damaged bone.[1]
- Experimental riboflavin deficiency in pigs

Toxic Causes

- As part of the enzootic calcinosis syndrome caused by poisoning with *Solanum malacoxylon* and others
- Fluorosis in cattle
- Chronic zinc poisoning in pigs and foals

Steroid Induced

The intraarticular injection or prolonged parenteral administration of corticosteroids in horses may lead to degenerative joint disease.

Biomechanical Trauma

- **Acute traumatic injury**—injury to, for example, joint surfaces, menisci, and ligaments, especially the cruciate ligaments of the stifle joints of breeding bulls, may lead to chronic progressive osteoarthritis. Injuries to the femorotibial ligaments of horses can predispose to osteoarthropathy of the stifle joint.
- **Repeated subacute trauma** to joint surfaces can lead to degenerative arthropathy. This is common in young racehorses in training, which may have their joint surfaces and surrounding tissues made susceptible to injury because of conformational defects and subtle deficiencies of calcium and phosphorus. Hard running surfaces may also contribute to the onset of degenerative joint disease.
- **Trauma caused by movement** is suspected of contributing to the erosive lesions on the articular surfaces of some horses affected by enzootic incoordination, the intervertebral joints of caudal thoracic and cranial lumbar vertebrae of old bulls with spondylitis, and the condition of bulls with inherited spasticity. Coxofemoral osteoarthritis may occur in aged horses with joint instability and in calves with hip dysplasia.

Degenerative coxofemoral arthropathy occurs in **young beef bulls** as early as 9 months of age. A congenital shallow acetabulum may predispose bulls to this condition. It may be secondary to hip dysplasia, but in some cases there is no evidence of this. The large, weight-bearing joints subjected to the greatest movement and concussion appear to be most susceptible. Rapidly growing bull calves appear to be most susceptible, and some of them have an inherited susceptibility.

Aging Process

Degenerative arthropathy in aged dairy cows and bulls may be a manifestation of the normal aging process. Degenerative joint disease and vertebral osteophysis occur in middle-aged bulls.

Osteoarthrosis of the distal tarsal joints (hock), commonly known as **bone spavin**, is common in Icelandic horses and strongly related to age. In Icelandic horses aged 6 to 12 years and used for riding, the prevalence of radiographic signs of osteoarthrosis in the distal tarsus increased from 18% in horses 6 years of age up to 54% in 12-year-old horses. The age of onset of radiographic signs reflect a predisposition to bone spavin and indicates a trait with medium to high heritability. There is a high prevalence of chondronecrosis in young Icelandic horses, indicating an early onset and slow progression of disease. The disease is the most common cause of culling as a result of disease in riding horses in the age group of 7 to 17 years.

Osteoarthrosis of the antebrachial joint of riding horses has been described. Affected animals were aged mares that developed osteoarthrosis and ankylosis. The cause is unknown.

Osteochondrosis

Osteochondrosis occurs in rapidly growing **cattle** raised in confinement on hard, usually concrete, floors and with minimal exercise. Osteochondrosis has been reported in rapidly growing bull beef calves fed a diet lacking adequate calcium, sodium, copper, and vitamins A, D, and E and grazing on improved native pasture, in which a common ancestral sire and gender (all males) might have been contributing factors. Severe osteochondrosis of multiple joints but with remarkable changes in the humeral head and glenoid of both shoulder joints in 10-month-old beef calves has been described.

Osteochondrosis in feedlot cattle may be associated with a high-calorie diet and rapid growth rate. It is thought that weight-bearing trauma in these rapidly growing animals is sufficient to cause degenerative lesions of certain joints, especially in animals with a skeletal conformation that results in abnormal stress on certain weight-bearing condyles of long bones. In a series of 42 cases of stifle lameness in cattle, 18 had evidence of subchondral bone cyst and ranged in age from 6 to 18 months. Subchondral bone cyst is considered as a common clinical manifestation of osteochondrosis.

Osteochondrosis similar to that seen in pigs has been recorded in purebred **Suffolk lambs** raised in a system designed to produce rapidly growing, high-value **rams**. The disease has been recorded in a single pedigree Suffolk ram.

Osteochondrosis is an important cause of lameness in **horses**. It is usually seen in young rapidly growing animals, and it affects males more commonly than females. Mares that are fed concentrates during pregnancy are more likely to produce foals that will develop clinical signs associated with osteochondrosis. Moreover, foals kept entirely on pasture for their first year of life are less affected with osteochondrosis than foals housed in box stalls.[3,4] The predilection sites of osteochondrosis in the horse and their general order of incidence are hock, stifle, scapula-humeral joint, fetlock, and cervical spine. The stifle, hock, and scapula-humeral joints are more commonly affected, but many other joints may also be affected, including the metatarsal and metacarpal bones and, rarely, the acetabula of young foals. There is a nutritional component to osteochondrosis, with magnesium supplementation of foals decreasing the prevalence[2] and copper deficiency appearing to interfere with normal bone-repair processes.[1] There is also a genetic component to osteochondrosis, but the mechanism has not been identified.

The epidemiology, heritability, and body measurements and clinical findings of osteochondrosis of hock and fetlock joints in Standardbred trotters have been examined. The incidence of the disease is high in the Swedish Standardbred population and well developed by the age of 18 months. The incidence of osteochondrosis is higher in horses born later in the foaling season than earlier, and the incidence was related to body size: affected horses were taller at the withers and had a greater circumference of the carpus. This suggests that differences in body size at birth and the first few months of the foal's life are of major importance in the development of osteochondrosis. The heritability estimates of osteochondrosis in the hock and fetlock joints of 753 Standardbred trotters 6 to 21 months of age were 0.52 and 0.21, respectively.

Osteochondrosis and arthrosis are considered to be major causes of "leg weakness" in rapidly growing **pigs**. Restricting the energy intake appears to decrease the prevalence and severity of osteochondrosis when gilts are examined at 100 kg, and osteochondrosis is more common in pigs with faster growth rates from weaning to 3 months of age.[5] The prevalence and severity of osteochondrosis in growing pigs are probably not related to floor type. Recent work has shown a significant relationship between body conformation and the presence of joint lesions. Pigs with a narrow lumbar region, broad hams, and a large relative width between the stifle joints are highly susceptible to poor locomotor ability as a result of lesions in the elbow and stifle joints, the lumbar intervertebral joints, and the hip joint.

PATHOGENESIS

A brief review of the structure and biochemistry of the normal articular joint will serve as background for understanding the pathogenesis of osteoarthropathy.

Articular cartilage is a tissue consisting of chondrocytes scattered in a matrix of collagen fibers and an amorphous intercellular substance containing proteoglycans. Articular cartilage contains no nerves, is avascular, and has a high matrix-to-cell ratio. The chondrocytes are the only living matter in cartilage, produce the fine strands of collagen, and are engaged in protein and proteoglycan synthesis. The matrix of the cartilage consists of water-soluble proteoglycans interspersed with collagen fibers, which are arranged in parallel rows superficially and crisscross rows closer to the calcified layer. This enables the cartilage to withstand shearing stresses superficially and compression more deeply.

The proteoglycans are glycosaminoglycan–protein complexes, bound by a link glycoprotein to a linear hyaluronic acid molecule. The glycosaminoglycans in articular cartilage are chondroitin 4-sulfate, chondroitin 6-sulfate, and keratan sulfate. About 75% of the proteoglycans exist on aggregates that protect them from degradation, and because of their high water content, they form large polyanionic complexes that have considerable elastic resistance to compression.

Nutrition of the articular cartilage is provided via the synovial fluid and is dependent on the capillary flow to the synovial membrane. Nutrients flow through the synovial fluid and diffuse through the cartilage to the chondrocytes. Proteoglycans are synthesized by the chondrocytes and secreted to the cell exterior. Proteoglycans are also degraded intracellularly by lysosomes. The normal equilibrium between anabolism and catabolism is maintained by several different low-molecular-weight proteins. When the equilibrium is disturbed and shifts toward catabolism, degeneration occurs.

Primary Osteoarthropathy

Primary osteoarthropathy is a result of normal aging processes and ordinary joint usage. The initial lesions occur in the superficial layers of the articular cartilages where, with increasing age, there is loss of the normal resilience of the cartilage, a lowering of the chondroitin sulfate content, and reduction in the permeability of the cartilaginous matrix, which results in progressive degeneration of the articular cartilage. There is grooving of the articular cartilage, eburnation of subchondral bone, and secondary hypertrophy of marginal cartilage and bone, with the formation of pearl-like osteophytes. In experimentally induced arthritis in the horse, the major changes include synovitis, increased synovial effusion, and superficial fibrillation with chondrocyte necrosis in the articular cartilage. These are comparable to the early changes in naturally occurring degenerative joint disease.

Secondary Osteoarthropathy

Secondary osteoarthropathy appears to be initiated by injuries or congenital conformational defects that create greater shearing stresses on particular points, in contrast to the intermittent compressive stresses typical of ordinary weight-bearing. These irregular stresses result in cartilaginous erosion, increased density of subchondral bone at points of physical stress, and proliferation of bone and cartilage at the articular margins.

Following acute trauma, the initial changes are often characterized by acute synovitis and capsulitis. As a result of the inflammatory response, leukocytes, prostaglandins, lysosomal enzymes, and hyaluronidase enter the synovial fluid, which becomes less viscous, affecting the nutrition of the cartilage. There is some evidence of immune complexes associated with collagen-type-specific antibodies in horses with secondary osteoarthritis. Cytokines can be detected in the synovial fluid after racing in horses with degenerative joint disease. The cartilage matrix undergoes a variety of changes, possibly because of chondrocyte damage with lysosomal enzyme release or as result of collagen fiber injury. There is an increase in water content and loss of orientation of the collagen fibers. Proteoglycans are lost, and although increased chondrocyte activity synthesizes proteoglycans, they are of lower molecular weight and altered glycosaminoglycan composition. This leads to loss of elasticity and surface integrity of the cartilage, resulting in increased friction, blistering, and ulceration. There is additional lysosomal enzyme release from the chondrocytes, resulting in matrix destruction and further proteoglycan destruction. The degrading enzymes enter the altered matrix and cause further degradation.

The first stage of matrix degradation involves discoloration, softening, and blistering of the tangential layer of the cartilage surface, a process known as early fibrillation. As the fissuring extends to the radial layer, microfractures occur, with loss of cartilage fragments (detritus) into the synovial fluid. As the cartilage is destroyed, the underlying bone is exposed and becomes sclerotic. Bony proliferation occurs in the floor of the cartilage lesions, whereas osteophyte formation occurs at the joint margins. The pathogenesis of degenerative joint disease indicates that the ideal treatment would be the use of a substance that would promote synthesis of matrix components and retard catabolic processes.

The major proteoglycan in cartilage is a high-molecular-weight aggrecan that contains chondroitin sulfate and keratin sulfate chains located on specific regions of the core protein. These macromolecules are continuously released into the synovial fluid during normal cartilage matrix metabolism. Cartilage proteoglycans are degraded early in the course of joint disease and released from the

cartilage into the synovial fluid, where they can be identified.

In horses with degenerative joint disease, proteoglycan fragments—glycosaminoglycans—have been determined in equine synovial fluid as indicators of cartilage metabolism in various types of arthritides. The intraarticular injection of corticosteroids depresses chondrocyte metabolism, alters the biochemical composition, and causes morphologic changes in the articular cartilage, which remains biochemically and metabolically impaired for several or more weeks.

In **femoral–tibial osteoarthrosis of bulls**, the secondary degenerative joint lesions are a result of rupture of the attachments of the lateral meniscus resulting in mechanical instability in the joint, with unusual mechanical stresses on the articular cartilage leading to degeneration. The cranial cruciate ligament becomes progressively worn and eventually ruptures, resulting in loss of all joint stability and the development of gross arthrosis. In cattle with severe degenerative joint disease of the coxofemoral joints, an acetabular osseous bulla may develop at the cranial margin of the obturator foramen.

Osteochondrosis

Osteochondrosis (dyschondroplasia) is characterized by a focal disturbance of the normal differentiation of the cells in the growing cartilage as a result of failure of the blood supply. The failure is associated with the process of incorporating blood vessels into the ossification front during growth,[6] but, experimentally, bacteremia can also result in vascular occlusion. The end result is a focal ischemic chondronecrosis, which can lead to formation of pseudocysts and true cysts in the subchondral bone.[7] **Osteochondrosis should therefore be considered as a disease that occurs multifocally at predilection sites**. Both the metaphyseal growth plate (the growth zone of the diaphysis) and immature joint cartilage (the growth zone of the epiphysis) are affected. The loss of normal differentiation of the cartilage cells results in failure of provisional calcification of the matrix and endochondral ossification ceases. Degeneration and necrosis of blood vessels in cartilage canals results in ischemia of an area of growing cartilage, followed by chondrocyte degeneration and death. The initial lesion occurs in growing cartilage, and *dyschondroplasia* is a more appropriate term. The primary lesion of osteochondrosis directly affects the differentiation and maturation of the cartilage cells and the surrounding matrix that are destined to become replaced by bone. This can occur at the two sites of endochondral ossification in long bones—the articular/epiphyseal cartilage complex and the metaphyseal growth plate. In osteochondrosis, the capillary buds fail to penetrate the distal region of the hypertrophic zone, which leads to a failure of the final stages of cartilage maturation and modification of the surrounding matrix. These changes lead to retention and thickening of cartilage with subsequent weakening of the articular/epiphyseal cartilage complex.

Typical lesions in the horse involve extensive cartilaginous and subchondral bone degeneration with flap formation and, ultimately, loose pieces in the joint. This is usually referred to as osteochondritis dissecans and is associated with synovial effusion and varying degrees of synovitis. Osteochondral fracture associated with severe pathologic changes to the subchondral bone occurs most commonly on the trochlear ridges and the lateral or medial malleoli of the hock. It is likely that osteochondrosis lesions develop in foals within the first few months of extrauterine life, which is much earlier than originally thought.

In **rapidly growing pigs** raised in confinement with minimal exercise, **osteochondrosis and arthrosis** are seen as degeneration of the deep layer of the articular cartilage and adjacent subchondral bone with degenerative lesions of the epiphyseal plate. Lesions in the epiphyseal plate may result in epiphysiolysis, which occurs most commonly in the femoral head. The typical lesions are usually symmetric and commonly involve the elbow, tarsocrural, stifle, and hip joints and the distal epiphyseal plate of the ulna.[5] Lesions also occur in the intervertebral articulations. The lesions are common in pigs when they are examined at slaughter (90 to 100 kg BW), and there might have been no evidence of clinical abnormality, or a proportion of the pigs with severe lesions might have been affected with leg-weakness syndrome. Osteochondrosis and *Erysipelothrix rhusiopathiae* are the most common causes of nonsuppurative joint disease of pigs examined at the abattoir. Thus not all lesions are clinical.

CLINICAL FINDINGS

The major clinical characteristic is a chronic lameness that becomes progressively worse over a long period of time and does not usually respond to treatment. The disease is insidious and generally not clinically apparent in the early stages. A common clinical history is that the affected animal becomes progressively more lame over a period of weeks and months and prefers long periods of recumbency. The lesion may develop slowly over a period of weeks and months during the convalescent stages of an acute traumatic injury to the joint when recovery is expected but the animal continues to be lame.

There is usually difficulty in flexing affected joints normally, which results in a stiff and stilted gait. In cattle confined to stanchions, one of the earliest and persistent signs is shifting of weight from limb to limb. In dairy cattle, as the lesions become more painful, there is a decline in appetite and milk production, prolonged recumbency, and considerable difficulty in rising from the recumbent state. In the early stages, there may be an apparent remission of the lameness, but relapses are common. The bony prominences of the joint eventually appear more prominent than normal, which is a result of disuse muscle atrophy of the affected limbs. Acute and marked distension of the joint capsule is not as common as it is in an infectious or suppurative arthritis, but joints can slowly distend over weeks to months (Fig. 15-8). The joint capsule of palpable joints is usually not painful on palpation. Passive flexion of affected joints may be painful, and it may be possible to elicit crepitus as a result of detached pieces of cartilage and bone and osteophytes surrounding the articular cartilage. However, crepitus is most common in the large movable joints, such as the stifle, and commonly in osteoarthropathy secondary to acute traumatic injury of the meniscus and cranial cruciate ligament of the joint.

Osteochondrosis in cattle is characterized by chronic long-standing lameness, either with or without joint effusion. Joint fluid analysis is usually normal or indicates nonseptic inflammation. The stifle joint is most commonly affected, followed by the hock joint. In osteochondrosis in young, rapidly growing bulls there is reluctance to move, stiffness, enlargement of the ends of long bones, and a straightened joint. Although there may be clinical evidence of lameness in less than 40% of affected cattle, radiographically, 88% of the lesions are bilateral. Young breeding bulls in the early stages of coxofemoral arthropathy may be reluctant to perform the breeding act and yet appear to have sufficient libido.

Osteochondrosis in the horse is characterized by a wide range of clinical signs, and in some cases lesions are not accompanied by clinical signs. The most common sign of osteochondrosis is a nonpainful distension of an affected joint. In foals under 6 months of age, a tendency to spend more time lying down is common. This is accompanied by joint swelling, stiffness, and difficulty keeping up with the other animals in the group. An upright conformation of the limbs may also be present. In yearlings or older animals the common clinical signs are stiffness of joints, flexion responses, and varying degrees of lameness.

In the horse with osteochondrosis of the shoulder joint there is intermittent lameness, characterized by a swinging leg and shoulder lameness with pain elicited by extension, flexion, or abduction of the limb. Secondary joint disease is also a common finding. In a retrospective study of osteochondrosis dissecans in 21 horses, affected animals were 8 months to 5 years of age. The usual age of onset of clinical abnormalities was 18 to 24 months. The common presenting complaints included joint effusion and lameness of

Fig. 15-8 **Bilateral tarsitis in a lactating Holstein–Friesian cow. Note the marked joint effusion centered on both tarsal joints and the excessively straight hindlimbs.**

Table 15-3 Laboratory evaluation of synovial fluid in diseases of the joints

Synovial fluid analysis	Normal joint	Degenerative arthropathy	Infectious arthritis
Gross appearance	Colorless, clear	Pale yellow, may contain flocculent debris	Turbid, yellow
Total volume	—	Normal or slight increase	Usually marked increase
Clot formation	No clot	No clot	May clot within minutes after collection
Erythrocytes (μL)	<4,000	6,000–12,000	4,000–8,000
Leukocytes (μL)	<250	250–1,000	50,000–150,000
Neutrophils (%)	7	10–15	80–90
Lymphocytes (%)	35–40	45–50	4–8
Monocytes (%)	45–50	35–40	1–3
Microbiology	—	—	May be able to culture bacteria, mycoplasma, or virus, but not always
Total protein (g/dL)	1.2–1.8	1.6–1.8	3.2–4.5
Relative viscosity	—	Slightly reduced	Decreased
pH	—	—	Decreased

Other laboratory analyses of synovial fluid include the following: sugar content, alkaline phosphatase activity, lactic dehydrogenase activity, aldolase activity, glutamic oxaloacetic transaminase activity, glutamic pyruvic transaminase activity, mucinous precipitate quality.

either gradual or sudden onset. The prevalence was higher in males than in females.

Common clinical findings in **pigs with osteochondrosis** are hyperflexion of the carpus, limb bowing, adduction of both forelegs at the level of the carpus, hyperextension of the fore and hind phalanges, and anterior curvature of the tarsus. One of the first clinical abnormalities of osteochondrosis and epiphysiolysis in young breeding boars may be inability to mount the sow—impotentia coeundi. Locomotory dysfunction involves primarily the hindlegs. There is pronounced swaying of the hindquarters and crossing of the hindlegs with each step, which makes the pig appear uncoordinated. Epiphysiolysis of the head of the femur occurs in young pigs from 5 months to 1 year of age. There is usually a history of slight to moderate lameness, sudden in onset and affecting one or both hindlimbs. The onset of lameness may coincide with some physical activity such as breeding, farrowing, or transportation. The lameness is progressive, and in about 7 to 10 days the animal is unable to use its hindlegs. Crepitus may be audible on circumduction of the affected limb, and radiography may reveal the separation.

DIAGNOSIS

Joint Fluid

The changes in the synovial fluid of joints affected with degenerative arthropathy are usually unremarkable and can be readily distinguished from the changes in infectious arthritis. A summary of the laboratory evaluation of synovial fluid in diseases of the joints is set out in Table 15-3. The isolation of an infectious agent from the synovial fluid of a diseased joint suggests the presence of septic arthritis, but failure to isolate an organism must not be interpreted as the presence of a noninfectious arthritis. In well-advanced cases of septic arthritis the number of organisms may be small, or they might have been phagocytosed by neutrophils in the joint fluid.

Total protein concentration and viscosity of synovial fluid of horses can be determined. Normal values are available, and the concentration and molecular weight distribution of hyaluronate in synovial fluid from clinically normal horses and horses with diseased joints have been compared. Synovial fluid viscosity is reduced in horses with infectious and chronic arthritides and with radiographic evidence of cartilage degeneration. The synovial fluid hyaluronate concentration can be used as a diagnostic marker for chronic traumatic arthritis. However, high-molecular-weight proteoglycans or other markers in the synovial fluid cannot be used for diagnosing or monitoring degenerative joint disease.

Infrared spectroscopy measures the infrared absorption patters of molecules in synovial fluid when exposed to infrared light. Infrared spectroscopy of synovial fluid

indicated that the infrared patterns from equine joints with traumatic arthritis differed from the pattern for corresponding healthy joints.[8] It remains to be determined whether this technology provides additional clinical information to that obtained by the routine analysis of synovial fluid. **Hematology and serum biochemistry** should be combined with appropriate hematology and serum biochemistry where indicated, although the results rarely change treatment protocols or prognosis. The concentration of hyaluronic acid in synovial fluid can be determined using an assay technique. The determination of serum calcium and phosphorus may reveal the existence of a dietary deficiency or imbalance of minerals.

Radiography

Radiography of the hock joints in a craniomedial–caudolateral oblique view and of the fetlock joints in lateromedial view are standard techniques for the diagnosis of osteochondrosis in the horse. Those joints with abnormal radiographs may be radiographed from additional perspectives. Horses with bony fragments or defects at the cranial edge of the intermediate ridge of the distal aspect of the tibia or defects at the lateral trochlea of the talus can be classified as having osteochondrosis. The radiographic progression of femoropatellar osteochondrosis in horses under 1 year of age at the onset of clinical signs has been examined. The full extent of the radiographic lesions may take several weeks to develop.

Arthroscopy

Arthroscopic examination and surgery of affected joints of horses with osteochondrosis can provide considerably more information than is possible from clinical and radiographic examination alone.

NECROPSY FINDINGS

In **degenerative joint disease** the joint cartilage is thin or patchily absent, and polished subchondral bone is evident. The articular surfaces are irregular and sometimes folded. Exposed bone may be extensively eroded, and osteophytes (small bony excrescences, appearing like pearls) may be present on the nonarticular parts of the joint on the circumference of the articular cartilage. The synovial fluid is usually only slightly increased in volume and appears amber-colored. Menisci and intraarticular cartilages and ligaments may be entirely absent, and there may be areas of calcification in the joint capsule and cartilages free in the synovium. When the stifle is affected, fractures of the head of the tibia occur commonly, usually a chip of the lateral condyle having become separated. In such cases, fractures of the lateral condyle of the distal end of the femur may follow. With either of these fractures, lameness is extreme, and the animal may often refuse to rise. When the hip joint of bulls is affected, the head of the femur becomes smaller and more flattened than normal, the acetabulum is shallower, and the round ligament is usually ruptured.

In **osteochondrosis** there is splitting and invagination of articular cartilage, loss of articular cartilage, chip fractures of condyles, exposed and collapsed subchondral bone, osteophyte formation around the circumference of the articular cartilage, and loose pieces of cartilage in the joint. In **equine osteochondrosis (dyschondroplasia)**, the histologic lesions can be divided into two groups. In one group, there are accumulations of small rounded chondrocytes, areas of necrosis, and chondrocyte clusters. In the second group, there are alterations in the appearance of the mineralized matrix, areas of necrosis, chondrocyte clusters, and an alteration in type VI collagen immunoreactivity within the chondrocyte clusters.

In the epiphyseal plates (e.g., the distal ulna in pigs with osteochondrosis), the cartilage is uneven and thickened, with hemorrhage, fibrous tissue, collapse of bone tissue in the metaphysis, and epiphyseal separation. Complete separation of the epiphysis occurs most commonly at the head of the femur. The ultrastructural appearance of normal epiphyseal cartilage of the articular–epiphyseal cartilage complex in growing swine has been examined and serves as a standard for comparison with the lesions in affected pigs. The lesions may be present in pigs at an early age as part of the usual growth pattern of cartilages.

DIFFERENTIAL DIAGNOSIS

Osteoarthropathy is characterized clinically by a chronic lameness that becomes progressively worse and usually does not respond to treatment. The gait is stiff, there is disuse muscle atrophy, the bony prominences of the joint are more apparent, but usually there is no marked distension and pain of the joint capsule, as in infectious arthritis. Examination of synovial fluid may aid in differentiation from septic arthritis.

Radiographically, there is erosion of articular cartilage, sclerosis of subchondral bone, and periarticular accumulations of osteophytes. In the early stages of the disease in large animals, radiographic changes may not be visible, and repeated examinations may be necessary.

The radiographic changes of osteochondrosis in the shoulder joint of the horse consist of the following:

- Alteration in the contour of the humeral head and glenoid cavity
- Periarticular osteophyte formation
- Sclerosis of the subchondral bone
- Bone cyst formation

TREATMENT

The treatment of arthropathy depends largely upon correction of the cause, but in most cases the lesions are progressive and irreparable, and food-producing animals should be slaughtered for salvage. Tarsal degenerative joint disease in cattle has been treated with intraarticular injections of corticosteroids and has provided temporary relief from pain and discomfort. However, the corticosteroids do not promote healing of the joint, and their use in arthropathy may actually accelerate erosion of articular cartilage, loss of joint sensation, and the development of "steroid arthropathy."

In the horse, there are many choices available for controlling inflammation in osteoarthritis. Treatment is symptomatic and largely nonspecific, but the long-term administration of antiinflammatory agents remains a central part of the treatment of equine joint disease.[9]

Nonsteroidal Antiinflammatory Agents and Opioids

Several nonsteroidal antiinflammatory drugs (NSAIDs), such as **phenylbutazone**, **flunixin meglumine**, **ketoprofen**, **naproxen**, and **carprofen**, are available treatment options. Each has associated toxicities. They are now the most commonly used drugs because of their analgesic, antipyretic, and antiinflammatory properties. They inhibit some component of the enzyme system that converts arachidonic acid into prostaglandins and thromboxanes. All cells, including chondrocytes and synoviocytes, possess arachidonic acid as a fatty acid constituent of phospholipids. Once released, arachidonic acid is oxidized by either cyclooxygenase (COX) or 5-lipooxygenase. COX oxidation leads to prostaglandin production, whereas lipoxygenase oxidation leads to leukotriene formation. The effect of NSAIDs is primarily from inhibiting COX, which blocks arachidonic acid conversion to prostaglandin.

Phenylbutazone is the most commonly used NSAID around the world to treat arthritis in horses, but oral administration at 2 mg/kg every 12 hours did not appear to have a clinically relevant effect on joint tissue metabolism.[10] This suggests that the major clinical effect of phenylbutazone in horses with osteoarthritis is analgesia. Some countries, such as the United States, do not permit the use of phenylbutazone in food-producing animals. The oral administration of **meloxicam** (0.6 mg/kg BW once daily) altered joint tissue metabolism, as demonstrated by decreased synovial fluid concentrations of PGE_2, substance P, bradykinin, and matrix metalloproteinase activity in horses with experimentally induced synovitis.[9] This suggests that meloxicam may have beneficial effects in limiting cartilage catabolism during acute synovitis.

Intraarticular morphine administration (0.05 mg/kg BW or 120 mg) is associated with substantial analgesic effects and beneficial antiinflammatory effects, resulting in less joint swelling and lower synovial fluid total protein concentration; leukocyte count;

and PGE2, bradykinin, and substance P concentrations in horses with experimentally induced acute synovitis.[11,12] The mechanism for the antiinflammatory effect of morphine is unknown.

Intraarticular Steroids

Various steroidal formulations for intraarticular administration are available, and correct dosage, frequency of administration, indications, and toxicity are factors to consider for each drug. They include methylprednisolone acetate, betamethasone, and triamcinolone acetonide.

Chondroprotective Agents

Various **chondroprotective** drugs, such as intraarticular **hyaluronic acid** and **polysulfated glycosaminoglycan**, and the oral neutraceutic agents **glucosamine-chondroitin sulfate** are also used to control inflammation and provide viscosupplementation. The allotransplantation of synovial fluid into the joints of horses with arthropathies has been examined.

There is a notable lack of treatment information based on randomized, blinded, placebo-controlled clinical trials in the horse to identify the efficacy of therapeutic agents for both symptomatic and disease-modifying activity in degenerative joint disease. Until there are validated outcome measures that can be used practically in clinical trials, there will always be uncertainty about whether these therapeutic agents have any real disease-modifying action.

Hyaluronic Acid

The beneficial effects of hyaluronic acid are claimed to be improved viscosity of the synovial fluid and thereby improved rheologic properties, lubrication of unloaded joints, and provision of an antiinflammatory and analgesic effect. The changes in the synovia following the intraarticular injection of **sodium hyaluronate** into normal equine joints and after arthrotomy and experimental cartilage damage have been examined, but in general the results are inconclusive.

Polysulfated Glycosaminoglycan

Polysulfated glycosaminoglycan has been reported to induce articular cartilage matrix synthesis and to decrease matrix degradation. Experimentally, intraarticular injection of **polysulfated glycosaminoglycan** provides some protection against chemically induced articular cartilage damage but not against physical defects of articular cartilage in the horse. The polysulfated glycosaminoglycans inhibit lysosomal enzymes and neutral proteases. A survey of the use of polysulfated glycosaminoglycans by equine practitioners for the treatment of lameness in horses found that the drug is moderately effective overall and is considered most beneficial in the treatment of subacute degenerative joint disease. Its efficacy for incipient and chronic forms of degenerative joint disease is considered comparable to that of sodium hyaluronate.

The prevention of further trauma should be ensured, and possible nutritional causes should be corrected. The treatment of active disease, particularly in soft tissues, that is contributing to articular degeneration includes rest, immobilization, physical therapy, intraarticular injections of corticosteroids, NSAIDs, joint lavage, and intraarticular injection of sodium hyaluronate, all of which have been used with variable success.

Other Treatments

Surgical therapy includes curettage of articular cartilage, removal of osteophytes, and surgical arthrodesis. In a retrospective study of stifle lameness in 42 cattle admitted to two veterinary teaching hospitals over a period of 6 years, 18 had radiographic evidence of subchondral bone cyst without radiographic evidence of degenerative joint disease. The prognosis in those with a subchondral bone cyst was favorable, with 75% returning to their intended function, whereas in cases of, septic arthritis only 22% returned to normal.

Chemical arthrodesis using the intraarticular injections of monoiodoacetate (MIA) has been described as an alternative to surgical arthrodesis for the treatment of degenerative joint disease of the distal tarsal joints. MIA causes an increase in intracellular concentration of adenosine triphosphate, resulting in inhibition of glycolysis and cell death. It causes dose-dependent cartilage degeneration characterized by cartilage fibrillations, chondrocyte death, and glycosaminoglycan and proteoglycan depletion. MIA produces reliable radiographic and histologic ankylosis of the distal tarsal joints. Resolution of the lameness required 12 months and occasionally longer. Soundness was achieved in 82% and 85% of horses at 12 and 24 months, respectively. Complications of the injections were uncommon and were probably related to periarticular injection or leakage of MIA, or to use of higher concentrations or volumes. Postinjection pain was marked in a small number of horses but was transient and managed effectively with analgesic drugs. The procedure is controversial. Some clinicians argue that arthrodesis should only be used where lameness is localized to the tarsometatarsal and centrodistal joints with objective means such as local analgesic techniques and when other more conservative treatments have failed.

CONTROL AND PREVENTION

Prevention of osteoarthropathy will depend on recognition and elimination of the predisposing causes: provision of an adequate diet and the avoidance of overnutrition during the first 3 months of extrauterine life, regular exercise for confined animals, the provision of suitable flooring to minimize persistent concussion, and the use of breeding stock that have a body conformation that does not predispose to joint lesions.

SEPTIC ARTHRITIS SYNOVITIS

Inflammation of the synovial membrane and articular surfaces as a result of infection occurs commonly in farm animals. It is characterized by varying degrees of lameness and a warm, swollen, and painful joint. The synovial fluid is usually abnormal, containing an increased leukocyte count and the pathogens causing the arthritis. The arthritis may be severe enough to cause systemic illness, and in some cases a draining sinus tract may occur.

ETIOLOGY AND EPIDEMIOLOGY

Specific bacterial infections of the joints are most common in newborn farm animals, in which localization of infection occurs in joints following bacteremia or septicemia. Surveys of Thoroughbred studs have shown that the incidence of infectious arthritis is higher in foals with other perinatal abnormalities and in which the ingestion of colostrum was delayed for more than 4 hours after birth. Calves with hypogammaglobulinemia are particularly susceptible to bacteremia and meningitis, ophthalmitis, and arthritis. Some of the important infectious causes of arthritis are as follows.

Calves

- Nonspecific joint-ill from omphalophlebitis associated with *Trueperella pyogenes, Fusobacterium necrophorum, Staphylococcus* spp.
- *Erysipelothrix rhusiopathiae* sporadically in older calves

- *Salmonella dublin, Salmonella typhimurium,* and *Mycoplasma bovis*

Lambs
- *E. rhusiopathiae* in newborn and recently tail-docked lambs
- Sporadic cases associated with *F. necrophorum, Staphylococcus* spp., *Corynebacterium pseudotuberculosis, Histophilus somni, Mannheimia haemolytica*
- *Chlamydophila* spp. causes polyarthritis extensively in feedlot lambs
- Tick pyemia is associated with *Staphylococcus aureus.*

Foals
- Part of neonatal septicemia, with gram-negative bacteria predominating[1]
- *Actinobacillus equuli, Rhodococcus equi, Salmonella abortivoequina* in the newborn
- *Chlamydophila* spp. has caused polyarthritis in foals.

Piglets
- Streptococci, Lancefield groups C, E, and L
- *Streptococcus suis*
- *E. rhusiopathiae* in pigs of any age—up to 65% of joints of pigs at slaughter are affected, and up to 80% of the farms from which the pigs come do not vaccinate for erysipelas. Mortality in preweaning groups of pigs may affect 18% of litters and 3.3% of the piglets, with a herd mortality of 1.5%
- In a 4-year period in a swine research station, 9411 piglets were born alive, and 9.8% were treated for lameness. About 75% of the cases were observed in piglets under 3 weeks of age. The incidence of lameness was much higher in piglets born from sows of parity 3 (11.4%) compared with piglets born to sows of parity 4 to 7 (8%).

Cattle
- *Histophilus somni* is a cause of synovitis.
- *Mycoplasma agalactia* var. *bovis* is a common cause of synovitis, arthritis, and pneumonia in young feedlot cattle.
- *Mycoplasma bovigenitalium* may cause mastitis in cows, with some animals developing arthritis.
- *Mycoplasma mycoides* may cause arthritis in calves vaccinated with the organism against contagious bovine pleuropneumonia. Calves already sensitive to the organism develop an immediate-type allergic reaction of the synovial membrane.
- *Brucella abortus*—occasional cows with brucellosis develop arthrodial synovitis.
- Some cases of ephemeral fever have sterile arthritis.
- BVD virus in young bulls, rarely
- Idiopathic septic arthritis in dairy heifers—the etiology is unknown.
- Septic arthritis of the proximal interphalangeal (pastern) joint in cattle as a result of perforating wounds—*T. pyogenes* is the most common cause in cattle.

Sheep and Goats
- As part of melioidosis
- *Mycoplasma* spp. of serositis—arthritis
- *Streptococcus dysgalactiae* in lambs and kids[2,3]

Horses
- Septic arthritis after penetrating wounds, intraarticular injection of corticosteroids, and surgery; young foals under 6 months of age usually associated with septicemia; adult horses without a known etiology.
- In a series of 34 cases of monoarticular infectious arthritis in adult horses admitted to a veterinary teaching hospital over a period of 10 years, 16 had a penetrating wound over the joint, 4 had a puncture wound of the sole, and in 5 the infection was iatrogenic (3 had received intraarticular corticosteroids, 1 had received intraarticular anesthesia, and 1 had sepsis after a purulent thrombophlebitis); in 9 cases, no cause could be determined.
- Spread to the joints from generalized strangles.
- Rare cases of nonerosive polysynovitis in a horse, possibly immunologic and immune-mediated polysynovitis in foals.
- *Acedosporium prolificans,* a newly recognized opportunistic fungus, has been associated with an incurable arthritis and osteomyelitis in a mature horse.

Pigs
- Glasser's disease
- *Mycoplasma* spp. in synovitis and arthritis of growing pigs, especially in housed pigs
- *Brucella suis* commonly infects bones, especially vertebrae, and joints.

All Species
Sporadic cases are a result of the following:
- Traumatic perforation of the joint capsule
- Spread from surrounding tissues (e.g., footrot to interphalangeal joints in cattle and pigs, interdigital abscess in sheep)
- Hematogenous spread from suppurative lesions, commonly in udder, uterus, diaphragmatic abscess, infected navel or tail, castration wound

PATHOGENESIS
In infectious arthritis that is hematogenous in origin there is usually a synovitis initially, followed by changes in the articular cartilages and sometimes bone. With almost any systemic infection, there may be localization of the infectious agent in the synovial membrane and joint cavity. The synovial membrane is inflamed and edematous, and there are varying degrees of villous hypertrophy and deposition of fibrin. Bacteria colonize synovial membranes, which makes treatment difficult. The synovitis causes distension of the joint capsule with fluid, and the joint is painful and warm. Successful treatment and elimination of infection at this early stage of synovitis will minimize changes in articular cartilage and bone, and healing will result. A progressive infectious synovitis commonly results in pannus formation between articular surfaces, with erosion of articular cartilage, infection of subchondral bone, and osteomyelitis. In the chronic stages, there is extensive granulation tissue formation, chronic synovitis, and degenerative joint disease with osteophyte formation, and ankylosis is possible. Depending on the organism, the arthritis may be suppurative or serofibrinous. Suppurative arthritis is particularly destructive of cartilage and bone, and commonly there is rupture of the joint capsule. In foals with septic arthritis, there may be a concurrent polyosteomyelitis, usually in either the epiphysis and/or the metaphysis of the long bones.

Calves With Experimentally Induced Infectious Arthritis
Septic arthritis induced by *E. coli* is a reliable and reproducible model of infectious arthritis in laboratory animals, including horses and calves. The inoculation of *E. coli* into the tarsal joint of newborn colostrum-fed calves resulted in septic arthritis in all calves. Clinic signs of septic arthritis appeared on day 2 after infection and persisted until day 9 for all calves. *E. coli* was cultured from synovial fluid on day 2 for one calf and until day 4 for five other calves. Polymerase chain reaction (PCR) for *E. coli* was positive in the synovial fluid of all calves. Synovial fluid neutrophil and white blood cell counts were increased on days 2 to 4. All bacterial cultures were negative on day 8, although clinicopathologic signs of inflammation persisted until day 20. Rapid recovery occurred within 1 week when an appropriate treatment was begun early in the course of the disease.

Lambs With *Streptococcus dysgalactiae* Polyarthritis
Streptococcus dysgalactiae is the most common cause of septic arthritis in lambs under 4 weeks of age in the United Kingdom.[3] It appears that a small proportion of ewes carry *S. dysgalactiae* in vaginal secretions, milk, and other secretions, and *S. dysgalactiae* can survive on straw or hay for up to 5 to 6 weeks.[2] The route of entry of *S. dysgalactiae* into lambs is uncertain but appears to be either via the umbilicus or following ingestion.[4]

Foals With Septicemia

Septicemic foals may develop infectious arthritis and a concurrent polyosteomyelitis because of the patency of transphyseal vessels in the newborn foal; this allows spread of infection across the physes with the development of lesions in the metaphysis, epiphysis, and adjacent to the articular cartilage. The syndrome is classified into four types according to the location of the lesions:

- A foal with **S-type** septic arthritis has synovitis without macroscopic evidence of osteomyelitis. This is most commonly seen in the first 2 weeks of life.
- Foals with **E-type** septic arthritis also have osteomyelitis of the epiphysis at the cartilage–subchondral bone junction. This is most commonly seen at 3 to 4 weeks of life.
- Those with **P-type** infections have osteomyelitis directly adjacent to the physis and do not have septic arthritis, although there may be a nonseptic effusion of the closest joint.
- Foals with **T-type** have an initial infection of the small cuboidal bones of the carpus and tarsus that spreads into the carpal or tarsal joints.

Horses

Septic arthritis has been reproduced experimentally in horses and the sequential synovial fluid changes monitored. Following intraarticular inoculation of *S. aureus,* clinical signs are evident as early as 8 hours after infection. A high and persistent neutrophilia is one of the earliest and most accurate diagnostic abnormalities. The total white blood cell count rises within 12 to 24 hours to a mean value of 100×10^9/L. Total protein also increases. Synovial fluid acidosis also occurs in infectious arthritis, which may interfere with the antibacterial activity of some antimicrobials. In experimental arthritis, the synovial pH declined from a mean value of 7.43 to 7.12. Bacteria could be detected in 40% of the smears of infected synovial fluid samples, and primary cultures of the fluid were positive in 70%. The intraarticular inoculation of *E. coli* into horses induces a reliable, reproducible, and controlled model of infectious arthritis consistent with the naturally occurring disease and has been used to evaluate the efficacy of gentamicin for treatment. The injection of *E. coli* lipopolysaccharide into various joints of horses can cause clinical signs of endotoxemia, and the synovial fluid total nucleated cell count and total protein are linearly responsive in increases in endotoxin.

Endothelin (ET)-1, a 21-amino-acid polypeptide, is locally synthesized in the joints of horses with various forms types of joint disease. It induces a potent and sustained vasoconstriction. Synovial fluid concentrations of ET-1 varies among horses with joint disease, with higher concentrations in animals with joint sepsis suggesting a pathogenic role in septic arthritis.

Synovial fluid in infectious arthritis in the horse may contain the proteolytic enzymes collagenase and caseinase, which may derive from both synovial cells and neutrophils. These enzymes are involved in the degradation of connective tissue and loss of cartilage matrix. Lavage of affective joints is intended to remove these enzymes.

Infectious arthritis may occur following traumatic injury to a joint, but the pathogenesis is obscure. Traumatic injury of the joint capsule resulting in edema and inflammation may allow latent organisms to localize, proliferate, and initiate a septic arthritis.

Septic arthritis occurs rarely in adult horses following injection of an intraarticular medication or elective equine arthroscopy without antimicrobial prophylaxis. In a retrospective and prospective case series involving 16,624 injected joints, the risk of septic arthritis was 1 case per 1,279 injections, with veterinarian and type of corticosteroid (triamcinolone and dexamethasone) being risk factors for infection.[5] The significant effect of the veterinarian suggests the presence of variable attention to strict aseptic technique. In 444 consecutive equine arthroscopies performed without prophylactic antimicrobial therapy, the incidence of septic arthritis in horses after surgery was 0.7%, which was similar to the infection rate (0.9%) in other studies where horses received antimicrobial prophylaxis.[6]

CLINICAL FINDINGS

Inflammation of the synovial membrane causes pain and lameness in the affected limb, sometimes to the point that the animal will not put it to the ground. Pain and heat are usually detectable on palpation, and passive movement of the joint is resented. The joint may be swollen, but the degree will depend on the type of infection. Pyogenic bacteria cause the greatest degree of swelling and may result in rupture of the joint capsule. Some enlargement of the epiphysis is usual, and this may be the only enlargement in nonpyogenic infections, particularly those associated with *E. insidiosa.*

Fever, inappetence to anorexia, endotoxemia, loss of body weight, and discomfort may occur in animals with only one severely affected joint or when several joints are less severely affected. In many of the neonatal infections, there will also be an accompanying omphalophlebitis (Fig. 15-9) and evidence of lesions in other organs and tissues, particularly the liver, endocardium, and meninges. Arthritis in older animals may also be accompanied by signs of inflammation of the serous membranes and endocardium when the infection is the result of hematogenous localization.

The joints most commonly involved are the hock, stifle, and knee, but infection of the fetlock, interphalangeal, and intervertebral joints is not uncommon. In chronic cases, there may by physical impairment of joint movement because of fibrous thickening of the joint capsule, periarticular ossification, and, rarely, ankylosis of the joints. Crepitus may be detectable in joints where much erosion has occurred.

In newborn and young animals, involvement of several joints is common. The joints may become inflamed simultaneously or serially. Lameness is often so severe that affected foals lie down in lateral recumbency most of the time and may have to be assisted to rise. Decubitus ulcerations as a result of

Fig. 15-9 Very early signs of septic arthritis of the left hock joint in a 7-day-old Shorthorn calf. The calf did not suckle colostrum and had a slightly enlarged and painful umbilicus of 2 days in duration. Decreased weight-bearing on the left leg with palpable joint distention of the left hock has just become evident.

prolonged recumbency are common. The gait may be so impaired as to suggest ataxia of central origin.

The **prognosis** in cases of advanced septic arthritis is poor. Neglected animals may die or have to be destroyed because of open joints or pressure sores. The subsequent development of chronic arthritis and ankylosis may greatly impede locomotion and interfere with the usefulness of the animal.

DIAGNOSIS

The diagnosis of septic arthritis requires aseptic arthrocentesis of infected joint(s) and synovial fluid analysis, including bacterial culture of the fluid. An important therapeutic question to be answered is whether infection is confined to the synovial structure of the joint or whether infection includes cartilage and subchondral bone (osteomyelitis). Imaging modalities are designed to identify extension of infection deeper to the synovial structures, of which radiography has been extensively used and is very helpful in chronic cases.

Arthrocentesis

Aspiration of joint fluid for culture and analysis is necessary for a definitive diagnosis. Careful disinfection of the skin and the use of sterile equipment is essential to avoid the introduction of further infection. Intravenous diazepam (0.1 mg/kg BW) is helpful is sedating foals for arthrocentesis. Joint fluid should be collected using an 18-g or 16-g needle to facilitate removal of viscous or purulent fluid.

Analysis of Joint Fluid

Total and differential cell count, total protein concentration, and specific gravity are determined. The classical changes in synovial fluid in large animals with septic arthritis are increased leukocyte count (particularly neutrophils), an increased protein concentration, and decreased fluid viscosity.

In infectious arthritis, the volume of joint fluid is increased, and the total leukocyte count is increased, with a high percentage (80% to 90%) of neutrophils. The severity of infectious arthritis may be manifested systemically by a leukocytosis with a marked regenerative left shift. In degenerative joint disease, the volume may be normal or only slightly increased, and the total and differential leukocyte count may be manifested within the normal range. In traumatic arthritis, there may be a marked increase in the number of erythrocytes. Special biochemical examinations of joint fluid are available that measure for viscosity, strength of the mucin clot, and concentrations of certain enzymes. The laboratory findings in examination of the joint fluid are summarized in Table 15-3.

Culture of Joint Fluid

Joint fluid must be cultured for aerobic and anaerobic bacteria and on specific media when *Mycoplasma* spp. infection is suspected. It is often difficult to isolate bacteria from purulent synovial fluid. The rates of recovery of organisms vary from 40% to 75%. In one study of suspected infectious arthritis in 64 horses admitted to a veterinary teaching hospital over a period of 8.5 years, positive cultures were obtained from 55% of the joints sampled. The most common organisms were *S. aureus, E. coli,* and *Pseudomonas aeruginosa,* accounting for more than half the isolates obtained.

There is no single test that is reliable for the diagnosis of septic arthritis. Failure to isolate organisms on culture does not exclude a bacterial cause, and organisms are often not observed in synovial fluid smears. Poor collection, storage, and laboratory techniques; prior administration of antibiotics; or partial success of the immune system in containing the infection may explain the failure to detect organisms. Arthrocentesis should be done before antibiotics are given, and a blood culture bottle should be inoculated immediately, a Gram stain made, and culture for anaerobes included. Positive cultures from synovial fluid can be expected in only about 65% of cases.

A biopsy sample of synovial membrane may be more reliable than synovial fluid for culture, but there is little evidence based on comparative evaluations to support such a claim. PCR has been examined in in vitro studies to detect selected bacterial species in joint fluid compared with microbial culture. The benefits would include rapid and accurate diagnosis infectious arthritis, ability to detect bacteria in synovial fluid in the presence of antimicrobial drugs, and diagnosis of infectious arthritis when culture results are inconclusive. However, initial studies found no difference between microbial culture and PCR analyses.

Serology of Joint Fluid

Serologic tests may be of value in determining the presence of specific infections with *Mycobacterium mycoides, Salmonella* spp., *Brucella* spp., and *E. insidiosa.* Radiographic examination may aid in the detection of joint lesions and can be used to differentiate between inflammatory and degenerative changes. In foals with arthritis and suspected osteomyelitis there may be radiographic evidence of osteolysis of the metaphysis or epiphysis.

Radiography

Radiography of the affected joint will often reveal the nature and severity of the lesions. Typical radiographic findings of septic arthritis include osteolytic lesions of the articular cartilage, increased width of intraarticular joint space, and soft tissue swelling. Osteomyelitic changes are seen in some cases. Because radiographic changes usually appear after 2 to 3 weeks when destruction of subchondral bone has become extensive, it may be necessary to take a series of radiographs several days apart before lesions are detectable.

Ultrasonography

Arthrosonography is an effective, fast, and noninvasive complement to traditional diagnostic techniques (arthrocentesis and radiography) for comprehensive evaluation of the pathology of joints and associated tendons of cattle and horses.[7] Ultrasonography should be performed before arthrocentesis because joint distention facilitates imaging, and the introduction of air into the joint can interfere with interpretation of ultrasonographic images. Ultrasonography is particularly valuable in septic arthritis cases that are the result of trauma and to assist in the identification of foreign bodies.

Ultrasonographic changes are variable and primarily depend on the duration of infection.[7] Distension of the joint cavities can be imaged; assessment of the echogenicity, acoustic enhancement, and ultrasonographic character of the exudate correlates well with findings by arthrocentesis, arthrotomy, or at necropsy. Joint effusion, which is the earliest indication of septic arthritis, can usually be detected with ultrasound by an experienced operator in the early stages. The synovial membrane, synovial fluid, ligaments, tendons, and periarticular soft tissue, only inadequately imaged by radiography, can be imaged with ultrasonography. In advanced septic arthritis, ultrasonography provides accurate information on the location of the soft tissue swelling, the extent and character of the joint effusion, and the involvement of concurrent periarticular synovial cavities.

Arthroscopy

Endoscopy is now used widely to define joint abnormalities more clearly and to gain access to the joint cavity as an aid in the treatment of septic arthritis.

Nuclear Scintigraphy

Nuclear scintigraphy is considered much more sensitive than radiography for detecting the presence of subchondral (cortical) bone involvement and can be performed in the standing sedated horse. Scintigraphy is only found at large referral hospitals and usually cannot be scheduled on the same day as admission because the diagnostic agents need to be ordered and delivered. Consequently, the use of nuclear scintigraphy for identifying the extent of infection in acute cases of septic arthritis has declined. Scintigraphy remains a valuable diagnostic technique in adult horses with chronic septic arthritis, particularly of the proximal limbs and vertebral column.

Magnetic Resonance Imaging and Computed Tomography

These imaging modalities are only found at large referral hospitals and require general anesthesia to prevent movement during

image acquisition. In general, the duration of anesthesia for imaging is shorter with magnetic resonance imaging (MRI) than computed tomography (CT). MRI and CT provide excellent anatomic information on articular structures, but imaging is usually confined to the distal limbs, including the carpus and hock, of adult horses and cattle because units are designed for human use.

MRI is regarded as the gold standard method for diagnosing subchondral osteomyelitis associated with septic arthritis in human medicine and is therefore likely to provide the best imaging modality for identifying the anatomic location of early cases of septic arthritis in large animals.[8] Magnetic resonance findings in adult horses with septic arthritis include diffuse hyperintensity within bone and extracapsular tissue on fat suppressed images, bone sclerosis, and cartilage and subchondral bone damage.[9] Intravenous gadolinium administration usually identifies synovial enhancement.[9] CT has the advantage of speed, permitting the evaluation of multiple joints, which is particularly advantageous in foals with septic arthritis.

NECROPSY FINDINGS

The nature of the lesions varies with the causative organism. The synovial membrane is thickened and roughened, and there is inflammation and erosion of the articular cartilage. There is usually an increase in the amount of synovial fluid present, varying from a thin, clear, serous, brownish fluid through a thicker, serofibrinous fluid to pus. There may be some inflammation of the periarticular tissues in acute cases and proliferation of the synovial membrane in chronic cases. In the latter, plaques of inspissated necrotic material and fibrin may be floating free in the synovial fluid. Infectious arthritis caused by *T. pyogenes* is characterized by extensive erosion and destruction of articular cartilage and extensive suppuration. There may be a primary omphalophlebitis in newborn animals, and metastatic abscesses may be present in other organs.

DIFFERENTIAL DIAGNOSIS

Infectious arthritis is characterized clinically by swollen joints that are painful and warm to touch, along with lameness of varying degrees of severity. The volume of joint fluid is usually markedly increased, and the leukocyte count is increased, with a high percentage of neutrophils. In the early stages of synovitis and in chronic nonsuppurative arthritis, the joint may not be visibly enlarged, and careful examination by palpation may be necessary to reveal abnormalities of the joint capsule. Lameness is common, however, even though only slight in some cases, and should arouse suspicion of the possibility of arthritis.

The diseases of the musculoskeletal system that cause lameness and stiffness of gait include the following:

- Degenerative joint disease
- Osteodystrophy and epiphysitis
- Osteomyelitis
- Degenerative myopathy
- Myositis
- Traumatic injuries of tendons and ligaments

Diseases of the nervous system, especially the peripheral nerves and spinal cord, may be confused with arthritis unless the joints are examined carefully.

Some severe cases of polyarthritis may cause recumbency that may be erroneously attributed to the nervous system.

Degenerative joint disease is characterized by an insidious onset of moderate lameness and stiffness of gait that becomes progressively worse over several weeks. The joint capsule is usually not grossly enlarged and not painful, and there is usually no systemic reaction. The total leukocyte count in the joint fluid is only slightly increased, and the differential count may be normal. Chronic arthritis is often difficult to differentiate clinically from degenerative joint disease. Chronic arthritis is more common in young animals than in older animals such as rapidly growing yearling bulls, adult bulls, and aged dairy cows and horses, in which degenerative arthropathy is most common. A sudden onset of acute lameness and marked swelling of a joint with severe pain suggests an infectious arthritis or traumatic injury to the joint. Marked swelling of several joints suggests infectious polyarthritis.

Osteodystrophy is characterized by the following:

- Lameness and stiffness of gait
- Usually, an absence of joint-capsule abnormalities
- Enlargements and deformities of the long bones in growing animals
- A number of animals being affected at about the same time

Radiography may reveal the abnormal bones, and the nutritional history may explain the cause.

Degenerative myopathy causes acute lameness and a stiff and trembling gait, often leading to recumbency and absence of joint or bone involvement.

Traumatic sprains of tendons or ligaments and fractures of the epiphyses may cause lameness and local pain; when they involve periarticular tissues, they may be difficult to differentiate from arthritis.

Arthritis is never present at birth and apparent fixation of the joints should arouse suspicion of a congenital anomaly. The differentiation between arthritis and diseases of the peripheral nerves or spinal cord, both of which can cause lameness or recumbency, may be difficult if the arthritis is not clinically obvious. Diseases of the peripheral nerves cause lameness as a result of flaccid paralysis and neurogenic atrophy. Lesions of the spinal cord usually result in weakness of the hindlimbs, weak or absent withdrawal reflexes, and loss of skin sensation.

TREATMENT

Parenteral Antimicrobials

Treatment should focus on **early diagnosis**; **removal of infected fluids and tissue** via joint lavage (tidal or though and through), arthroscopy, arthrotomy, or possibly closed suction drainage; **effective antimicrobial therapy**; and **controlling inflammation**. Acute septic arthritis should be treated as an emergency to avoid irreversible changes in the joint. The conservative approach is the use of antimicrobials given parenterally daily for several days and up to a few weeks in some cases, but this provides a lower success rate than when antimicrobial treatment is accompanied by removal of infected fluids and tissue. Antimicrobials that perfuse into septic joints in therapeutic concentrations when administered parenterally include the natural and synthetic penicillins, cephalosporins, tetracycline, trimethoprim-potentiated sulfonamides, neomycin, gentamicin, kanamycin, and amikacin, with species preferences regarding preferred antimicrobial protocols.

The relative efficacy of antimicrobials administered parenterally versus by intraarticular injections is uncertain. Trimethoprim–sulfadiazine, given to calves parenterally, results in therapeutic concentrations of the drug in the synovial fluid of calves, and penetrability was not enhanced or restricted by experimental joint inflammation. Oxytetracycline and penicillin given parenterally readily penetrate the synovial membrane of both normal neonatal calves and those with experimental arthritis. Because peak synovial joint fluid levels of oxytetracycline and penicillin exceeded the minimum inhibitory concentrations for organisms such as *T. pyogenes,* the use of parenteral antimicrobials for the treatment of infectious arthritis in calves is appropriate. Ceftiofur at 1 mg/kg BW intravenously every 12 hours for 20 days, along with joint lavage, was successful in treating experimental septic arthritis associated with *E. coli.* The duration of antibiotic therapy is empirical; 3 weeks is recommended. Cephapirin administered parenterally to normal calves or those with arthritis resulted in synovial fluid levels approximately 30% of serum levels. The use of ampicillin trihydrate in calves with suppurative arthritis, at a dose of 10 mg/kg BW intramuscularly, resulted in a peak serum concentration of 2.5 µg/mL, 2 hours after injection; the highest concentration in normal synovial fluid was 3.5 µg/mL at 4 hours, and the highest concentration in suppurative synovial fluid was 2.7 µg/mL at 2 hours. Marbofloxacin at 4 mg/kg BW intramuscularly daily for 10 days was effective for the treatment of infectious arthritis in calves.

In **foals** and **horses** with septic arthritis, the selection of the antimicrobial of choice will depend on the suspected cause of the arthritis. The antimicrobial susceptibilities of bacterial isolates from horses with septic

arthritis/synovitis or osteomyelitis after fracture repair vary widely. A combination of a cephalosporin and amikacin is recommended before culture and susceptibility results are available. Commonly used dosage protocols include penicillin G potassium (22,000 IU/kg BW IV every 6 hours) with aminoglycoside gentamicin (11 mg/kg BW IV every 24 hours) or amikacin (20 mg/kg BW IV every 24 hours) or the third-generation cephalosporin ceftiofur (2.2 mg/kg BW IM every 12 hours). In azotemic foals, care needs to be taken while administering aminoglycosides, and monitoring should be in place to detect nephrotoxicity. Amoxicillin at 40 mg/kg BW IV is effective for the treatment of infectious joint disease in horses. The administration of trimethoprim–sulfadiazine at 30 mg/kg BW orally once daily to horses with experimentally induced *S. aureus* arthritis was ineffective in maintaining adequate levels of both drugs in infected synovial fluid. In contrast, the use of the same drug at 30 mg/kg BW orally given every 12 hours was effective in maintaining therapeutic concentrations of both drugs in the serum and in the joint fluid. Amphotericin B given intravenously daily for up to 30 days combined with joint drainage has been used for the treatment of *Candida* sp. arthritis in the horse.

In **piglets at 2 weeks of age, streptococcal arthritis** is most likely, and it will respond quickly to penicillin given parenterally. Likewise, acute arthritis associated with erysipelas in pigs will respond beneficially if treated early before there is pannus formation.

Synovitis caused by *Histophilus somni* infection responds quickly to systemic treatment. However, in other specific types of infectious arthritis the response is poor, and recovery, if it does occur, requires several days or a week. Mycoplasmal arthritis in cattle is relatively nonresponsive to treatment, and affected cattle may be lame for up to several weeks before improvement occurs; complete recovery may not occur. Chronic arthritis as a result of infection of pigs with *E. insidiosa* will commonly develop into a rheumatoid-like arthritis and be refractory to treatment.

Failure to respond to conservative therapy has been attributed to the following:

- Inadequate concentrations of antimicrobials achieved in the joint cavity
- Presence of excessive amounts of exudate and fibrin in the joint, making the infectious agent inaccessible to the antimicrobial
- Antimicrobial-resistant infections

It is often not possible to determine which situation is responsible.

If conservative treatment is not providing sufficient improvement and the value of the animal warrants extended therapy, a joint sample should be obtained for culture and susceptibility testing. The most suitable antimicrobial may then be given parenterally and/or by intraarticular injection. Strict asepsis is necessary to avoid introduction of further infection.

Intraarticular Antimicrobials

Antimicrobials infused into the joint should not be cytotoxic, and gentamicin (500 mg), amikacin (125 mg), soluble ceftiofur, and cefazolin (500 mg) are commonly used with minimal to no apparent effects on developing cartilage. The combined intraarticular and intravenous administration of gentamicin to normal horses can result in concentrations 10 to 100 times greater than after intravenous administration alone. In addition, gentamicin concentration in synovial fluid remained above the minimum inhibitory concentration for many common equine bacterial pathogens for at least 24 hours after treatment. The intraarticular administration of gentamicin is advantageous for the treatment of infectious arthritis in animals in which the systemic administration of the drug may be contraindicated, especially in the presence of impaired renal function or endotoxemia. Continuous infusion of gentamicin into the tarsocrural joint of horses for 5 days is an acceptable method of treating septic arthritis.

Antimicrobial-impregnated polymethylmethacrylate beads and gentamicin-impregnated collagen sponges have been used for the treatment of orthopedic infections involving bone, synovial structures, and other soft tissues. The antimicrobials diffuse from the nonbiodegradable beads in a bimodal fashion. There is a rapid ("burst") release of 5% to 45% of the total amount of antimicrobial within the first 24 hours after implantation and then a sustained elution that persists for weeks to months, depending on the antimicrobial used. For effective diffusion, the antimicrobials must be water soluble, heat stable, and available in powder form. Aminoglycosides (gentamicin, amikacin) and third-generation cephalosporins (e.g., ceftiofur) have been incorporated most commonly into the beads, but to be successful the drug must retain its antimicrobial effect after heating. The major disadvantage with polymethylmethacrylate beads is that they must be removed because they act as a foreign body and also provide unknown slaughter withdrawal times in food-producing animals. Long-term placement of intraarticular catheters has also been used in horses with septic arthritis, but aseptic methods must be maintained at the catheter site and during continuous or intermittent antimicrobial infusion, which can be challenging in a mobile animal. Moreover, a catheter should always be considered a two-way street and a potential vehicle for bacterial contamination of the joint. Whether placement of intraarticular catheters, polymethylmethacrylate beads, or gentamicin-impregnated collagen sponges have any substantive clinical advantages over intraarticular injections at approximately 3-day intervals has not been determined. Intraarticular ceftiofur injection every 3 days accompanied by wound management has become favored by some in the treatment of septic arthritis of the distal interphalangeal joint in cattle.

Regional limb perfusion with antimicrobials has been used for the treatment of experimentally induced septic arthritis. The antimicrobial is infused under pressure to a selected region of the limbs through the venous system. The concentration of the antimicrobial in the septic synovial fluid will usually exceed those obtained by intravenous administration. However, there are insufficient data available to evaluate the procedure in naturally occurring cases of septic arthritis. Therapeutic concentrations of cefazolin are achieved in the synovial fluid of clinically normal cows when injected intravenously distal to a tourniquet, and the technique could be used as an alternative to systemic administration of antimicrobials to provide adequate concentrations in a joint cavity. Regional limb perfusion appears better suited to treatment of more extensive infections such as septic arthritis secondary to penetrating wounds or accompanied by infected tendons or osteomyelitis.

Lavage of Joint

Drainage of the affected joint and through-and-through lavage of the joint is also desirable along with the systemic administration of antimicrobials. Aspiration and distension–irrigation of the joint cavity using polyionic electrolyte solutions buffered to a pH of 7.4 is recommended (Fig. 15-10). The irrigation removes exudates and lysozymes that destroy articular cartilage. A through-and-through lavage system may also be used with drainage tubes. General or local anesthesia should be provided. The distended joint is identified by palpation, the hair is clipped short, and the skin is prepared with appropriate surgical disinfection. A 2-cm 16-g needle is inserted into the joint cavity, avoiding direct contact with the bones of the joint. A second needle is inserted into the joint as far as possible from the first needle to cause any fluid perfused into the joint to pass through as much of the joint cavity as possible. Next, 0.5 to 1 L of a balanced crystalloid solution such as lactated Ringer's solution warmed to 37° C (99 F) is flushed through the joint using a hand-pumped pressure bag to keep a steady fluid flow into the joint. The only antimicrobial solution documented to be safe to be added to joint lavage solutions is 0.1% povidone-iodine solution, which produces minimal synovitis and no articular cartilage damage or joint irritation.

Arthroscopy

Arthroscopy provides excellent visualization of most parts of an affected joint and can be

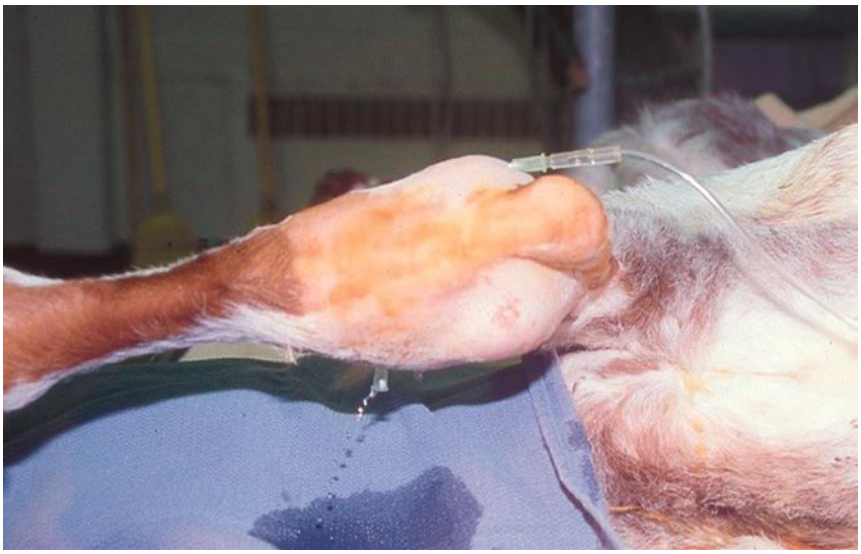

Fig. 15-10 Through-and-through needle lavage of the left hock joint of the Shorthorn calf in Figure 15-9. Warmed lactated Ringer's solution is lavaged through the joint with periodic joint distention (present) to facilitate lavage of the entire joint. The calf made a complete recovery.

used to access the joint for the treatment of septic arthritis. The endoscope can be used to explore and debride the affected joint during the same intervention. Purulent exudate can be removed, and necrotic areas within the synovial membrane can be debrided.

Surgical Drainage and Arthrotomy

Failure to respond to parenteral and intraarticular medication may require surgical opening of the joint capsule, careful debridement, and excision of synovium and infected cartilage and bone. This may be followed by daily irrigation of the joint cavity with antimicrobials and saline. A lavage system can be established and the joint cavity infused with an antimicrobial and saline daily for several days. Arthrotomy with lavage was more effective in eliminating joint infections by providing better drainage than arthroscopy, synovectomy, and lavage. However, with arthrotomy the risk of ascending bacterial contamination is greater, and the major difficulty is to eliminate the infection from the joint and incision site. Infected sequestra and osteomyelitis of subchondral bone will prevent proper healing. Curettage of septic physeal lesions in foals may be necessary.

Open drainage and intraarticular and parenteral antimicrobials have been used to treat persistent or severe septic arthritis/tenosynovitis. Although joint lavage through needles is still effective in many horses with acute infectious arthritis or tenosynovitis, in those with chronic or recurring septic arthritis, open drainage is indicated to remove the inflammatory exudate from the synovial space. Infected synovial structures are drained through a small (3-cm) arthrotomy incision left open and protected by a sterile bandage. Joint lavage using antimicrobials is done daily, and parenteral antimicrobials are given intensively.

Septic pedal arthritis in cattle may be treated successfully by the creation of a drainage tract to promote adequate drainage. In cattle with septic arthritis of the digit, placement of a wooden block under the unaffected digit decreases weight-bearing on the affected digit and provides for earlier, less painful ambulation.

Arthrodesis or Artificial Ankylosis

Surgical arthrodesis can be used for the treatment of chronic septic arthritis in horses and calves. Septic arthritis of the distal interphalangeal joint is a common complication of diseases of the feet of cattle. Facilitated ankylosis of the joint is a satisfactory alternative to amputation of the affected digit in valuable breeding animals. In a series of 12 cases of septic arthritis of the distal interphalangeal joint treated by use of facilitated ankylosis, the success rate was 100%.

Physical Therapy

The local application of heat, by hot fomentations or other physical means, is laborious, but if practiced frequently and vigorously, it will reduce the pain and local swelling. Analgesics are recommended if there is prolonged recumbency. Persistent recumbency is one of the problems in the treatment of arthritis, particularly in foals. The animal spends little time feeding or sucking and loses much condition. Compression necrosis over bony prominences is a common complication and requires vigorous preventive measures.

Stall rest for at least 3 to 4 weeks is recommended to minimize excessive exercise because the joint cartilage appears to be more vulnerable to injury after an acute inflammatory episode.

Antiinflammatory Agents and Adjunctive Therapy

NSAIDs are used routinely parenterally to decrease the inflammatory response and to provide analgesia. A common dose rate in foals with septic arthritis is 1.1 mg/kg BW IV every 24 hours for flunixin meglumine. In experimental synovitis in the horse, similar to septic arthritis, phenylbutazone was more effective than ketoprofen in reducing lameness, joint temperature, synovial fluid volume, and synovial fluid prostaglandin. Topical application of a fentanyl transdermal "patch" to the thorax or groin may provide additive analgesia, but scheduled drug requirements and reporting may make such treatment impractical.

Hyaluronic acid is protective for joint health because it is an important constitutive component of articular cartilage and synovial fluid. Horses with septic arthritis have depleted hyaluronic acid content, and consequently foals with septic arthritis benefit from the intraarticular administration of hyaluronic acid (10 mg) because this results in glycosaminoglycan loss from articular cartilage and has antiinflammatory properties.

Prognosis for Survival and Athletic Use in Horses With Septic Arthritis

The factors affecting the prognosis for survival and athletic use in 93 foals treated for septic arthritis have been examined. The femoropatellar and tarsocrural joints were most commonly affected. Osteomyelitis or degenerative joint disease were detected in 59% of the foals. Failure of transfer of passive immunity, pneumonia, and enteritis were common. Treatment consisted of lavage, lavage and arthroscopic debridement with or without partial synovectomy, or lavage and arthrotomy to debride infected bone and parenteral antibiotics. Seventy-five foals survived and were discharged from hospital, and approximately one-third raced. Isolation of *Salmonella* from synovial fluid was associated with an unfavorable prognosis for survival, and multisystemic disease was associated with an unfavorable prognosis for survival and ability to race. The key to successful outcome for septic arthritis is rapid diagnosis and initiation of treatment. The presence infection in multiple joints is associated with a poor outcome.[1]

In a series of 507 horses treated for joint disease at one equine hospital during a period of 7 years, the risk factors affecting discharge from the hospital were examined; 58% of foals, 78% of yearlings, and 94% of racing adults were discharged. Foals with a less severe lameness, duration of less than 1 day, and infectious arthritis had increased odds of discharge.

Factors associated with the short-term survival rate of 81 foals with septic arthritis were evaluated. Seventy-seven percent of the foals were discharged from the referral hospital, with nonsurvival being associated with

multiple joint involvement; detection of gram-negative, mixed bacterial intraarticular infection; and the presence of degenerate neutrophils in the joint fluid.[10] Initiation of treatment within 24 hours of first evidence of clinical abnormalities and the use of multiple treatment modalities were positively associated with survival.[10] In general, little information is available about athletic performance in horses following septic arthritis.

CONTROL

The control of infectious arthritis is of major importance in newborn farm animals. The early ingestion of adequate quantities of good-quality colostrum and a clean environment for the neonate are necessary. The prophylactic use of antimicrobials may be considered to reduce incidence. Some of the infectious arthritides associated with specific diseases can be controlled through immunization programs. For example, vaccination of piglets at 6 to 8 weeks of age will provide protection against both the septicemic and arthritic forms of erysipelas.

LAMENESS IN PIGS AND DEGENERATIVE JOINT DISEASE (OSTEOCHONDROSIS, OSTEOARTHROSIS, EPIPHYSIOLYSIS AND APOPHYSIOLYSIS, LEG WEAKNESS IN PIGS)

LEG DISORDERS

Leg disorders are divided into three major groups[1]: (1) infectious arthritis, (2) physical injuries, and (3) osteochondrosis.

Leg weakness is a locomotory disability of pigs that is not associated with infectious disease. It is a combination of noninfectious arthropathy and osteopathy and is a significant cause of culling in pig herds. The causes are defects of conformation, osteochondrosis (including epiphysiolysis), arthrosis, lumbar intervertebral disk degeneration, and spondylosis. The clinical syndrome varies from lameness to difficulty in rising to recumbency. The characteristic signs are carrying a hindleg, sitting on the haunches for long periods of time, and a shuffling gait. All of the conditions affecting the limbs are related to the growth patterns in the respective limb bones. Rickets is seen from 8 weeks to physeal closure, osteomalacia from 8 weeks onward, osteochondrosis (OCD) from 0 to 30 weeks, epiphyseal separation from 15 weeks to physeal closure, and spondylosis in older sows or boars.

LAMENESS

Lameness is deviation from normal gait. Joint kinetics have been described,[2] and lameness is closely associated with floor conditions.[3] One of the key decisions in examining pigs that are not showing signs of normal locomotion is to ascertain whether the pigs have abnormalities in the nervous, skeletal, muscular, or joint systems. In most cases lameness will involve the joints for a variety of reasons because these are the most stressed structures in the locomotory system. Patience in examination is essential, and noting the progression of signs is also very important. What the clinician will see and what the pathologist and laboratory diagnostician sees are usually two different things.

Lameness in pigs is associated with several etiologic disease groups: (1) trauma and bone fractures; (2) infections, such as arthritis, abscesses, tendonitis, and osteomyelitis; (3) overgrown feet, heels/claws, and wear conformation; and (4) osteochondrosis/osteoarthropathy, which is probably the most important group. The most common combination is trauma/infection/weak conformation.

AGE-RELATED CHANGES IN PIGS

Young Pigs

Examination of young pigs for lameness is not easy. They are quick on their feet, bunch often, and need to be marked individually for further identification. You need to identify and mark those that are not walking or behaving normally or, if very young, not suckling properly. In young pigs purulent arthritis is common (usually *S. suis*, but may be others, including streptococci, *S. aureus, E. coli*).[4-6] In a Swedish study, 75% of lame piglets had polyarthritis (more than one joint affected).[5]

The risk factors[7] include the following:

- Poor mothering, poor milk supply, poor colostral antibody protection, and agalactia
- Skin lesions, particularly at the carpal joints as piglets struggle to suckle
- Foot lesions associated with very poor flooring—rough edges, jagged metal (always worse than plastic), old plastic, poor concrete finish, and so forth—which causes damage to the tender feet of neonates, leading to bruised heels, erosion of heels, coronary band lesions, and subsequently septic arthritis
- Arthritis is ubiquitous, principally as a result of bad hygiene in the farrowing house; the importation of nonimmune gilts; poor management; no all-in/all-out system; improper cleaning, disinfection, and drying; lack of bedding; fully slatted floors; and lack of creep heating and feeding.

Most of the factors in the first two categories have disappeared by weaning because the piglet skin hardens and underfloor conditions generally improve.

The situation can be improved by proper management of sows and gilts; batch farrowing followed by cleaning, disinfection, and drying; proper building maintenance; bird and rodent control; treatment of sows for agalactia; use of cross-fostering if there are large litters; and use of vaccines if appropriate. It was shown that repairing floors and doubling the straw decreased the amount of abrasions,[5] and the level of lameness decreased from week 1 to week 3.

Osteodystrophy has been associated with hypervitaminosis A in growing pigs.

Growers and Finishers

In growers and finishers all of the groupings of disease type are important. See how they react to walking. Usually lame pigs have an arched back, sit for longer periods, are reluctant to stand or move, are easily bullied, and tend to sit or lie down as soon as possible. If they are not lame they get up quickly and move quickly. In these animals the infectious causes involve *M. hyosynoviae, M. hyorhinis, S. aureus, Erysipelothrix* spp., and *H. parasuis*. In addition, OCD is important. In a survey of 1000 pigs,[8] 14% had OCD, and every pig with OCD gained 100 g/day less than the unaffected pigs.

The risk factors include low herd immunity (need to increase by exposure or vaccination); the importation of carriers onto the farm (e.g., *S. suis, Erysipelas* spp., *M. hyosynoviae,* and *H. parasuis* in particular); mixing of different ages of pigs (need all-in/all-out system by age); and stress as a result of excessive mixing, moving, and handling (reduce if possible).

A hereditary form of rickets has been described in which there is no enzyme to convert D2 to D3 in the kidney. Normally, rickets derived from dietary causes is normally seen in pigs of 2 to 6 months, and they have swollen joints, particularly the carpal, humeral, elbow, and stifle joints. Cases of rickets from dietary causes are very

uncommon and should not happen in this day and age, but cases do occur, particularly in the pigs of "back garden" and enthusiastic amateurs. The clinical signs include a stunted and unthrifty appearance, lameness, fractured long bones, and paresis. In young, weaned, growing pigs, there is a failure of mineralization of the osteoid and cartilage matrix, especially in the growth plates. At necropsy, the bones are pale and soft, particularly the ribs, which bend rather than snap under pressure and are radiolucent. Because the bones bend and don't fracture, there is often evidence of recent or healing fractures.

Rickets develop as a result of the following:

- Inadequate concentrations of calcium, phosphorus, and/or vitamin D in the ration
- Improperly balanced calcium and phosphorus in the ration, resulting in a ratio greatly different from 1 to 2:1
- Inadequate concentrations of the active vitamin D
- No vitamin D synthesis in a dark environment
- No proper ration analysis
- Excess iron in the diet

Kyphosis/lordosis ("kinky back" or lordosis/kyphosis) can be seen as a congenital abnormality, but it has also been seen in association with precocious behavior causing relaxation of the spinal ligaments and also by breeding for extra vertebrae in the spinal column, resulting in too much muscle weight for the skeleton.

Older Animals

In older animals the disease is mainly of the infectious disease group, particularly polyarthritis and spondylitis. The risk factors are low herd immunity, the importation of carriers, mixing of pigs with different immunities, and episodes of stress. In these animals prevention is by isolation and quarantine of new imports, thorough mixing of pigs to ensure equal susceptibility and resistance, vaccination where possible (use the right strain, store vaccines correctly, and use them properly), and, importantly, reduction of adverse nutrition (look after P, Ca, and ratios, and make sure they are mixed at the right proportions).

A case-control study of factors associated with arthritis detected at slaughter in pigs from 49 farms in Finland showed that 93% to 96% of pigs had osteochondritic lesions in joints, both in the control group and the group with high incidence of arthritis at slaughter, and infection was found only rarely.[9] Bursitis is a common feature in this age group,[10] as are other foot lesions.[11,12] Osteomyelitis is an uncommon problem but may result in lameness or pathologic fractures of vertebrae with compression of the spinal cord. It may follow septicemia or a local progression, as in tail-biting abscessation.

Adults

In a survey of cull sow bone and joint integrity in the Moorepark Research Farm herd in Ireland, it was found that there was no relationship between lameness and joint pathology in sows. Osteochondritic lesions were found in all the sows and were most common in the medial condyle of the humerus and the anconeal process of the ulna.[13,14] A study of lameness and fertility in sows and gilts in loose-housed herds in Finland[15] showed that 8.8% of the animals (646 in 21 herds) were lame. The most common clinical diagnoses were osteochondrosis, infected skin lesions, and claw lesions. Sows on slatted floors had twice the chance of being lame than those on solid floors. Yorkshire pigs were more likely to be lame than Landrace or crossbred pigs. Lameness was not a risk factor for nonpregnancy. With sows, fighting in loose-housing systems is an important factor, especially if there are limited numbers of feeders. Slipping on concrete-based flooring systems with badly drained, water-soaked floors is also a hazard. In these cases rubber mats may help. In sows there is commonly medial claw atrophy (hypoplasia) and an overgrown lateral claw. Quite often it is the younger animals that are affected, especially in loose-housed animals. Lesions at the coronary band are also not uncommon. Claw lesions may be primary, with secondary conditions to follow. In two commercial sow herds,[16] less than 4% of sows had lameness, with heel erosions being the most common cause and overgrowth of dewclaws second.

One of the most common lesions in this age group is cracked feet, either of the sole or wall or heels; affected animals are lame, but if treated, a proportion will always get better. OCD in sows will often cause an intermittent lameness, whereas animals with arthritis are persistently lame. In a survey of sows at casualty slaughter in 2005, 22% had fractures, 12% arthroses, and 15% osteomyelitis in the spine and other arthritides. All of the four groups are a problem in sows. Lameness is always on the list of culling for sows.[17]

Prevention is attention to all the items previously listed: inspect, trim, and treat feet regularly; check for wet floors, sharp edges, and newly laid concrete (treat with sodium carbonate); correct width of slats for age of animal; remove steps and steep slopes; check drainage angles; improve hygiene; perform regular cleaning, disinfection, and drying; reduce fighting; provide manipulable materials, particularly straw; have stable subgroups and provide good feeding and ad lib water; improve horn quality, possibly by increasing biotin and vitamin E in the diet; and, most important, improve genetic selection techniques.

Piglets often have fractures if laid on by sows, especially if they are hypoglycaemic or weak. Older piglets may fracture bones when they are stuck in fences or equipment. Finishing pigs may fracture bones during transport. Fractures found in several animals at the same time may be a result of electrocution or sometimes outdoor lightning strike. Vertebrae, particularly in the thoracic area of the spine, humerus, neck of the scapula, pelvis, and neck of the femur are the usual sites. Sometimes the fractures are in the lumbosacral junction, resulting in separation of spinal cord and nerves. In these cases decomposition occurs quickly. Fractures have been described as part of lactational osteoporosis (downer sows) that occurred in first-litter sows when they were moved from the farrowing quarters and involved the pelvis, spine, femur, and other bones. It was caused by early mating, rapid growth rates, high milking yield of the sows, large litters, and insufficient nutrients in the diet to provide for both milk and sow growth, and thus calcium and phosphorus were drawn from the skeleton. Lactational osteoporosis is a result of an imbalance between bone formation (osteoblast activity) and bone resorption (osteoclast activity). There is often calcium deficiency. Sows bones decalcify to mobilize calcium for milk production. The specific gravity of bone in these animals will be 1.018, whereas the normal is 1.022. The ratio of cortex to total area is 0.2 or less compared with 0.3 in the normal cross section of the sixth rib. The bones are structurally normal but of lower mass. Complicating factors include long periods of restricted exercise (sow stalls, farrowing crates), and it is particularly a problem during the first litter when gilts are still growing and there is an even higher demand for calcium and phosphorus. At necropsy the most frequent sites for lesions are the proximal one-third of the humerus and the proximal one-third of the femur. Comminuted spiral fractures extend from the metaphysis down into the diaphysis.

Osteomalacia has been described as a result of deficiencies or imbalances of calcium, phosphorus, and vitamin D but may also be a result of the inability to consume sufficient food. Large quantities of unmineralized osteoids develop, thereby weakening the bones. This is attributable to a higher secretion of parathyroid hormone in the lactating sow.

Proliferative osteitis of the femoral greater trochanter and medial epicondyle of the humerus has been described, usually in gilts after the first weaning. Affected animals are seen dog-sitting, and they rise with pain and discomfort; the pathology is a hemolytic mass in the muscle.

Ankylosing spondylitis has been identified in culled sows and boars at abattoirs, but it is thought that the condition starts as early as the first year of life. Pigs have a painful lumbar region, may develop kyphosis, and waddle when walking or drag the hindfeet. The cause is probably multiple—wear and tear, spinal trauma, poor nutrition, genetics, arthritis of spinal joints, and so on.

Vertebrae may eventually fuse when alleviation occurs. Spondylosis results in bridging of the vertebrae, with possible trapping of the vertebrae.

Arthrosis is sometimes referred to as arthropathy, osteoarthrosis, or osteoarthritis and is a nonspecific degenerating condition of cartilage that develops in chronic joint disease. The incidence increases with age (animals less than 18 months had 7% incidence, but those over 18 months had 82%). It is the result of instability resulting from osteochondrosis and the surface lesions in the joint that have filled with osseous repair tissue. Pathologically, the lesions include fibrillation of joint cartilage, ulceration of the articular surface, osteophyte production, and thickened synovial membranes and joint capsule.

Tumors are not common but include an osteosarcoma of the maxilla occluding the nasal cavity, secondary tumors from a malignant melanoma, congenital melanomas, and multiple myeloma[18] and a glioblastoma in the ventral cerebral cortex of a 6-month-old Yorkshire gilt.

OSTEOCHONDROSIS

Leg weakness in pigs is a very loose term that includes a wide variety of conditions and is best discarded. Degenerative joint disease would be a much better general term to describe the lameness of young rapidly growing pigs affected with noninfectious joint diseases, which include osteochondrosis (OC), epiphysiolysis, and degenerative osteoarthrosis (OA). Degenerative joint disease is characterized by varying degrees of intermittent but progressive lameness in rapidly growing pigs from 4 to 8 months of age, and pathologically it is characterized by the presence of OA and OC. The disease is of major economic importance because of the high culling rate of breeding-age swine.

Degenerative joint disease is, in fact, a dyschondroplasia that affects growth cartilage, both physeal and epiphyseal, in most breeds of rapidly growing pigs, which results in cartilage and bone lesions.

The term *dyschondroplasia* should be used to describe the majority of lesions affecting growth plates, especially physeal growth cartilage or physes and lesions involving the articular epiphyseal cartilage complex (AECC). Dyschondroplasic foci may undergo calcification and ossification; alternatively, the chondrocytes may die, and the necrotic chondrocytes and the denatured matrix are removed by fibrous connective tissue that ossifies. Occasionally, features develop at the chondro-osseous interface with the metaphysis or within the calcified portion of the zone of hypertrophying chondrocytes; cysts or clefts that contain blood persist and appear to stop the ossification front. Osteochondrosis is defined as a focal disturbance of endochondral ossification and is regarded as having a multifactorial etiology, with no single factor accounting for all aspects of the disease. The most commonly cited factors are genetics, rapid growth, anatomic conformation, trauma, and dietary imbalances. Only heredity and anatomic conformation are confirmed by the scientific data. The term *osteochondrosis* should be used to describe a group of syndromes that cause limb deformities or degenerative joint disease in young, fast-growing pigs of either sex. Currently the consensus is that it is the effect of rapid growth (early excess weight) and lack of exercise on the developing cartilage that is at fault. The lesions appear to develop when pigs are less than 1 month old, when there is little muscle mass, indicating that heavy musculature is not the prime cause but helps in the exacerbation of the disorder. It has been observed in pigs as young as 1 day old. However, in these young pigs the AEEC and growth plates are proportionately thicker and possibly susceptible to stress. This results in a thickening of part of the growth plate that causes interference with metaphyseal growth. This in turn results in deformation of bones, joints, and ultimately limbs. It is this distortion that may lead to incongruity of joints, with subsequent development of osteoarthritis and other degenerative joint diseases.

In the past, many of the lesions affecting the AEEC were examined at a stage when degenerative joint disease (DJD) had already become established. In these cases, the articular surface was advanced, and subchondral bone was often exposed. However, examination of early lesions shows that the lesions are initiated as microscopic foci of chondrolysis at or near the interface of the articular cartilage and epiphyseal growth cartilage. The lesions may progress at this site, and lysed cartilage persists in the deeper layers of the AEEC, at the chondro-osseous interface, and within the bone of the epiphysis. The recently replicated cells die, and there is either failure of matrix production or disruption of the formed matrix. Clusters of chondrocytes often develop at the periphery of the lesion in an attempt to repair the lesion. The soft denatured cartilage is probably subject to further damage during joint movement, so that flaps, fissures, and craters develop. When the AEEC is breached and subchondral bone is in contact with the joint space, the joint becomes painful, and lameness develops.

There is a consensus view that vascular injury within cartilage canals is part of the pathogenesis, although there are opponents of this view. With no normal vascularization, there is no subsequent ossification. The position with regard to OCD has recently been summarized[19] and describes it as being a premature regression of the blood supply to the epiphyseal growth cartilage, leading to ischemic necrosis of the cartilage canals. Research suggests that there are three different manifestations of OCD: (1) *osteochondrosis latens* (OCL), where there are foci areas of cartilage necrosis at the epiphyseal growth cartilage that are not visible grossly but are visible on microscopic examination; (2) *osteochondrosis manifesta* (OCM), where endochondral ossification becomes visible on microscopic and radiographic examination as thickened or uneven cartilage; and (3) *osteochondritis dissecans* (OCD), characterized by lesions of fissured articular cartilage protruding into the underlying bone.

There is still much confusion as to whether there is an association between OCD and lameness. Our considered opinion is that it is referable to the individual animal and depends entirely on the extent and severity of the lesion, the joints affected, the "meatiness" of the animal, and the age at which the animal is affected. In many cases, the situation is complicated by secondary processes such as osteomyelitis, fractures, and damage to greater trochanter and tubercle.

Epiphysiolysis and apophysiolysis are now considered to be part of the abnormalities of the AEEC, with fractures occurring at the weakened epiphyseal sites in the femur and tuber ischiadicum, respectively.

Diagnosis of these conditions is achieved by ruling out other causes of lameness and then by confirming with a postmortem examination of cull sows.

SYNOPSIS

Etiology The specific cause is unknown but is probably a failure of vascularization of cartilage.

Epidemiology Occurs in majority of breeds of rapidly growing pigs and young breeding females and males. Lesions are commonly present at slaughter. May be related to nutrition and rapid growth rate, genetic predisposition, and type of flooring, but there are no reliable correlations.

Signs There may be no clinical findings or possibly lameness and inability to breed.

Clinical pathology Radiographic evidence of osteochondrosis.

Lesions Osteochondritic lesions of varying degrees of development, severity, and healing.

Diagnostic confirmation Lesions at necropsy.

Differential diagnosis list As listed for the various ages.

Other causes of lameness include the following:

- Polyarthritis attributable to infectious causes
- Laminitis
- Nutritional osteodystrophy attributable to calcium, phosphorus, and vitamin D imbalance
- Hypovitaminosis A causing hindlimb paresis

Treatment None.

Control Uncertain. Select breeding stock with sound legs and gait.

ETIOLOGY

The cause of the articular abnormalities is not known. The etiology and factors underlying these syndromes are poorly defined, partly because of the difficulty of definitive clinical examination of affected pigs and the frequent lack of apparent significant pathologic changes in necropsy examination of mild cases. There are no specific associations between degenerative joint disease and infectious diseases.

The growth plates that close last are the ones that are most susceptible (medial condyles of humerus and femur, ulna, costochondral junctions, and the 6th to 8th lumbar vertebrae). Many terms have been used to describe the condition, including osteochondritis, osteoarthritis, degenerative joint disease, arthropathy, arthritis, polyarthritis, and metaphyseal dysplasia, to name but a few. Most of these titles are inaccurate because the condition has its origin in the growth cartilage, and bones are affected secondarily.

EPIDEMIOLOGY

Occurrence

Recently, a study of 9,411 newborn piglets showed that 9.8% were treated for lameness. For parity 3 sows, the level had risen to 11.4%, but by parities 4 to 7, only 8% were treated. The treatments were in pigs of less than 3 weeks of age in 73% of the cases. Litters with 12 or more pigs had the highest incidences of lameness. Osteoarthritic changes are strongly associated with osteochondrotic changes in the humeral and femoral condyles. Osteochondrosis has been recorded as early as 1 day of age, so the lesions may be congenital. There may be some degree of change in up to 85% of pigs.

The osteochondrosis complex (OCD) is the most common cause of lameness in breeding pigs.[20]

However, a recent study[14] has shown no relationship between lameness and OCD, but all the sows studied had evidence of OCD (particularly in the medial condyle of the humerus and anconeal process of ulna).

We can say, in summary, that nearly all sows have some evidence of leg weakness, and in many circumstances leg weakness is a cause of culling. The reason for this is quite simple: the legs are the components of locomotion that are most influenced by genetics, nutrition, management, environment, and microorganisms and infection. Overfeeding is the cause that results in too much weight and not enough bone to support the weight.

There is a correlation between body conformation and the presence of joint lesions. Pigs with a narrow lumbar region, broad hams, and a large relative width between the stifle joints were highly susceptible to poor locomotory ability as a result of lesions in the elbow and stifle joints, the lumbar intervertebral joints, and the hip joint. It is postulated that inherited weakness of muscle, ligaments, cartilage, and joint conformation results in local overloading of the joint and the development of OC and OA. Some breeds, such as the Duroc, have more problems of structure and movement in the front legs than the rear, but OC is not responsible for the leg weakness. OC has been recorded in wild boar–Swedish Yorkshire crossbred pigs, in which the growth rate was low. It is probably not related to floor type. It is not associated with adventitious bursitis.

The intensification of the swine industry has required that pigs grow rapidly and with high feed efficiency. Under such intensified conditions, rapidly growing pigs develop lesions of the bones and joints, especially the femur. Most pigs near market weight have varying degrees of OC. Except for severe lesions, which usually occur in a relatively small proportion of the total population examined, the lesions seen at slaughter often have no detrimental effect on the growth rate of pigs up to market weight. An advanced degree of OC, however, can result in severe degenerative joint disease and lameness in breeding stock. The disease occurs in both male and female pigs, and the incidence of lame pigs can be as high as 20% to 30%. It is a particular problem in gilt and boar testing stations, where it may necessitate slaughter of affected animals before the testing period is complete. The lesions develop most commonly in growing pigs, particularly boars from 20 to 30 weeks of age, raised in confinement. The onset occurs when pigs are between 4 and 8 months of age, which coincides with a period of maximal growth rate. The peak period of clinical manifestation is from the late grower stage until 18 months of age, although the effect of OA may carry through to the adult period. Extensive multicentric degenerative joint disease in adult sows and boars can cause severe lameness, which often warrants euthanasia. However, sows ranging in age from 1.5 to 3.0 years and culled for impaired reproductive performance, with no history of lameness, may have lesions of the femoral condylar surface.

Risk Factors

Numerous risk factors contribute to the disease, including nutrition and rate of growth, genetic and breed predisposition, sex, type and quality of flooring, and exercise and confinement conditions. The pig carries 53% to 51% of its weight on the forelimbs and 47% to 49% on the hindlegs when young, but the weight supported on the hindlimbs is greater at 90-kg and 105-kg body weights. In a study of gilts and sows in Denmark, approximately 12% of gilts showed stiff locomotion, but 53% of gilts had at some time showed the same sign. Buck-kneed forelegs, upright pasterns, legs turned out wide, standing under position, and swinging hindquarters were associated with stiff locomotion or lameness. Weak pasterns on the hindfeet were associated with stiff locomotion and lameness. Weak pasterns on hindlegs and splayed digits on forelegs were associated with brisk movement (freedom from locomotor problems). The following leg weakness signs at the gilt stage were found to have a significant effect on the longevity of the sows: buck-kneed forelegs, swinging hindquarters, and standing under position on the hindlegs.

Nutrition and Rate of Growth

The disease is associated with rapid early growth, but it does not appear to be related to protein, vitamins A and D, or calcium and phosphorus imbalance in the ration. Maximal mineralization of bones is not necessary to prevent leg weakness. Only almost complete absence of calcium and phosphorus causes lameness. Disturbances of the Ca : P ratio below 0.5 or over 3.0 are necessary to produce lameness. Recently it has been suggested that long-term acidosis may be associated with the condition because bone is not formed as phosphorus is removed from the bone. In this context the acidification of pig diets has been suggested as a contributory cause. It has also been shown that the presence of deformed forelimbs is not associated with low levels of vitamin C in plasma. Rapid growth, especially during the early period, was thought to have a significant influence on the occurrence, and there is also some breed variation in susceptibility. However, in some feeding trials of pigs from weaning to slaughter weight, there was no direct effect of rapid growth rate on the incidence and severity of OC. In other feeding trials, average daily gain of gilts was an important factor in the severity of lesions of OC. Decreasing the rate of gain by restricting energy intake appeared to decrease the prevalence and severity of OC when gilts were slaughtered at 110 kg. However, it was shown that when pigs were fed waste food and grew more slowly, they had an increased prevalence and score for OC compared with pigs fed a commercial feed concentrate. Decreasing the concentration of protein in the diet of gilts from 16% to 12% resulted in less longitudinal bone growth but did not decrease the incidence of OC. A simple association between growth rate and the incidence or severity of joint lesions has not been consistently demonstrated, and a reduction in the growth rate of pigs does not control the disease.

A significant favorable association between leg action and daily gain has been noted. There has also been speculation that growth hormone could influence the development of lesions of OC by exerting a direct effect on differentiation and colonization of epiphyseal chondrocytes. There is no consistent relationship between the incidence of osteochondrosis and selection of pigs for lean tissue growth rate. It may be simply that more feed means more growth, which makes the stress on developing cartilage greater and therefore predisposes to OC.

Genetic and Breed Predisposition

It has been proposed for many years that selection of pigs for increased growth rate resulted in a concomitant increase in the incidence and severity of musculoskeletal disease. Genetic studies indicate that the heritabilities of leg weakness are low to moderate (0.1 to 0.3). A more recent study suggested from 0.01 to 0.42 for leg weakness and OC and that both are associated with production traits (lean percentage and back-fat thickness). Genetic analysis of the incidence of OC and leg weakness in the Swedish pig progeny testing scheme revealed a low to moderate heritability. Genetic control of leg weakness has been achieved by various researchers, and thus inheritance is probably an important risk factor for this disease complex. The genetics of leg weakness have been described in Finnish Large White and Landrace populations. Meaty breeds are the most severely affected, including the Duroc and the Dutch and Swedish Landrace.

Inheritance may not be polygenic; it may be just one gene that controls OC, the MEP gene.

Osteochondrosis also occurs in crossbred Wild Boar–Yorkshire pigs with a genetically decreased growth rate, raised under the same conditions as finishing pigs. The distribution and extent of OC was similar to that of purebred Swedish Yorkshire pigs. This suggests that it is not limited to rapidly growing pigs. There are significant breed differences in the periarticular and meniscal ossifications seen on x-ray. Recently the quantitative trait loci for locomotion and osteochondrosis-related traits have been identified in Large White–Meishan crossbred pigs. Correlations between breeding values for longevity and for OC were low but significant, in a favorable direction. Higher OC scores were associated with a higher risk of being culled.

It has been seen in wild boar in Slovenia.

Type of Flooring

Insecure footing because of unfavorable floor surfaces and the presence of foot lesions may change the posture of the animal and cause local overloading of certain joints. The effect of the quality of floor has been examined, and there is no clear evidence that the hardness of floor contributes to an increased incidence of leg weakness associated with joint disease. However, the incidence and severity of joint lesions may be related to the duration of confinement in pigs confined individually. Exercise will prevent abnormalities such as bow legs, flexion of the carpus, and sickle-legs from impairing the mobility of boars, but it does not influence the severity of joint lesions. The milder syndromes of poor movement and lameness associated with defects in leg conformation in the grower stage are not necessarily associated with bone or joint lesions and may regress spontaneously or improve if affected pigs are placed on pasture. However, severe lameness at this age, and occurring in replacement stock and young adults, is frequently associated with severe bone and joint lesions, which may be irreversible. A recent study has looked at type of floor (solid floor plus straw, solid floor no straw, and fully slatted). The slatted floors were worst for leg weakness and the floors with straw best. The different types of floor affected leg weakness and claw disorders differently.

Trauma probably exacerbates the late lesions by damaging further the blood supply to the blood vessels of the cartilage.

Exercise and Confinement

There is some limited evidence that a high lean growth rate may predispose toward leg weakness under confinement rearing. It may be that the growth rate at different ages is more important. Trauma during handling, penning, and transportation may be associated with a relatively high frequency of OC, but the evidence is very limited. A high stocking density had an adverse effect on four of the signs of leg weakness (knock knees, turned-out forelimbs or hindlimbs, standing with the legs under the body). A recent study of housing and treadmill training did not show any adverse effects on leg weakness. It has even been seen in pigs on grass and on deep litter and in wild boar.

Economic Importance

In Scandinavia, breeding pigs culled because of lameness had a 100% frequency of OC or OA, and up to 40% of boars in a performance test station had osteochondrosis or osteoarthrosis. A conservative estimate suggests that 3% of sows and 10% of boars are culled for unsoundness associated with OC and OA. The hidden costs include a reduced pool for selection of high-performance boars and gilts, the maintenance of pigs that cannot be used for breeding, increased mortality among piglets crushed by lame sows, reduced feed intake and growth rate in lame pigs, and transportation costs of replacement stock.

PATHOGENESIS

The initial stage of pathogenesis is thought to consist of the formation of fragile cartilage, failure of chondrocyte differentiation, subchondral bone necrosis, and failure of blood supply to the growth cartilage. Some of the literature supports the idea that the failure of blood supply is the crucial lesion, either from the epiphyseal or metaphyseal side. In a summary, the primary lesion could be described as a focal ischemic necrosis of growth cartilage initiated by necrosis of cartilage canal blood vessels. The necrotic cartilage does not undergo mineralization or vascular penetration, and then focal failure of endochondral ossification occurs when the ossification front approaches the lesion.

The condition has been seen as early as 1 day of age, and the lesions develop with age. The essential lesion is the necrosis of cartilage canals and surrounding cartilage. Lesions may be seen to be developing and healing at the same time. In growing animals, the superficial layer of joint cartilage is articular cartilage, and the deeper layer is epiphyseal cartilage that undergoes endochondral ossification as the animal matures. The articular cartilage persists in the mature animal, whereas the epiphyseal cartilage becomes a layer of calcified cartilage and underlying subchondral bone. The cartilage of the physis is known as the growth plate and is involved in metaphyseal growth. The normal growth plate cartilage has a well-ordered structure, with the chondrocytes of the proliferative and hypertrophic regions arranged into columns.

Osteochondrosis is a generalized disease in which there are focal areas of failure of endochondral ossification in the physeal (metaphyseal growth) and epiphyseal growth cartilage. The underlying defect may be an abnormality of the chondrocytes, which do not undergo normal hypertrophic ossification. They accumulate rough endoplasmic reticulum, lipid droplets, and mitochondria. The surrounding matrix contains deposits of electron-dense material that may prevent normal vascularization and therefore ossification. The hypertrophic region is disorganized and greatly extended compared with normal tissue. The matrix surrounding the clustered chondrocytes is altered compared with that in normal cartilage. The primary abnormality is an increased thickness of the joint cartilage combined with degenerative changes that result in infoldings and erosion of the articular cartilage. Defects of the growth plates (physes) result in short, deformed bones.

Pathologically, severe clinical cases are characterized by osteochondrosis and secondary degenerative joint disease, especially involving the medial aspects of the larger joints; epiphysiolysis; and lumbar intervertebral disc degeneration and spondylosis. Osteochondrosis has been used to encompass lesions involving the physes and the articular epiphyseal complexes. However, because of morphologic changes that have been observed in growing pigs, dyschondroplasia is now the preferred term to be used generically and then qualified by the location and nature of the morphologic description because the causes may be different.

Osteochondrosis occurs commonly in growing pigs at predilection sites of the medical condyle of the humerus and femur, the epiphyseal plates of the distal ulna, and the femoral head and the intervertebral joints. The 6th to 8th costochondral junctions may also be affected. It may heal spontaneously or it may progress to osteochondritis dissecans and OA. Its progression in either direction is influenced by local loading and by joint stability, which depends on joint shape and muscle

and ligamentous support. The age-related changes and OC in the articular and epiphyseal cartilage have been described. The cartilage increases with age up to 5 weeks and then begins to decrease in thickness. Deleterious influences such as defects in conformation; heavy musculature with skeletal immaturity; muscular weakness resulting from myofibrillar hypoplasia, myopathies, or lack of exercise; inadequate flooring; or even simple trauma may adversely affect this progression and lead to severe skeletal change.

Porcine synovial fluid contains both hyaluronic acid and chondroitin sulfate, and ratio of chondroitin sulfate to hyaluronic acid is not influenced by relatively advanced stages of osteochondrosis. Treatment of lame boars with glycosaminoglycan polysulfate improves leg soundness score and results in an increase in the hyaluronic acid concentration of the cubitus joint synovial fluid and in the proportion of aggregated proteoglycans in the articular cartilage of the medial femoral condyle. It is suggested that the hyaluronic acid accounts for most of the viscosity of synovial fluid and for efficient lubrication of the joint.

Well-established lesions typical of OC associated with the physes can be found in young pigs between 25 and 30 days of age. The earliest change associated with a dyschondroplasia of the physis is a focus of persistent hypertrophied chondrocytes that do progress but heal. Lesions associated with physes and articular epiphyseal complexes develop continuously and regress as pigs grow older. Changes in cartilage canal vessels appear to be important in the pathogenesis. There is no evidence that vascular damage is a factor in the pathogenesis of the lesions.

Because foci of dyschondroplasic lesions are associated with physes of pigs between birth and the stage of rapid growth, they could be regarded as part of the usual growth patterns in contemporary commercial swine. However, clinical signs of dyschondroplasias, or degenerative joint disease secondary to dyschondroplasias, usually do not appear until pigs are almost 6 months of age.

Radiologic Monitoring of Lesions

Osteochondrosis can be diagnosed radiologically. Radiologically, the lesions were similar in Yorkshire pigs and Landrace but more severe in the Landrace and similar to the Danish Landrace.

The development of epiphyseal osteochondrosis in pigs from 42 to 147 days of age has been followed radiologically. Osteochondritic lesions were seen radiologically in the articular–epiphyseal (A-E) complexes of the humeral condyles of 42-day-old pigs and in the femoral condyles at 63 days of age, in contrast to earlier reports indicating that lesions were not visible radiologically until 100 days of age. The osteochondrosis lesions of the A-E complexes develop, become progressive, and subsequently become either stable, regressive, or even more progressive as the pigs grow. This supports the observations that the lesions develop and become progressive and regress as the pigs grow. The humeral medial condyles have more pronounced lesions and are more frequent than the lateral ones.

Radiologic monitoring of the development and sequelae of physeal osteochondrosis lesions of the growth plate cartilage and A-E complexes of the forelimbs and hindlimbs in young breeding swine found that the majority of distal ulnar lesions healed by 18 to 20 months, and some started fusing at 18 to 21 months. The distal ulna healed without complications in most animals, and the most severe lesions healed faster than the mild or moderate ones. In a recent study, periarticular ossifications at the elbow joint were found in the radiographs at a prevalence of 0.9%. Meniscal ossifications were seen as single or multiple foci at the cranial aspect of the joint at a prevalence of 2.6% and had a bilateral occurrence of 20%. Meniscal ossifications were associated with turned-out hindlegs and stiff locomotion in the hindlegs and negatively associated with growth rate.

CLINICAL FINDINGS

Palpation is an important method of examination of lame pigs. Lame pigs are usually stiff on either front or back legs or both. The key is to send affected animals for slaughter quickly on diagnosis, provided they are fit to travel and inspected at the abattoir or rapidly placed in a quarantine area to prevent further injury and to supervise the effects of treatment.

OC and OA produce leg weakness that varies in severity from locomotor abnormality resulting from conformation and leg defects such as narrow lumbar area and broad hips, hyperflexion of the carpus, bowing of the forelimbs and "knock knees," hyperextension of the phalanges, and lateral angulation of the foot and sickle hocks, to more severe lameness and, in the extreme, inability to rise and paresis. Nine signs of leg weakness are described: buck-kneed forelegs, steep hock joints, turned-out forelimbs and hindlimbs, upright pasterns on the hindlegs, stiff locomotion, standing under on the hindlimbs, swaying hindquarters, goose-stepping hindlegs, and lameness and tendency to slip. The four most common signs are buck knees, small inner claws on forefeet, small inner claws on hindfeet, and upright pasterns on the hindlegs.

The clinical syndrome is a locomotor disorder usually involving the hindlimbs. Often the most rapidly growing pigs are lame. The lameness may be acute, intermittent, chronic, progressive, or a combination of these. An insidious onset is common, and pigs are unwilling to move, the stride is shortened, and the limbs are held in partial flexion. The carpal joints may be underextended while the metacarpophalangeal joints are overextended, giving the limb an abnormal S-shaped profile. The pelvic limbs are commonly held straight, and the back is slightly arched. In some cases, affected animals will assume a kneeling position with flexed carpal joints and walk on those joints.

Mild cases show stiffness, especially immediately after a period of lying down, and lameness. Slowness to rise and a tendency to walk with short steps on tiptoes, frequently in association with a marked inward curve of hindlimb motion during forward progression and side-to-side motion of the buttocks, are frequently seen. More severely affected pigs sit on their hindquarters and are reluctant to stand. They carry one or both hindlimbs more forward under the body and walk with a short, goose-stepping gait. Wasting is not a feature except in severely affected animals, and the locomotor disorder may be minor unless exacerbated by physical exertion.

The syndrome is of particular importance in breeding animals because it may interfere with successful mating. Boars may show initial interest in mounting but subsequently slide off the sow or dummy before mating is complete, presumably as a result of the pain of the limb lesions.

There may be no meaningful association between visual scores for physical soundness in the live animal and the degree of joint damage. Some pigs with severe lesions are not lame; conversely, other pigs are severely lame with minor lesions.

Epiphysiolysis

Separation of the epiphyses probably occurs when the process of endochondral ossification reaches or approaches the cartilage defect. The resulting fracture may extend in a jagged crack through primary and secondary spongiosa. It may be that the traumatic forces applied to the epiphyseal cartilage at the site of empty spaces near atrophic blood vessels or at eosinophilic streaks cause further separation and epiphyseal lysis.

The defect involves the proximal femoral epiphysis. There is separation along the proximal femoral epiphysis and the metaphyseal bone. It is a traumatic occurrence at a site of a growth defect in the cartilage with a combination of excess tension in the hip joint across a weakened physeal region in the femur, which then separates. It occurs from 5 months to 3 years of age (epiphyses fuse at 3 to 7.5 years of age). It may develop from an extended eosinophilic streak (area of matrix degeneration) or from areas of necrosis in the growth of cartilage rather than from areas of metaphyseal dysplasia.

Usually, it is a severe and sudden-onset lameness, occasionally insidious. Animals lie down, are unable to rise unless assisted, and usually eat and drink. It may be unilateral or bilateral, and manipulation reveals

crepitation. It can be confused with fractures of the femur, spinal canal abscesses, or lumbosacral fractures. It may become a center of necrosis if secondary bacterial infection occurs.

Epiphysiolysis contributes to the leg-weakness complex. In this case, repeated trauma and consequent microfractures significantly contribute to the retention of a thick and irregular epiphyseal cartilage and to fibrous tissue formation. Epiphysiolysis of the femoral head produces severe unilateral lameness, and if bilateral, it is usually manifest by marked reluctance to rise and severe locomotor disability. Initial signs are frequently deceptively mild and follow physical exertion, such as in mating, transport, farrowing, or fighting, but they progress to severe lameness over a 7- to 10-day period.

Apophysiolysis

Epiphysiolysis of the tuber ischii is known as apophysiolysis. It may also occur following physical exertion but is more common in second- or third-parity sows and is manifest by "paralysis," with the hindlimbs in forward extension under the body of the sow. These animals dog-sit and are unable to rise. In many instances, the injury occurs when the animals arrive on the farm or are first mated. In pigs the anconeal process does not arise from a separate ossification center, so apophysiolysis of the anconeal process is a better description than epiphysiolysis of the anconeal process.

Bilateral separation of the ischiatic tuberosities along their physes has been recognized in young sows. Most affected animals are heavily pregnant, most dog-sit with the hindlimbs forward, and palpation elicits crepitus. It is associated with slippery floors excessively pulling the biceps femoris tendons from the tuber ischiadicum. Unilateral lesions cause a moderate to severe lameness, but bilateral separation may prevent the sow from rising or walking. The pain and muscle contraction frequently make it difficult to determine the site and severity of the lesion by simple clinical examination, and palpation following general anesthesia or radiography may be required for proper clinical assessment. Physical examination should include complete palpation of all limbs for heat, swelling, and pain. The palpable parts of the pelvis should be examined, with particular emphasis on the ischial tuberosities. Passive flexion, extension, and rotation of each limb along with auscultation over the joint may reveal evidence of crepitus or a pain response.

Although the lesions of the physes and articular epiphyseal complexes are detectable in pigs under 14 days of age, they are not detectable radiographically in live animals until the pigs are over 100 days of age. Only 21% of the lesions associated with the physes and 22% of the lesions associated with the articular epiphyseal complexes were detectable in radiographs of bones of live pigs.

Meniscal ossifications were observed as simple or multiple small, smooth, firm, and irregular swellings in the cranial horn of the lateral meniscus. The periarticular osseous foci were seen as focal firm swellings at the craniomedial aspect of the elbow joint.

CLINICAL PATHOLOGY

The carpal, elbow, tarsal, and stifle joints can be radiographed for evidence of joint lesions, with the lesions then scored according to a system. It is also possible to use ultrasonics for diagnosis.

NECROPSY FINDINGS

At necropsy, the cartilage is not normal, and cracks, fissures, and necrosis are seen below the cartilage. The pathology has been reviewed for osteochondrosis.[19]

The scapulohumeral, humeroradioulnar, carpal, coxofemoral, femorotibial, and tarsal joints should be examined. Typically, in osteochondrosis, the changes are feathery hypertrophy of villi, focal full-thickness cartilage buckles, ulcers or flaps of cartilage, and no changes in the draining lymph nodes. Joint mice and synovitis may also be seen. Deformation, or even fractures, may occur in the long bones.

Histologically, osseous trabeculae may be seen with clusters of chondrocytes; between the trabeculae, lined by flat osteoblasts, there are adipocytes. The osseous center is formed of mineralized cartilage that has blended into more or less fibrous cartilage, but toward the joint cavity the meniscal ossifications are covered by hyaline cartilage.

DIFFERENTIAL DIAGNOSIS

The syndrome must be differentiated from other diseases that cause lameness and paralysis in growing and young adult pigs, including the following: infectious polyarthritis; laminitis; traumatic foot lesions; foot lesions produced by biotin deficiency and footrot; osteodystrophy resulting from calcium, phosphorus, and vitamin D imbalance in rations; vitamin A deficiency; and viral encephalomyelitis.

TREATMENT

There is no effective treatment. Early cases may recover spontaneously after being placed outside on pasture or housed individually, inside, on deep straw litter. Recently it has been suggested that meloxicam at a dosage of 0.4 mg/kg is efficacious and safe for the treatment of noninfectious locomotor disorders in pigs. Treatment with 2.5-D vitamin D had no effect on the incidence and severity of OC/OA lesions. Animals that are affected with clinical signs should be removed from the herd quickly for casualty slaughter and, if necessary, should be humanely destroyed as soon as possible.

CONTROL

Because the etiology is unknown, it is not possible to provide specific control measures. The hereditary nature of the disease suggests that the selection of breeding stock with sound legs and a low incidence of lesions would be an effective long-term control measure. Genetic control of leg weakness has been documented by various researchers. Selection of boars for leg soundness has dramatic effects on the structural soundness of their crossbred progeny, and therefore selection of structurally sound replacements must be maintained if leg weakness in market or breeding pigs is to be avoided. Divergent selection for leg soundness in Duroc pigs has been dramatic. Progeny of leg-soundness sires had significantly better measures for all leg traits at 104 kg than did progeny of leg-weakness sires. Differences between the two progeny groups indicated that the realized heritability for front-leg soundness exceeded 0.50.

Selection of breeding stock will require careful genetic selection, examination of all pigs that are to be retained for breeding, and necropsy of siblings of affected pigs of the same gender, to identify genetic lines of pigs that have a low incidence of lesions. A recent study showed that the increase in wild boar alleles in crosses with Large White pigs reduced the prevalence of OC. It has been suggested that the selection of pigs based on the joint lesion score could lead to a better leg and joint condition both visually and pathologically. Reduction of growth rate and exercise may help, but they are not a real methods of control. Improvement of nutrition and housing may help to remove the traumatic component of cartilage damage. Increasing the calcium and phosphorus in the diet also does not help.

Infectious Diseases of the Musculoskeletal System

BORRELIOSIS (LYME BORRELIOSIS, LYME DISEASE)

SYNOPSIS

Etiology Spirochete *Borrelia burgdorferi sensu lato* complex with different genospecies. In North America, genospecies *B. burgdorferi sensu stricto;* in Europe, *B. burgdorferi sensu stricto, B. afzelii,* and *B. barinii.* Other genospecies possibly associated with clinical disease are *B. spielmanii, B bisentii, B. lusitaniae,* and *B. valaisiana*

Epidemiology Occurs in North and South America, Europe, Asia, and Australia in cattle, sheep, horses, dogs, and humans. Transmitted by *Ixodes* spp. ticks from small wild animals, which are host reservoirs to domestic animals and humans. Larval ticks feed on small mammals; nymphal ticks feed on a broader range of hosts, including rodents, birds, sheep, and cattle; adult ticks feed on deer, horses, cattle, and dogs. All stages feed on humans.

Signs In horses: chronic weight loss, sporadic lameness, persistent fever, swollen joints, muscle stiffness, depression, anterior uveitis, neurologic signs, abortion, and weak foals. In cattle and sheep: polyarthritis, chronic weight loss, fever.

Clinical pathology Serology (indirect immunofluorescent antibody test [IFAT], enzyme-linked immunosorbent assay [ELISA]), culture, polymerase chain reaction (PCR), immunohistochemistry (IHC).

Lesions Polysynovitis, lymphadenopathy, interstitial myocarditis, nephritis, meningoencephalitis.

Treatment Tetracyclines and penicillin.

Control No specific control measures available; tick control.

ETIOLOGY

Borrelia burgdorferi, a gram-negative aerobic, microaerophilic, motile, spiral-shaped bacterium belonging to the family Spirochaetaceae, is the causative agent of Lyme borreliosis (Lyme disease). The *Borrelia burgdorferi sensu lato* complex comprises at least 12 genospecies, of which only a few have been associated with clinical disease. Of these different species, *B. burgdorferi sensu stricto, B. afzelii,* and *B. garinii* have been recognized as pathogens associated with clinical disease in mammals. The more recently identified species *B. spielmanii, B. bisentiii, B. lusitaniae,* and *B. valaisiana* have also been incriminated as potentially pathogenic species in humans and mammals.[1]

EPIDEMIOLOGY

Occurrence and Prevalence of Infection

A disease complex consistent with Lyme borreliosis in humans with characteristic skin lesions was first described at the end of the nineteenth century, but the etiology of the condition remained unknown until 1982, when W. Burgdorfer identified the causative agent.[2] Currently, Lyme borreliosis is recognized as the most common vector-borne disease in the northern hemisphere.[3] The disease predominantly occurs in North America and Europe but has also been reported in parts of Asia and in Latin American countries, including Brazil, Mexico, and Colombia.[1]

In the United States the infection is primarily prevalent in three regions: the Northeast (from Massachusetts to Maryland), the Midwest (Wisconsin and Minnesota), and the Pacific region (California and Oregon). The disease occurs most commonly in areas with an appropriate density of the insect vector, intermediate hosts, and the environmental conditions favoring transmission.

The different genospecies of *B. burgdorferi sensu lato* differ in their geographic occurrence. Whereas **in North America** Lyme disease is most commonly associated with ***B. burgdorferi sensu stricto,*** in **Europe, *B. afzelii*** is most prevalent in the north, ***B. burgdorferi sensu stricto*** in the western part of the continent, and ***B. lusitaniae*** in the Mediterranean basin. *B. spielmanii* has been isolated in Germany, France, the Netherlands, Hungary and Slovenia, the Ukraine, and other countries. *B. valaisiano* was found to occur in central Europe, the United Kingdom, and Russia.[1]

The prevalence of vector ticks infected with *B. burgdorferi sensu lato* has been studied in different countries and occurs at rates of 22% to 35% in Germany, 10% to 35% in the Netherlands, 40% in Bulgaria, 38% in Slovakia, 5.4% in Poland, and 12.9% in Ontario, Canada.[4-9] The prevalence of infection with *B. burgdorferi* for different animal species has been studied for different geographic regions. These data must be interpreted cautiously because they reflect the degree of exposure of an animal population (seroprevalence) but are not associated with the prevalence of clinical disease (disease prevalence).

Cattle

Seroprevalence studies of cattle in the United Kingdom indicate that the seropositivity rate increased from 44% to 67% after the cattle were turned out to a pasture heavily infested with ticks. The seropositivity rate was found to be higher in cattle with digital dermatitis ("Morbus Mortellaro"; 71%) than in cattle without the lesions (7.3%). This observation nonetheless should be interpreted cautiously because there was a significant age difference between cows with digital dermatitis (adult cows) and unaffected cows (1- to 3-year-old heifers), and an effect of age on the seroprevalence rate is well established in other animal species.[4]

In a study conducted during the grazing period of 2002 in Bavaria, Germany, including nearly 300 cattle, a seroprevalence of 45.6% was determined. Within-herd prevalence rates ranged from 20% to 100%. The antibody titer was associated with the number of ticks found on the animal but not with its age.[10]

In Japan, the seroprevalence of infection varied from 8% to 15% and was higher during the summer months; cows with arthritis had higher titers to the organism than healthy cows. Similar observations have been made in dairy cows in Minnesota and Wisconsin in areas with endemic *B. burgdorferi* infections. In Wisconsin, the peak seasonal incidence of clinical disease in horses and cattle occurs in May, June, and October, which correlates with emergence of *I. dammini* in the spring, usually March and April, and again in September.

Sheep

Seroprevalence studies in sheep infested with *Ixodes ricinus* in Scotland indicate an infection rate in lambs of 2.7%, with 24% to 40% in young sheep and 0% to 6% in ewes. There is also evidence for transmission of Lyme disease to sheep in Cumbria in the United Kingdom in grassland and heath communities where wild fauna are uncommon and sheep are thought to be the main host for all feeding stages of the tick. However, there was no evidence of clinical disease associated with the infection. Serologic surveys of infection in sheep in Norway indicate that 10% of animals tested are seropositive with the enzyme-linked immunosorbent assay (ELISA) test, with a range of 0% to 20% between counties. The geographic distribution of seropositive animals correlated with the known distribution of *I. Ricinus,* with the highest proportion of seropositive animals found in the southern coastal areas of Norway. The majority of animals appear to become infected during the first 2 years of life; the animals were all healthy at the time of sampling.

Horses

Geographic surveillance of horses in Europe and North America suggests that exposure of horses to *B. burgdorferi* is widespread. Seroprevalence rates for horses have been reported from several European countries, including France (31% to 48%),[11] Germany (16.1%), Sweden (16.8%), Denmark (29%), Italy (15.3% to 24.3%),[12,13] Poland (25.6%),[14] and Slovakia (47.8%).[13]

Serologic surveys of horse populations in the United States revealed that in the New Jersey–Pennsylvania area, approximately 10% of horses have significant serum antibody titers to the organism. Infection appears

to be uncommon in horses in Texas. In Cape Cod horses, the seroprevalence was 35%, which was found to be age-specific and considered to be a reflection of exposure because of the relative absence of disease. It was found that 7% to 13% of horses admitted to a veterinary teaching hospital were seropositive to the organism and the frequency of antibody response varied according to the geographic origin of the horses. A retrospective study on seroprevalence of infection with *B. burgdorferi* in Minnesota based on 1260 serum samples submitted to a diagnostic laboratory between 2001 and 2010 revealed an average seroprevalence of 58.7%.[15] Because of the selection bias in this study, which was based on blood samples obtained from horses with health issues, this value likely overestimates the overall prevalence in the equine population in the region.

Lyme disease in the horse is rare but it is clinically important in the United Kingdom. In areas where the disease occurs in humans, the seroprevalence of infection in horses was 49% compared with 3% to 4% in horses from other areas. Horses with unexplained lameness associated with fever and tick infestation had high levels of antibody to the organism. Within endemic areas, up to 60% of mares and yearlings on one farm were serologically positive. On such farms, there may be a clustering of clinical cases in foals after weaning. However, there is no evidence that abortion in mares is associated with infection.

Wildlife

In Ontario, epidemiologic studies indicate a widespread but low level or scattered distribution of infection in wildlife reservoirs in the south, with occasional spillover into human and canine populations. Serologically, the organism was found to be circulating in populations of white-footed mice, field mice, and white-tailed deer.

A serologic survey including over 600 wild boars in the Czech Republic found seroprevalence rates between 8.9% and 25.0% depending on the region of the country, with the highest prevalence rates in the rural and forested regions. Seroprevalence rates increased in the spring months of March and April, with peak values in May.[16]

Zoonotic Implications

Lyme borreliosis was first recognized when a cluster of suspected juvenile rheumatoid arthritis cases occurred among residents of Lyme, Connecticut. An arthropod-transmitted disease was suspected as the etiologic agent because, in addition to recurrent, short-lived joint pain, patients had an expanding, red, annular rash resembling erythema chronicum migrans similar to a lesion identified in Europe in the late nineteenth century associated with tick bites, and the rash was responsive to penicillin. An infectious cause was confirmed when spirochetal bacteria isolated from *Ixodes* ticks and from blood, cerebrospinal fluid (CSF), and other tissues of patients were shown to be identical. Subsequently, *B. burgdorferi* was identified in ticks in numerous regions of the United States, and infection was associated with clinical disease in other animals, including dogs and horses.

The disease has been recognized in most areas of the United States and in at least 20 countries spanning every continent. In the United States, the northeastern states of Connecticut, Massachusetts, and New York; the midwestern states of Wisconsin, Minnesota, Michigan, Illinois, and Indiana; and the western states of California and Nevada are considered as the most endemic areas, especially in wooded and grassy parts of these regions.

Lyme borreliosis is the most common tick-transmitted disease of humans in the northern hemisphere. In the United States, roughly 20,000 clinical cases are reported to the Centers for Disease Control and Prevention every year. Depending on the region, this is equivalent to incidence rates of up to 10 per 100,000 population.[1] Incidence rates reported from European countries vary widely and range from 0.6 per 100,000 population in Ireland and the United Kingdom to 130 per 100,000 in Austria to 155 per 100,000 in Slovenia.[17]

The geographic prevalence of borreliosis in humans and animals is related to the distribution of the various *Ixodes* spp. and the location of herds of deer, which are preferred hosts for the ticks. Geographic areas with dense vegetation and high humidity promote the development of the tick. Risk of infection is correlated with the opportunity of being bitten by an infected tick and dependent on the density of vector ticks in an endemic area, the proportion of ticks infected, and the duration and extent of the susceptible host's activities in that area.

Methods of Transmission

B. burgdorferi cycles between reservoir hosts and tick vectors. Reservoir hosts are defined as those animal species that can infect a significant number of ticks feeding on them but do not normally develop clinical disease. Reservoir hosts are critical for maintaining the agent in a geographic region. At present, 16 species of birds, 7 medium-sized mammals, and 9 small mammal species are considered to be able to transmit *B. burgdorferi* to vector ticks.[4] The white-footed mouse (*Peromyscus leucopus*) is considered to be the main reservoir for *B. burgdorferi* in the eastern United States. Rodents incriminated as reservoir hosts in the western part of the United States include the white-footed mouse, the brush mouse (*Peromyscus boylii*), the western gray squirrel (*Sciurus griseus*), the duskyfooted wood rat (*Neotoma fuscipes*), and the California kangaroo rat (*Dipodomys californicus*).[1] It is suggested that migrating birds acting as carriers may account for the widespread nature of the infection. Pheasants and some passerine birds, including European blackbirds and song thrushes, are considered to be maintenance hosts.

Ungulates, including deer, sheep, cattle, and goats, feed large numbers of ticks, and seroprevalence rates in these species in tick-infested regions can be high. Nonetheless, an increasing body of evidence suggests that ungulates do not infect a high proportion of ticks—most of which are adult-stage ticks—that feed on them.[17]

The spirochete is **transmitted by *Ixodes* ticks,** including *I. scapularis,* the deer tick, in the northeastern and midwestern United States; *I. pacificus,* the black-legged tick, in the western United States; *I. ricinus,* the sheep tick, in Europe; and *I. persulcatus* in Asia. The life cycle of an ixodid tick is 2 to 3 years and includes the stages of egg, larvae, nymph, and adult. Ticks transmit spirochetes during feeding with their saliva. Spirochetes migrate from the midgut, where they are found in unfed ticks, to the tick's salivary glands, a migration that is thought to be activated by ingestion of blood. Because ixodid ticks only feed once at each developmental stage, infection is usually acquired by one stage and transmitted by the next (transstadial transmission). Ticks in the larval stage feed on small mammals and are not infected before their meal, suggesting that transovarial transmission does not occur. Both immature stages of the tick (larvae and nymphs) feed on the white-footed mouse, which makes the life cycle of the organism dependent on horizontal transmission from infected nymphs to mice in the early summer and from infected mice to the larvae in late summer. White-footed mice are susceptible to oral infection and transmit the infection to one another by direct contact. Infection with the spirochete does not cause clinical or pathologic changes or alter the biological features of the mouse. These combined factors indicate a long-standing relationship between the mouse and the spirochete. Nymphal ticks feed on a broader range of animal species, such as rodents, squirrels, birds, dogs, sheep, and cattle. Infected nymphs can transmit *B. burgdorferi* to their second host, and uninfected nymphs can contract infection from an infected host. The adult tick feeds primarily on larger animals such as deer, horses, cattle, sheep, and dogs. All three stages of the tick will feed on humans.

The white-tailed deer is the preferred host for the adult stage of the tick and often harbors large numbers of adult ticks. Adult ticks are likely to be responsible for transmission of infection to horses and cattle.

Transmission of Lyme disease requires prolonged attachment of the tick to its host of at least 18 hours.[4] This lag time between

attachment of the tick and infection of the host has been proposed to be caused by the delay between activation of *B. burgdorferi* in the tick's midgut at the onset of a blood meal and the appearance of the bacterium in the tick's salivary glands.[17]

The ticks *Dermacentor variabilis* and *Amblyomma americanum,* tabanid flies, and mosquitoes have also been shown to carry the organism.

The organism can be found in the urine of infected animals, and it is possible that transmission may occur through close contact without the bite of a tick. Infected cattle purchased from an endemic area could shed the organisms in the urine and transmit them to animals in a different herd.

Transplacental transmission of the organism from infected dams to their fetuses also occurs through in utero infection and can be a cause of mortality in foals and calves.

PATHOGENESIS

Borrelia are highly motile and invasive, and they localize in selected tissues, thereby evading the host's immune response.[4] They spread through tissues and can directly transcytose endothelial layers. *B. burgdorferi* predominantly migrates within connective tissue, which may protect it from humoral antibodies. Following infection there is multisystemic inflammation, resulting in polyarthritis, generalized lymphadenitis, pleuritis, peritonitis, interstitial pneumonia, encephalitis, and in utero infection causing in fetal infection. In humans, the progression of Lyme borreliosis is divided into early localized, early disseminated, and late stages. In humans, the skin is the most frequently affected tissue. Erythema migrans, borrelial lymphocytoma, acrodermatitis chronica atrophicans, neuroborreliosis, myocarditis, arthritis, and ocular disease are possible outcomes of infection.

Borreliosis has been reproduced in ponies by exposure to *Ixodes* ticks infected with *B. burgdorferi.* Infection with *B. burgdorferi* was detected in skin biopsies and various tissues at necropsy by culture and PCR. Clinical signs were limited to skin lesions, all ponies seroconverted, and there were no significant other lesions.

Immune Mechanisms

B. burgdorferi is able to persist in the mammalian host because of active immune suppression, induction of immune tolerance, phase and antigenic variation, intracellular seclusion, and incursion into immune privileged sites, all of which are survival strategies. Vaccination with outer surface protein A (OspA) from the organism prevented *B. burgdorferi* infection in animal and human studies. Vaccination of 1-year-old ponies with recombinant OspA (*osp. A* gene derived from *B. burgdorferi* B31) with adjuvant (aluminum hydroxide) followed by challenge with *B. burgdorferi*–infected adult ticks provided protection against skin infection compared with unvaccinated controls.

CLINICAL FINDINGS

The symptoms of Lyme borreliosis in animals are poorly defined, and a broad spectrum of clinical manifestations have been attributed to *B. burgdorferi* infection. High seroprevalence rates in different animal species in endemic regions with low disease prevalence suggest that the large majority of infected animals remain asymptomatic.[18] On the other hand, the diagnosis of Lyme borreliosis is often based on clinical signs consistent with the disease (e.g., lameness or arthritis) in combination with positive serology, which can be considered as presumptive diagnosis at best. To complicate matters, many of the symptoms associated with Lyme disease have not been reproducible under experimental conditions.[18]

Horses

Infection with *B. burgdorferi* in horses in the majority of cases does not cause clinical disease, as is suggested by the large number of seroconverted animals without history of disease. Clinical signs attributed to *B. burgdorferi* infection in horses include chronic weight loss, persistent mild fever, intermittent or shifting lameness, laminitis, swollen joints, muscle stiffness, and anterior uveitis. Neurologic signs such as depression, behavioral changes, dysphagia, head tilting, and encephalitis have also been reported. Polyarthritis and swelling of tendon sheaths in horses of all ages are commonly reported. Infection of pregnant mares has been associated with abortion and the birth of weak foals that die soon after birth. An unexplained increase in early embryonic loss or failure of conception in mares has been associated with Lyme disease antibodies but not confirmed.

Cattle

In cattle, signs and symptoms attributed to infection with *B. burgdorferi* include persistent mild fever, chronic weight loss, decreased milk production, lameness, and polyarthritis.[1] Erythema of the udder or the skin between the digits and edematous lesions on the hairless skin of the udder have been described in cows with *B. burgdorferi* infection.

Sheep

In sheep, lameness, swollen joints, unthriftiness, and a persistent fever are commonly reported clinical signs.

CLINICAL PATHOLOGY

Detection of Organism

B. burgdorferi is difficult to isolate because it is present in low numbers in blood or tissues. The microorganism is fastidious, is microaerophilic, and requires enriched bacteriologic media, making culture slow, difficult, and expensive; special stains are required to visualize it. Aseptically collected blood, cerebrospinal fluid, urine, and colostrum can be examined under dark-field microscopy or in a culture.

Amplification of plasmid or chromosomal DNA of the microorganism by **polymerase chain reaction (PCR)** can be attempted, but because of the low number of microorganisms, lack of detection does not rule out infection.[1] On the other hand, positive PCR confirms the presence of bacterial DNA but does not prove the pathogen was alive, and it could be the result of leftover fragments from a previous infection.[18] **Immunohistochemistry** has been used to detect bacterial antigen in tissue.[1]

Serology

Serologic testing is the most practical method of making at least a presumptive diagnosis of *B. burgdorferi* infection. Serum and synovial fluid samples may contain antibodies to the organism in horses. The indirect immunofluorescent antibody (IFA) test has been used with reliable results in horses and cattle. The ELISA is ideal for high-volume testing; the results are quantitative, and the test can detect total immunoglobulin or class-specific IgM and IgG antibodies to the organism. An ELISA and immunoblots using certain antigens of the spirochete are more specific for the diagnosis of Lyme borreliosis in horses. Western blotting techniques and the ELISA have been used for serologic surveys and for examination of synovial fluids of horses in the United Kingdom, where the incidence of infection is common in some areas. The positive results in horses are not as a result of cross-reactions with *Leptospira,* which has been suspected.

Subclinical infections are common in domestic animals, and the interpretation of serologic results must be done in conjunction with the clinical findings. Antibody titers higher than 1/64 or 1/100 are considered as positive. Positive antibody results are an aid to diagnosis but are not conclusive evidence of current infection or clinical disease. False-positive results may be a result of infection with other *Borrelia* species.

NECROPSY FINDINGS

Polysynovitis, lymphadenopathy, and emaciation are present. Multifocal interstitial myocarditis, glomerulonephritis, interstitial pneumonitis, and polysynovitis have been described in cattle. In the horse, polysynovitis and meningoencephalitis have been reported. Using PCR amplification of DNA, necropsy tissues may be positive for *B. burgdorferi* DNA.

Samples for Confirmation of Diagnosis

- **Bacteriology**—kidney, joint synovium, lung, choroid plexus (PCR)

- **Histology**—formalin-fixed kidney, joint synovium, heart, brain, lung, lymph node (LM, IHC)

DIFFERENTIAL DIAGNOSIS

Diagnosis is dependent on recognition of clinical signs, a history of possible exposure to infection by the bites of ticks, and identification of the spirochete in the affected animal. Because clinically normal animals have antibodies to the organism, a positive antibody result is not conclusive of current infection or clinical disease. Other diseases causing muscle stiffness, lameness, polyarthritis, lymphadenopathy, and fever must be considered in the differential diagnosis.

TREATMENT

Procaine penicillin, oxytetracycline, doxycycline (10 mg/kg PO q12h for 3 weeks) and ceftiofur (2.2 mg/kg IM q12h) have been used for treatment of Lyme disease in horses. Experimentally infected horses treated with oxytetracycline for 3 weeks were negative on culture and PCR following treatment.[4] Penicillin or oxytetracycline daily for 3 weeks has also been recommended for use in cattle.

Treatment recommendations are largely based on empirical evidence, and the efficacy of these treatments is difficult to assess. In many cases where the treatment was found to be effective, the diagnosis was presumptive; an unapparent coinfection with another pathogen cannot be ruled out. For example, horses with presumed Lyme disease that responded to oxytetracycline may actually have been infected with *Anaplasma phagocytophilum*, which is transmitted by the same vector, causes similar clinical signs, and is highly susceptible to tetracycline.[4]

TREATMENT

- Procaine penicillin G (44,000 IU/kg q24 IM, for 3 weeks) (R-2)
- Oxytetracycline (6 to 12 mg/kg IV q24h for 3 weeks) (R-2)

CONTROL

Prevention of Lyme borreliosis in domestic animals and humans is dependent on reduction of the risk of tick bites at the environmental or individual animal level. Knowledge of the ecologic requirements for the tick-borne diseases that are present in an area is necessary for selection and implementation of the most effective integrated prevention strategies. Protective measures may include the avoidance of tick-infested areas; the use of protective clothing, repellents, and acaricides; tick checks; and modifications of landscapes in or near residential areas. After a tick bite has occurred in humans, the body of the tick should be grasped with medium-tipped tweezers as close to the skin as possible and removed by gently pulling the tick straight out, without twisting motions.

A commercial adjuvanted vaccine is available for use in dogs. An experimental vaccine composed of recombinant OspA protected ponies against *B. burgdorferi* infection, and further studies are necessary to determine duration of protection after vaccination, safety, and cross-protection against the possible heterogeneous OspA structures that may be present among new *B. burgdorferi* strains isolated in the United States.

A human vaccine was available in the United States but was withdrawn by the manufacturer in 2002. Problems included poor demand, high costs, the need for a series of three vaccinations and boosters to maintain adequate titers, failure to obtain adequate titers in a small subset of vaccines, and theoretical concerns with vaccine-induced autoimmune arthritis.[1]

MALIGNANT EDEMA, CLOSTRIDIAL MYONECROSIS (GAS GANGRENE)

SYNOPSIS

Etiology Acute wound infection associated with organisms of the genus *Clostridium*.

Epidemiology All ages and species of animals are susceptible. Sporadic disease affecting individual animals following injections; outbreaks following contamination of wounds produced by management procedures.

Clinical findings Acute onset with fever and toxemia. Inflammation and swelling at site of a wound, with heat, edema, pain on palpation, and usually subcutaneous emphysema.

Clinical pathology No diagnostic change in hematology or serum biochemistry. Fluorescent antibody staining.

Necropsy findings Gangrene of the skin with edema of the subcutaneous and intermuscular connective tissue around the site of infection.

Diagnostic confirmation Demonstration of the causal organisms by fluorescent antibody staining.

Treatment Antibiotics, surgical debridement.

Control Vaccination. Prophylactic antibiotics.

ETIOLOGY

Clostridium septicum, C. chauvoei, C. perfringens, C. sordellii, and *C. novyi* have all been isolated from lesions typical of malignant edema of animals. In some cases there can be mixed infections. The occurrence of malignant edema caused by *C. chauvoei* is discussed in the section on blackleg.

C. sordellii has been associated chiefly with malignant edema of cattle, but it has been found to be a cause of malignant edema and swelled head in sheep. However, swelled head of rams, in which the lesions of malignant edema are restricted to the head, is most commonly associated with *C. novyi* infection.

In a retrospective study of 37 horses with clostridial myonecrosis, *C. perfringens* was isolated from 68%, *C. septicum* from 16%, and the remainder were mixed infections with these two species. *C chauvoei, C. novyi,* and *C. fallax* have been isolated incidentally.

EPIDEMIOLOGY

All ages and species of animals are affected. The clostridia bacteria that cause malignant

edema are **common inhabitants** of the animal **environment** and intestinal tract, and although some of the causative species have a restricted distribution, the disease has a worldwide occurrence. The disease occurs sporadically, affecting individual animals, except in circumstances where a management procedure in a group of animals results in an outbreak.

Source of Infection

The infection is usually **soil-borne**, and the resistance of spores of the causative clostridia to environmental influence leads to **persistence** of the infection for long periods in a local area. A dirty environment that permits contamination of wounds with soil is the common predisposing cause.

Transmission

In most cases a wound is the **portal of entry**. Deep puncture wounds accompanied by trauma provide the most favorable conditions for anaerobial growth, and malignant edema occurs most frequently under such conditions. Infection may occur through surgical or accidental wounds following vaccination, intramuscular injection of drugs, venipuncture, or through the umbilical cord in the newborn. Dormant spores of *C. perfringens* and other clostridial species can be found in the normal muscle of horses, and it is possible in some cases that these may be activated by anaerobic conditions produced by the injected material.

Animal and Management Risk Factors

In horses, intramuscular injection of drugs, commonly in association with the treatment of colic, is the common precipitating factor.[1] Certain drugs may have a greater propensity to initiate muscle necrosis and disease, but these drugs are also commonly used in the treatment of colic. Perivascular leaking of drugs is also a precipitating cause in horses. In all species there is risk with the intramuscular injection of drugs such as anthelmintics and nutritional supplements, some of which can cause significant tissue damage at the site, particularly if proper asepsis is not practiced.

Outbreaks can occur in sheep after management practices such as shearing and docking, or following lambing. Outbreaks have also been observed in cattle following **parturition**, sometimes associated with lacerations of the vulva. An unusual method of infection occurs when crows that have eaten infected carrion carry the infection to live, weak sheep and to lambs when they attack their eyes. Castration wounds in pigs and cattle may also become infected. Unless treatment is instituted in the early stages the death rate is extremely high.

The practice of **dipping** sheep immediately after they are shorn may cause a high incidence of malignant edema if the dip is heavily contaminated. The disease "**swelled head**," a form of malignant edema, occurs in young rams 6 months to 2 years old when they are run in bands and fight among themselves.

Importance

Outbreaks of malignant edema are probably less common as a result of education of farmers and the availability of vaccines. In the wrong circumstances and with improper hygiene, severe disease can still occur.

PATHOGENESIS

Potent necrotoxins are produced in the local lesion and cause death when absorbed into the bloodstream. Locally the exotoxins cause extensive edema and necrosis followed by gangrene.

CLINICAL FINDINGS

Clinical signs appear within 6 to 48 hours of infection. There is always a local lesion at the **site of infection** consisting of a soft, doughy swelling with marked local erythema accompanied by severe pain on palpation. At a later stage the swelling becomes tense and the skin dark and taut. Emphysema may or may not be present, depending on the type of infection, and may be so marked as to cause extensive frothy exudation from the wound. With *C. novyi* infections, there is no emphysema. A high fever (41 to 42° C; 106 to 107° F) is always present; affected animals are depressed, are weak, and show muscle tremor and usually stiffness or lameness. The mucosae are dry and congested and have very poor capillary refill. The illness is of short duration, and affected animals die within 24 to 48 hours of the first appearance of signs. New cases continue to appear for 3 to 4 days after shearing or other precipitating cause.

When infection occurs at **parturition**, swelling of the vulva accompanied by the discharge of a reddish-brown fluid occurs within 2 to 3 days. The swelling extends to involve the pelvic tissues and perineal region. The local lesions are accompanied by a profound toxemia, and death occurs within 1 to 2 days.

In "**swelled head**" of rams, the edema is restricted initially to the head. It occurs first under the eyes and spreads to the subcutaneous tissues of the head and down the neck.

In **pigs**, the lesions are usually restricted to the axilla, limbs, and throat and are edematous, with very little evidence of emphysema. Local skin lesions consisting of raised, dull red plaques distended with clear serous fluid containing *C. septicum* and causing no systemic illness may be encountered in pigs at abattoirs.

In horses, emphysema, detected by palpation or ultrasound, is an early sign.[1]

CLINICAL PATHOLOGY

Antemortem laboratory examination of affected farm animals is not usually undertaken, usually because there are carcasses for postmortem examination.

Examination of a Gram-stained smear of aspirated fluid from edematous swellings or swabs from wounds will give an early diagnosis, allowing therapy early in the course of the disease. A PCR has been developed to allow the rapid identification and differentiation of the clostridia associated with malignant edema in livestock.

Hematologic examination in horses may reveal abnormal white blood cell counts, either leukocytosis or leukopenia with toxic degeneration of granulocytes and a regenerative left shift. Elevated activity of muscle enzymes such as CPK, AST, and LDH match the degree of muscle tissue involvement. Blood-gas analysis conducted in affected horses revealed severe acidemia and metabolic acidosis.[1]

NECROPSY FINDINGS

Tissue changes occur rapidly after death, particularly in warm weather, and this must be kept in mind when evaluating postmortem findings. There is usually gangrene of the skin with edema of the subcutaneous and intermuscular connective tissue around the site of infection. There may be some involvement of underlying muscle, but this is not marked. The edema fluid varies from thin serum to a gelatinous deposit. It is usually bloodstained and contains bubbles of gas, except in *C. novyi* infections when the deposit is gelatinous, clear, and contains no gas. A foul, putrid odor is often present in infections with *C. perfringens* and *C. sordellii.*

Subserous hemorrhages and accumulations of serosanguineous fluid in body cavities are usual. In "swelled head" of rams, the edema of the head and neck may extend into the pleural cavity and also involve the lungs.

The **histologic** picture of malignant edema consists of abundant edema fluid, emphysema, and neutrophils within the connective tissues. Muscle is not spared, but the damage is focused along fascial planes.

Samples for Confirmation of Diagnosis

- Bacteriology—fascial tissue, placed in an airtight container; four air-dried smears of fluid from lesion (anaerobic CULT, FAT)
- Histology—fixed sample of lesion

DIFFERENTIAL DIAGNOSIS

The association of profound toxemia and local inflammation and emphysema at the site of a wound is characteristic.

- **Blackleg**—the disease is differentiated from blackleg by the absence of typical muscle involvement and the presence of wounds
- **Anthrax** in pigs and horses
- **Photosensitivity** in white-faced sheep with swelled head

TREATMENT

Affected animals should be treated as emergency cases because of the acute nature of the disease. Specific treatment requires the administration of penicillin (high doses of crystalline penicillin intravenously, repeated at 4- to 6-hour intervals) or a broad-spectrum antibiotic. Antitoxin aids in controlling the toxemia but is expensive and must be given very early in the course of the disease. An NSAID and supportive therapy are recommended. Local treatment consists of surgical incision to provide drainage, along with irrigation with hydrogen peroxide. In horses, early and aggressive treatment with myotomy and fasciotomy, repeated if indicated, coupled with IV potassium penicillin is reported to allow recovery rates approaching 70%. The success rate in treating horses with infections with *C. perfringens* was higher than that with *C. septicum*.

TREATMENT AND CONTROL

Treatment

Penicillin G sodium/potassium (40,000 IU/kg IV q6–8h) (R-2)

Surgical incisions to drain and flush with dilute H_2O_2

Flunixin meglumine (2.2 mg/kg IV q24h) (R-2)

Ketoprofen (3 mg/kg IM q24h) (R-2)

Carprofen (1.4 mg/kg IM as single dose) (R-2)

Meloxicam (0.5 mg/kg SC/IV as single dose) (R-2)

Diclofenac (2.5 mg/kg IM as single dose) (R-2)

Control

Penicillin (44,000 IU/kg IM q24 for 3 days for animals at risk) (R-2)

CONTROL

Hygiene at lambing, shearing, castration, and docking is essential to the control of the infection in sheep. Vaccination with a specific or multivalent clostridial bacterin-toxoid will prevent the occurrence of the disease in enzootic areas. Penicillin can be given prophylactically to animals at risk for the disease.

BLACKLEG

SYNOPSIS

Etiology Infectious necrotizing myositis associated with *Clostridium chauvoei*. Common in cattle but occurs occasionally in other species.

Epidemiology Cattle 6 months to 2 years of age that are rapidly growing and on a high plane of nutrition. Seasonal occurrence in warm, wet months. There are often multiple cases in at-risk animals. Sheep of all ages—occurs as outbreaks predisposed by wounds from shearing, docking, castration, dystocia.

Clinical findings Lameness and pronounced swelling of upper limb. Myonecrosis of skeletal or cardiac muscles, severe toxemia, and a high case-fatality rate. May be found dead.

Clinical pathology Culture from needle biopsy. No diagnostic change in hematology or serum biochemistry.

Necropsy findings Myositis; dark, rancid odor, metallic sheen on the cut surface.

Diagnostic confirmation Fluorescent antibody identification of *C. chauvoei* in lesion.

Treatment High doses of penicillin in early stages. Surgical debridement.

Control Vaccination.

ETIOLOGY

Blackleg, or clostridial myositis of skeletal and/or heart muscle tissue, is associated with *Clostridium chauvoei (feseri)*, a gram-positive, spore-forming, rod-shaped bacterium. The spores are normally found in soil and are highly resistant to environmental changes and disinfectants and persist in soil for many years.

EPIDEMIOLOGY

Occurrence

Blackleg is an acute febrile disease primarily affecting cattle and sheep, with worldwide occurrence. The condition is characterized by severe necrotizing myositis of striated and occasionally cardiac muscle tissue and severe toxemia with high mortality. Although black leg is widely considered a disease of ruminants, available reports suggest that swine, mink, freshwater fish, wales, frogs, and ostriches are also susceptible to infection. In recent years at least two cases of fatal disease associated with *C. chauvoei* in humans have been reported.[1,2] Although sheep of any age can be affected, cattle between 6 months and 2 years of age most commonly develop clinical disease. The disease incidence shows a seasonal pattern, with peak incidences observed during the warmer period of the year. In general, several animals of a herd or flock are affected within a short period of time. The disease is enzootic in particular areas, especially when they are subject to flooding. The **case-fatality rate** in blackleg approaches 100%.

Source of Infection

Blackleg is a **soil-borne** infection. In sheep, infection with *C. chauvoei* is assumed to predominantly occur through penetrating lesions of the skin or mucosa, but the primary portal of entry for the organism in cattle is still in dispute. It is presumed that infection primarily occurs through the mucosa of the digestive tract after ingestion of contaminated feed or may be associated with erupting teeth. Spores of *C. chauvoei* have been found in the spleen, liver, and alimentary tract of healthy animals, and contamination of the soil and pasture may occur from infected feces or decomposition of carcasses of animals that died of the disease. Clinical disease develops when spores are caused to proliferate by yet undetermined mechanisms. Tissue trauma and anoxia have been incriminated as potential triggers.

Transmission

Whereas in cattle the disease usually occurs without a history of trauma, in sheep, skin wounds from **shearing**, **docking,** and **vulvar or vaginal lacerations from parturition** or the fresh **navel** at birth are the most common routes through which *C. chauvoei* penetrates and infects muscle tissue to cause clinical disease. Infections of the vulva and vagina of the ewe at **lambing** may cause serious outbreaks, and the disease has occurred in groups of young ewes and rams up to a year old, usually as a result of infection of skin wounds caused by **fighting**. Occasional outbreaks have occurred in sheep **after vaccination** against enterotoxemia. Presumably the formalinized vaccine causes sufficient tissue damage to permit latent spores of the organism to proliferate.

A special occurrence is in **fetal lambs**. Ewes exposed to infection at shearing develop typical lesions, but ewes treated with penicillin are unaffected, except that the pregnant ewes in the latter group show distended abdomens, weakness, and recumbency as a result of edema and gas formation in the fetus, from which *C. chauvoei* can be isolated.

Risk Factors

Environment Risk Factors

Blackleg of cattle has a **seasonal incidence**, with most cases occurring in the warm months of the year. The highest incidence may vary from spring to autumn, likely depending on when calves reach the susceptible age group. There appears to be an increased disease incidence in years of high rainfall, which has been explained by increased anaerobiosis in water-saturated soils in combination

with enhanced pasture growth stimulating feed intake of pastured cattle.[3] Outbreaks of blackleg in cattle have occurred following excavation of soil, which suggests that disturbance of the soil may expose and activate latent spores.

An outbreak of blackleg has also been reported in housed cattle in a nonendemic blackleg area in Norway.[4]

Animal Risk Factors

Blackleg is usually a disease of cattle and to a lesser degree of sheep, but outbreaks of the disease have been recorded in deer and horses. In cattle, the disease is most commonly seen in young stock between the ages of 6 months and 2 years, although disease occurs occasionally in younger animals and cattle up to 3 years. In the field, **risk factors** include rapidly growing cattle and a high plane of nutrition. Elevation of the nutritional status of sheep by increased protein feeding increases their susceptibility to blackleg. In sheep, there is no restriction to age group. In calves and sheep, atypical outbreaks of sudden death occur in which the lethal lesion is a clostridial cardiac myositis.

In pigs, blackleg is not common, although a gas gangrene type of lesion may be associated with *C. chauvoei* or *C. septicum* infection.

Economic Importance

Blackleg is a cause of severe financial loss to cattle raisers in many parts of the world. For the most part, major outbreaks are prevented by vaccination, although outbreaks still occur occasionally in vaccinated herds or cattle incompletely vaccinated.

PATHOGENESIS

With spores of *Cl. chauvoei* normally found in soils, ingestion of such spores through contaminated pasture or silage is unavoidable. Spores of *C. chauvoei* have been found not only in the digestive tract but also the spleen and liver healthy animals. Because *C. chauvoei* appears to be present in tissue in a dormant state before disease occurs blackleg—at least in cattle—has also be termed as "endogenous" clostridial infection, in contrast to malignant edema that is considered an exogenous infection, because the pathogen gains access to the tissue through mucosal or skin breaks and directly causes clinical disease.[5]

Whereas in sheep the clinical disease in most cases has been related to tissue laceration and trauma, the stimulus that results in growth of the latent bacterial spores in cattle is unknown. There is usually no history of trauma. Once returned to its vegetative state, *C. chauvoei* produces a number of toxins, such as oxygen-stable and oxygen-labile hemolysins, DNase, hyaluronidase, and neuramidase, which cause severe **necrotizing myositis** locally in skeletal muscles and a **systemic toxemia** that is usually fatal.

CLINICAL FINDINGS

Cattle

If the animal is observed before death there is severe lameness, usually with pronounced swelling of the upper part of the affected leg. On closer examination the animal will be found to be very depressed, have complete anorexia and ruminal stasis, and have a high temperature (41° C; 106° F) and pulse rate (100 to 120/min). Pyrexia is not present in all cases. In the early stages, the swelling is hot and painful to the touch but soon becomes cold and painless, and edema and emphysema can be felt. The skin is discolored and soon becomes dry and cracked.

Although the lesions are usually confined to the upper part of one limb, occasional cases are seen where the lesions are present in other locations, such as the base of the tongue, the heart muscle, the diaphragm and psoas muscles, the brisket, and the udder. Lesions are sometimes present in more than one of these locations in one animal. The condition develops rapidly, and the animal dies quietly 12 to 36 hours after the appearance of signs. Many animals die without signs having been observed.

Sheep

When blackleg lesions occur in the limb musculature in sheep, there is a stiff gait, and the sheep is disinclined to move because of severe lameness in one limb or, more commonly, in several limbs. The lameness may be severe enough to prevent walking in some animals but be only moderate in others. Subcutaneous edema is not common and gaseous crepitation cannot be felt before death. Discoloration of the skin may be evident, but skin necrosis and gangrene do not occur.

In those cases where infection occurs through **wounds** of the skin, vulva, or vagina, there is an extensive local lesion. Lesions of the head may be accompanied by severe local swelling as a result of edema, and there may be bleeding from the nose. In all instances, there is high fever, anorexia, and depression, and death occurs very quickly. Sheep and cattle with cardiac myositis associated with *C. chauvoei* are usually found dead.

Horses

The clinical syndrome in horses is not well defined. Pectoral edema, stiff gait, and incoordination are recorded.

CLINICAL PATHOLOGY

The disease is usually so acute that necropsy material is readily available but, failing this, it may be possible to obtain material suitable for cultural examination by needle puncture or swabs from wounds. There are no constant changes in hematologic parameters or serum biochemistry.

NECROPSY FINDINGS

Cattle found dead of blackleg are often in a characteristic position: lying on the side with the affected hindlimb stuck out stiffly. Bloating and putrefaction occur quickly, and bloodstained froth exudes from the nostrils and anus. Clotting of the blood occurs rapidly. Incision of the affected muscle mass reveals dark-red to black, swollen tissue with a rancid odor and thin, sanguineous fluid containing bubbles of gas. Freshly cut surfaces are often dry and may have a metallic sheen. The heart and all skeletal muscles, including those of the tongue, diaphragm, and lumbar region, must be checked because the lesion may be small and escape cursory examination. The thoracic cavity and the pericardial sac may contain excess bloodstained fluid with variable amounts of fibrin. This serositis is often overlooked or is misinterpreted as a component of pleuropneumonia. The lungs are usually congested and may be atelectatic as a result of abdominal tympany.

In **sheep**, the muscle lesions are more localized and deeper, and the **subcutaneous edema is not so marked, except around the head**. Gas is present in the affected muscles but not in such large amounts as in cattle. When the disease has resulted from infection of skin wounds, the lesions are more obvious superficially, with subcutaneous edema and swelling and involvement of the underlying musculature. When invasion of the genital tract occurs, typical lesions are found in the perineal tissues and in the walls of the vagina and occasionally the uterus. In the special case of pregnant ewes, typical lesions may involve the entire fetus and cause abdominal distension in the ewe.

Histologically, blackleg cases feature myonecrosis, edema, emphysema, and an unimpressive neutrophilic cellulitis. Organisms may be few in number but can usually be seen in tissue sections. Smears from the affected tissue should be made and material collected for bacteriologic examination. The isolation and identification of *C. chauvoei* and *C. novyi* is difficult because of the fastidiousness of these species in culture and rapid postmortem contamination of the tissues by clostridial species from the gastrointestinal tract. Thus it is essential that tissues be examined as soon after death as possible. Most laboratories use fluorescent antibody tests performed on tissue smears to complement (or substitute) anaerobic culture.

"False blackleg" may be associated with *C. septicum* and *C. novyi,* but this disease is more accurately classified as malignant edema. Mixed infections with *C. chauvoei* and *C. septicum* are not uncommon, but the significance of *C. septicum* as a cause of the disease is debated. However, in a study of 176 cases of clostridial myositis in cattle, *C. chauvoei* either alone or with *C. septicum* was demonstrated in 56%. In 36%, *C. novyi* was found alone or with *C. septicum*. This

indicates that maximum protection to cattle can be provided only by a multivalent vaccine that contains the antigens of *C. chauvoei, C. novyi,* and *C. septicum.* A multiplex PCR based on the flagellin gene sequence has been used to identify pathogenic clostridia in clinical specimens.

Samples for Confirmation of Diagnosis

- Bacteriology—muscle, placed in air-tight container; four air-dried impression smears of surface of freshly cut lesion (anaerobic CULT, FAT, PCR)
- Histology—fixed samples of suspected muscle lesion

DIFFERENTIAL DIAGNOSIS

In establishing a diagnosis when a number of animals are found dead in a group not kept under close observation and postmortem decomposition is so advanced that little information can be obtained, one must depend on one's knowledge of local disease incidence, season of the year, age group affected, and pasture conditions, and on a close inspection of the environment in which the animals have been maintained. More frequent observation should be established so that sick animals or fresh cadavers will be available for examination.

- **Malignant edema**—in typical cases of blackleg in cattle a definite diagnosis can be made on the clinical signs and the necropsy findings. Definitive identification of *Clostridium chauvoei* is by fluorescent antibody staining. Diagnosis on gross postmortem findings from other causes of clostridial myositides is hazardous and may result in improper recommendations for control
- **Anthrax**
- **Lightning strike**
- **Bacillary hemoglobinuria**
- Other causes of sudden unexpected death

TREATMENT

Treatment of affected animals with **penicillin and surgical debridement** of the lesion, including fasciotomy, is indicated if the animal is not moribund. Recovery rates are low because of the extensive nature of the lesions. Large doses (44,000 IU/kg BW) should be administered, commencing with crystalline penicillin intravenously and followed by longer-acting preparations. Blackleg **antiserum** is unlikely to be of much value in treatment unless very large doses are given.

TREATMENT AND CONTROL

Treatment

Penicillin G sodium/potassium (44,000 IU/kg IV q6–8h) (R-2)

Clostridium chauvoei antitoxin (only in early stages, but doubtful efficacy)

Control

Multivalent clostridial vaccine including at least *C. chauvoei, C. septicum,* and *C. novyi* (R-2)

Penicillin (44,000 IU/kg IM q24 for 3 days for animals at risk) (R-2)

CONTROL

Cattle

On farms where the disease is enzootic, annual vaccination of all cattle between 3 and 6 months with two vaccinations given 4 weeks apart followed by an annual booster vaccination is generally recommended. This should be done just before the anticipated danger period, usually spring and summer. Maternal immunity persists for at least 3 months and will interfere with active immunity in calves vaccinated before this age.

In an **outbreak**, all unaffected cattle should be vaccinated immediately and injected with penicillin intramuscularly. Movement of the cattle from the affected pasture is advisable. If antibiotics are not given, new cases of blackleg may occur for up to 14 days until immunity develops, and constant surveillance and the early treatment of cases will be necessary.

Sheep

With sheep in areas where the disease is enzootic, the **maiden ewes** should be vaccinated twice, with the last vaccination given about 1 month before lambing and a subsequent yearly booster given at the same time before lambing. This will prevent infection of the ewes at lambing and will also protect lambs against umbilical infection at birth and infection of the tail wound at docking, provided the tail is docked at a young age. If an **outbreak** commences in a flock of ewes at lambing time, prophylactic injections of penicillin and antiserum to ewes requiring assistance are recommended.

A single vaccination of **wethers** can also be carried out 2 to 3 weeks before **shearing** if infection is anticipated. Because of the common occurrences of the disease in young sheep, vaccination before they go on to pasture and are exposed to infection of skin wounds from fighting is recommended in danger areas. The duration of the immunity in these young vaccinated animals is relatively short, and ewes in particular must be revaccinated before they lamb for the first time. Clostridial vaccines have **poorer antigenicity** in sheep and goats than in cattle.

In both sheep and cattle, it is advisable to use a **combined vaccine** containing at least *C. chauvoei, C. septicum,* and *C. novyi,* where these organisms occur in the area and cause clostridial myositis.

There is limited information on which to base the previous recommendations because there is limited information on the **efficacy** of available individual manufacturers' vaccines.[6] There is variability in the immune response and its duration with different vaccines. **Vaccine failure** has been associated with an inadequate spectrum of the antigens in the vaccine, and in these circumstances a bacterin prepared from a local strain of *C. chauvoei* is preferred. Vaccines combined with anthelmintics or with trace elements are used in some areas to minimize the number of injections required when processing sheep.

It is important that **carcasses** of animals dying of blackleg are destroyed by burning or deep burial to limit soil contamination.

BOVINE FOOTROT (INFECTIOUS BOVINE PODODERMATITIS, INTERDIGITAL PHLEGMON, INTERDIGITAL NECROBACILLOSIS, FOUL IN THE FOOT)

SYNOPSIS

Etiology Biotypes A and AB of *Fusobacterium necrophorum.* Other organisms can facilitate infection.

Epidemiology All ages susceptible. Infected feet are source of infection. Transmission highest where conditions are wet underfoot and in wet, humid seasons.

Clinical findings Sudden onset of lameness and fever, drop in milk production with typical fissuring, necrotic lesion in the skin at the top of the interdigital cleft.

Clinical pathology Not routinely done.

Diagnostic confirmation Clinical findings. Culture may be done.

Treatment Antimicrobials.

Control Avoidance of abrasive underfoot conditions. Footbaths, antimicrobials, vaccination.

ETIOLOGY

Footrot is usually described as a contagious disease as a result of localized infection by *F. necrophorum,* a gram-negative non–spore-forming anaerobe.[1,2] Other bacteria, primarily *Porphyromonas levii* (originally classified as *Prevotella melaninogenica* or *Bacteroides melaninogenicus*),[3] are present at variable rates in clinically infected cattle and may play a role in the development of clinical disease. Experimentally, the subcutaneous inoculation of only *F. necrophorum* into the interdigital skin of cattle will result in typical lesions of interdigital phlegmon.

F. necrophorum has traditionally been categorized into four biotypes: A (called *F. necrophorum* subsp. *necrophorum*), B (called *F. necrophorum* subsp. *funduliforme*), AB (taxonomic status is unresolved), and C (which is nonpathogenic). The majority of isolates of *F. necrophorum* obtained from the feet of cattle and sheep belong to biotypes A and AB; they produce a soluble exotoxin, a **leukotoxin**, that is produced by *F. necrophorum* strains carrying the *lktA* gene. Leukotoxin appears to play an important role in the pathogenesis of clinical disease. The isolates obtained from lesions that are not classified as interdigital necrobacillosis and from clinically normal feet are predominantly biotype B and cause few experimental lesions and produce little or no leukotoxin.

Strains of *Bacteroides nodosus* that are associated with the nonprogressive form of ovine footrot are occasionally isolated from the feet of cattle with footrot[1,2] and cause mild interdigital dermatitis. It is possible they may predispose to the much more severe dermatitis that characterizes bovine interdigital phlegmon.

EPIDEMIOLOGY

Occurrence

The disease is common in most countries and accounts for 5% to 15% of cases of lameness in dairy cattle.

Usually the disease is sporadic, but under favorable conditions, as many as 25% of a group may be affected at one time. An epidemiologic study of footrot in pastured cattle in Denmark over a 12-year period revealed that annual incidence ranged from 0.1% to 4.8%, but in most years it was below 1%. The incidence was higher in some breeds than others, higher in some geographic areas than others (usually where the fields were smaller and soil higher in pH), and higher 4 to 8 weeks after periods of high rainfall.

Transmission

Discharges from the feet of **infected animals** are the probable source of infection. Duration of the infectivity of pasture or bedding is unknown. Infection gains entrance through **abrasions** or damage to the skin in the interdigital cleft. Introduction of the infection to a farm by transient cattle is often observed, but again the disease may not develop on some farms in spite of the introduction of the infection. Contaminated footbaths can be a source of infection.

Environmental Risk Factors

In many but not all regions, the incidence is much higher during **wet, humid weather** or when conditions are **wet underfoot**. Stony ground, lanes filled with sharp gravel and pasturing on coarse stubble also predispose to the condition. A high incidence can occur, with beef cattle at high stocking densities on irrigated pastures. The observation that the disease is common on some farms and does not occur at all on others suggests that there may be factors that limit the persistence of infectivity in certain soils or environments.

Abrasions to the skin of the feet are more likely to occur when the skin is swollen and soft as a result of continual wetting. The increased incidence in wet summer and autumn months may be so explained in part, although wet conditions may also favor persistence of the infection in pasture. In housed cattle, the incidence is higher in **loose-housed** cattle than tied cattle. Unhygienic cubicle passageways and poorly maintained straw beds may predispose to infection.

Host Risk Factors

Cattle of all ages, including young calves, may be affected, but the disease is much more common in adults. The highest incidence occurs in cows in the **first month of lactation**. A field observation is that *Bos indicus* cattle are much more resistant to infectious footrot than *Bos taurus* breeds, and variations in prevalence have been observed among dairy breeds.

Economic Importance

Footrot is of greatest economic importance in dairy cattle, in which it reaches the highest level of incidence because of the intensive conditions under which they are kept. A 2010 study estimated that each case of footrot costs dairy producers US$121.[4] In beef cattle at range the incidence is usually low, but many cases may occur in purebred herds and in feedlot cattle. Lame cows will lie down for longer and eat less, have difficulty rising, and are at greater risk for teat trampling and mastitis. Loss of production occurs, and an occasional animal may suffer a serious involvement of the joint and other deep structures of the foot necessitating amputation of a digit. The disease is not fatal, but some cases may have to be slaughtered because of joint involvement.

PATHOGENESIS

The pathogenesis is not completely understood, but with the experimental SC inoculation of the virulent biotype of *F. necrophorum* into the interdigital skin of cattle, the typical lesion of footrot develops in approximately 5 days. This suggests that any injury or constant wetting of the skin of the cleft that interferes with its integrity will allow the organism to invade the tissues. There is acute swelling and necrosis of the skin and SC tissues, which may spread to adjacent tendon sheaths, joint capsules, and bone if treatment is delayed or ineffective.

CLINICAL FINDINGS

Severe foot **lameness** appears suddenly, usually in one limb only, and may be accompanied by a moderate systemic reaction with a **fever** of 39 to 40° C (103 to 104° F). There is temporary depression of milk yield in cows, and affected bulls may show temporary infertility. The animal puts little weight on the leg, although the limb is carried only when severe joint involvement occurs. Swelling of the coronet and **spreading of the claws** are obvious.

The typical lesion occurs in the skin at the top of the **interdigital cleft** and takes the form of a **fissure** with swollen, protruding edges that may extend along the length of the cleft or be confined to the anterior part or that part between the heel bulbs. Pus is never present in large amounts, but the edges of the fissure are covered with **necrotic material,** and the lesion has a **characteristic odor**. Occasionally in early cases no external lesion may be visible, but there is lameness and swelling of the coronet. Such cases are usually designated "blind fouls" and respond well to parenteral treatment. A hand-held infrared thermographic unit may be helpful in identifying cattle with footrot, particularly when the difference in temperature between the plantar aspect is compared with the other hindfoot or front foot.[5]

A more severe form of the disease that is peracute in onset and refractory to conventional therapy has been termed "super foul" or "super footrot," although there does not seem to be a persuasive reason to develop a descriptive term from separate footrot. With this type there is sudden onset of acute lameness, severe interdigital swelling, and rapid progression to necrosis and deep erosion of the interdigital space with swelling of soft tissue above the coronary band. The hindfeet or all four feet may be affected.

Spontaneous recovery is not uncommon, but if the disease is left untreated, the lameness usually persists for several weeks, with adverse effects on milk production and condition. The incidence of **complications** is also higher if treatment is delayed, and some animals may have to be destroyed because of local **involvement of joints and tendon sheaths**. In such cases the lameness is severe, the leg is usually carried, and the animal strongly resents handling of the foot. Swelling is usually more obvious and extends up the back of the leg. There is poor response to medical treatment, and surgical measures are necessary to permit drainage. **Radiologic examination** may be of value in determining the exact degree of involvement of bony tissue.

Long continued irritation may result in the development of a wart-like mass of fibrous tissue, the **interdigital fibroma**, in the anterior part of the cleft and chronic mild lameness. Interdigital fibroma occurs commonly without the intervention of footrot, the important cause being inherited defects in foot conformation in heavy animals.

CLINICAL PATHOLOGY

Bacteriologic examination is not usually necessary for diagnosis, but direct smears of the lesion will usually reveal large numbers of a mixture of *Fusobacterium* and *Bacteroides* spp. Routine differentiation between virulent and nonvirulent bovine isolates of *F. necrophorum* can be done by assessment of the cultural characteristics of the colonies grown on blood agar. Proteomic analysis of plasma from cattle with footrot identified increased concentrations of innate immune recognition molecules, acute-phase proteins, and cell-adhesion and cytoskeletal proteins.[6]

DIFFERENTIAL DIAGNOSIS

The characteristic site, nature, and smell of the lesion; the pattern of the disease in the group; and the season and climate are usually sufficient to indicate the presence of true footrot.

NECROPSY FINDINGS

Necropsy examinations are rarely carried out in cases of footrot. Dermatitis is followed by necrosis of the skin and subcutaneous tissues. In complicated cases there may be suppuration in joints and tendon sheaths.

Interdigital Dermatitis/Stable Footrot

Interdigital dermatitis occurs commonly in cattle that are housed for long periods. Although the condition occurs most commonly when the cattle are kept under unsanitary conditions, it is also seen in well-managed herds. The causative agent has not been established, but *Bacteroides nodosus* can be isolated.

The initial lesion is an outpouring of sebaceous exudate at the skin–horn junction, particularly at the bulbs of the heel. There is a penetrating foul odor, the lesion is painful to touch, and there is little swelling and no systemic reaction. More than one foot is commonly affected. In long-standing cases there is separation of the horn at the heel bulb, and this is followed by secondary bacterial infection of the sensitive structures of the foot. Often there is a purulent dermatitis of the interdigital space. Stable footrot does not respond satisfactorily to the standard parenteral treatments used in footrot, but local treatments as set out as follows are effective.

Verrucose Dermatitis

Verrucose dermatitis is a proliferative inflammatory lesion of the **skin of the plantar surface** of the foot extending from the bulb of the heels to the fetlock joint. The condition is seen particularly in feedlot cattle that are overcrowded in wet muddy conditions and may occur in outbreaks. **All four feet** may be affected, there is considerable pain and lameness, and, on smear of the lesion, *F. necrophorum* is present in large numbers. The treatment of verrucose dermatitis consists of washing the affected skin with a disinfectant soap, followed by daily applications of 5% copper sulfate solution. When many animals are affected, a daily walk-through and soaking in a foot bath containing the copper sulfate solution is very effective.

Traumatic Injury

Traumatic injury to bones and joints, puncture by foreign bodies, bruising of the heels, and gross overgrowth of the hoof can usually be distinguished by careful examination of the foot. **Laminitis** is the major cause of lameness in most herds, but with this condition there are no skin lesions present.

TREATMENT

Parenteral administration of antibiotics or sulfonamides and local treatment of the foot lesion are necessary for best results. **Immediate treatment** as soon as possible after the onset of swelling and lameness will give excellent recovery in 2 to 4 days. In the experimental disease, when treatment was delayed for a few days after the onset of signs, severe lesions developed and recovery was extended. Under field conditions, the disease may be present in cattle at pasture for several days before being recognized, making it necessary to confine them for daily treatment until recovery is apparent.

Antimicrobials

Long-acting antimicrobial formulations are preferred to decrease labor associated with daily treatment and hospital pen space requirements.[7] Oxytetracycline, 10 mg/kg BW IV daily, or long-acting tetracycline, 20 mg/kg BW IM, is preferred because of cost and excellent efficacy, but some prefer ceftiofur because of injection-site swelling and longer withdrawal period with oxytetracycline. Tulathromycin (2.5 mg/kg SC) and Florfenicol (40 mg/kg SC) are also effective as one-time treatments. Ceftiofur, 1 to 1.1 mg/kg BW IM, or procaine penicillin G, 22,000 IU/kg BW IM twice daily, or once daily for 3 consecutive days, are effective but need multiple treatments. Sodium sulfadimidine (150 to 200 mg/kg BW) solution given by IV injection is highly effective. Sulfabromomethazine at the rate of 30 g/kg grain was given for two consecutive days to calves weighing 150 kg, and results were excellent. Sulfonamides are not approved for use in lactating dairy cattle in many countries.

Local Treatment

Local treatment necessitates restraint of the affected leg, and this procedure is greatly facilitated by a restraint table or the administration of a very small dose of xylazine. The foot is scrubbed, all necrotic tissue is curetted away, and a local dressing is applied under a pad or bandage. Any **antibacterial**, and preferably **astringent**, dressing appears to be satisfactory. A wet pack of 5% copper sulfate solution is cheap and effective. Any suitable antibacterial ointment preparation may be applied and secured with a bandage, which may be left on for several days. The main advantage of local treatment is that the foot is cleaned and kept clean. If conditions underfoot are wet, the animal should be kept stabled in a dry stall.

In cattle running at pasture, or in the case of large numbers of feedlot cattle, examination of the foot and local treatment are often omitted because of the time and inconvenience involved. However, identification of the animal with a marker is considered necessary in outbreaks to avoid unnecessary confusion in the days following, and examination of the foot is deemed necessary to ensure that foreign bodies are not involved. Local treatment may not be necessary in the early stages of the disease if the animal can be prevented from gaining access to wet, muddy areas.

Surgical Drainage

Surgical drainage may be necessary in refractory cases or when complications with spread to deeper tissues have occurred.

CONTROL

Prevention of foot injuries by filling in muddy and stony patches in barnyards and lanes will reduce the incidence of the disease. Lanes and bedding should be kept clean and dry. The incorporation of biotin in the diet, although reducing the incidence of lameness caused by white-line lesions, has no effect on the incidence of interdigital phlegmon.

Footbaths

Provision of a footbath containing a 5% to 10% solution of formaldehyde or copper sulfate, in a doorway so that cattle have to walk through it twice daily, will practically eliminate the disease on dairy farms. A mixture of 10% copper sulfate in slaked lime is often used in the same manner. Similar measures can be adopted for small groups of beef animals; however, it is thought that providing dry footing and removing abrasive objects provides more effective control than footbaths.

Antibacterials

Feeding chlortetracycline to feedlot cattle 500 mg/head per day for 28 days, followed by 75 mg/d throughout the finishing period, has been recommended, but controlled comparative trials have not been carried out. The

feeding of organic iodides (200 to 400 mg) of ethylene diamine dihydroiodide (EDDI) in the feed daily has been used for many years as a preventive against the disease in feedlot cattle. Feeding EDDI in an ad libitum salt mixture at a level of 0.156% EDDI (0.125% iodine) is also effective in reducing the incidence of footrot. Dosing cattle daily with zinc sulfate by including it in the feed has no prophylactic effect.

Vaccination

Commercial vaccines against bovine interdigital phlegmon are available, but their efficacy has not been established in controlled comparative trials. A mineral-oil adjuvant vaccine containing whole cells or fractions of *F. necrophorum* provided about 60% protection from experimentally induced interdigital phlegmon. A similar vaccine containing *Bacteroides nodosus* appeared to reduce the severity of lesions but not the incidence compared with nonvaccinates.

TREATMENT AND CONTROL

Treatment

Oxytetracycline (20 mg/kg IM/SC of long-acting formulation) (R-1)

Ceftiofur crystalline suspension (long-acting formulation, 6.6 mg/kg, once) (R-1)

Tulathromycin (2.5 mg/kg SC, once) (R-1)

Florfenicol (40 mg/kg SC, once) (R-1)

Procaine penicillin 22,000 IU/kg IM daily for at least 3 days) (R-2)

Oxytetracycline (6.6 mg/kg IM daily for 3 days) (R-2)

Ceftiofur sodium (1.1 or 2.2 mg/kg IM BW daily for 3 days) (R-2)

Florfenicol (20 mg/kg IM, repeated at 48 hours) (R-2)

Control

Decrease moisture on the ground by scraping and improving drainage (R-1)

Minimize exposure to items that traumatize the interdigital cleft (R-1)

Vaccination using a bacterin against *Fusobacterium necrophorum* and leukotoxin (R-3)

BOVINE DIGITAL DERMATITIS, PAPILLOMATOUS DIGITAL DERMATITIS OF CATTLE (MORTELLARO'S DISEASE), FOOT WARTS, HAIRY FOOT WARTS, "HEEL WARTS"

SYNOPSIS

Etiology Causative agent(s): primary causative agents are thought to be anaerobic spirochetes *Treponema medium/Treponema vincentii*–like, *Treponema phagdenis*–like, and *Treponema denticola/Treponema putidum*–like, and other foot-adapted *Treponema* strains. Other bacterial may play a role in establishing clinical disease.

Epidemiology Worldwide disease after first report in 1974; more common in dairy cattle housed in wet, unhygienic conditions.

Clinical findings Lesions located most commonly on caudal aspect of hindfeet; early lesions have a red, granular (strawberry-like) appearance and are very painful; mature lesions are less painful and more proliferative and may have long wart-like projections.

Diagnostic confirmation Clinical signs are sufficiently diagnostic; no additional diagnostic tests required.

Treatment Sustained topical treatment with topical bandage over gauze with 10 mL oxytetracycline in oil (100 mg/mL) is considered the gold standard treatment.

Control Footbaths—5% copper sulfate (not in European Union), 5% formaldehyde—new proprietary formulations are under active development; vaccination ineffective.

Digital dermatitis (DD) is a painful, erosive, papillomatous-like lesion of the skin of the feet of cattle. The region proximal and adjacent to the interdigital skin midway between the heel bulbs of the plantar surface of the foot is most frequently affected. Early lesions are circumscribed, with a red, granular appearance and variable degrees of proliferation of filiform papillae. Mature lesions tend to be more proliferative and may have long papillary fronds. Lameness is severe, particularly when evaluated against the size and location of the lesion, and economic losses result from decreased milk production and reproductive performance.

ETIOLOGY

The etiology is uncertain, but it is very likely that anaerobic spirochetes in the genus *Treponema* play a primary role in infection. A mixed population of gram-negative bacteria, including anaerobes, microaerophilic organisms, and spirochetes, has been demonstrated in or isolated from DD lesions, but spirochetes are consistently observed in superficial lesions and deeper layers of the epidermis in cattle with DD. At least 17 different spirochetal phylotypes within the genus *Treponema* have been identified in lesions,[1] and the most common isolates are *Treponema medium/Treponema vincentii*–like; *Treponema phagdenis*–like; and *Treponema denticola/Treponema putidum*–like, with the latter being recognized as a new species, *Treponema pedis*.[2,3,4] Other bacterial may play a role in establishing clinical disease. PCR measurement of a small subunit of ribosomal RNA or its gene (16S rDNA) has been used for phylogenetic analysis, with *T. phagedenis*–like or *T. denticola/T. putidum*–like in 51% of DD cases and *T. medium/T. vincentii*–like in 38% of DD cases.[2,5] The phylogenetic cluster distribution appears to vary from country to country, leading to the suggestion that the total amount of treponemes is an important determinant of disease outcome, with the presence of specific phylotypes being of lesser importance.[6] Quantitative 16s rRNA clonal analysis indicates that all DD isolates are more than 99% identical to *T. phagedenis*–like, which is an inhabitant of the human genital tract.[7] *Treponema* spp. have been isolated from the gingival tissue of 14% of dairy cattle, but only in the housing season and only in cattle with visible DD lesions, and from the rectal tissue of 15% of dairy cattle.[8] This finding suggests colonization of sites other that the foot in dairy cattle. Cow feces and environmental manure slurry have been shown to be potential reservoirs of treponemes that cause DS.[9]

A spirochete isolated from cases of severe virulent ovine footrot in Australia and the United Kingdom and Ireland is closely related to a treponeme isolated from human periodontitis and bovine digital dermatitis. This suggests the possibility of cross-species transmission, and that a number of spirochetes could be involved in the pathogenesis of either DD or severe virulent ovine footrot.

EPIDEMIOLOGY

Occurrence and Prevalence of Infection

The disease was first described in Italy in 1974 as **Mortellaro's disease**. It occurs primarily in dairy cattle and has been reported as a cause of lameness in dairy cattle worldwide, although beef cattle can also be affected. Surveys of dairy farms in California in the United States found that 25% to 75% of farms have had the disease, and about 10% of cows have been affected, with a range from 1% to 99% of cows in affected herds.

Factors associated with high herd incidence of DD (>5%) include geographic location, herd size, type of land lactating cows accessed on a daily basis, flooring type where lactating cows walked, percent of cows born

off the farm, use of a primary hoof trimmer who trimmed cows' hooves on other farms, and lack of washing of hoof-trimming equipment between cows. It is likely that undisinfected hoof-trimming equipment plays a role in transmission of infection from farm to farm.[10] Seasonal differences occur and may be a result of a combination of weather, housing, and management. The incidence may be higher during the winter months, when the weather is cold and wet and cows are kept in confined housing, than during the summer months when cows are on pasture.

Risk Factors

Host Risk Factors

First-parity cows have the highest odds of DD, and the odds decrease, in a dose–effect manner, as parity increases. The odds of DD increase with increasing days in lactation.

Other risk factors include loose housing, slatted floors, housing under wet and unhygienic conditions, and the introduction of subclinically infected cows into susceptible populations. The plantar and palmar regions of the foot may be more conducive to the development of DD because these anatomic sites are exposed to more moisture. Exposure to slurry increases the permeability of the skin and therefore the susceptibility to DD.[11] Epidemiologic observations indicate that the risk of DD is associated with environmental conditions that cause moist feet in commercial dairy herds. Interdigital dermatitis and heel horn erosion predispose the foot to DD, and all three diseases appear to have similar causative mechanisms that focus on increased exposure of the foot to moisture.[6] Moreover, feet affected with clinical DD lesions have an increase prevalence in heel horn erosion, further supporting a common etiology for these foot conditions.[12] Nonhealing white-line disease and sole ulcers appear to be more common in herds endemically affected with DD,[13] and *T. medium*/*T. vincentii*–like is consistently isolated from these lesions.[14]

The greater incidence of the lesions in the hindfeet is considered to be associated with more exposure to deeper slurry during feeding times than the forelimbs. The plantar and palmar regions of the interdigital cleft are therefore more susceptible to being continually moist compared with the more open dorsal locations. The bovine gut and feces appear to be an important reservoir of infection,[15] but direct skin-to-skin contact could also be an important transmission route for DD treponemes.[16] The anatomic location of DD lesions also has an effect on the efficacy of topical treatment with antibiotics.

Immune Mechanisms

T. phagedenis–like spirochetes isolated from active DD lesions in dairy cattle are associated with serum IgG_2 antibodies, and most react with lipopolysaccharide. Both the antibody and blastogenic responses were reduced in convalescent dairy cattle, suggesting the immune response to the spirochetes has short duration. The presence of IgG_2 spirochete antibodies detected by ELISA does not necessarily describe an active immune protective response by affected cows but reflects prior infection and repeated exposures to treponemes.

Cattle and sheep with DD and severe virulent ovine footrot, respectively, and that may be infected by the same group of treponemes, have increased seropositivity rates to both treponeme isolates, with different patterns of reactivity between farms.

Environmental and Management Risk Factors

Case-control studies in dairy farms indicate that the odds of having a higher proportion (>5%) of affected cows were about 20 times more likely in dairy farms with muddier corrals than in farms with drier ground surfaces in corrals. The disease appears to be more common in free-stall confined herds where feet are constantly exposed to moisture and manure conditions. The feet often become coated with a layer of dried feces, which may provide the anaerobic conditions necessary for bacterial growth.

Buying replacement heifers was associated with a 4.7-fold increase in the odds of a higher occurrence of disease than in herds that did not purchase heifers. There also may be a positive relationship between risk and the number of heifers purchased. Herd size was positively associated with the presence of the disease. Cows in dairy herds that used a footbath were less likely to have DD than those herds not using one. Animals housed in a straw yard were 3.2 times less likely to be affected compared with cattle on slatted floors. Feeding with a larger variety of dietary components (hay, milk, concentrates plus silage) was a protective measure.

Pathogen Risk Factors

Molecular typing of DD-associated *Treponema* isolates has found some genetic relatedness to those of the related human-associated *Treponema* spp. associated with human periodontal disease. These *Treponema* strains have adhesion properties and produce high levels of chymotrypsin-like protease and high levels of proline iminopeptidase, which are major virulence factors.

Economic Importance

The economic losses associated with the lameness accompanying DD in lactating cows include loss in milk production, the effects on reproductive performance, and the costs of treatment, including the time required to recognize the lesions, the costs of individual medication of affected cows if necessary, and the costs of construction and maintenance of a footbath. Lameness has an important effect on milk yield, with the total mean estimated reduction in milk yield per 305-day lactation being 360 kg. Lameness has an important effect on reproductive performance. Dairy cows with claw lesions have a higher calving-to-conception interval and a greater number of services per conception.

PATHOGENESIS

DD is an acute or chronic ulcerative lesion of the skin of the bulbs of the heel or interdigital cleft. In the early stages of the lesion, there is loss of superficial keratin, with a concurrent thickening of the epithelium by both hyperplasia and hypertrophy of epithelial cells. Superficial layers are eosinophilic and undergo necrotic change with the appearance of small holes. Large numbers of spirochetes are present around the holes. Loss of superficial layers of keratin stimulates epidermal proliferation and hyperplasia. In advanced cases, large numbers of spirochetes infiltrate the eroded dermis and may destroy the epidermis. DD is characterized by erosion of the superficial layers of the epidermis, epithelial hyperplasia and hypertrophy, pain, and mild swelling. Lesions usually occur on the hindfeet and are prone to bleeding. Early lesions are circumscribed with a red, granular (strawberry-like) appearance and variable degrees of proliferation of filiform papillae. Mature lesions are more proliferative and may have long wart-like projections, thus the term "hairy wart" disease.

CLINICAL FINDINGS

DD typically occurs in dairy cattle as lameness episodes of variable severity. Affected cattle can be lame and reluctant to move. The affected limb is often held trembling in partial flexion as if the animal is in pain. Less severely affected limbs are rested on the toes and animals may walk on their toes, which become markedly worn and may even expose the sensitive laminae. Affected cattle lose weight and may not eat normally if they have to walk some distance to obtain feed. Milk production may decline if the lesions are severe enough.

Clinical inspection of the foot has been the most effective diagnostic procedure. Lesions are confined to the digits and do not occur above the dewclaws. The feet of the hindlimbs are most commonly affected. The plantar surface of the feet is most commonly affected, but the palmar aspects may also be involved. The majority of lesions are medium to large, measure 2 to 4 cm across at their largest dimension, and are **located on the skin at its junction with the soft perioplic horn of the heel and midway between the two claws**. Most lesions are situated proximal and adjacent to the plantar/palmar interdigital space and rarely involve the interdigital skin. The surface of the lesion is moist, prone to bleeding, and intensely painful to the touch. The lesions are circular to oval in shape, raised, and variable in color and in degree of papillary proliferation. The washed

surfaces are typically red and granular or a composite of white–yellow, gray, brown, or black papillary areas mixed with red granular areas (strawberry-like) (Fig. 15-11). Filiform papillae commonly protrude from the surface of the lesions. Most lesions are circumscribed or delineated by a discrete line of raised hyperkeratotic skin with long wart-like projections. The lesions are restricted to the skin and do not extend into the deeper soft tissues. If untreated, DD can persist for months associated with persistent lameness, reduced milk production, impaired reproductive performance, and premature culling.

More advanced lesions may lead to progressive separation of horn from the sensitive laminae, resulting in a typical underrun sole that may extend forward from the heel to reach halfway to the toe. Outbreaks of the disease may occur in dairy herds, in which up to 75% of all cows may be affected over a period of several months.

The presence and nature of any DD lesions on the plantar aspect of the foot are categorized using a scoring system.[17] The scoring system utilizes the size of the lesion, pain reaction, and clinical appearance and consists of five categories:

- M0, normal skin, no signs of disease
- M1, small (0.5 to 2 cm in diameter) DD lesion that is usually not painful
- M2, erosive hyperemic DD lesion greater than 2 cm in diameter that is usually painful on palpation (Fig. 15-11)
- M3, healing stage of M2 manifest as the presence of a scab with minimal pain
- M4, hyperkeratotic cutaneous DD lesion that is usually not painful on palpation (Fig. 15-11)

The consensus view is that lesion progression proceeds as follows: M0 → M1 → M2 → M3 → M4, although definitive experimental evidence is lacking. The duration of M3 appears to be very short. Lesion area (as measured by digital photography) appears to provide the most sensitive measure of treatment efficacy but has not been frequently applied.

A screening method for the detection of lesions of dairy cattle has been described. At the milking parlor and once the cows are in place for milking, a water hose is used to wash the cows' feet. Then, using a powerful flashlight, the digits are carefully inspected for DD lesions. A DD case is defined as a cow with a circular or oval-shaped, well-demarcated, alopecic, moist, erosive foot lesion, surrounded by a white hyperkeratotic ridge or hypertrophic hairs. Lesions bleed easily and are very painful. When struck by a concentrated jet of water from a hose, the animal frequently reacts by pulling the foot away and sometimes shaking it. The screening method has a sensitivity of 0.72 and a specificity of 0.99. This method can be approximated by turning a parlor hose fully on and using the following scoring system: (0) no movement of the foot after application of the water stream; (1) cow picks up foot and returns it to the floor within 2 seconds of application of the water stream; (2) cow picks up the foot and holds the foot up above the floor for more than 2 seconds. Use of a borescope (an extended rigid tube that provides a focused visual image of the foot at the end of the scope) in the milking parlor does not provide any additional diagnostic information to that provided by application of a water hose to wash the cows' feet.[18]

Infrared thermography does not appear to be of clinical value in detecting DD lesions and is of marginal clinical value in detecting other skin and claw lesions.[18] Improvement in clinical utility can be obtained by examining clean feet and comparing hindfeet to front feet,[19] but these requirements make the test impractical.

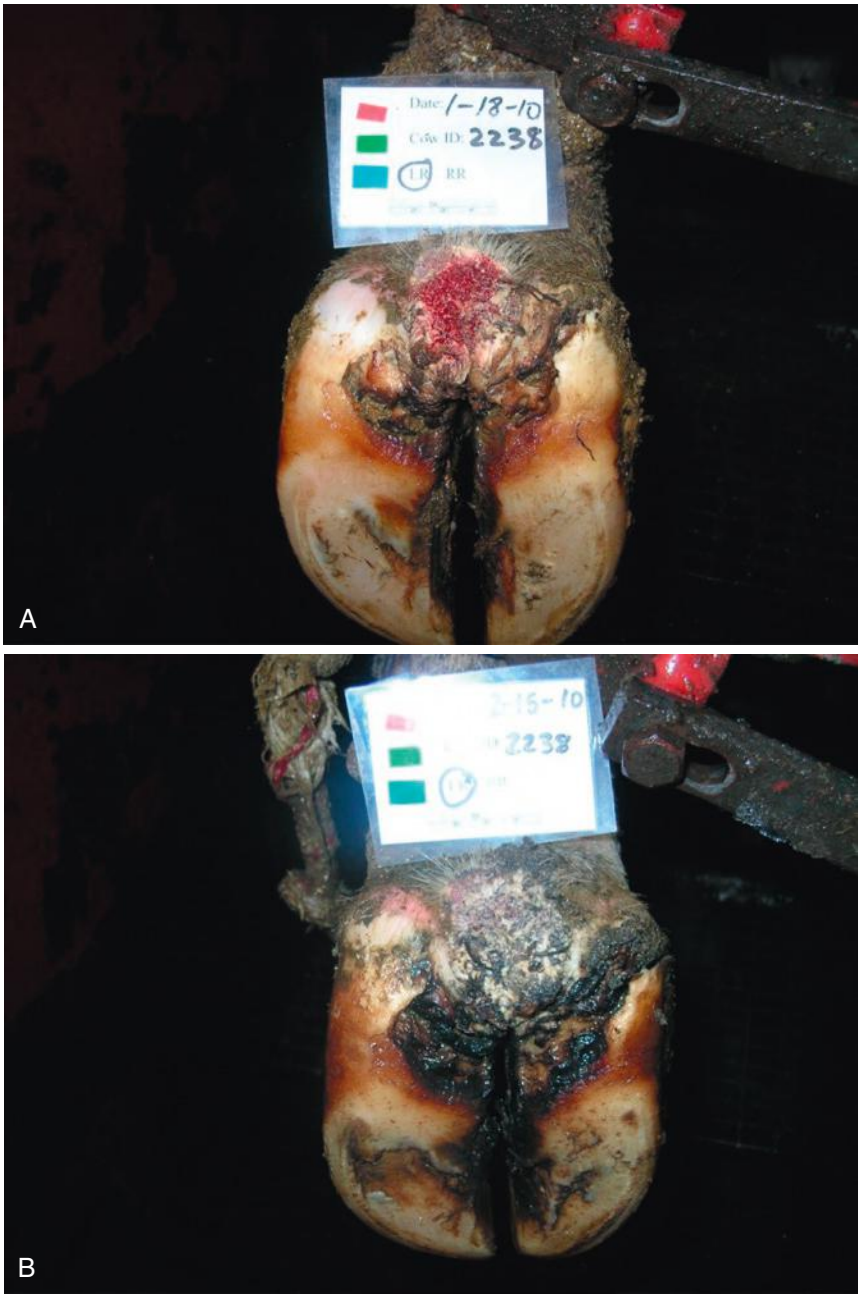

Fig. 15-11 Progression of a painful M2 lesion (A) to a mature M4 lesion accompanied by heel horn erosion (B) 4 weeks later on the same foot of a 3-year-old Holstein–Friesian cow. Pictures generously provided by Dr. Tessa Marshall, United States.

CLINICAL PATHOLOGY

Detection of Organism

Smears of the exudate and scrapings of the surface of the lesions are submitted for culture and for staining for spirochetes. Culture is extremely difficult, which has resulted in the increased application of PCR to identify the presence of spirochetes.

Dark-field microscopy of the scrapings may reveal profuse motile spirochetes with vigorous rotational and flexing movements. Biopsy specimens of the lesions can be submitted for histologic examination and special silver staining to identify the spirochetes.

Serology

Using an ELISA, in cattle with DD, there is a significant humoral response to certain strains of spirochetes isolated from lesions.[20] Animals without DD lesions show little or no response.

PATHOLOGY

The majority of lesions are 2 to 4 cm across their largest dimension, circular to oval, raised, and variable in color. Washed surfaces are typically either extensively red and granular or a composite of white–yellow, gray, brown, and/or black papillary areas interspersed with red granular areas. The surface of the lesions is covered by filiform papillae, 0.5 to 1 mm in caliber and 1 to 3 mm in length. Most lesions are characteristically circumscribed or delineated by a discrete line of raised hyperkeratotic skin, often bearing erect hairs 2 to 3 times longer than normal. The surfaces are also partially to completely alopecic, moist, prone to bleed, and intensely painful to touch. Histologically active lesions are characterized by zones of acute degeneration, necrosis, and inflammatory cell infiltration within the stratum corneum, usually associated with focal thinning. Using immunocytochemical staining and PCR of lesion biopsies, *Treponema* spp. has consistently been identified.

DIFFERENTIAL DIAGNOSIS

Digital dermatitis must be differentiated from the following:

Interdigital dermatitis—moist, gray thickening of the skin, with focal areas of shallow ulceration and hyperkeratosis. It is less painful and rarely has a granular, tufted, or papillomatous surface.

Heel horn erosion (slurry heel)—occurs commonly in dairy cows standing for long periods in slurry. The intact smooth horn of the heel develops deep, black fissures, which may become totally eroded. There is no liquefaction necrosis of keratin characteristic of digital dermatitis.

Interdigital necrobacillosis (footrot)—a necrotizing infection of the interdigital skin. There is marked painful, deep swelling of the tissues of the interdigital cleft; cracking of the skin may occur, with release of a foul-smelling discharge. Response to treatment with antimicrobials is good unless the lesion is advanced.

Verrucose dermatitis—occurs in cattle kept in deep muddy yards and is characterized by marked painful proliferative dermatitis of the plantar surface of pastern from the bulbs of the heels to the fetlocks. *Fusobacterium necrophorum* is usually present in the lesions. Affected cattle are lame and respond to topical treatment and use of a footbath with a suitable antimicrobial.

Interdigital fibroma (corn)—develops from the fold of skin adjacent to the axial wall of the hoof in the interdigital space. The lesion consists of firm fibrous tissue and may extend the entire length of the interdigital cleft. Lameness is caused by the presence of the corn in the interdigital cleft; advanced corns must be removed surgically.

TREATMENT

Treatment and control of DD have used two main approaches: (1) individual treatment of lesions by application of a topical antibiotic or disinfectant at the lesion site or, less frequently, parenteral antibiotic treatment, or (2) herd treatment using footbaths.[21,22] Evaluation of treatment efficacy is challenging because the M2 lesion appears to have a much higher level of infectivity than other lesion categories. Mathematically derived models of transition rates indicate that the speed in identifying acute M2 lesions and the efficacy of treatment of M2 lesions play important roles in determining whether lesions become more severe or heal.[17] The challenge is that accurate diagnosis requires clinical inspection of the foot, which is labor intensive.[20] Consequently, efficacy studies are frequently confounded by case definitions. Many treatments have not undergone rigorous evaluation and are likely to be ineffective. As an example, a survey of 65 French dairy farmers identified 30 different products that were used for individual treatment of DD and 31 products that were used for herd treatment of cows with DD.[23] The large number of treatments emphasizes the need for more randomized clinical trials related to treatment and control of DD.

Topical Antimicrobials

The consensus view is that the gold standard treatment is topical antimicrobial application with 10 mL of long-acting oxytetracycline (200 mg/mL in an oil base) in cotton ball or gauze, covered by a bandage, resulting in 2 g of tetracycline applied per treatment. The oil formulation is thought to help retain the antimicrobial in the gauze, resulting in sustained topical antimicrobial exposure. This treatment protocol does not result in detectable milk residues, and field efficacy is supported by in vitro susceptibility results; however, this treatment is not practical when large numbers of animals are affected. Moreover, there is one report that this treatment protocol resulted in a low healing rate in cows with a large lesion size in an endemic herd that had long-term application of tetracycline for treating DD.[24] An alternative equivalent treatment that does not require a bandage is application of a tetracycline paste consisting of 175 mL of propylene glycol, 175 mL of vinegar, and 150 g of tetracycline hydrochloride applied directly to the lesion with a paintbrush, resulting in 2 to 5 g of tetracycline applied per treatment.[25] This treatment protocol exposes more tetracycline to the environment than treatment involving application of a foot bandage. In general, application of a bandage over the lesion after application of a treatment should result in longer topical application times, and consequently it should be expected that a topical treatment followed by bandaging should be more effective than topical spray without bandaging.[26]

In vitro studies have identified the following minimum bactericidal concentrations for 90% of *Treponema* spp. isolated from DD lesions:[2,7,16] penicillin G (<0.06 to 0.19 µg/mL), erythromycin (<0.06 to 0.19 µg/mL), ampicillin (<0.06 to 4 µg/mL), oxytetracycline (0.5 to 6 µg/mL), ceftiofur (6 to 8 µg/mL), spectinomycin (48 µg/mL), lincomycin (8 to 48 µg/mL), enrofloxacin (8 to 192 µg/mL), rifampin (>128 µg/mL). These results support the routine use of topical oxytetracycline and suggest that topical lincomycin will be ineffective and that topical macrolides might provide an effective treatment.

Topical antimicrobial sprays or ointments are used on individual animals after the lesions have been cleaned. Direct spraying of the lesions with oxytetracycline at 25 mg/mL in 20% glycerine in deionized water once daily for 5 days using a garden-type spray applicator was effective. Only affected cows and individual lesions should be treated. The anatomic location of DD lesions has an effect on the efficacy of topical treatments. The use of oxytetracycline solution (25 mg/mL in distilled water) as a topical spray on cows with DD lesions was most effective on lesions located on the heels or dewclaws compared with those in the interdigital cleft; this result confirms the obvious conclusion that topical treatments need to be applied directly on the lesion and not near the lesion to be effective.

Oxytetracycline solution (100 mg/mL), acidified ionized copper solution, acidified sodium chlorite, or placebo given as a topical spray three times daily, after washing the lesions, for 3 weeks was effective in decreasing the lameness associated with the disease. In a Swedish dairy herd, topical oxytetracycline was more effective for the treatment of DD in cattle with heel-horn erosion than hoof trimming alone and more effective than glutaraldehyde. The use of an oxytetracycline solution topically at doses of 15 mL of a solution containing 100 mg oxytetracycline/mL sprayed twice daily for 7 days, or a one-time application of a bandage of cotton soaked with 20 mL of a solution containing 100 mg oxytetracycline/mL, has a low risk of causing volatile antibiotic residues in milk. Topical treatment with chlortetracycline cured painful digital dermatitis lesions at 79% per week (M2 to other categories).[27]

Lincomycin at a dose of 25 mL of a solution containing 0.6 mg lincomycin/mL or valnemulin at a dose of 25 mL of a solution containing 100 mg/mL valnemulin, given as an individual topical spray for two treatments 48 hours apart, resulted in significant improvement within 14 days after the first treatment.

Nonantibiotic Topical Formulations

The efficacy of oxytetracycline has been compared with nonantibiotic solutions, a commercial preparation of soluble copper, peroxide compound and a cationic agent, 5% copper sulfate, acidified ionized copper solution, hydrogen peroxide–peroxyacetic acid solution, and tap water for the treatment of DD. The commercial formulation of soluble copper, peroxide compound, and a cationic agent appeared to be as effective as oxytetracycline. A nonantimicrobial cream containing soluble copper with peroxide and a cationic agent was compared with topical lincomycin. The efficacy of the treatments was not different for decreasing pain or lesion activity, but lincomycin was more effective in decreasing lesion size and preventing recurrence. Cows with 3 or more lactations were more likely to have a healed lesion at 29 days compared with first- and second-lactation cows.

The efficacy of a number of disinfectants, including proprietary formulations, has been evaluated in vitro. A 5% copper sulfate solution was extremely effective in killing *Treponema* spp., but its effectiveness was markedly affected by the presence of manure.[28] Organic chemicals such as glutaraldehyde and formaldehyde (formalin) were effective in vitro and have the benefit of being degraded in manure, but they are not as effective as 5% copper sulfate. Salicylic acid applied under a bandage is effective.[26] A nonantibiotic proprietary formulation based on a reduced soluble copper solution, peroxide compound, and a cationic agent was most effective for the treatment of DD, once daily for 5 days, compared with other similar formulations and oxytetracycline.

A nonantibiotic paste, Protexin Hoof-Care, containing formic acid (6.8%), acetic acid (3.74%), copper (3.29%), and zinc sulfate (0.40%), and essential oils (peppermint/eucalyptus, 0.16%) with a pH of 3.5 has been compared under controlled conditions with topical oxytetracycline and is considered an effective alternative to the antibiotic for the treatment of DD. Only one topical application is required after cleaning the lesion. Advantages include the following: no prescription is required, no withdrawal time is required, and it does not result in any concerns about antibiotic residue in meat or milk.

Cleaning the Surface of the Lesion

It is very important to wash and clean the surface of the lesion with a disinfectant soap before the topical administration of any medication. Topical treatment failures are commonly associated with failure to adequately wash and clean the surface of the lesion.

Bandaging the Lesion

Whether or not the lesion should be bandaged after cleaning and medicating is controversial. Bandaging requires additional restraint to handle the leg and foot, is labor intensive, and is an additional cost. However, field observations indicate topical treatment under a bandage is particularly effective, with most cows showing remarkable improvement in 24 to 48 hours. Furthermore, when properly applied, the bandage and the topical medication have the potential of reaching lesions in the interdigital cleft.

Antimicrobials Parenterally and Topically

Antimicrobial therapy is indicated and effective, and various methods of administration have been used, including parenteral and topical application in individual animals and footbaths for medication of large numbers of animals.

Parenteral Antimicrobials

Although parenteral antibiotic treatment can be effective (depending on the antimicrobial class), milk withdrawal and cost are major concerns regarding this being a routine recommendation. Procaine penicillin, at 18,000 U/kg BW IM twice daily for 3 days, or intramuscular ceftiofur sodium at 2 mg/kg daily for 3 days, was highly successful for the treatment of DD in dairy cattle in California. IV regional administration of tetracycline hydrochloride into the lower lateral digital or median vein after application of a tourniquet proximally on the limb provides has been used[29] but appears to provide a much more complicated treatment protocol that topical tetracycline and bandage. However, the use of parenteral antimicrobials on an individual basis is labor intensive, costly, and not feasible when large numbers of animals are involved. In addition, drug residues in the milk are more likely when animals are treated parenterally. Recurrence after treatment may also occur. In one report, the lesions recurred in 18% of cows treated with antibiotics parenterally.

Footbaths

Some veterinarians prefer to focus treatment protocols on footbaths. The benefits of footbaths include mass treatment and a potential decrease in the transmission of infection from carrier cows to noninfected animals. Footbaths containing antimicrobials and germicides have been used for treatment of groups of animals and for control of the disease. The most important benefit of using footbaths is that all animals are treated for DD at the same time. Types of footbaths include walk-through and stand-in (stationary). The walk-through footbath, commonly located in milking-parlor exit lanes, is most popular in loose housing systems. Portable walk-through footbaths constructed of rubber, fiberglass, or hard plastic are also available and can be relocated as needed. The portable footbath is also the most convenient type for individual treatment situations that may involve bathing two, or possibly all four, feet for prolonged periods. Unfortunately, only a small number of randomized clinical trials have been published that document the efficacy of footbath solutions or topical antiseptic solutions in treating and preventing DD in lactating dairy cows. Copper sulfate is the most commonly used antiseptic footbath solution to treat and control DD because of its widespread availability, low cost, and ease of use. Repeated topical application of 8% copper sulfate solution has been shown to be effective in healing DD lesions, but is not as effective as daily application of a topical chlortetracycline spray to the lesion.[30] Copper sulfate footbaths have been shown to have some efficacy at reducing DD lesions, whereas other studies have shown little to no response. A 2015 systematic review[31] identified only one study that clearly demonstrated the efficacy of copper sulfate footbaths in decreasing the number of cattle with DD lesions; however, that one study provided unequivocal evidence of efficacy.[32] This study demonstrated that a 5% copper sulfate footbath solution applied at 4 consecutive milkings each week was effective in healing DD lesions but did not alter the new infection rate of cows with DD.[32] Copper sulfate footbaths also help to harden the horn on the foot,[33] but it is unclear what role this might play in preventing or treating DD. An acidified ionized copper sulfate footbath solution has been shown to be superior to a 4% formaldehyde (formalin) footbath in preventing new cases of DD.[34] Negative aspects of formaldehyde use include irritation to mucous membranes and carcinogenic effects in humans.[33]

After 150 to 300 cows pass through, the copper sulfate solution in the footbath is thought to become ineffective and is disposed of by land application. Government agencies have expressed concern that the frequent application of $CuSO_4$ solutions in footbaths will result in unacceptably high concentrations of copper in the soil; for example, the use of $CuSO_4$ solutions in footbaths has been restricted to low concentrations (0.5% $CuSO_4$) in the Netherlands,[27] and 5% $CuSO_4$ footbath solutions are not permitted in the European Union. There is therefore widespread interest in developing alternative antiseptic solutions for the treatment and control of DD in dairy cattle. A well-controlled study in Denmark failed to document efficacy of commercially available hoof-care products containing glutaraldehyde, quaternary ammonium compounds,

or organic acids (acetic acid, peracetic acid, and hydrogen peroxide) in treating and preventing DD in dairy cattle.[35]

Optimal footbath dimensions are 3.0 to 3.7 m long, 0.5 to 0.6 m wide, and a 28-cm step-in height.[36] Proper construction includes systems for efficient drainage, cleaning, and refilling. Footbaths should be filled to a depth of at least 10 cm (4 in.) to ensure coverage of the typical lesion site for DD. The capacity of a rectangular footbath varies according to its dimensions, which can be calculated using the formula: width × length × depth × 7.46 = capacity in gallons. (Multiplying the number of gallons by 3.8 will provide capacity in liters.) The size of the footbath needed will depend on the number of feet that will be treated with the system. Footbaths must be carefully monitored for excessive contamination with dirt and feces.

Not only is the optimal footbath formulation unknown, but the optimal footbath frequency is also unknown. It has been suggested to use hygiene scoring to determine the frequency of foot bathing, whereby 20% of cows in the free-stall barn are scored; if more than 50% of the cows receive a score of "poor," then the footbath frequency should be 5 days a week. The maximum number of cows that can be treated with a footbath varies according to the cleanliness of the cows, size of the bath, type and concentration of the medication used, housing system, weather conditions, and cow flow patterns. One recommendation suggests one footbath is sufficient for 150 to 200 cows and that DD may be controlled with a single monthly passage through a footbath containing 5 to 10 g/L of oxytetracycline or 1 to 3 g/L of lincomycin in 200 L of water or erythromycin at a rate of 50 g/150 L of water. A common recommendation is that a foot bath can treat 150 to 200 cows per change of solution, used three times per week in outbreaks, once every week or two for maintenance. Other observations, however, suggest that as few as 30 to 50 cows through a footbath may cause major shifts in pH and solids loading, and the largest increment of change in pH occurred with the passage of the first 32 cows through the bath.

Some footbaths are set up with a "prerinse" water bath to reduce contamination of the active ingredients by gross fecal matter on the feet of the cows. It is unclear whether this prerinse footbath provides any advantages. In summary, footbaths make biological sense for the treatment and control of DD. However, most of the recommendations regarding their use, footbath formulation, frequency of use, and optimum number of cows are based on uncontrolled field observations.

Antibiotics in Footbaths

Antibiotics are commonly used in footbaths for the treatment and control of DD, but their use should be discouraged. Use of footbath solutions containing antimicrobials, such as tetracycline, chlortetracycline, lincomycin, or erythromycin, has decreased in popularity because of concerns over antimicrobial residues in the environment and the potential for increased antimicrobial resistance in bacteria. Most of the antibiotics require a veterinary prescription and must be used according to specific recommendations and compliance with withdrawal periods as necessary. Antibiotics in footbaths are rapidly neutralized in the presence of excessive contamination from mud and manure. This is a significant limitation in large herds or in housing situations in which muddy conditions are present.

Tetracycline in 6 to 8 g/L of water has been used in a footbath for treatment of DD. Tetracycline powder (324 g/lb) at 20 to 40 g per gallon (U.S.) to deliver 0.5% to 1% has been used. Lincomycin mix at 0.5 to 4 g/gallon (U.S.) is also used. A mixture of lincomycin and spectinomycin in 150 g/200 L of water for treatment and 125 g/200 L of water for control was also effective. Walking cows through a footbath containing erythromycin, at a concentration of 35 mg erythromycin/L, after two consecutive milkings is effective. Four days after treatment, four of the measured signs (exudation, reddening, creaminess, and pain) were all significantly improved.

Treatment Failure

The possible causes of treatment failure include inconsistent application of treatments or the failure to periodically retreat all feet of all cows in the herd every 2 to 3 months with a topical spray, improper formulation of the medication, the neutralization of the antibiotics by manure, and the inaccessibility of the medication when the lesion is in the interdigital cleft. In addition, ideally lesions should be washed and cleaned thoroughly before applying the medication.

CONTROL

Because the risk factors that predispose to the lesions are uncertain, specific environmental control strategies have not been examined using controlled field trials. Recurrence rates of DD vary from 40% to 52% after 7 to 12 months. Thus it makes biological sense to have an infectious disease control system in place in the herd to provide optimum control.

- **Housing, environment, and management.** The high incidence of the disease in dairy cattle in drylot and free-stall housing suggests that a high infection rate may be associated with high population density and contamination of bedding and the environment. Providing environmental conditions that promote clean and dry ground surfaces and bedding appears to be a logical strategy. Improving cow comfort by providing clean stalls, corrals, and alleys and dry and comfortable bedding, reducing the stocking rate, and improving ventilation to allow drying of stalls and alleys may decrease the incidence and severity of clinical cases. Hoof trimming, mobile tilt tables, and livestock trailers should be thoroughly cleaned and disinfected to prevent potential transmission of the agent of DD. The optimal disinfectant has not been identified.
- **Biosecurity.** For herds that are free of DD, the most important control consideration is the purchase of herd replacements. According to the 1996 NAHMS survey in the United States, the odds of DD infection were 8 times greater in herds that purchased replacements from outside sources compared with those that did not. Herd replacements should be purchased from herds known to be free of DD. Quarantine procedures may be applicable but often impractical.
- **Footbath.** Successful control is possible by single passage of cattle through a footbath containing 5 to 6 g/L oxytetracycline or 150 g lincomycin/spectinomycin in 200 L water; however, use of antimicrobials in footbaths should be discouraged. For optimum results the heels of affected cows should be spray washed before entering the footbath. Repeating the footbath treatment in 4 to 6 weeks is recommended. Regular footbaths with 5% copper sulfate solution and formalin 3% to 5% solution once weekly, according to the incidence of the disease, may be necessary in certain circumstances. Regular inspection of the feet of cattle is recommended to monitor the occurrence of the lesions.
- **Vaccination.** There is no evidence that a vaccine is effective for the control of DD. An effective vaccine will be challenging to develop. Koch's postulates have not been fulfilled for DD, and natural immunity does not appear to be long lasting. Humoral immunity is elicited in cows with DD, and clinical disease is less common in older cows.

TREATMENT AND CONTROL

Treatment

Topical antimicrobial application with 10 ml of long-acting oxytetracycline (200 mg/ml) in cotton ball or gauze, covered by a foot bandage (R-1)

Application of a tetracycline paste consisting of 175 mL of propylene glycol, 175 mL of vinegar, and 150 g of tetracycline hydrochloride applied directly to the lesion with a paintbrush (R-2)

Direct spraying of lesions with oxytetracycline at 25 mg/mL in 20% glycerine in deionized water once daily for 5 days (R-2)

Control
Optimal footbath formulation and frequency of application is unknown; some evidence supporting use of weekly (or more frequent) footbaths with 5% copper sulfate solution (not permitted in the European Union) or formaldehyde 3% to 5% solution (R-2)

Footbath containing an antimicrobial (R-3)

Vaccination with *Treponema* bacterin (R-3)

INFECTIOUS FOOTROT IN SHEEP

SYNOPSIS

Etiology *Dichelobacter nodosus*. Strains vary in virulence to produce benign and virulent footrot.

Epidemiology Main source of infection is lesion discharge from other infected sheep. *D. nodosus* typically survives in the environment for only a few days. Highly contagious disease with high attack rate in warm, wet conditions. Lesions are present on both claws of the foot and commonly in more than one foot. Significant effect on productivity.

Clinical findings Inflammation of the skin at the skin–horn junction in the interdigital area with underrunning of the soft horn in benign (nonprogressive) footrot. Progresses to underrunning of the hard horn and inflammation of the sensitive laminae in virulent (progressive) footrot and severe lameness.

Clinical pathology Gram-stained smears and culture to confirm the presence of the organism; protease and polymerase chain reaction (PCR) tests for strain virulence.

Diagnostic confirmation Clinical.

Treatment and control Topical treatment with bactericides in footbaths at time of transmission to minimize new infections, parenteral antibiotics for treating virulent footrot, vaccination, culling. Goats and cattle can carry *D. nododus* and so must be included in control programs.

ETIOLOGY

Dichelobacter (*Bacteroides*) *nodosus* is the essential causal pathogen. It is a highly specialized organism in the small taxonomic group, the Cardiobacteriaciae. *F. necrophorum* aids *D. nodosus* in the invasion of the foot and contributes in the inflammatory reaction. Two other bacteria, a treponeme originally known as *Spirochaeta* (*Treponema*) *penortha* and a motile fusiform bacillus, are commonly present in affected feet but are thought to have no primary etiologic importance.

The type IV fimbriae of *D. nodosus* are recognized as a major virulence factor, are highly immunogenic, and provide the basis for the classification of *D. nodosus* strains into two major classes based on the genetic organization of the fimbrial gene region, with class I containing strains of serogroups A, B, C, E, F, G, I, and M and class II consisting of serogroups D and H. The serologic diversity observed in the fimbriae is as a result of sequence variation in the fimbrial subunit protein and the fimbriae are the major immunoprotective antigens, although protection is serogroup-specific.

Within this typing scheme there are strains that have major and minor prevalence in the disease. For example, footrot introduced into Norwegian flocks around 2008 was predominantly serogroup A, with 96% of virulent isolates belonging to this serogroup.[1]

EPIDEMIOLOGY

Geographic Occurrence

Footrot of sheep is common in all countries where there are large numbers of sheep, except that it does not occur in arid and semiarid areas unless the sheep have access to wet areas such as subirrigated swales.

Host Occurrence

Sheep are the species principally affected, but goats are also susceptible. Infection has been identified in farmed red deer and in cattle and is considered the cause of overgrown and deformed claws in wild mouflon in Europe. With environmental conditions of moisture and warmth, the disease in sheep has a high attack rate, and a large proportion of a group of sheep can be affected within 1 to 2 weeks. Both claws of a foot and more than one foot (usually all) on the sheep will be affected. The disease is common, and in high-risk areas the prevalence of infected flocks is high.

Source of Infection

The source of infection of *D. nodosus* is discharge from the active or chronic infection in the feet of affected animals. The major reservoir of infection for virulent strains of sheep is other sheep because the isolates from cattle and deer generally produce the benign form of footrot in sheep. Culture has demonstrated that the organism does not usually survive in the environment for more than a few days, 2 weeks at the most, although PCR techniques suggest that maximum environmental survival could be up to 24 days.[2] It can survive virtually indefinitely in lesions on chronically infected feet.

Two classifications of footrot have made based on the site of survival and perpetuation of the organism in a flock and the importance of this to control strategies:

1. **Virulent footrot (progressive footrot) and intermediate footrot**—strains survive between footrot transmission periods in pockets of infection in previously underrun ovine hoof
2. **Benign footrot (nonprogressive footrot)**—strains survive in the interdigital skin, and the organism can be demonstrated in the interdigital skin of a high proportion of asymptomatic sheep and cattle.

Methods of Transmission

Infection is usually introduced into a flock by the introduction of carrier sheep, although sheep can become infected from the environment when footrot-free sheep use yards, roads, or trucks that have been used by footrot-infected sheep in the immediate past. For example, transmission occurred when sheep were held for 1 hour in a yard that 4 hours previously had contained a flock of sheep in which less than 1% had footrot. Spread within a flock is facilitated by the flocking nature of sheep and heavy

environmental contamination around communal drinking and feeding areas. Spread from ewe to lamb in intensive systems can be rapid, within 5 to 13 hours.[3,4]

Host Risk Factors

Age and Sex

Footrot occurs in sheep of all ages, with rams or ram lambs often more severely affected than ewes.[4] In a flock outbreak, the age-specific incidence and severity of lesions in ewes tends to increase with age, and older lambs have more severe lesions than younger lambs. Prior natural infection does not provide immunity at a subsequent challenge for sheep that have had the disease. However, sheep do vary in their resistance or susceptibility to footrot infection. This appears to be, in part, immunologically mediated, with the ability of some sheep to mount a strong T-cell response and to produce agglutinating antibodies to *D. nodosus* fimbriae being an important factor in conferring resistance to severe infection.

Breed

Merino sheep are the most susceptible to footrot. British breeds, particularly Romney Marsh, are less susceptible and suffer from a milder form of the disease; they respond better to vaccination by suffering fewer subsequent attacks of footrot but have worse reactions to a multivalent vaccine than Merinos. In the natural disease, some animals never become infected, a few become infected but recover, and most become infected and persist as chronic cases. There is evidence that this variation is genetically determined, and selection for resistance, based on exposure to the disease and rigorous culling of affected individuals, has been demonstrated in Merino, Corriedale, Romney, Perrendale, and Targhee breeds.[4] Substantial genetic variation in resistance to footrot has been demonstrated, both within flocks and between the progeny of different sires, among both Merino and Sottish Blackface breeds.[5,6]

Environmental Risk Factors

Climate and Season

Moistness of the pasture and environmental temperature are major determinants for the transmission of footrot. Wetness and warmth favors persistence of the bacteria in pasture and increases the susceptibility of feet to injury and dermatitis, thus facilitating spread of the disease from carrier sheep. There must be continued moisture on the ground for transmission to occur. Thus in drier temperate climates, such as Australia, transmission tends to occur predominantly in the spring and, to a lesser degree, autumn. In cooler, wetter temperate climates, such as New Zealand and the United Kingdom, the transmission period can be much longer. The daily mean temperature must also be above 10° C (50° F) for transmission to occur, and so in colder climates transmission is reduced or does not occur during the winter. There is a linear relationship between the prevalence of farms with footrot and yearly rainfall.

Transmission and outbreaks of footrot occur in winter in housed sheep when conditions underfoot are wet and in summer with sheep on irrigated pastures.

Management

Any practice that concentrates sheep in small areas will favor spread of the disease when environmental conditions favor transmission. Routine foot trimming may increase risk of infection and clinical disease.

Failure to isolate introduced sheep until their footrot status has been determined, straying sheep, and the presence of at least one footrot-infected farm within a 1-km radius with severe footrot are confirmed risk factors for the introduction of footrot into a flock.[7,8]

Pasture Type

Footrot is commonly associated with lush or improved, irrigated, and clover-dominant pastures. Long mature grass may result in interdigital abrasions as it is dragged through the interdigital space and facilitates infection, as may penetration of interdigital skin by barley grass seeds (*Hordeum murinum*). Skin penetration by larvae of the nematode *Strongyloides* spp. may also predispose to infection.

Pathogen Factors

The major *D. nodosus*–encoded virulence factors that have been implicated in the disease are type IV fimbriae and extracellular proteases, and the fimbrial subunit gene, *fimA,* is essential for virulence.

There is considerable variation in the virulence of strains of *D. nodosus.* Some produce benign footrot, whereas others produce deep lesions that facilitate their survival and confound eradication programs. As a result, they have traditionally been subdivided into benign, intermediate, and virulent strains to conform with the types of clinical footrot they are associated with in the field. The virulence of each strain depends on its keratinolytic capacity; virulent strains produce more extracellular protease, and an earlier production of elastase, than benign strains. The separation of the hard horn of the claw from the germinal layer, which is a characteristic of virulent footrot, has been associated with infection with strains that produce a heat-stable protease with a single isoenzyme pattern, whereas benign strains have thermolabile protease. Infection associated with more than one strain is reported, and up to five serogroups including up to eight strains have been reported from a single foot.

The genome of *D. nodosus* has been fully sequenced,[9] and this has allowed further investigation of the factors that determine its virulence. Acidic protease V2 (AprV2) is the main thermostable protease responsible for most elastase activity and differs from its benign counterpart, AprB2, by only a single amino acid.[10] It is one of three thermostable proteases that act synergistically, the others being AprV5 and a basic protease, BprV. AprV5 is needed to activate all three proteases, whereas BprV degrades hoof horn matrix more efficiently than its counterpart from benign strains, BprB.[11]

A molecular genetic analysis of *D. nodosus* isolates from four European countries, Switzerland, France, Germany, and Norway, found a perfect correlation between the clinical presentation of footrot and the presence of either AprV2 or AprB2.[12]

Economic Importance

Benign footrot is generally considered to cause little if any economic effect, and its occurrence is confined to the warm, wet seasons. However, even benign footrot infections can depress body weight, wool growth, and wool quality in some countries, especially in Merinos.

In contrast, virulent footrot causes a severe loss of body condition, and this, combined with a moderate mortality rate, a reduction in wool production, the disruption of the general routine of the farm, and the expense of labor and materials to treat the disease adequately, makes footrot one of the most costly of sheep diseases. Estimates of the total annual cost to industry in Australia are estimated at $32.3 m and $12.1 m for virulent and benign footrot, respectively, and £24 m in Britain.[13,14] In addition, there are welfare concerns, societal pressures encountered by owners of footrot-infected flocks, and, in control areas, the community costs of statutory footrot control programs.

In controlled studies, virulent footrot causes an 11% depression in body weight and an 8% reduction in clean fleece weight of affected sheep. The magnitude of the loss can be related to the virulence of the infecting organism and the severity of disease.

The effects on body weight are most severe during the active transmission period of the organism and development of clinical disease, but there may be compensatory growth during the recovery period. Both greasy and clean fleece weight are significantly depressed by footrot, with a linear association between the extent of the depression and the severity of the disease. Wool fiber diameter is also decreased, which can partially compensate for decreased fleece weight in the final price for wool. Some sheep with severe disease may develop a break in the wool, which can then incur price discounts of up to 50%.

Feet of sheep affected with footrot are attractive to blowfly strike. Necrotic exudate with accompanying maggots from affected feet can be deposited on the fleece to result in a focus of body strike.

PATHOGENESIS

Maceration of the interdigital skin from prolonged wet conditions underfoot allow for infection with *F. necrophorum*. This initial local dermatitis associated with infection with *F. necrophorum* at the skin and the skin–horn junction may progress no further, but the hyperkeratosis induced by this infection facilitates infection by *D. nodosus* if it is present. The preliminary dermatitis has been named "ovine interdigital dermatitis" and is also called "foot scald."

OVINE INTERDIGITAL DERMATITIS, FOOT SCALD

This disease is seasonal and occurs when moist conditions underfoot, or trauma from pastures or frost, produce maceration of the interdigital skin, allowing invasion by *Fusobacterium necrophorum,* a ubiquitous organism in feces and soil.

Lesions are in the interdigital space, where there is hyperemia, or swelling and blanching, and wetness of the interdigital skin. There is no, or only minimal, separation at the skin–horn junction ("underrun"). Lambs are more commonly affected, particularly in spring, but the disease can involve all ages of sheep. Most or all feet on a sheep are affected, and it is present in a large proportion of the age cohort of the flock.

In Australia and New Zealand, the disease is not usually associated with severe or chronic lameness and is often found incidentally when examining sheep for other reasons.

In Britain it is reported as a common cause of lameness, but this might reflect a lack of cultural differentiation from the less virulent forms of infectious footrot that can present with identical clinical findings. Examining Gram-stained air-dried smears of lesion material will reveal the absence of *Dichelobacter nodosus.*

Control is by avoiding grazing lambs on long grass or in muddy conditions. The disease will regress spontaneously when the pasture dries up or sheep are moved to drier paddocks, but it can be treated with topically applied oxytetracycline or by walking animals through a footbath containing 10% zinc sulfate (preferably standing in the solution for 1 to 3 minutes, then allowing the feet to dry on grating or in a woolshed) or 3% formalin.

Ovine interdigital dermatitis can predispose to infectious footrot or to foot abscess.

Benign and Virulent Footrot

It is assumed that the pili of *D. nodosus* facilitate attachment of the organism to the epithelium of the foot. When the feet of sheep with interdigital dermatitis are colonized with a strain of *D. nodosus* that has little keratinolytic ability, there is underrunning of the soft horn but no further progression, and this infection has been given the name of benign or nonprogressive footrot. Benign footrot cannot be easily distinguished on clinical examination from ovine interdigital dermatitis. Colonization with keratinolytic and virulent strains leads to the clinical disease of virulent footrot. The underrunning lesion is the result of keratolytic activity, and the associated inflammation is a consequence of a combined activity of *D. nodosus* and *F. necrophorum*. A designation of intermediate footrot is used to provide a midclassification of severity between benign and virulent footrot, with the classification of infected sheep into these categories based on a foot lesion scoring system (see following discussion). There is much difficulty in specifying exactly the characteristics of these clinical forms in natural outbreaks, partly because more than one strain is commonly involved, but also because the severity of the lesions is modulated by breed, previous treatments, and varying geographic and climatic conditions.

CLINICAL FINDINGS

Sheep

Virulent Footrot

In a flock, a sudden onset of lameness of several sheep is the usual presenting sign of footrot because the disease is not detected before this occurs. The pain associated with infection is severe, and affected sheep will limp or carry the affected leg. Usually more than one foot is affected, and affected sheep may graze on their knees.

On close examination the earliest sign of virulent footrot is swelling and moistness of the skin of the interdigital cleft and a parboiled and pitted appearance at the skin–horn junction in the cleft. This inflammation is accompanied by slight lameness, which increases as necrosis underruns the horn in the cleft. The underrunning starts as a separation of the skin–horn junction at the axial surface just anterior to the bulb of the heel and proceeds down the axial surface and forward and backward. There is destruction of the epidermal matrix beneath the hard horn, which is subsequently separated from the underlying tissues. In severe cases both the axial and the abaxial wall and the sole are underrun, and deep necrosis of tissue may lead to the shedding of the horn case. The separation may not be obvious on superficial visual examination but can be detected by trimming the feet with a knife or secateurs. There is a small amount of distinctive, gray, foul-smelling exudate, but abscessation does not occur.

Both claws of the one foot will be involved, and commonly more than one foot is involved. When extensive underrunning has occurred, lameness is severe. A systemic reaction, manifest by anorexia and fever, may occur in severe cases. Recumbent animals become emaciated and may die of starvation. Secondary bacterial invasion and/or fly strike may result in the spread of inflammation up the legs.

Benign Footrot

Benign footrot is manifest with interdigital lesions, a break at the skin–horn junction, and separation of the soft horn, but the disease does not progress beyond this stage to severe underrunning of the hard horn of the foot. The interdigital skin becomes inflamed and covered by a thin film of moist necrotic material; the horn is pitted and blanched.

It is difficult to distinguish between an established infection with benign footrot and the early stages of virulent footrot. With virulent footrot, it is common to find all stages and severity levels of the disease in the same flock. A large number of sheep (e.g., 100 in large flocks or mobs) should be examined to differentiate benign from virulent footrot, and it may be necessary to reexamine the flock after a period of time to determine whether the disease has progressed to the virulent type.

Scoring Systems

Several scoring systems, based on severity and persistence, have been devised to aid in epidemiologic and control programs and can be used to categorize the severity of disease, hence the virulence of associated strains of *D. nodosus,* within a flock. In the Australian system, a score of 0 (normal foot) to 4 (severe underrun) is allocated to each foot of each sheep, then the score is used to classify the severity of disease in that flock or a cohort.[4] Feet scored 0 have no evidence of necrosis or inflammation or cleavage of horn. Scores of 1 and 2 are confined to sheep with interdigital lesions, whereas a gradation of scores from 3 to 4 reflects progressive underrunning and separation of horn from the underlying laminar, with 3 representing underrunning of the soft horn. In this score system, most benign footrot cases score 1 or 2, with some allowance for scores of 3. Intermediate footrot in a cohort is defined when 1% to 10% of the cohort have a score of 4. Virulent footrot is defined by greater than 10% of the cohort with a score of 4. It has been suggested that the scoring system may not always be reliable because the severity of disease can be influenced by climate. However, a large field study in Australia found that a cohort of sheep with scores defining intermediate footrot maintained that clinical classification when moved to a climate that would have promoted the development of more severe disease. Evaluation of the repeatability of scoring systems has found that scoring is usually consistent within the same observer, but that differences can arise between observers through observer bias and different observer thresholds.[15,16]

Symptomless Carriers

Symptomless carriers may be affected for periods of up to 3 years. Most such animals have a misshapen foot, and a pocket of infection beneath underrun horn can be found if

the foot is pared. A less common form of the chronic disease is an area of moist skin between the claws without obvious involvement of the claw.

Goats

Footrot is associated with *D. nodosus* and is manifested by severe interdigital dermatitis. There may be some separation of the skin–horn junction at the axial surface, but the disease is less invasive, and there is much less underrunning of the horn of the sole or the abaxial surface of the foot compared with sheep.

Cattle

Infection with *D. nodosus* is also associated primarily with a severe interdigital dermatitis, and there may be lameness. There is fissuring and hyperkeratosis of the interdigital skin, with pitting and erosion at the skin–horn junction in the cleft. There is also fissuring, pitting, and erosion on the horny bulbs of the heel. There may be underrunning at the heel, but it is usually minimal.

CONTAGIOUS OVINE DIGITAL DERMATITIS (CODD)

CODD is a relatively new disease described in the United Kingdom and is still poorly understood.[17,18]

It is manifest with severe, rapidly spreading lameness and is more common in adults than lambs. Commonly there is a history of poor response to conventional methods of footrot control. The initial lesion is a proliferative or ulcerative lesion at the coronet, with subsequent extensive underrunning of the hoof horn and, in some cases, complete separation of the hoof. Interdigital lesions are absent. It may affect only one claw on one foot. Spirochetes similar to the *Treponema* isolates from bovine digital dermatitis are associated with CODD lesions, but these are also recovered from heathy feet.[19]

Fusobacterium necrophorum and *Dichelobacter nodosus* may also be present in some flocks. Their contribution to CODD is unclear, although vaccination against *D. nodosus* had a mild protective effect against new CODD infections (32% compared with 62% against footrot).[18]

Response to formalin and zinc sulfate footbaths is poor, but the disease responds to long-acting parenteral amoxicillin.[17,18] Topical application of lincomycin and spectinomycin solutions has also been used.

CLINICAL PATHOLOGY AND NECROPSY FINDINGS

In countries that do not have a large sheep industry, identification of *D. nodosus* in most laboratories is made by examining an air-dried smear of exudate, taken from underneath some underrun horn at the advancing edge. Smears can be stained with Gram stain or a fluorescein-stained antibody.

In countries with lager sheep industries and where footrot is more common, culture of *D. nodosus,* examination of protease type, and the use of highly sensitive PCR tests are undertaken. PCR tests can be used to detect gene sequences and identify particular strains and are useful where eradication from flocks or areas is the aim.[20,21] Gene probes and nucleotide sequencing, to differentiate virulent from benign strains, are also used in regions with eradication programs and in epidemiologic studies.

The two most commonly used protease tests are the gelatin gel and elastase protease thermostability tests. A comparison of tests, using more than 2800 isolates collected from 12 flocks in southeastern Australia, found that 91%, 64%, and 41% were classed as virulent by the gelatin gel, elastase, and *intA* PCR tests, respectively.[19] The latter tests for an inserted genetic element that is unrelated to protease, and it was developed as a further test for cases where a gelatin gel test indicated a virulent *D. nodosus* isolate but this was inconsistent with a field assessment of benign footrot.[22]

Serum antibody develops as early as 2 weeks after natural infection, and the level obtained is proportional to the severity of the early clinical disease. The antibody response is not long lasting, falling to pre-infection levels within a few months after resolution of the foot lesions. An ELISA for serologic detection of infected sheep has some value for diagnosis of flock infection, but it lacks specificity and is inaccurate in older sheep and so is not routinely used.

Necropsy of sheep for diagnosis of footrot is not needed.

DIFFERENTIAL DIAGNOSIS

Diagnosis of virulent footrot is clinical, is based on a whole-flock approach, and postmortem examination is not necessary.

Because of the rigorous control measures required sometimes by law to control or eradicate infectious footrot of sheep, it is imperative that the diagnosis be made with great care. The greatest problem is in the identification of carrier sheep in the nontransmitting periods. A number of conditions may be confused with footrot, especially when they occur under the same environmental conditions (Table 15-4).

- **Foot abscess**—a major differential and can be present in several sheep in a flock at the same time. It usually affects only one foot, is not contagious, and is characterized by extensive suppuration. The abscess occurs in a single claw on the foot, and there is obvious local heat and pain on palpation.
- **Contagious ovine digital dermatitis**
- **Shelly toe**—the name given to a condition where there is separation of the wall of the foot in Merino sheep and occasionally in other breeds on improved pasture. The abaxial wall of the hoof separates from the sole near the toe, and the crevice formed becomes packed with mud, gravel, and manure. The hoof in the region is dry and crumbly. The cause is not known but it is probably a form of laminitis.
- **Suppurative cellulitis**—associated with *Fusobacterium necrophorum,* commences as an ulcerative dermatitis of the pastern above the bulb of the heel and extends up the leg to the knee or the hock and more deeply into subcutaneous tissues.

Other diseases with foot lameness include:

- Contagious ecthyma
- Bluetongue
- Foot-and-mouth disease
- Ulcerative dermatosis
- Strawberry footrot
- Laminitis
- Lameness associated with *Erysipelothrix insidiosa,* and occurring after dipping

TREATMENT AND CONTROL

The time-honored method of treatment of footrot has been the application of topical bactericidal agents to the foot. These agents are most effective early in the transmission period, before any extensive underrunning of the horn. When there is underrunning of the horn, the underrun horn must be removed so as to expose the infection to the topical agent. This approach has been used successfully for treatment, control, and eradication purposes. However, it requires extensive paring of affected feet, which is labor intensive, time consuming, and distressing to both the operator and the sheep. Consequently, paring is now recommended mainly for diagnosis, and treatments usually minimize the need for extensive paring of the feet. These include the use of topical zinc sulfate, the use of parenteral antibiotics, and the recognition of vaccination as an adjunct to treatment and a strategy for control.

Where eradication of virulent or intermediate footrot from a flock is the aim, control measures are usually applied during the periods favorable for transmission. This reduces the number of infected sheep that have to be treated more intensively once transmission is reduced or negligible.

Topical Treatment

In general, parenteral treatment with antibiotics, without paring of the feet, has replaced topical antimicrobial treatment of individual or small numbers of sheep. To be reasonably effective most topical treatments require that all underrun horn be carefully removed so that the antibacterial agent can come into contact with infective material. This necessitates painstaking and careful examination and paring of all feet because as incomplete paring will leave pockets of infection. With severely underrun feet, it is impossible to expose all of the underrun areas without

Table 15-4 Differential diagnosis of lameness accompanied by foot lesions in sheep

Disease	Epidemiology	Foot lesions	Other lesions	Other clinical signs	Response to treatment	Diagnostic microbiology
Infectious footrot	Serious outbreaks in wet, warm weather. High morbidity. Few chronic lame sheep in dry seasons.	Interdigital dermatitis, underrunning of horn medial aspect of claw. Strong smell of necrotic horn.	—	Very severe lameness. Walk on knees.	To penicillin and streptomycin, erythromycin excellent.	*Dichelobacter nodosus* on smear, or fluorescent antibody test
Benign footrot (scald)	High morbidity in wet, warm weather. Disappears with dry weather.	Interdigital dermatitis, no smell, almost no underrunning of horn.	—	Mild lameness.	Not treated.	*D. nodosus* avirulent strains not distinguishable microbiologically
Infectious bulbar necrosis	Adult sheep, usually less than 10% affected. Serious in wet seasons.	Toe abscess usually in front feet. Heel abscess in hindfeet. Swelling, pain, discharge of pus.	—	Very severe lameness.	Good to sulfonamides or penicillin-streptomycin.	*F. necrophonum* and *Actinomyces* (*Corynebacterium pyogenes*)
Contagious ecthyma	Lambs mostly or nonimmune adults. Dry summer.	Raised proliferative lesions with tenacious scabs on coronet skin.	Lesions around mouth almost always.	Rarely lambs have septicemia. Lameness mild only.	—	—
Ulcerative dermatitis	Spread by physical contact at mating. Morbidity usually 20%.	Raw granulating ulcers in interdigital space and on cornet. No pus.	Around mouth and genitalia usually.	Moderate lameness.	—	—
Bluetongue	Insect-borne disease. Variable morbidity.	Coronitis, separation of horn. Are late in syndrome.	Severe erosions around mouth and nasal cavities.	High fever, salivation. Severe lameness and recumbency.	—	Virus isolation
Strawberry footrot	In summer, high morbidity; carrier sheep infect.	Proliferative dermatitis, piled up scabs. Heal in 5–6 weeks. Coronet to knee or hock.	—	No itching or lameness.	—	*Dermatophilus congolensis*
Foot-and-mouth disease	May present like outbreak of contagious footroot.	Vesicles at coronary band and skin of interdigital cleft.	Vesicles in mouth.	All ages.	—	Virus demonstration
Infestation with *Strongyloides* or trombiculid mites	Wet summer conditions. Local distribution only.	Nonspecific dermatitis of skin of lower legs.	—	—	Organophosphates for trombiculids.	Parasites in scrapings

causing hemorrhage because it may be necessary to remove all of the sole and the wall of the claw. Very sharp instruments, including a knife and hoof secateurs, are needed to do the job properly, and they should be disinfected after each use. The parings should be collected and buried or burned. Sheep restraint cradles make the task of paring safer, more accurate, and less arduous for the operator.

With small numbers of sheep, topical treatment may be applied by brush, spray, or aerosol. Topical treatments are likely to be washed off the feet, and thus their efficacy under wet conditions is inevitably reduced. Local applications include chloramphenicol (10% tincture in methylated spirits or propylene glycol), oxytetracycline (5% tincture in methylated spirits), cetyltrimethyl ammonium bromide or cetrimide (20% alcoholic tincture), zinc sulfate (10% solution), copper sulfate (10% solution), and Dichlorophen as a 10% solution in either diacetone alcohol or ethyl alcohol.

Chloramphenicol is prohibited for use in food animals in many countries. It is also expensive, but it is reasonably effective under both wet and dry conditions. Oxytetracycline must be used as a 5% tincture for optimum results and is not as efficient as chloramphenicol under wet conditions, but it gives reasonable results when the weather is dry. Cetrimide is a relatively cheap product and appears to be as effective as chloramphenicol under all conditions. It is likely that in different countries, with different climates and environmental conditions, the efficiency of particular treatments will vary. When only a few sheep are affected, bandaging may help maintain local concentrations of the topical preparation.

Footbathing for Treatment and Control

Footbathing is a more practical approach to topical treatment and is used for control during transmission periods when dealing with large numbers of sheep. All sheep should be footbathed, but it is good practice to divide the flock into affected and unaffected mobs or groups by examination before the initial footbathing, then graze them separately following footbathing to minimize subsequent infection of uninfected sheep.

After several footbaths and inspections the majority of the flock should be free of infection, and the residual infected sheep are culled.

Preparations suitable for footbathing include 10% zinc sulfate, with or without a surfactant to aid wetting, 5% formalin, or 5% copper sulfate. Regardless of the agent used, it is recommended that the sheep be kept standing on concrete, wooden slats, or dry ground for 1 to 2 hours after treatment, although this may be logistically difficult with large flocks.

The relative merits and disadvantages of the various preparations used are as follows.

Zinc Sulfate Solution (10% to 20%)

Zinc sulfate solution is as effective as formalin, is more pleasant to use, and is generally the preferred topical chemical for the treatment of footrot. Its ability to penetrate the hoof horn is enhanced by the addition of the surfactant sodium lauryl sulfate to the footbath solution. Significant cure rates can be achieved without prior paring, which removes a significant labor cost from the treatment and control of the disease.

Cure rates, without paring, are higher in sheep that have moderate rather than severe lesions in their feet. Some paring of chronically affected, overgrown feet may be required to allow the treatment access to pockets of infection in the anterior aspects of the sole and also of feet that have underrunning that has progressed to the abaxial area of the digit. Sheep are stood for 1 hour in a footbath containing a 10% to 20% zinc sulfate solution with 2% sodium lauryl sulfate with sufficient depth to cover the coronet. The treatment is repeated in 5 days, then after a further 21 days the sheep are individually examined to determine their status and retreated or culled, depending on the strategy of treatment and control in the flock. Zinc sulfate footbathing can provide protection to the foot against reinfection for periods of at least 2 weeks and can be used effectively during periods of active spread of the disease. Repeated daily footbathing (10 min each day for 5 days) in a zinc sulfate solution with surfactant has eradicated (as opposed to controlled) virulent footrot in sheep associated with some strains but was ineffective against a strain that produced severe underrunning.

Thirsty sheep that drink from the footbath may die of acute zinc poisoning, and contamination with zinc can defoliate pasture at the exit of the footbath.

Formalin Solution (5%)

Formalin solution does not deteriorate with pollution but causes extreme discomfort to sheep that have heavily pared feet. Consequently, its use for sheep with severe lesions is discouraged on humane grounds. The feet of the sheep must be pared and all infected areas exposed before treatment. Formalin is unpleasant to work with in enclosed areas and has toxicity for humans, and its use may be banned in some countries for this reason. Sheep should be passed through the footbath every 1 to 4 weeks during periods of high risk for transmission.

The use of solutions containing more than 5% formalin, footbathing at intervals of less than 1 week, or prolonged footbathing may cause irritation of the skin. Farmers can be neglectful in maintaining proper concentrations of formalin in footbaths, and frequent use of the bath combined with hot weather can result in a concentration of 30% formalin. Such concentrations cause extensive cellulitis around the coronets, and a high proportion of animals may be so badly affected that they need to be destroyed. The hoof horn also becomes hardened and deformed. The safest precaution is to empty the footbath and prepare a new mixture.

Copper Sulfate Solution (5%)

Copper sulfate solution colors the wool, deteriorates with pollution, corrodes metal, and may cause excessive contamination of the environment with copper. The feet of the sheep must be pared and all infected areas exposed before treatment. Copper sulfate footbathing appears to harden the horn, which can be an advantage but also a disadvantage if further paring is required at a later date. A patented copper salt preparation (not copper sulfate) has reasonable efficacy without the disadvantages of copper sulfate.

Antibiotic Treatment

Footrot can be treated with antibiotics without the necessity of paring of the feet. Treatment is considerably more effective if done during dry periods and when the sheep are kept on dry floors for 24 hours after treatment, because in wet conditions the concentration of antibiotic at the tissue level is much reduced. In conditions are unfavorable for eradication, such as in the United Kingdom, prompt treatment of lame sheep with parental antibiotics is associated with a significantly lower prevalence of lameness compared with farmers who treated by foot-paring and applying topical treatment (<2% compared with 9%).[23,24]

D. nodosus is susceptible in vitro to penicillin, cefamandole, clindamycin, tetracycline, chloramphenicol, erythromycin, sodium cefoxitin, tylosin tartrate, nitrofurazone, and tinidazole and has the least susceptibility to sulfonamides and the aminoglycosides. However, in vitro tests may have little relevance to field application because of differences in the penetrance of antibiotics to the affected part of the foot.

Antibiotics and their dosage shown to be effective against virulent footrot are presented in the accompanying box. Many of these treatments are "off label," and some are not approved for use on sheep in some countries. Choice of antibiotic will be influenced by the withholding period required before sheep culled because they are not cured can be sent to market. Use of lincomycin/spectinomycin in sheep has precipitated severe outbreaks of salmonellosis in some flocks.

TREATMENT AND CONTROL

Treatment:

- Penicillin/streptomycin (single IM dose of 70,000 U/kg procaine penicillin and 70 mg/kg dihydrostreptomycin) (R-1)
- Erythromycin (single IM dose of 10 mg/kg) (R-1)
- Long-acting oxytetracycline (single IM dose of 20 mg/kg) (R-1)
- Lincomycin/spectinomycin (single SC dose of 5 mg/kg lincomycin and 10 mg/kg spectinomycin) (R-2)
- Gamithromycin (single SC dose of 6 mg/kg) (R-2)[25]
- Long-acting amoxicillin (single IM dose of 15 mg/kg) (R-2)[18]

Control:

- Multivalent or autogenous mono- or bivalent vaccination (R-1)

Australian studies with large numbers of sheep have demonstrated cure rates of approximately 90% using oxytetracycline, erythromycin, and lincomycin/spectinomycin, and slightly less for penicillin/streptomycin. Following treatment, sheep are kept in a dry environment for 24 hours, such as a wool shed, then moved to a "clean" dry pasture and inspected 3 to 4 weeks later. At this time sheep that are still clinically affected (i.e., not cured) are culled.

Reinfection will occur in footrot spread periods; thus, in general, the use of antibiotics for control of footrot should be confined to the summer period when there is reduced or no spread. Cure can occur even in severely affected sheep, and extensive paring before treatment does not improve cure rates. Cure rates fall to 60% if sheep are in a wet environment following treatment, although cure rates are improved slightly if sheep are footbathed at the time of antibiotic administration.

In naturally infected sheep on 10 farms in southern Germany, significantly higher cure rates were recorded 3 weeks after treatment with gamithromycin (94%) compared with oxytetracycline (79%), although this study involved only 20 sheep per farm.[25] Antimicrobial resistance has been reported in anaerobic bacteria isolated from ovine footrot,[26] and all farms had used oxytetracycline in topical applications for at least 3 years. Consequently, a decreased susceptibility to oxytetracycline may have contributed to this result.

Antibiotics are particularly valuable for the treatment of late-pregnant sheep that develop footrot, where more prolonged yarding for footbathing, paring, and topical treatment could lead to problems such as pregnancy toxemia. Antibiotics have no role in the prevention of footrot, but a combination of vaccination and antibiotic treatment can increase cure rates, especially in areas that have extended transmission periods and so are not well suited to eradication programs.[18]

Vaccination

Vaccination against footrot can significantly increase short-term resistance to infection and is an important component of control strategies, especially in circumstances where climate and management practices make other control strategies difficult to apply. Vaccination also shortens the clinical course in infected sheep and can be used as a treatment strategy. In neither case is vaccination 100% effective.

Pilus antigens are the major host-protective immunogens and confer protection against challenge with homologous strains. Immunity is associated with circulating antibody, but high levels of pilus-specific circulating antibody are required for adequate diffusion into the epidermis and protection against the disease. There is a positive correlation between antibody titer and footrot resistance in the first few months following vaccination. Immunity can be passively transferred with gammaglobulins from immunized sheep to naive recipients and from vaccinated ewes to their lambs via colostrum to provide protection for the first 8 weeks of life.

Vaccines must contain adjuvants for an adequate antibody response, and vaccination with oil-adjuvant vaccines is accompanied by significant local reaction, including local swelling at the injection site and abscessation in a proportion of animals. This reaction is more severe in British breeds than in Merinos. In milk goats and sheep, vaccination can result in a significant drop in milk production. The potential gains from vaccination need to be weighed against this effect in a decision to use vaccination as a method of control rather than other control procedures.

Multivalent Vaccines

Commercial multivalent vaccines have contained up to 10 strains of *D. nodosus* representative of the most common serogroups associated with footrot. The extent to which these vaccines will give protection or promote earlier cure depends on the relationship of the vaccine pilus types to those associated with the footrot problem. Vaccine failure is generally attributable to the occurrence of footrot associated with strains of the organism not present in the vaccine or for which there is no cross-protection, and to individual animal variation in response. It is now recognized that there is a limitation to the number of strains that can be incorporated in current vaccines because of antigenic competition. Mixing different *D. nodosus* fimbriae in vaccines may lead to inadequate host responses to individual antigens, and an alternative approach is to identify *D. nodosus* strains present in a given geographic region, enabling the development of optimized and localized strain-specific vaccines.[5,27-30]

Field trials have shown a wide variation in the therapeutic effect of multivalent vaccination, with a reduction in footrot incidence varying from 27% to 54% in sheep in which there was no routine foot care to 69% to 91% in flocks in which vaccination was coupled with routine foot care such as trimming and footbathing. The effect is to reduce the incidence, severity, and duration of the infection. The improvement seems to be as a result of accelerated healing of the lesions with some protection against reinfection. For optimum effect, two vaccinations are required, and the duration of this effect depends on the adjuvant and the breed of sheep. Even so, the duration of the protection is limited to 4 to 12 weeks in most studies. It can be very effective in control when coupled with a culling policy of sheep that remain clinically infected.

Whereas vaccination is of value for control of an existing flock infection, it may not be economic to use vaccination as a strategy to prevent infection of a footrot-free flock. The use of footrot vaccines may be prohibited in areas where there are footrot eradication programs.

Mono- and Bivalent Vaccines

The use of vaccines targeting only the strains of *D. nodosus* present was first tested in 40 flocks in Nepal with a recombinant fimbrial vaccine against two virulent serogroups. These were vaccinated annually for 4 years, with no virulent footrot detected after the first year of vaccination.[5] Subsequently, a monovalent whole-cell vaccine was used for 2 years in a chronically infected flock in Bhutan, and footrot was not detected after the first year of vaccination.[27] Further trials were conducted in two Australian flocks.[28] In the first, the prevalence of infection was reduced from 44% to 0.5% within 4 months of a monovalent vaccination, and no cases were detected 16 months later. In the second, a bivalent vaccine reduced the prevalence from 8.5% to 0.3% after 6 months, with no cases detected 18 months after vaccination. In both cases a few sheep that were not fully cured within 6 to 12 weeks of the second dose of vaccine ("nonresponders") had to be culled from each flock.

Where multiple virulent serotypes are present, sequential vaccination with specific mono- or bivalent vaccines has been demonstrated to be an effective strategy.[29] This was undertaken after antigenic competition was demonstrated when bivalent vaccines were administered concurrently, but not when given 3 or more months apart.[29] Virulent footrot was eradicated from 5 of 12 commercial flocks that had 3 or less serogroups at the start of the study.[5,29] Where one or two serogroups were present, there was a rapid reduction in prevalence. However, where multiple serogroups were present, additional rounds of vaccination with different bivalent vaccines were given at 1-year intervals.[29] This controlled but did not eliminate all strains of virulent footrot in the remaining trial flocks, and so shortening the intervaccination interval was proposed as a means of accelerating this program.[5,29,30]

Summary of Control Procedures in Infected Flocks

The objective of control programs in a footrot-infected flock is to maintain the lowest possible prevalence of disease by reducing the incidence of new infections and preventing the development of advanced lesions. This is achieved most cost-effectively through strategies that are based on whole-flock control, with minimal need for handling of individual animals. This less-labor-intensive approach is most likely to be adopted by sheep owners and includes routine footbathing, with or without vaccination, during transmission periods. Sheep that are affected with virulent footrot can also be treated with parenterally administered antibiotics or culled, depending on the relative proportion affected. The exact timing of these operations will vary by country and the prevailing climatic conditions.

Genetic Selection

Whereas there are breed effects on susceptibility and an apparent high heritability for resistance, genetic selection for resistance has not been used in control programs on farms. Resistance can be determined by direct challenge of a candidate ram, which is undesirable in ram-breeding flocks, but antibody response to vaccination cannot be used as a surrogate.

ERADICATION

Eradication of virulent footrot is a desirable but not always feasible objective. The simplest form of eradication is destocking (culling) the whole flock or just those mobs affected with virulent footrot. This assumes that it will be possible to restock with sheep that have a high degree of assurance of not being infected with virulent footrot, but this is not always the case. Eradication can also be achieved through treatment and control programs, especially in climates where the transmission periods are shorter. Conversely, eradication is more difficult where rainfall is heavy and pastures remain moist for most of the year.

Area eradication of virulent footrot is more challenging, task but has proceeded satisfactorily in several regions in Australia and in Norway.[31,32] In the Australian state of New South Wales, choice of eradication strategy was influenced by flock size, with destocking more often chosen for smaller flocks (those less than 500 sheep). Time spent in quarantine was considerably shorter when specialist contractors were used to inspect and treat sheep and longest when footbathing was the main eradication option chosen.[31] In Norway, virulent footrot has been eradicated from about 70% of the flocks in which this was attempted.[32]

Currently the eradication of benign footrot is not justified economically, nor is it possible with existing knowledge because benign footrot strains can be carried in the interdigital skin of asymptomatic sheep.

The principles for successful eradication from a flock have been described as follows:[5]

1. Correct diagnosis of the form of footrot present in the flock
2. Knowledge of seasonal trends and patterns of transmission in that environment
3. Ability of the operator (or contractor) to recognize footrot in its different forms
4. Acceptance that eradication is a costly and time-consuming investment
5. Understanding that in flocks with a high initial prevalence, it may take 2 or more years to eradicate the disease
6. Acceptance that eradication should only be attempted if the flock can protect itself from reinfection, either from neighboring flocks or introduced sheep

Further, eradication programs are based on the following facts:

1. *D. nodosus* persists in the flock in infected feet.
2. Infection in the foot can be detected and the infected sheep cured or culled.
3. The organism does not persist in pasture for long periods and does not transmit in dry periods.

Paddocks kept free of sheep for 14 days can be considered free of infection. If all infected animals are culled or cured and infection removed from the pasture, eradication is achieved. Eradication of the disease should be undertaken during a dry summer season, but active measures must be taken to reduce the incidence of infection and spread during the transmission period in the preceding spring. Regular footbathing, at intervals of 1 to 4 weeks, and possible vaccination are usually parts of this strategy.

In the eradication phase during the nontransmission period, all feet of sheep are examined, and affected or suspicious sheep are segregated. When examinations are carried out during dry weather, the feet are likely to be hard and the disease at a quiescent stage. In such circumstances minor lesions may be missed, necessitating careful "diagnostic" trimming and examination of all feet. Clean sheep are run through a footbath (10% zinc sulfate or 5% formalin) and put into fresh fields, whereas the affected sheep are isolated and treated with antibiotics and/or footbathing. Sheep that do not respond may be treated intensively, for example, with an additional antibiotic treatment or two footbathings for 1 hour in 10% zinc sulfate, but preferably should be culled. The apparently clean mob should be reinspected at least twice more during the nontransmission period to ensure these sheep are in fact not infected. Eradication programs often fail because too much effort is invested in trying to cure the infected sheep rather than reinspecting the clean ones.

In areas where flocks are small and there are insufficient fields to carry out this program completely, it has been found to be sufficient to treat all affected sheep weekly but to put all affected sheep back in the flock and the flock back onto the infective pasture, provided conditions are dry.

Culling is an important strategy in footrot eradication, and if the number of infected sheep is small, immediate culling may be the most economic strategy. The use of autogenous mono-and bivalent vaccines can successfully eradicate virulent footrot, with a dramatic decrease in cases within 3 to 6 months of vaccinating.[27-30] Culling of persistent cases that do not respond to the vaccine is an important part of this strategy.

Introduced Sheep

Most breakdowns in eradication occur because of inefficient examination and treatment or the introduction of affected sheep without first checking that they are free from the disease. Introduced sheep should be run as a separate group from the main flock until they have been proven to be footrot-free following a transmission period. Similar isolation of introduced sheep should also be practiced in flocks free of the disease. This is also an important management practice in flocks that have disease to minimize the risk of introduction of different strains of the organism.

FOOT ABSCESS IN SHEEP

Foot abscess includes two diseases: heel abscess and toe abscess.

HEEL ABSCESS/INFECTIOUS BULBAR NECROSIS

Heel abscess follows damage to the interdigital skin. This may be physical damage from sharp stones or stubble, or from friction produced by overgrown feet, but most commonly results as an extension from ovine interdigital dermatitis into the soft tissues of the heel associated with *Fusiformis necrophorum* and *Arcanobacterium* (*Actinomyces; Corynebacterium*) *pyogenes*. In interdigital dermatitis, the organisms can invade deep into the interdigital skin. The joint capsule of the distal interphalangeal joint is extremely vulnerable to invasion on the axial interdigital area, and this leads to abscessation.

Most flocks experience cases of heel abscess, but the yearly incidence is usually less than 1%. Heel abscess occurs mainly during very wet seasons, as does footrot, but the former is limited largely to adult sheep, especially ewes heavy in lamb, and rams. Interdigital dermatitis and heel abscess are frequently present in the flock at the same time. An increased prevalence in a flock of young rams may be a result of close flocking and increased muddying of pasture because of this high concentration of livestock. Usually only one foot and one claw will be involved, although in severe outbreaks all four feet may become affected. Most commonly, the medial claw of the hindfoot is affected.

In the initial stages the affected digit is hot and painful. There is an acute lameness—the affected sheep holds the foot off the ground while walking. There is swelling and inflammation of the interdigital skin and pain on pressure across the heel. Pressure in this area may result in the discharge of pus from sinuses in the interdigital space. When the phalangeal joints are involved, there is severe swelling at the back of the claw, and the infection may extend to break out at one or more points above the coronet, with a profuse discharge of pus.

Treatment of Heel Abscess

The treatment of foot abscess is by surgical drainage, parenteral treatment with sulfonamides or a combination of penicillin and streptomycin, and the application of a local bandage. Therapy should be continued for several days. Recovery is not rapid. Because of the frequent involvement of the distal interphalangeal joints with heel abscess, treatment with antibiotics without surgical intervention is unlikely to be successful, but some cases heal spontaneously in 6 to 8 weeks.

TOE ABSCESS

Toe abscess is a lamellar suppuration with purulent underrunning of the horn at the toe. It results from damage to the sole, white line, or wall of the foot and is a common sequela to overgrown feet. Most commonly, it involves a digit on the **front** feet. The affected digit is hot, and there is pain on pressure across the sole and toe. There is severe lameness, swelling of the coronet with pain and heat apparent, and usually rupture and purulent discharge at the coronet between the toes. Penetration to deeper structures may also occur.

Treatment of Toe Abscess

The only treatment of toe abscess is by surgical drainage, and the response is rapid. Toe granuloma can be a sequela, but more commonly toe granuloma is a response to overzealous foot paring.

LAMB ARTHRITIS

In the United Kingdom, *Streptococcus dysgalactiae* is a significant cause of outbreaks of arthritis in lambs, especially during the first 3 weeks of life. It occurs more commonly in lambs that are lambed indoors. Affected lambs are lame in one or more legs and are often found recumbent. There is minimal joint swelling in the initial stage of the disease, and for this reason differential diagnoses include nutritional myopathy, swayback, and spinal abscess. Infection is present in any joint but most common in the tarsal and atlanto-occipital joints. Some die with systemic disease and myocarditis. Survivors may be chronically lame.

CHLAMYDIAL POLYARTHRITIS

Virulent chlamydia, including *Chlamydia* (formerly *Chlamydophila*) *pecorum,* can be isolated from the joints and eyes of lambs with polyarthritis.[1,2] Intestinal infection with *C. pecorum* is also common in pastured lambs between 3 and 9 months of age, but it is not associated with clinical disease.

Chlamydial polyarthritis is a common disease of sheep in feedlots in the United States, but the mortality rate is low. The strain associated with arthritis is not common in the United Kingdom, and polyarthritis in the United Kingdom has been associated with a chlamydial strain distinct from *C. pecorum*. Outbreaks of polyarthritis caused by *C. pecorum* have also been reported with increased frequency in 3- to 6-month-old lambs Australia.[2] In sheep grazing pasture the morbidity may be as high as 80%, but deaths are usually less than 1%. PCR testing has demonstrated that mixed infections of *Chlamydophila* are often present in the conjunctivae of sheep, but there is no consistent association with the onset of disease.[2]

In calves, the disease is uncommon but often fatal, and response to treatment is poor; affected calves are often destroyed. The experimental disease in calves begins as chlamydemia, followed by localization in the joints.

The clinical signs in calves and lambs include gross swelling of most limb joints but especially the larger joints, lameness, stiffness, unwillingness to move, recumbency, depression, conjunctivitis, and fever of 39° to 42° C (102° to 108° F). The navel is unaffected, but there may be signs caused by localization of the infection in other organs (e.g., pneumonia, encephalomyelitis, and renal abscess). Clinically, the disease is indistinguishable from polyarthritis caused by other infections such as *Mycoplasma* and *Haemophilus* spp.

Response to treatment with oxytetracycline is variable, and residual effects of infection, such as poor growth and ill-thrift, commonly occur.

CHRONIC PECTORAL AND VENTRAL MIDLINE ABSCESS IN HORSES (PIGEON FEVER)

C. pseudotuberculosis biovar equi has been associated with a high regional prevalence of chronic abscessation in horses in California, Texas, and Colorado and can cause disease in horses in other states.[1] Six phenotypes are recognized on culture, but there is no association between phenotype and clinical form of the disease.[2]

The incidence of the disease is 9.2 per 10,000 horses and appears to be increasing, and this change might be related to climatic changes.[1,3] The disease is most prevalent in Texas (35 cases per 10,000 horses), Colorado (18 per 10,000), and Oregon (12 cases per 10,000), with California reporting 6 cases per 10,000 horses.[1] Within Texas, prevalence of the disease increased from 0.9 in 2005 to 10 cases per 100,000 horses at risk in 2011.[4] There is no apparent breed or sex predisposition and cases occur in horses of all ages, but the majority are adult horses and there are few cases under 1 year of age.[1] Usually, only a single horse on a farm is affected. A small proportion of farms have endemic infection, with a prevalence of disease of 5% to 10% and recurrent infections each year. In some years spread to naive horses results in epidemic disease.

Cases can occur in all months of the year but are most common in dry months in autumn, with a peak prevalence in November, December, and January; internal abscesses are more common in late autumn and January, with a smaller peak in June and July, and ulcerative lymphangitis is more common in March, April, and May.[1,4] There is a variation in the prevalence from year to year, and[1,4] in both Texas and California, years with high prevalence of the disease have been preceded by seasons with higher-than-normal rainfall and conditions that promote high insect populations. Insects, such as horn flies (*Habronema irritans*), that produce a ventral midline dermatitis during feeding may predispose to infection, and the organism has been detected by PCR populations of *H. irritans, Stomoxys calcitrans,* and *Musca domestica.* Feeding of infected house flies (*Musca domestica*) on experimentally induced wounds on the pectoral region caused disease in ponies, demonstrating that house flies are mechanical vectors of infection and can spread the disease to equids.[5] Flies are not the host of the organism, being mechanical vectors only, and the source appears to be soil. *C. pseudotuberculosis* persists and multiplies in a variety of soil types and under a range of environmental conditions.[6] Addition of feces to the soil enhances growth of the organism.[6]

Patterns of spatial and temporal clustering indicate that disease is transmitted directly or indirectly from horse to horse with an incubation period of 3 to 4 weeks.

The disease occurs in a region where caseous lymphadenitis is also common in sheep, although the disease in sheep is usually caused by *C. pseudotuberculosis biovar ovis*. Stable hygiene, insect control, and isolation of infected horses might aid in control.

Disease caused by *C. pseudotuberculosis* occurs in captive elk, although the biovar involved is not reported.[7]

External Abscesses

The most common form of the disease is an external abscess (97% of reported cases), with internal abscess formation (2%) and ulcerative lymphangitis (1%) being much less common manifestations of infection.[1] However, the most common clinical manifestation of infection varies geographically, with California reporting 49% of cases as being internal abscesses and ulcerative lymphangitis being most common in Texas (96%).[1] These occur in a variety of areas on the body, but in the majority of cases they are in the pectoral, axillary, inguinal, or ventral midline regions.[8] Affected horses are usually markedly lame. The abscesses can reach a diameter of 10 to 20 cm, with a surrounding area of edema, before they rupture 1 to 4 weeks later. Clinical signs include local swelling, lameness, pain on palpation, ventral edema, reluctance to move, midline dermatitis, fever, and depression in the early stage, followed eventually by rupture of the abscesses.

Treatment of external abscesses is by hot packs to encourage opening and by surgical drainage and lavage. Ultrasound can aid in the detection of deeper abscesses. NSAIDs can be used to control swelling and pain. Recovery rates are excellent and are not improved by antimicrobial therapy.

Internal Abscesses

Internal abscesses occur at a variety of sites but predominantly in the liver and can occur in horses with no external abscessation. The diagnosis should be suspected in horses, in the region and the season, with a clinical history of external abscess, fever, anemia, and colic and laboratory evidence of leukocytosis with neutrophilia, anemia, hyperglobulinemia, hyperfibrinogenemia, and elevated activity of hepatic-associated enzymes.[8] Abdominocentesis in most cases shows an elevated protein and nucleated cell count, and the organism can be cultured.

Treatment is with antimicrobial therapy, but the case-fatality rate is high if the abscess cannot be drained. *C. pseudotuberculosis* is sensitive to concentrations of most common antibiotics achieved in vivo with MIC90 values for chloramphenicol less than or equal to 4 µg/mL, enrofloxacin less than or equal to 0.25 µg/mL, gentamicin less than or equal to 1 µg/mL, penicillin at 0.25 µg/mL, rifampin less than or equal to µg/mL, tetracycline less than or equal to 2 µg/mL, trimethoprim-sulfamethoxazole (TMS) less than or equal to 0.5 µg/mL, ceftiofur at 2 µg/mL, and doxycycline less than or equal to 2 µg/mL.[9]

The value of a **synergistic hemolysis inhibition serologic** test in diagnosis has been examined. The test was useful for detecting internal infection in horses that did not have external abscesses (likelihood ratio of 2.98 [95% CI 2.2 to 4.1] with a titer ≥ 512), but it was not useful when horses had external abscesses.[10]

An autogenous vaccine has given protection against experimental challenge, but in field trials, there has been no difference in the incidence of infection between vaccinated and control horses.

Otitis media interna, meningitis, and unilateral orchitis are documented forms of the disease.[11,12] *C. pseudotuberculosis* is also recorded as a cause of pericarditis and pleuritis in a horse and in association with suppurative facial dermatitis following trauma.

INFECTIOUS POLYARTHRITIS (GLÄSSER'S DISEASE, PORCINE POLYSEROSITIS, AND ARTHRITIS)

SYNOPSIS

Etiology *Haemophilus parasuis* (HPS) rarely a primary pathogen in respiratory disease.

Epidemiology Common in pigs postweaning to 4 months of age. Sporadic outbreaks. Environmental stressors are risk factors. There may be significant losses.

Signs Sudden onset of anorexia, dyspnea, lameness, swollen joints, fever, nervous signs, and death. Three types: hyperacute (death), acute, and endemic. Glässer's disease not yet seen in wild boar.

Clinical pathology Culture organisms from serous membranes.

Lesions Peritonitis, pleuritis, synovitis, meningitis.

Diagnostic confirmation Culture organism and a variety of new techniques.

Differential diagnosis Erysipelas, mycoplasmal and streptococcal arthritis, other serositis; also *Actinobacillus pleuropneumoniae* infection, vitamin E deficiency, *Escherichia coli*, and *Actinobacillus suis*.

Treatment Antimicrobials.

Control Minimize stressors at weaning and in nursery barns. Limited commercial vaccines.

Glässer's disease is a contagious disease of young pigs characterized by arthritis, pericarditis, pleurisy, peritonitis, and meningitis. In a study in the United Kingdom, it was found to be common in herds with a history of chronic respiratory disease.

ETIOLOGY

Initially, the agent was thought to be *Haemophilus influenzae* suis, but it is now known to be *Haemophilus parasuis* (HPS). Now recognized as one species, it is, however, extremely pleomorphic. It is a gram-negative bacterium that requires V factor for its growth. A modified classification of 15 major serotypes has been achieved, although many are still untypeable. The current serotyping is based on reactions between antisera and surface antigens, which leads to a classification based on 15 serotypes. Serotyping originally used a GID test, but this has been replaced by indirect hemagglutination assay (IHA), which has increased the proportion of typeable strains from 60% to 80%. The study of these polysaccharides is under way.[1-3]

Most studies have shown that serotypes 4 and 5 are the most common strains involved in Glässer's disease. In many instances, the serotype is not an indicator of virulence because different strains within one serotype may have a different virulence. HPS, as with other *Haemophilus* spp., has an affinity for the mucosa of the oropharyngeal and upper respiratory tract. HPS can be isolated from the nasal cavity, tonsillar area, and trachea. Several strains may be found in the same nose, and there may be several types in the same herd.[4] HPS isolates are genetically heterogeneous within the same serovar and between serovars. The gene content and diversity of the loci encoding the biosynthesis of the capsular polysaccharides of the 15 serovars have recently been described.[5]

EPIDEMIOLOGY

The colonization of the respiratory tract is rapid, with 50% of pig noses colonized by 7 days and 100% by 60 days,[4] and there is a turnover of the strains.

Most countries have different distributions of serotypes. In the United Kingdom, 5 is the most common, followed by 4 and 7 in equal numbers, and the rest are largely nontypeable. In Denmark, 5 is followed by 13 and 4 and then the nontypeable.

It may be a true commensal organism in the upper respiratory tract. It is responsible for severe polyserositis in young pigs, and it may also occasionally cause arthritis in older pigs and the individual sow. The organism,

like the others with a similar name, *Actinobacillus suis* and *Streptococcus suis,* has been called one of the "suis-cides" of pigs, which are responsible for considerable economic loss in high-health herds and herds that practice very early weaning. HPS is also commonly isolated from lungs with lesions of enzootic pneumonia.

Pigs infected with virulent isolates of HPS can remain healthy and serve as reservoirs for transmission to naïve pigs, and heterologous protection is possible.[6]

Although the disease occurs worldwide, reports used to be rare and mainly from Europe. However, since the onset of separate-site production and the occurrence of porcine reproductive and respiratory syndrome, virulent forms of swine influenza, and diseases associated with porcine circo virus type 2 (PCV-2), HPS has become one of the most common of the so-called secondary infections. It is a significant contributor to the porcine respiratory disease complex (PRDC). When it first appears in naive or specific-pathogen-free herds, it may be a common cause of sudden death; such cases may be numerous, and these situations it also affects younger animals. When the disease becomes endemic, it may affect older animals, with fewer sudden deaths but more chronic polyserositis. The disease has also been observed in Australia, the United States, Canada, and the United Kingdom. The disease accounted for less than 1% of total mortalities of pigs submitted to veterinary diagnostic laboratories over an 11-year period in Ontario. However, the disease was the second most common cause of mortality in test station boars. In a survey of 19 excellent specific-pathogen-free pig herds, 16 were positive, and the average number of culture-positive pigs per herd was 6/10 for positive herds.

It is probably spread by aerosol and certainly by nose-to-nose contact. The disease occurs as sporadic outbreaks—usually in weanling to 4-month-old pigs that have been recently chilled, transported, weaned, or moved to different pens. The onset is sudden, with several pigs in the group affected, and occurs within 2 to 7 days of the initiating stress. Occasionally, it causes arthritis in older animals, or even sow herds. The case-fatality rate is high in untreated pigs. Acute myositis in primary specific-pathogen-free sows has been associated with HPS.

Little is known of the method of transmission of the disease. The causative organisms are facultative pathogens and can be frequently isolated from pig lungs diseased from other causes, even though they are generally not present in normal lungs. It is probable that a respiratory carrier state does exist and that invasion with subsequent septicemia and polyserositis is initiated by stress situations in young pigs that have lost maternal immunity but have not yet gained active immunity. Piglets probably acquire the infection soon after birth, but maternal antibody protects them from clinical disease until they are 2 to 4 weeks of age. Animals that are weaned early are likely to have this infection, so the supposition is that most pigs acquire the infection at or immediately after birth. *H. parasuis* has been found in the tonsil using IHC and EM.

There are several pathogenic serovars of HPS. Serotypes 3, 6, 7, 8, 9, and 11 are considered to be avirulent; 15 more pathogenic; and 1, 4, 5, 10, 12, 13, and 14 virulent. However, this pattern cannot be considered permanent because genes can be shared, and in any case up to 50% of isolations are considered nontypeable. In the United States and Canada, 15.2% were classified as nontypeable, 26.2% in Germany, 29.3% in Spain, and 41.9% in Australia. In a particular pig herd, many strains can be isolated, but in most cases, one or two strains predominate. In many herds the nontypeable outnumber the typeable. Of seven reference strains examined, only serotypes 1 and 5 were pathogenic, and the seven strains have common antigenic determinants. Within specific-pathogen-free herds, many herds have common strains; no strains are common to both conventional and specific-pathogen-free herds, which is a reflection of little or no movement of pigs between these types of herd. Specific-pathogen-free pigs are often free of this organism and are highly susceptible to the infection, even at several months of age, if they are mixed with conventionally raised pigs that may be infected. Outbreaks with rapid spread and high mortality have been reported in specific-pathogen-free pigs. It has been suggested that the causative bacteria are common in most herds and that the disease arises only when pigs from uninfected herds are introduced to a contaminated environment, especially if they have been exposed to environmental stress during transport. When infection is introduced into a previously noninfected herd, the disease may act as a contagious disease until herd immunity is developed or the infection eliminated. Recently it has been suggested that the nasal cavity strains may be nonpathogenic and form a completely different population to the pathogenic strains. Serotypes from nasal and tracheal cultures were shown to be similar in one study. They found that there was a lower level of colonization in the litters of the young sows. The genetic diversity of the strains is not well understood. Several serotypes may be isolated from the same herd or even from the same pig. High-pathogenicity porcine respiratory and reproductive syndrome virus (PRRSV) has been shown to accelerate the colonization and load of HPS in conventional pigs.[7]

The organism probably does not survive outside the host, and therefore transmission is direct, with most of the transmission occurring during birth.

PATHOGENESIS

One of the key factors may be that maternal antibody does not last a long time and may be gone by 2 to 4 weeks of age but will last until 6 to 8 weeks if sow antibody titers are high. It is the animals that become infected after their maternal protection has waned that have resulting clinical disease. Serovar 5 is highly virulent when inoculated into specific-pathogen-free piglets at 6 to 8 weeks of age. Bordetella bronchiseptica increases HPS colonization of the nasal cavity. However, it is also said that previous infection with PRRSV has no effect on the occurrence. The severity of the disease increases with the increase in the dose of the organisms.

The nonpathogenic isolates probably only colonize the upper respiratory tract. The pathogens colonize the upper respiratory tract and then descend to the lower respiratory tract by evading phagocytosis[8,9] and by using adhesion factors.[10] The pathogens escape from the respiratory tract,[11] enter the bloodstream, and attach to the endothelial cells;[11,12] they survive because the capsule prevents the killing of the organism.[4] Entrance to the bloodstream is more likely when the animal is stressed or immunity is suspect. The organism then establishes the pathology at the serosal surfaces using hemolysins, proteases, and neuraminidases. The outcome is determined by the innate and adaptive immunity (colostrum, previous exposure, concurrent infections, etc.). The blood cellular immune responses have been described, which suggests that there is an increased trafficking of inflammatory cells.[13] There is a response to iron restriction.[14] The pathogen enters the endothelial cells and induces apoptosis and produces IL-6 and IL-815.[16] The virulent strains survive against the phagocytes and complement system, and the nonvirulent are phagocytosed. HPS acquires iron for growth through the surface receptors.[17]

The precise relationship between protein patterns, serovars, and virulence potential remains to be defined. The major virulence factors and the protective antigens are still largely unknown. Only a small number of organisms in the region of 104 to 106 are sufficient to produce disease. The pathogenesis has recently been described.[15] A new technique called differential display reverse transcription PCR (RT-PCR) has been used to search for virulence factors. The pathogenic HPS may have an outer membrane protein, fimbriae, and lipopolysaccharides; a cytotoxin has yet to be described, but it may be a membrane neuraminidase. The outer membrane protein may be important, and it is iron regulated.[18] Fibrinous meningitis, polyserositis, and polyarthritis are typical. Fatal septicemia can occur spontaneously or following the intraperitoneal inoculation of pigs with HPS. The intranasal inoculation of HPS into cesarean-derived

colostrum-deprived pigs results in a suppurative rhinitis, which may represent an initial event in the pathogenesis of the systemic infection in pigs. After infection with HPS, there was a highly significant rise in radical formation, and monocyte proliferation was reduced. Neutrophils reacted inconsistently. In this experimental study, the CD25+ marker cells were markedly reduced. Experimental infections showed that not all field isolates are pathogenic, and it may be that route of infection and dosage are most important in determining the outcome of infections. In a new study, polyacramide gel electrophoresis (PAGE) typing of HPS and virulence potential based on site were looked at together. PAGE group I had 83.4% of the isolates from the upper respiratory tract (these were mostly of serotype 3 or nontypeable), but of the PAGE group II isolates, 90.7% of all the isolates were from the systemic sites (these are mostly serotypes 1, 2, 4, 5, 12, and 14). It may be that there is also a tropism for some sites because some strains are only found in the brain and others in the pericardium. This means that the systemic sites are the best sites for the identification of pathogenic HPS. Most practitioners have the opinion that the problem is more apparent when there is predisposing viral infection, particularly porcine respiratory and reproductive syndrome (PRRS), swine influenza, or porcine circo virus type 2 (PCV-2). Although most practitioners would say that the prevalence of PRRS-associated HPS infections has increased the natural occurrence of HPS, experimental confirmation is lacking. Only PRRS consistently increased the isolation of HPS from the lung.

On the other hand, both PRRS and *B. bronchiseptica* increase the colonization of the upper respiratory tract by HPS. There is no additive effect here. There is no doubt that the occurrence of the vasculitis plays a part in the pathogenesis.

CLINICAL FINDINGS

The incubation period depends on the strain.[11] Clinical disease occurs because of a mismatch between immunity and colonization by virulent strains. This may be a result of early decline of colostral immunity, later or slow HPS colonization, mixed pig flows, and the purchase of breeding stock that are carriers.

In the naive herd and where specific-pathogen-free animals have entered commercial herds, sudden death may be the only feature. Some people are of the opinion that there may be polyserositic, arthritic, and meningitic forms. A virulent type 10 outbreak has been described.[19] A wide variety of signs may be seen, including fever, depression, and reluctance to move, progressing to prostration, convulsions, and sudden death. The depression is a marked feature. The mortality rate may be high, and many pigs that survive become "poor doers."

The onset is sudden, with a fever, an unusual rapid and shallow dyspnea with noisy lung fields, an anxious expression, extension of the head, and mouth-breathing. There may be a serous nasal discharge, and coughing may occur. Depression and anorexia are observed. The animals are very lame, stand on their toes, and move with a short, shuffling gait. All the joints are swollen and painful on palpation, and fluid swelling of the tendon sheaths may also be clinically evident. In many animals there may be just a single joint affected, which is often the hock. A red to blue discoloration of the skin appears near death. Most cases die 2 to 5 days after the onset of illness. Animals that survive the acute stage of the disease may develop chronic arthritis, and some cases of intestinal obstruction caused by peritoneal adhesions occur. Meningitis occurs in some pigs, particularly when these are naive or where there is an acute onset, and is manifested by muscle tremor, paralysis, and convulsions. Although Glässer's disease can occur in pigs of any age, weanling pigs are most commonly and most seriously affected. In chronic cases, pigs may lose part of an ear as a result of ischemic necrosis. There may be also wasting piglets, which fade and die. In some instances in which there is a severe peritonitis, there may be scrotal swelling as the fluid drains down the tunica vaginalis.

Another type of syndrome of necrosis of the masseter muscles was described in which sows had swollen, cyanotic heads, with HPS isolated from the affected muscles. Purulent rhinitis has also been described.

CLINICAL PATHOLOGY

The disease is essentially a polyserositis and arthritis, and as a result the organism is recoverable from joint fluid and pleural exudate. Material aspirated from joints may be serous, fibrinous, or purulent. It may just be a few fibrin tags that have organized from an initial fibrinous exudate. The disease can be diagnosed serologically on the presence of precipitins in the serum of recovered pigs, and complement-fixing antibody can be detected following infection. But these are not reliable methods. In an experiment in which 183 specific-pathogen-free pigs were given infections, the hemoglobin concentrations and hematocrit fell. Leukopenia developed 1 to 2 days after infection, with leukocytosis later. Any changes in the cerebrospinal fluid were not related to the clinical signs. One of the common findings in HPS infections is vitamin E deficiency, and this is most likely to be as a result of the toxic oxygen radical damage.

NECROPSY FINDINGS

Glässer's disease generally is associated with three main lesions: fibrinous polyserositis and arthritis, signs of septicemia, and toxemia.

In some cases there are no gross lesions, and all that is seen is a small amount of peritoneal fluid or a very thin fibrin strand (tag).

Serofibrinous or fibrinous pleuritis, pericarditis, and peritonitis are usually present, but the exudate is scanty in some cases. Pneumonia may also be apparent. There is inflammation and edema of the periarticular tissues, and the joint cavities contain turbid fluid and discoid deposits of yellowish-green fibrin. A suppurative rhinitis is also possible. A fibrinopurulent meningitis is common. In specific-pathogen-free pigs, the lesions may be minimal, and only successful isolation of the organism permits the differentiation of Glässer's disease from other causes of sudden death. The distinction may be a difficult one because of the fastidious culture requirements of HPS. Eventually, all surfaces are covered with a thick mat of fibrin, and the individual organs may be difficult to recognize. This eventually becomes fibrotic. The spleen and liver may be enlarged.

Histologically, acutely affected serosal surfaces are thickened by neutrophils entrapped in a matrix of fibrin. As these lesions age, fibrous adhesions may develop and lead to chronic pleuritis, arthritis, and pericarditis. Such cases are often culture-negative, even when selective media are used. Most isolates are made from the lungs. Petechial hemorrhages may also be found on the kidney (the so-called "turkey egg," which is not pathognomonic for anything except septicemia in its widest sense, with over 30 agents known to cause it).

Samples for Confirmation of Diagnosis

Bacteriology

The collection of samples from animals that have been dead for several hours is not worth considering even at the best of times and certainly not when HPS is suspected. An acutely affected live pig, freshly autopsied, will give much better results, especially if there is no overheating of the carcass postmortem or subsequent cooling because the organism is temperature-sensitive. Transport media to the laboratory will also be beneficial in recovery rates. It is said that culture of the nasal swabs will be as rewarding as collecting tracheal swabs, but it is likely that the larynx and below are normally sterile. What you isolate from the nasal cavity may then be a commensal population of largely nontypeable species, whereas the trachea harbors the pathogenic forms. Other authors say that they are the same serotypes. These authors have also found that a lower level of colonization was found in the litters of young sows, and a low level of colonization at weaning probably predisposed pigs to clinical disease in the nursery, assuming the presence of a virulent serotype.

Culture swabs from serosal surfaces, including joints and meninges. It is essential

to collect samples from areas that are not enclosed in fibrin. Nasal swabs are more easily collected than tracheal but may indicate a different population of HPS. It is usually said that it is difficult to isolate from fluids but is easier from the lesions. It is necessary to have a fresh pig with no antibiotic therapy. It may also be necessary to use Amies transport medium to preserve HPS on the way to the laboratory.

H. parasuis is a gram-negative rod existing as a coccobacillus to long filamentous chains. There is usually a capsule, but the expression of this is influenced by culture. NAD or V factor is required for growth (chocolate agar or staph streak, and then there is satellite growth). The availability of NAD may determine growth capabilities. After 24 to 48 hours the colonies are small, translucent, and nonhemolytic on chocolate agar.

Histology

Histology includes formalin-fixed brain, synovial membranes, liver, lung (LM). Immunohistochemistry can be used to show the organisms in the cytoplasm of neutrophils and macrophages in the lungs and in the mononuclear cells in the subscapular and medullary sinuses of the lymph nodes. Immunofluorescence was observed on the bronchiolar epithelium in the alveoli and in the lung parenchyma.

Modern techniques have been applied. The results are better if you use both the Angen[20] and Olvera[8] PCR techniques, with few false positives.

Serology

Recently, an indirect hemagglutination test has been described for the serotyping of field isolates. A new indirect hemagglutination technique has just been described, and it is rapid and effective. It is also much more sensitive than the immunodiffusion test.

DIAGNOSIS

The best cases to examine are those that have received no antibiotics and are acute cases. The organism is very likely to die out if subjected to too much heat or cold.

There is a need to have the samples taken from the lesions as quickly as possible, transported to the laboratory quickly in transport media (Amies medium), preferably chilled if overnight transport, and plated as quickly as possible. It requires to be cultured on chocolate agar or blood agar with a staph streak.

Once cultured, strain typing can be achieved. There are 15 strains and many that are untypeable. The relative strain virulence is shown in Table 15-5.

Novel genotyping was first described in 2008, and an improved species specific PCR has been described since.[15] The complete genome of HPS was described.[2,10] Demonstration of HPS requires culture and PCR identification. There is a correlation between clinicopathologic outcome and the typing of HPS field strains.[21]

Table 15-5 Virulence of strains

HPS serotype	Virulence	Effects
1, 5, 10, 12, 13, 14	High	Death within 96 hours
2, 4, 15	Moderate	Severe polyarthritis
8	Low	Mild lesions
3, 6, 7, 9, 11	Nonpathogenic	No signs or lesions

A detailed analysis of diagnostic analyses and the occurrence of strains in the Netherlands is available,[22] in which strains 3 and 10 were not identified. In this study ERIC-PCR and *hsp60* gene typing were also employed because 145 of the strains could not be serotyped.

A multiplex nested PCR has been described[23] that works for *S. suis* and *M. hyorhinis* and HPS. It is extremely useful when samples are negative after isolation and can be used on formalin-fixed and paraffin-embedded tissues as well.

Usually, HPS can be identified by either of two conventional PCR20 tests or by an RT-PCR,[24] but sometimes *A. indolicus* gives a false positive. A RT-PCR for HPS has been validated.[25] However, a recent paper has suggested that it may fail to recognize an HPS strain, so false negatives may be found.[26]

Researchers in China have described loop-mediated isothermal amplification for rapid detection of HPS and found it more sensitive than nested PCR. It appears to be best used for internal organs and tissues because there are many nonpathogenic types of HPS in the respiratory tract.

The first improvement in the diagnosis of HPS occurred with the development of an oligonucleotide-specific plate hybridization assay that could be used on the nasal swabs. The assay detects fewer than 100 cfu/mL in a pure culture and gives a positive result when HPS is present in the ratio of 1 : 103 to 1 : 104 in a mixed culture. The assay is more sensitive than culture for detection of HPS in nasal swabs.

In-situ hybridization will demonstrate a patchy to multifocal distribution of HPS in the lung. A repetitive-element-based PCR (rep-PCR) has been developed, which is a technique that compares very favorably with traditional microbiology. The rep-PCR uses repetitive sequences within the bacterial genome to produce strain-specific fingerprints, allowing comparison and differentiation between *H. parasuis* strains. This enables comparison of these strains and allows the source of virulent strains to be identified.

Another new technique is ERIC-PCR, and this is very successful compared with conventional microbiological techniques. Identification and differentiation of *H. parasuis* using a species-specific PCR with subsequent DNA fingerprinting using the digestion of PCR products using Hind III endonuclease has been described. This restriction fragment length polymorphism (PCR-RFLP) enabled eight patterns to be determined for the nontypeable strains.

Recently, a technique for the computer-based analysis of HPS protein fingerprints has been described that is a considerable improvement on serotyping. It was shown that there is a high genetic diversity within the serovars. At least 12 different strains within the type 4 serovar, and genetic diversity in the other serotypes as well, were described. Nontypeable isolates were divided into 18 genotypes. The major advantage of this technique is that there is no need for isolation, culture, and biochemical identification of the isolates. In addition, all strains can be identified, not just those of certain serotypes. At the moment, there is no direct demonstration of a linkage between PCR-RFLP, OMP patterns, and serotyping and rep-PCR. In a recent study, 32 strains were grouped into six serovars and 11 genotypes. This led to the hypothesis that HPS strains with a similar distribution of repetitive sequences can express different antigens. A lot of work is still required to relate genome classification to the real virulence of the strain.

DIFFERENTIAL DIAGNOSIS

The clinical signs and pathology are not pathognomic because similar pictures can be seen with Escherichia coli, Mycoplasma hyosynoviae, Mycoplasma hyorhinis, Erysipelothrix rhusiopathiae, and Streptococcus suis.

The unusual combination of arthritis, fibrinous serositis, and meningitis is sufficient to make a diagnosis of Glässer's disease, but differentiation from the many similar disease entities apparently caused by other agents can only be confirmed by bacteriologic examination.

The disease may be confused with erysipelas, mycoplasma arthritis, and streptococcal arthritis on clinical examination. Mycoplasmosis is a much milder disease and is manifested principally by the presence of a few unthrifty or lame pigs in the litter just before weaning, rather than an acute outbreak with a high mortality. Differentiation between cases of Glässer's disease with meningitis and the other diseases of the nervous system in young pigs, especially streptococcal meningitis and Teschen disease, may not be possible without necropsy examination.

TREATMENT

Pigs are usually ill with this disease, and thus parenteral treatment is required first. A high

Table 15-6 Antimicrobial resistance in Spain and the UK.[27]

	Spain	UK
Florfenicol	0	0
Penicillin	60	0
Erythromycin	40	0
Tilmicosin	40	0
Enrofloxacin	20	0
Ceftiofur	7	0
Tiamulin	40	3
Ampicillin	57	7
Oxytetracycline	40	7
Trimet/sulpha	53	10
Spectinomycin	23	10
Gentamycin	27	10
Neomycin	33	20

proportion of HPS strains are resistant or multiresistant.[27] In China, over 70% of the strains were resistant to enrofloxacin.[28] Resistance has been reported for penicillin, and certain strains are resistant to tetracyclines, erythromycin, and other aminoglycosides (Table 15-6). This requires attention to the sensitivity patterns of the organism in different countries. If pigs are sick with HPS, then parenteral treatment is a must as the first step. This can be followed by water medication for at least 5 days. It has long been known that ill animals will not eat, but it is currently appreciated that sick pigs do not drink as much as when they are healthy, and therefore there is the tendency to underdose until they are well enough to drink their normal amounts.

Treatment with penicillin, trimethoprim–sulfadoxine, or oxytetracycline is effective in the early stages of the disease.

Tilmicosin can be used for effective treatment because it is concentrated in the macrophages and neutrophils. These can migrate to the site of infection, and therefore there may be higher levels of antibody in the tissue. Long-acting medication can also be useful (tulathromycin, ceftiofur).

CONTROL

It is essential to protect high-herd-health units by not importing new stock into a unit also thought to be free, and vice versa, because both groups can be exposed. Never bring high-herd-health stock into a low-health unit. Multisourcing pigs into a grow-out unit is especially suicidal.

Control of PRRS and PCV-2 is important because HPS is associated with both of these.[29,30] Control is only possible if there is (1) diagnosis of infection, (2) identification of prevalent strains, (3) use of autogenous vaccines, and (4) management of new strains.

There are three main approaches:

1. Prophylactic medication
2. Optimization of pig immunity
3. Management techniques to maximize immunity

IgG antibodies kill HPS via the classical complement pathway.[31,32] It is therefore best to vaccinate piglets before weaning, or the sows to boost maternal antibody, but if you do, then delay vaccinating the piglets until maternal antibody has waned. Always vaccinate the replacement breeding stock.

Avoidance of undue exposure to adverse environmental conditions at weaning is recommended. Avoidance of undue fluctuations of temperature is absolutely essential. Prophylactic dosing at the time of shipping or medication of feed or drinking water on arrival with the previously mentioned drugs may be of value in preventing outbreaks. Feeding a mixture of 3% sulfamonomethoxine and 1% trimethoprim at 160 and 240 ppm for 5 days and challenging with *H. parasuis* at 3 days prevented clinical disease, and bacteria were not recovered. There are resistance genes for tetracyclines and beta-lactam antibiotics.[33] Maternal antibody does not interfere with vaccination of pigs at 1 to 3 weeks of age. Maternal immunity lasts about 20 days, but if the sows are vaccinated, then it may last 60 days.[4]

Humoral immunity is protective against experimental Glässer's disease.[34] A formalin-killed bacterin administered before weaning with two injections at 5 and 7 weeks of age has proved highly effective in preventing the disease. A formalin-killed whole-cell culture bacterin developed in Ontario is effective in protecting 4-week-old pigs against experimental challenge with the organism. A recent trial showed that vaccinating sows at 80 and 95 days of pregnancy with a commercial bacterin containing HPS 2, 3, and 5 was useful in reducing pneumonic lesions and arthritic joint changes in subsequently challenged piglets. Vaccination of piglets seemed to have no effect, and vaccination of the sows seemed to have no effect on the colonization of the nasal mucosa by HPS or on the timing of colonization.

Autogenous vaccines against homologous strains have been shown to work, but vaccination failures do occur. There may be little cross-protection between strains. A new serotype 5 vaccination was described, and the subsequent challenge with serotypes 1, 12, 13, and 14 produced different responses in control pigs.

The vaccines against this bacterium are whole-cell bacterins that are protective only against serotypes 1, 4, 5, and 6.[35] Vaccination has three important components. First, there is the decision of commercial or autogenous vaccination, and this depends on the strains in the field and whether they are in the commercial vaccine. Second, the timing of vaccination should take into account the length of persistence of maternal antibody and the peak of piglet mortality. If this peak is at 2 to 3 weeks, then the sows should be vaccinated. The piglets should then be vaccinated at weaning and 2 weeks later. Third, because sow and piglet vaccination together is not recommended because the sow's vaccination can produce maternal antibody that interferes with the piglet's active immunity, you should make a choice of one or the other. A new departure is the production of a genetically inactivated vaccine, the ghost vaccine.[36]

Recently, the technique of introducing known populations of live HPS to the young piglet shortly after birth, thus allowing a slow rate of acquisition of organisms, has been advocated. All-in/all-out by age is absolutely essential to prevent carry-over of infection, and it is likely that nose-to-nose transmission is important, so solid partitions between different litters may help.

When it comes to disinfection, it has been suggested that chloramine may be useful[37] in deactivating HPS.

ARTHRITIS RESULTING FROM ERYSIPELAS

ERYSIPELAS IN SHEEP

Erysipelas in sheep is caused by infection with the soil-borne organism *Erysipelas rhusiopathiae* (formerly *Erysipelas insidiosa*). Pigs are the most important reservoir of infection, with up to 50% of healthy pigs carrying the bacterium in lymphoid tissues. The disease in sheep is manifested as arthritis in lambs, postdipping lameness, and rarely endocarditis. Sheep other than newly born lambs deprived of colostrum are generally quite resistant to infection with this organism.

Arthritis in Lambs

Acute and chronic forms of arthritis are seen.[1] Acute nonsuppurative arthritis occurs most commonly after tail docking, especially when a cold knife is used, but can also follow umbilical infections at or soon after birth. The organism persists in the soil and gains entry via the umbilicus or tail-docking and/or mulesing wounds. The latter practice is used to make merino lambs less susceptible to flystrike, mainly in Australia, but is gradually being phased out. Up to 50% of lambs marked may be affected, especially if tail docking is performed in muddy or unhygienic conditions. The mortality rate is low, but some affected lambs lose weight and have permanently swollen joints, leading to trimming of meat or rejection of the whole carcass at abattoirs.

Clinical signs appear about 14 days after birth or tail docking. There is a sudden onset of lameness with some swelling of the affected joints, typically the carpus, tarsus, hock, or stifle. Recovery is slow, and a high proportion of affected lambs have chronic lameness and swollen joints.

Chronic fibrinous polyarthritis also occurs in 2- to 6-month-old lambs, affecting several joints, and lambs may be lame on all four legs.[1] Up to 20% of lambs may be affected, although severe outbreaks with a higher prevalence are associated with spreading pig slurry or running free-range pigs on areas grazed by sheep. Arthritis in mature ewes can also occur in these circumstances.[2]

At necropsy the joint capsule is thickened, and there may be erosions of articular cartilage and slightly increased amount of synovial fluid that has a turbid appearance. There is no obvious suppuration as occurs with septic arthritis caused by streptococcal infection. In chronic cases the organism is usually only isolated from joints, but PCR testing indicates that it is also a multisystemic disease.[1]

Improved hygiene at tail docking will usually reduce the prevalence of *Erysipelas* arthritis, but a formalin-killed bacterin is available in many countries and may be indicated where there is a persistently high prevalence of infection.

Postdipping Lameness

The use of plunge dips to control ectoparasites in sheep can be followed by a high incidence of laminitis if the insecticide solution does not contain a suitable disinfectant. Dips that become grossly contaminated with organic matter are most likely to cause *Erysipelas* infection. The organism gains entry through skin abrasions and causes cellulitis, with extension to the laminae of the feet but without involving the joints. Up to 90% of a flock may be affected, although the incidence is usually about 25%. Similar outbreaks of lameness caused by *Erysipelas rhusiopathiae* have occurred without dipping, usually when sheep have to walk through wet, muddy areas likely to be contaminated with the organism.

Severe lameness begins 2 to 4 days after dipping, usually in one leg. The affected legs are hot and swollen from the coronet to halfway up the metacarpus or metatarsus, and the hair over the affected area usually falls out. Sheep rapidly lose body condition, but deaths are rare except in recently weaned lambs, in which septicemia may develop. Affected lambs show fever, malaise, and anorexia.

At necropsy there is subcutaneous edema of the area, sometimes with hemorrhage and inflammation extending to the coronet of the feet. Most cases recover spontaneously in 10 to 14 days, but long-acting penicillin will assist recovery. Wet dipping is now less common, but where dipping is still routinely practiced the use of fresh dipping solution each day and inclusion of a bacteriostatic agent into the solution will help prevent this condition.

Postdipping lameness can be differentiated from footrot by the history of recent dipping and lack of underrunning of the hoof tissue, from foot abscess by the lack of abscessation, and from strawberry footrot by the lack of any proliferative dermatitis.

MYCOPLASMA HYOSYNOVIAE IN PIGS

Mycoplasmal arthritis caused by *M. hyosynoviae* occurs in growing and finishing pigs from 35 kg upward and is characterized clinically by lameness, frequently in newly purchased stock.

ETIOLOGY

M. hyosynoviae causes arthritis in growing pigs. *M. hyoarthrinosa* has been associated with a syndrome similar to that produced by *M. hyosynoviae,* but they may be the same species. Other mycoplasmas, including *M. flocculare* and *Acholeplasma* spp., have been isolated from pigs but appear to have no propensity to produce arthritis.

EPIDEMIOLOGY

M. hyosynoviae is a causative organism with a very wide heterogeneity and is resident on the pharyngeal mucosa and tonsil. Shedding is less frequent than with *M. hyorhinis,* and the organism cannot usually be isolated from the pharynx of piglets before 7 weeks of age and is regarded as rare before 12 weeks. This is true even when most of the sows in a herd are tonsillar carriers. There is a very varied pattern of carriage. It appears that transference is fairly rare but can be the source of infection for the other littermates. There is some variation in virulence between strains. With virulent strains, bacteremia with subsequent arthritis follows within a few days of minor stress, such as vaccination, movement, regrouping, or a change in weather. The overall prevalence of clinical disease appears to be low, but it achieves significance in certain herds that experience a persistent problem. The reasons for this are still unclear. Infection profiles between herds vary considerably. In some herds in the United Kingdom, the incidence may be higher, with 21% of sows culled because of lameness primarily associated with *M. hyosynoviae.* It appears that there is a latent period between the tonsillar infection and the development of generalized infection and arthritis, which may be accounted for by the long persistence of maternal antibodies of 8 to 16 weeks. The active serologic response possibly indicating immunity only seems to occur when there is the onset of arthritis. It is more prevalent in heavily muscled pigs with straight-legged conformation, and there is variation in breed susceptibility. Morbidity in problem herds is generally 5% to 15% but may reach 50%. Mortality is rare, but 2% to 15% may become chronically affected.

Abattoir studies have suggested that 5% to 10% of pigs may be affected. Transmission of infection is by direct contact or possibly by aerosol infection.

M. hyosynoviae can survive drying for up to 4 weeks and may be capable of survival in the environment for longer periods than most mycoplasmas. A further consideration of the importance of these diseases must be given to their possible contribution to the occurrence of carcass condemnation from arthritis.

PATHOGENESIS

The most important thing to remember about pathogenesis is that pigs can carry the infection in their tonsils and their synovial fluid without clinical signs of lameness and may therefore not be diagnosed as carriers and can act as a potential source of infection to others.

Systemic infection by mycoplasma may occur following stress. Clinical disease is manifest if localization occurs, but this is probably the exception rather than the rule. In the experimental disease, the incubation period varies from 4 to 10 days. After

experimental intranasal infection with *M. hyosynoviae,* septicemia usually takes about 2 to 4 days to manifest. *M. hyosynoviae* produces synovitis with some arthritis, especially in the larger joints of the hindlimbs.

CLINICAL FINDINGS

Diagnosis is often difficult to make clinically. Often there is no fever and perhaps only a change in the gait of the pig. In these herds the sows are nearly always culled for lameness before the fourth parity, which constitutes a huge economic loss. Failure to treat leads to chronic lameness. Clinical disease occurs primarily in pigs over 3 months of age and in replacement stock brought into these problem herds.

With *M. hyosynoviae* infection, there is a sudden onset of acute lameness in one or more limbs, usually without fever. Lameness may be referable to one or more joints, and the stifle, hock, and elbow joints are most commonly affected. In many cases the pigs may lie in sternal recumbency. The lameness is severe, although clinical swelling of the affected joint may be minimal. In the majority of affected pigs, clinical recovery occurs after 3 to 10 days, but some may become permanently recumbent. In the United Kingdom, the condition is often associated with delivery of high-herd-health gilts to more conventional farms, with the condition occurring 2 days to 4 weeks after the delivery or with a change of housing. Other outbreaks have followed the introduction of pigs to straw yards, whereas contemporary animals kept in fully slatted accommodation have been unaffected. *M. hyosynoviae*–infected pigs may require humane slaughter.

CLINICAL PATHOLOGY

Blood cell counts remain within the normal range, but there is an increase in leukocytes and protein in synovial fluid. The organisms may be detected by immunofluorescent techniques, and complement-fixing antibody develops following infection.

PATHOLOGY

Synovial hypertrophy with an increased amount of serosanguinous synovial fluid occurs in affected joints with hyosynoviae. Sometimes the amount of fluid is considerable. Chronic cases show thickening of the joint capsule with a varying degree of articular erosion and pannus formation. Joint lesions are most likely to be found in the carpus, shoulder, stifle, and tarsus. Quite often with *M. hyosynoviae* infections, one joint—usually the hock—is affected.

Microscopically, there is usually edema, hyperemia, hyperplasia of synovial cells, and an increased density of subsynovial cells. Lymphocytes and plasma cells are present in the affected serosal and synovial membranes of subacute to chronic cases. There is often a significant villus hypertrophy of the synovial membrane. In the chronic phase, there may be some fibrosis. A full description of the phases of infection has recently been described. The organism is more easily demonstrated during the acute stage of the disease.

DIAGNOSIS

Clinical signs may help. Joint fluid may be helpful in that it is often clear or yellowish-brown and may contain flakes of fibrin. In streptococcal arthritis, the fluid is often hemorrhagic and turbid.

Samples for Confirmation of Diagnosis

- Histology—synovial membrane, liver, lung, heart. Sometimes the mycoplasmas can be seen between the synoviocytes on the tips of the villi of the synovial membrane.
- Mycoplasmology—culture swabs from serosal surfaces, joints. Selective media is usually required to suppress *M. hyorhinis.*
- *M. hyosynoviae* is best grown in anaerobic conditions, where it outgrows *M. hyorhinis.*
- Synovial fluid has been taken from the hock joint under general anesthesia and cultured. Isolation from the joints of lame pigs was twice as high as from littermates that were not lame. Approximately 8% to 9% of synovial fluid samples from nonpatent arthritis samples from Danish slaughterhouse pigs were positive. The same authors also showed that blood culture was also effective.
- Antigen detection. An in situ hybridization technique for the differentiation of *M. hyosynoviae, M. hyorhinis,* and *M. hyopneumoniae* has been described for use with formalin-fixed tissues.
- PCR can be used to amplify a p36 or p46 gene to differentiate *M. hyorhinis* and *M. hyosynoviae* infections for use in cultures and in blood samples.
- Serology—it has been shown that herds with *M. hyosynoviae* arthritis had higher serologic responses and more carriers among growers of 16-week-old pigs than did the unaffected herds, but by the end of the finishing period, the serologic response and carrier prevalence were as high in herds with arthritis as without.
- An indirect ELISA has been developed using membrane lipoprotein antigens and appears to be specific.

The differential diagnosis of mycoplasma infections must include *S. suis* and *H. parasuis.*

TREATMENT

When gilts and sows are treated, they do not appear to have a reduced overall survival time, indicating that treatment is cost-effective.

Treatment with tylosin at 1 to 2 mg up to 15 mg/kg BW IM or Lincomycin at 2.5 mg/kg BW IM for 3 consecutive days has been recommended. Lincomycin was effective in one outbreak, but the outbreak flared up again as soon as it was removed. Oxytetracycline also can be used. Early treatment of *M. hyosynoviae* arthritis with 8 mg of betamethasone IM has been found to reduce the occurrence of chronic lameness. Tiamulin at both 10 and 15 mg/kg BW IM daily for 3 days is effective for treatment of pigs affected with arthritis associated with *M. hyosynoviae* and is as effective as Lincomycin. Recently, enrofloxacin has been used at 2.1 mg/kg IM or SC for 3 days. It is essential to treat the in-contacts and to isolate the treated animals until the clinical signs have disappeared. Valnemulin was highly active against *M. hyosynoviae,* whereas tiamulin and enrofloxacin were much less active.

CONTROL

The control of mycoplasmal joint disease rests largely in the avoidance of stress situations. The administration of tylosin or tetracyclines in the drinking water or feed during unavoidable stress such as weaning can reduce the incidence. The use of tiamulin as a single injection before moving pigs from one house to another was sufficient to prevent 50% of the cases of the disease. Early weaning at 3 to 5 weeks of age has been recommended as a method of preventing infection of pigs with *M. hyosynoviae* and thus of reducing the occurrence of the disease in growing pigs. However, in one study *M. hyosynoviae* was not eliminated in herds where the piglets were commingled after 4 weeks and reared in herds using all-in/all-out management. In fact, the herd had widespread infection when the herd was 4 months old. The authors concluded that elimination of *M. hyosynoviae* requires that the pigs are moved immediately from weaning at an age of no more than 4 weeks. If newly arrived gilts are under threat, usually 14 to 21 days after arrival, then a course of treatment such as Lincomycin in the water for 2 to 3 days may prevent the infection.

FOOTROT IN PIGS (BUSH FOOT)

Footrot in pigs is similar clinically to footrot in other species. It is a term describing septic conditions of the claws of the foot, which burst at the coronet.

ETIOLOGY

The majority of cases result from secondary infection of traumatic lesions. These are erosions of the sole and wall of the claw that occur in pigs reared on rough, abrasive

flooring. These lesions do not usually produce lameness, unless they are extensive, but when pigs are also reared in dirty conditions, infection and subsequent lameness may occur.

Foot lesions are common in pigs of all ages, and bruising of the sole–heel junction, one of the earliest lesions observed, can be seen in piglets less than 24 hours old. If the bruising is severe and further trauma is not prevented, necrosis will follow quickly. The cause may be a combination of factors, including trauma, contact dermatitis, and subsequent infection. Wet conditions underfoot may cause maceration of the horn and exacerbate the abrasive effect of the flooring. Foot abscess in neonatal pigs is associated with being reared on woven-wire floors. Dietary deficiency, especially biotin deficiency, may also result in foot lesions that predispose to secondary infection.[1,2]

Fusiformis necrophorum, Trueperella pyogenes, Staphylococci and an unidentified spirochete have been isolated from affected feet. In an outbreak of the disease on a semiextensive pig farm, *Dichelobacter nodosus* and other anaerobic bacteria, including *Prevotella, Peptostreptococcus, Fusobacterium, Porphyromomonas, Bacteroides,* and *Eubacterium,* have also been isolated from affected feet.

EPIDEMIOLOGY

The disease is probably universal. A study of the prevalence and distribution of foot lesions in finishing pigs in England found that 94% of pigs had at least one foot lesion. The prevalence of the different lesions was as follows: toe erosion (33%), sole erosion (62%), heel erosion (13%), heel flaps (14%), white-line lesions (55%), false sand cracks (24%), and wall separation (11%). The hindfeet are more commonly affected than the front feet, and on each foot the lateral digits were significantly more frequently affected than the medial digits. Sole erosions, heel flaps, wall separation, and false sand cracks were observed more frequently on the lateral than the medial digit.

Erosive lesions on the foot are common and have been reported at an incidence as high as 65%. They have been reproduced experimentally, and the nature of the flooring has a marked influence on claw wear in pigs. Recently poured alkaline concrete and poorly laid concrete with constituents leading to a rough abrasive surface lead to a high incidence. A slope inadequate to allow proper drainage may also be an important predisposing factor. All ages of pigs are susceptible, but clinical lameness is uncommon. In individual herds where the unfavorable predisposing factors prevail, a high incidence of infection and clinical lameness can occur. The disease may cause reproductive inefficiency as a result of reluctance to stand or mount for mating.

PATHOGENESIS

Perforation of the horn leads to infection of the sensitive laminae. The infection may track up the sensitive laminae to the coronary band and discharge to the exterior. Elastolytic activity is a virulence factor involved in the pathogenesis of footrot in pigs associated with *Dichelobacter nodosus* and *Prevotella melaninogenica.*

CLINICAL FINDINGS

Where the disease is caused by abrasion of the horn by rough concrete surfaces, a number of characteristic lesions occur, including the following:

1. Erosion of the sole at either the toe or the heel
2. Bruising of the sole with hemorrhagic streaks in the horn
3. Separation of the hard horny wall from the heel or sole to produce a fissure at the white line
4. A false sand crack in the posterior third of the lateral wall of the claw

In the majority of cases these do not produce lameness, and they do not have any apparent effect on productivity. However, when they are extensive, where infection has occurred, and when more than one foot is affected, severe lameness is apparent. In most cases only the lateral digit of one foot is affected. Heat and obvious pain when moderate pressure is applied to the affected claw are constant findings. Necrosis extends up between the sole and sensitive laminae and may discharge at the coronet, causing the development of a granulomatous lesion, or it may extend to deeper structures of the foot with multiple sinuses discharging to the exterior. A minimal amount of purulent material is present. Productivity is affected with this type of lesion. With deeply infected feet, the recovery rate is only fair with treatment. A permanently deformed foot may result, and destruction of the pig may be necessary in severe cases. Secondary abscessation in other parts of the body is an occasional sequela and may result in partial carcass condemnation.

Foot abscesses in neonatal pigs are characterized by necrotic pododermatitis, severe osteomyelitis, arthritis, and tenosynovitis. The primary sites of injury are located at either the point of the toe at the white line, the bulb of the heel, or the haired skin around the coronet, including the interdigital area. The least severe lesions are superficial abrasions or ulcerations of the hoof wall, heel bulb, or interphalangeal skin, with only minimal inflammatory changes in deeper tissues. The most severely affected digits have focal superficial abscesses, or deep, diffuse, purulent inflammation and fibrosis around tendons, joints, and bones. The hindlimbs are more commonly affected than the forelimbs, and in the hindlimbs the medial claws are most likely to have lesions, whereas in the forelimbs the lateral claws are more likely to be affected. Approximately 6% of piglets develop foot abscess before weaning. About one-third of litters may be affected, and most litters have only one or two affected pigs. Discharge of pus from the coronary band is common, and the horny claw may slough, leaving sensitive laminae of one or more claws or accessory digits exposed. Skin necrosis may be present over the carpi, fetlocks, hocks, coronary bands, and elbows in about 75% of pigs during the first week of life.

CLINICAL PATHOLOGY

Bacteriologic examination of discharges from the lesions may aid in deciding the treatment to be used. In foot abscesses of neonatal pigs, bacteria isolated include the following:

- *Trueperella pyogenes*
- *Staphylococcus* spp.
- Beta-hemolytic *Streptococcus* spp.
- *Actinobacillus* spp.
- *Escherichia coli*

NECROPSY FINDINGS

Necrosis of the laminar tissue with indications of progression from an infected sole are the usual findings. There may be progression to tenosynovitis.[3]

DIFFERENTIAL DIAGNOSIS

Most other causes of lameness in pigs are not manifested by foot lesions. Bursitis, adventitious bursitis, and laminitis may occasionally be found. In young pigs they are not uncommon as a result of bad flooring (sharp metal and plastic and coarse concrete). These are seen as early as 24 hours, peak at 4 to 8 days, and are usually gone by 14 days. In adult pigs housed indoors, an overgrowth of the hoof may occur and be followed by underrunning of the sole, necrosis, and the protrusion of granulation tissue, causing severe lameness and often persistent recumbency. The general appearance of these feet is not unlike that of canker in horses. Swelling of the hoof is caused by an extensive fibrous tissue reaction. Vesicular exanthema and foot-and-mouth disease are characterized by the presence of vesicular lesions on the coronets and snout.

TREATMENT

There are few published reports of treatment of footrot in pigs. Rubber mats in the farrowing house may prevent some of the worst effects for piglets. Use of a broad-spectrum antimicrobial or penicillin given parenterally seems rational, and the use of Nuflor was said to be a successful treatment.

CONTROL

Prevention of excessive wear of the feet by the use of adequate bedding and less abrasive flooring in pig pens is suggested as a reasonable control measure. Slats should be round

edged and have a minimum width of at least 100 mm. Any existing dietary deficiency should be corrected. Of particular interest is the response to biotin supplementation of the diet of pigs in the prevention of foot lesions of various kinds. Regular foot care and paring of excessive growth is important. Formalin foot baths (5% to 10%, 2 to 3 times a week) may also reduce bacterial infection.

ROSS RIVER VIRUS

ETIOLOGY

Ross River virus is an alphavirus within the Semliki Forest complex of togaviruses. These are small enveloped viruses with a single-stranded, positive sense RNA genome. There is considerable sequence homology between Getah and Ross River virus genomes.[1] Ross River virus causes disease in both humans and horses.

EPIDEMIOLOGY

Ross River virus is found in most areas of continental Australia, Tasmania, West Papua and Papua New Guinea, New Caledonia, Fiji, Samoa, and the Cook Islands.[2] There is geographic genetic variability among isolates of Ross River virus. There is serologic evidence of lack of infection of cattle by RRV in the Coromandel region of New Zealand.[3]

The virus is arthropod borne, and infection is through the bite of an infected mosquito. The virus is maintained in the mosquito–vertebrate–mosquito host cycle typical of arboviruses. The vertebrate hosts of Ross River virus include a large number of eutherian, marsupial, and monotreme mammals and birds.[2] Macropod species, including kangaroos and wallabies, are assumed to be the most important amplifying hosts, although this is debated. There is a high prevalence of serologically positive Western Grey kangaroos (48%).[4]

There is a high incidence of Ross River virus infection of horses in endemic regions of Australia, and the prevalence was shown to be increased with year-round mosquito activity. The proportion of seropositive horses in Queensland, an area in with year-round mosquito activity, was approximately 80%, whereas that of horses around the Gippsland lakes in southern Australia, a region with seasonal mosquito activity, was 50%. Outbreaks of clinical disease attributed to Ross River virus infection of horses occurred in southeastern Australia in late 2010 and early 2011 and were also associated with serologic and virological evidence of infection by Murray Valley encephalitis virus and Kunjin virus (a lineage of West Nile virus).[5] During the outbreak, which was associated with unusually wet summer conditions in an area characterized by hot, dry summers, 392 horses on 271 premises were suspected or confirmed to have been infected by one or more of these arboviruses.

Zoonotic Implications

Disease associated with Ross River virus infection is common in humans in Australia, with an estimated 4800 cases per year, and much larger numbers during epidemics of the disease.[2] The horse is thought to be an amplifying host of the virus because experimentally infected horses can infect mosquitoes. Direct transmission from the horse, however, would be primarily occupational. The disease in humans is characterized by mild pyrexia and constitutional signs initially, with subsequent development of a rash on the skin and oral lesions. Arthritis or arthralgia is common and affects primarily the wrists, knees, ankles, and small joints of the extremities. These signs and symptoms can persist for 2 to 3 months, and the disease can relapse.

CLINICAL SIGNS

The disease associated with Ross River virus infection of horses is typified by pyrexia; petechial hemorrhages; submandibular lymphadenopathy; lameness, including "stiffness"; swollen joints or distal limbs; inappetence; reluctance to move; and mild colic.[5,6] Horses are often described as being ataxic, although the neurologic basis of this sign is unclear. Any previous skepticism regarding the pathogenicity of Ross River virus in horses was addressed by the outbreak of disease caused by Ross River virus during 2010 and 2011 in southeastern Australia. Disease associated with confirmed Ross River virus infection was characterized by ataxia, stiff gait, depression, edema, listlessness, pyrexia, and reluctance to walk. Horses infected experimentally with Ross River virus have minimal clinical signs of disease. The duration of disease caused by Ross River virus in horses is uncertain, and some veterinarians consider that the disease can persist for weeks to months, and it can recur in horses.

There are insufficient reports of disease to determine whether characteristic or diagnostic abnormalities in serum biochemistry or hematology occur in affected horses. An elevated concentration of fibrinogen in plasma was reported in all of three horses with the presumptive disease that were tested.

DIAGNOSIS

Diagnosis of infection by Ross River virus is confirmed by virus isolation from serum or heparinized blood samples collected during the acute phase of the disease or detection in serum of antibodies to the virus. Detection of IgM antibodies to Ross River virus is indicative of recent infection, whereas detection of IgG or neutralizing antibodies is indicative of more distant infection. Seroconversion confirms exposure, and presumably infection, by the virus. Isolation of Ross River virus has been achieved from horses with IgM antibody to the virus but not with IgG antibody, likely because of the temporal pattern of antibody appearance in the blood of infected horses.[6] In addition to culture of the virus in mice or tissue culture, Ross River virus can be detected in blood and synovial fluid using an RT-PCR. It is important to remember that subclinical infection of horses in endemic regions is very common and that this high rate of subclinical infection increases the risk of incorrect diagnosis of infection by the virus. It is possible that clinical abnormalities in a horse with Ross River viremia or serum antibodies to the virus are actually not attributable to infection by Ross River virus. This is extremely significant in that there are no reports of postmortem examination of horses with disease confirmed to be caused by Ross River Virus. Thus case definition in terms of postmortem confirmatory diagnostics has not been established.

TREATMENT

Treatment of affected horse is supportive. Affected horses might benefit from administration of analgesics and antipyretics such as phenylbutazone. Administration of antimicrobials is not indicated in uncomplicated cases.

CONTROL

Control measures have not been evaluated, but minimizing the exposure of horses to infected mosquitoes is prudent, although the efficacy of this technique in preventing infection is unknown. There is no vaccine to prevent infection or disease of horses by Ross River Virus. There is an experimental vaccine for humans.[7]

Nutritional Diseases Affecting the Musculoskeletal System

SELENIUM AND/OR VITAMIN E DEFICIENCIES

Several diseases of farm animals are associated with a deficiency of either selenium (Se) or vitamin E (VE) alone or in combination, usually in association with predisposing factors such as dietary polyunsaturated fatty acids, unaccustomed exercise, and rapid

growth in young animals. All of these diseases are described under one heading because both Se and VE are important in the etiology, treatment, and control of the major diseases caused by their deficiencies.

There are also **selenium–vitamin E–responsive diseases** because, with some exceptions, they can be prevented by adequate supplementation of the diet with both nutrients. In some regions of the world, particularly New Zealand and in parts of Australia and North America, diseases such as ill-thrift in sheep and cattle and poor reproductive performance respond beneficially to Se. Although these cases usually occur in Se-deficient regions, they may not be attributable solely to Se deficiency. Thus there are some reasonably well-defined **selenium-deficiency diseases** and some ill-defined "**selenium-responsive" diseases**.

There is more concern with these diseases now because it is becoming increasingly important to make sure that milk and meat are not deficient in Se and VE from the human nutrition point of view. Deficient meat makes for deficient humans.

More and more oxidants, antioxidants, and oxidative stress disorders are featuring in human and animal diseases. At least theoretically, oxidative stress should be easily prevented with antioxidants, but such therapy is controversial.[1]

In addition, there is an increasing recognition of the importance of toxic oxygen radicals (free-oxygen radicals) produced in the body that are neutralized by antioxidants and that may or not be effective resulting in an oxidative stress.[2,3] This focus is particularly important in ruminant medicine[4] with respect to sepsis, mastitis, pneumonia, and retained placenta.

ETIOLOGY

The Se- and VE-responsive or deficiency diseases of farm animals are caused by diets deficient in Se and/or VE, with or without the presence of conditioning factors such as an excessive quantity of polyunsaturated fatty acids in the diet. Almost all of the diseases that occur naturally have been reproduced experimentally using diets deficient in Se and/or VE. Conversely, the lesions can usually be prevented with Se and VE supplementation. In certain instances, such as, for example, in hand-fed dairy calves, the incorporation of excessive quantities of polyunsaturated fatty acids was a major factor in the experimental disease. The presence of polyunsaturated fatty acids in the diet may cause a conditioned VE deficiency because the vitamin acts as an antioxidant. In the case of naturally occurring muscular dystrophy in calves, lambs, and foals on pasture, the myopathic agent, if any, is unknown, and selenium is protective. However, Se is not protective against the muscular dystrophy associated with the feeding of cod liver oil to calves.

SYNOPSIS

Etiology Dietary deficiencies of selenium and vitamin E and conditioning factors such as dietary polyunsaturated fatty acids.

Epidemiology

- **Enzootic muscular dystrophy** occurs in young, rapidly growing calves, lambs, goat kids, and foals born to dams in selenium-deficient areas with unsupplemented diets. Occurs worldwide and common in Australasia, United Kingdom, and Great Plains of North America where soils are deficient in selenium. Vitamin E deficiency in animals fed poor-quality forage and diets high in polyunsaturated fatty acids. Outbreaks of muscular dystrophy precipitated by exercise.
- **Mulberry heart disease** in finishing pigs.
- **Selenium-responsive diseases** occur in Australasia and are not obvious clinically but respond to selenium supplementation. Selenium and vitamin E deficiency may be involved in reproductive performance, retained placenta in cattle, and resistance to infectious disease such as bovine mastitis. Controversial.

Signs Muscular dystrophy characterized by groups of animals with stiffness, weakness, and recumbency; severe in myocardial form. Mulberry heart disease characterized by outbreaks of sudden death in finishing pigs.

Clinical pathology Increased plasma levels of creatine kinase. Low serum levels of selenium and vitamin E. Glutathione peroxidase activity.

Necropsy findings Bilaterally symmetric pale skeletal muscle; pale streaks in myocardial muscle. Hyaline degeneration of affected muscle.

Diagnostic confirmation Low selenium and vitamin E in diet and tissues; increased creatine kinase and muscle degeneration.

Differential diagnosis list

Acute muscular dystrophy in calves and yearlings

- *Haemophilus somnus* septicemia
- Pneumonia

Subacute enzootic muscular dystrophy:

- **Musculoskeletal diseases**—polyarthritis, traumatic or infectious myopathies (blackleg), osteodystrophy, and fractures of long bones
- **Diseases of the nervous system**—spinal cord compression, *Haemophilus somnus* meningoencephalitis and myelitis, organophosphatic insecticide poisoning
- **Diseases of the digestive tract**—carbohydrate engorgement resulting in lactic acidosis, shock, dehydration, and weakness
- Muscular dystrophy in lambs and kids—enzootic ataxia and swayback
- Muscular dystrophy in foals—traumatic injury to the musculoskeletal system and polyarthritis; meningitis; traumatic injury to the spinal cord

Treatment Vitamin E selenium parenterally.

Control Selenium and vitamin E supplementation of diet; strategic oral and/or parenteral vitamin E and selenium to pregnant dams or young animals on pasture.

Se is an essential nutrient for animals, and diseases caused by Se inadequacy in livestock are of worldwide distribution.

Biological Functions of Selenium and Vitamin E (VE)

Selenium

Selenium is the component of over 30 selenoproteins[5] that protect cells from damage by free radicals, the cause of many chronic diseases.[6] The Se is present as selenocysteine in the selenoproteins. It is the 21st amino acid. The selenoproteins also participate in the metabolism of thyroid hormones, control reproductive functions, and exert neuroprotective effects. In addition to its antiproliferative and antiinflammatory effects, SE also stimulates the immune system via the macrophages, neutrophils, and lymphocytes. Se stimulates the T-helper cells, cytotoxic T cells, and natural killer (NK) cells. It is aided by VE and sulfur-containing amino acids. Se-containing proteins may have a role in muscle formation and repair.[7] Deficiencies can result in nutritional muscular dystrophy (white-muscle disease) in lambs, kids, calves, and poultry; exudative diatheses in poultry; and necrotic liver degeneration and mulberry heart disease in pigs. In cattle, it is also associated with parturition problems, placental retention, and metritis. Se deficiency also contributes to the formation of ovarian cysts and increased early embryonic mortality. VE and Se also facilitate leukocyte migration into the mammary glands and enhance neutrophil phagocytosis, which helps in the fight against mastitis.

One of these proteins is selenoprotein W, first identified in sheep suffering from Se deficiency; the majority of its functions are unknown, but it serves as an antioxidant, responds to stress, and is involved in cell immunity.[8] In sheep given sodium selenite and selenium nanoparticles, it was shown that expression of transferrin and its receptor genes was considerably increased during supplementation by both Se components for 10 to 20 days and then decreased significantly.[9] It is close to sulfur in terms of properties.[10] It is largely absorbed through the duodenum and the cecum by active transport through a sodium pump.

Long-term supplementation (0.3%) with organic Se modulates the gene-expression profiles in leukocytes of adult pigs; 28 genes

were up-regulated and 24 down-regulated by the Se supplementation, leading to improved expression of genes that are related to enhanced immunity of pigs.[11]

Glutathione Peroxidases and Tissue Peroxidation

Se is a biochemical component of the enzyme glutathione peroxidase (GSH-PX).[12] The activity of the enzyme in erythrocytes is positively related to the blood concentration of Se in cattle, sheep, horses, and pigs and is a useful aid for the diagnosis of Se deficiency and to determine the Se status of the tissues of these animals. The enzyme from the erythrocytes of both cattle and sheep contains 4 g atoms of selenium per 1 mol of enzyme. Se is also a component of thyroid gland hormones and is very important in converting T4 to T3 (i.e., inactive to active).[13]

Plasma GSH-PX protects cellular membranes and lipid-containing organelles from peroxidative damage by inhibition and destruction of endogenous peroxides, acting in conjunction with VE to maintain the integrity of these membranes. Hydrogen peroxide and lipid peroxides are capable of causing irreversible denaturation of essential cellular proteins, which leads to degeneration and necrosis. GSH-PX catalyzes the breakdown of hydrogen peroxide and certain organic hydroperoxides produced by glutathione during the process of redox cycling. This dependence of GSH-PX activity on the presence of Se offers an explanation for the interrelationship of Se, VE, and sulfur-containing amino acids in animals. The sulfur-containing amino acids may be precursors of glutathione, which in turn acts as a substrate for GSH-PX and maintains sulfhydryl groups in the cell. Se is also a component of several other proteins, such as the selenoprotein of muscle (selenoflagellin), Se-transport proteins, and the bacterial enzymes formate dehydrogenase and glycine reductase. Se also facilitates significant changes in the metabolism of many drugs and xenobiotics. For example, Se functions to counteract the toxicity of several metals, such as arsenic, cadmium, mercury, copper, silver, and lead.

Vitamin

VE is important in the general immune response because it affects the blood cell populations and, in particular, the persistence of the immune response. Together with vitamins A and D and Se, it increases reproductive performance.[14]

The term "vitamin E" is a generic description encompassing two families of lipid-soluble compounds, the tocopherols and the tocotrienols, of which alpha-tocopherol is the most active.[15] VE is an antioxidant that prevents oxidative damage to sensitive membrane lipids by decreasing hydroperoxide formation. The vitamin has a central role in protection of cellular membranes from lipoperoxidation, especially membranes rich in unsaturated lipids, such as mitochondria, endoplasmic reticulum, and plasma membranes.

Cows discriminate against the 2S isomers of the synthetic form, which contains all eight isomers (4 of 2R and 4 of 2S). This means that 1 g of all-rac is actually 0.5 g of the RRR form.[15]

It has been observed that low serum alpha-tocopherol levels are possibly indicative of a disposition to left-sided displaced abomasum in early-lactating dairy cows.[16] Organic farms have more VE than conventional ones, and grass clover silage is the best source of VE compared with hay, maize, or grain. Silage is a better source of tocopherols than hay as a result of high storage losses in the latter, and ensiled grasses and legumes have more VE than maize silage.[17]

Interrelationships Between Selenium and Vitamin E

An important interrelationship exists between Se, VE, and the sulfur-containing amino acids in preventing some of the nutritional diseases caused by their deficiency. If VE prevents fatty acid hydroperoxide formation, and the sulfur amino acids (as precursors of GSH-PX) and Se are involved in peroxide destruction, these nutrients would produce a similar biochemical result, that is, lowering of the concentration of peroxides or peroxide-induced products in the tissues. Protection against oxidative damage to susceptible nonmembrane proteins by dietary Se, but not by VE, might explain why some nutritional diseases respond to Se but not to VE. On the other hand, certain tissues or subcellular components may not be adequately protected from oxidant damage because they are inherently low in GSH-PX even with adequate dietary Se. Damage to such tissues would be expected to be aggravated by diets high in unsaturated fatty acids and to respond adequately to VE but not to Se. The variations in GSH-PX activity between certain tissues, such as liver, heart, skeletal, and myocardial muscles, would explain the variations in the severity of lesions between species.

There are both selenium-dependent GSH-PX and nonselenium-dependent GSH-PX activities in the tissues and blood. The nonselenium-dependent enzyme does not contain Se and does not react with hydrogen peroxide but shows activity toward organic hydroperoxide substrates. The spleen, cardiac muscle, erythrocytes, brain, thymus, adipose tissue, and striated muscles of calves contain only the selenium-dependent enzyme. The liver, lungs, adrenal glands, testes, and kidney contain both enzymes. Hepatic tissue contains the highest level of nonselenium-dependent enzyme.

VE can prevent a toxic reaction to oral iron (ferrous sulfate) or iron dextran IM. When 0.1 ppm of Se and 50 IU VE/kg are added during the gestation of sows, glutathione peroxidase activity increased in 2-day-old pigs, especially if the iron injection is given before colostrum ingestion.

EPIDEMIOLOGY

Enzootic Nutritional Muscular Dystrophy

Enzootic nutritional muscular dystrophy (NMD) was the first disorder linked with Se and was associated with a high mortality, especially in ruminants, and impaired production in growing and adult animals.

Occurrence

This type of muscular dystrophy occurs in all farm animal species, but most commonly in young, rapidly growing calves, lambs, goat kids, and foals born from dams that have been fed for long periods, usually during the winter months, on diets low in Se and VE. It is an important cause of mortality in goat kids from birth to about 3 months of age. Goat kids may require more Se than lambs or calves, which may explain the higher incidence of the disease in kids. The disease in kids may also be associated with low α-tocopherol levels and normal Se status.

NMD in horses occurs most commonly in foals to about 7 months of age. In reported cases, the concentration of Se in the blood of the mares was subnormal, the concentrations of Se and VE in the feedstuffs were subnormal, the level of unsaturated fatty acids in the feed was high, and VE and Se supplementation prevented the disease. The disease is not well recognized in adult horses, but sporadic cases of dystrophic myodegeneration are recorded in horses from 5 to 10 years of age. The disease also occurs in grain-fed yearling cattle. Stressors such as being turned outdoors after winter housing, walking long distances, the jostling and movement associated with vaccination, and dehorning procedures and similar management practices are often precipitating factors. The disease has occurred in steers and bulls 12 to 18 months of age under feedlot conditions. There may even be laboratory evidence of subclinical myopathy in normal animals in a group from which an index case occurred. Outbreaks of severe and fatal NMD have occurred in heifers, at the time of parturition, that were previously on a diet deficient in both Se and VE. The disease may also occur sporadically in adult horses that are deficient in Se. Muscular dystrophy has occurred in Bohemian Red Poll mature dairy cows in the Czech Republic moved from a stanchion barn into loose box housing that resulted in increased locomotor activity and stress associated with the change in housing conditions.

Myopathy and hepatic lipidosis in weaned lambs deficient in VE without concurrent Se deficiency has been described.

There are two major syndromes of myopathy:

- An acute form—myocardial dystrophy, which occurs most commonly in young calves and lambs and occasionally foals
- A subacute form—skeletal muscular dystrophy, which occurs in older calves and yearling cattle.

The two forms are not mutually exclusive.

Geographic Distribution

NMD occurs in most countries of the world but is common in the United Kingdom, the United States, Scandinavia, Europe, Canada, Australia, and New Zealand. In North America, it is common in the Northeast and Northwest and uncommon on the relatively high-Se soils of the Great Plains, where Se toxicity has occurred. It is one of most common deficiency diseases of farm livestock in the United States. In the Czech Republic, the incidence of Se deficiency in cattle is high and most frequently diagnosed in heifers, feeder bulls, grazed beef cattle, and dairy cows in the dry period. Surveys of live cattle in the Czech Republic and in cattle tissues obtained at slaughter have found significant deficiency of Se. Poor-Se status, as assessed from blood, muscle, and liver Se concentrations, was found in 80%, 70%, and 73% of the tested animals, respectively. White-muscle disease has occurred in lambs in Turkey, where the levels of Se in the hay and soil are deficient. The mean values of Se in the soil and hay were 0.03 ppm and 0.07 ppm, respectively.

NMD is endemic in grazing goats on the Mexican plateau because of Se deficiency in the soil and forages. In two different locations of the plateau, the concentration of Se in the soil was 0.047 and 0.051 ppm; in the forages, 0.052 and 0.075 ppm; and in the serum of goats, 0.02 and 0.21 ppm, respectively. The pH of the soil was 6.1 and 5.9, respectively. The mean concentration of Se in the serum of kids with clinical signs of NMD was 36% lower compared with kids from the same farm that were normal.

Based on bulk-tank milk Se concentrations compared with serum Se concentrations in dairy herds in Prince Edward Island, Canada, 59% of the herds were at some point marginal or deficient in Se, which places them at risk of disease and suboptimal production. The periods of greatest risk were in the fall and winter, when 5% and 4%, respectively, of herds fell in the range of true deficiency. Herds in which Se supplementation was provided from a commercial dairy concentrate were over 4 times more likely to be selenium adequate than herds not using this method, and adjusted average daily milk yield was 7.6% greater in herds determined to be selenium adequate compared with selenium-marginal herds. In Chile, bulk-tank milk samples may show low levels of Se as a result of low-Se soil.[18]

Soils, and therefore the pastures they carry, vary widely in their Se content, depending largely on their geological origin. In general, soils derived from rocks of recent origin (e.g., the granitic and pumice sands of New Zealand) are notably deficient in Se. Soils derived from igneous rocks are likely to be low in Se. Sedimentary rocks, which are the principal parent material of agricultural soils, are richer in Se. Forage crops, cereal grains, and corn grown in these areas are usually low in Se content (below 0.1 mg/kg dry matter [DM]) compared with the concentration in crops (above 0.1 mg/kg DM) grown in areas where the available soil Se is much higher and usually adequate. The disease occurs in pigs, usually in association with other more serious diseases, such as mulberry heart disease and hepatosis dietetica.

Selenium in Soil, Plants, and Animals

Selenium in Soils

Soils containing less than 0.5 mg/kg of Se are likely to support crops and pastures with potentially inadequate Se concentrations (<0.05 mg/kg DM).

Selenium in Plants

Plants vary in their uptake of Se, but it is not a requirement for plant growth. The Se content of different pasture species on the same soil type does vary widely, but slow-growing and more deeply rooting species contain slightly higher concentrations. In New Zealand, the most deficient soils consist of rhyolitic pumice in the central volcanic plateau of the North Island. Peat soils in the Waikaito River Valley are also deficient. North Island coastal sands and stony soils in several locations are considered to be selenium responsive, whereas most of the South Island is at least marginally deficient.

Se deficiency occurs in most soils in the Balkan region; for example, the Se in wheat is so low that the daily requirement would not be met.[19] In the United States, the states of the Pacific Northwest and of the northeastern and southeastern seaboard are generally low in Se. In Canada, western prairie grains generally contain relatively high levels of Se, whereas in the eastern provinces, soils and feedstuffs usually have low Se concentrations. Most soils in the Atlantic provinces of Canada are acidic, and consequently, the forages are deficient in Se. Most forage samples contain less than 0.10 mg/kg DM of Se, and enzootic nutritional muscular dystrophy is common throughout the region.

Surveys in the United Kingdom found that the Se status may be low in sheep and cattle fed locally produced feedstuffs without any mineral supplementation. In some surveys, up to 50% of farms were low in Se, which places a large number of animals at risk. There are also differences in the Se concentrations of different feeds grown in the same area. For example, in some areas 75% of cattle fed primarily corn silage, or 50% of the cattle fed sedge hay, might be receiving diets inadequate in Se.

Factors Influencing the Availability of Soil Selenium to Plants. The Se concentration in soil varies with type, texture, and organic matter of the soil and with rainfall. In a study of various diets, it was found that the availability of Se increased when a 70% grain diet was fed, as a result of the high content of nonstructural carbohydrates.[20] Other influencing factors include the following:

- **Soil pH**—alkalinity encourages Se absorption by plants, and the presence of a high level of sulfur, which competes for absorption sites with Se in both plants and animals, with both factors reducing availability.
- The assimilation by plants is influenced by the physicochemical properties of the soil (redox status, pH, and microbial activity).
- Variation between plants in their ability to absorb selenium—"**selector" and "converter" plants** are listed under the heading of "Selenium Poisoning"; legumes take up much less Se than do grasses.
- **Seasonal conditions also influence the selenium content of pasture**, with the content being lowest in the spring and when rainfall is heavy. Blood Se levels in dairy cows in the United States were lower during the summer and fall than during the winter and spring. In this way, a marginally deficient soil may produce a grossly deficient pasture if it is heavily fertilized with superphosphate, thus increasing its sulfate content, if the rainfall is heavy and the sward is lush and dominated by clover as it is likely to be in the spring months.

Environmental sulfur from various anthropogenic activities has been suspected to be a significant factor in contributing to several health problems in livestock. Livestock producers near natural sour gas desulfurization plants have reported that sulfur emissions are responsible for an increased occurrence of nutritional muscular dystrophy, weak calves, and retarded growth. Experimentally, a moderate increase in dietary sulfur does not impair Se and copper status or cause related disease in cattle.

Selenium in Animals

There may be wide variations in the serum Se concentrations and glutathione peroxidase activities in cattle grazing forages of various Se concentrations within the same geographic area. The Se status of beef cows can vary between geographic areas within a region of a country, which is likely attributable to variations in Se concentration of the soil and plants in these areas. Beef herds from areas with adequate soil levels of Se, herds provided with supplemental feed on pasture, and herds in which pregnancy diagnosis was done had higher average herd blood Se values than other herds. In growing cattle the recommended dose is 100 mu g/kg

DM, and for pregnant and lactating females it is 200 mu per g/kg. In a study of Belgian Blue cattle, it was found that they have a higher requirement for Se as a result of the hypermusculature of the breed[21] and that yeast selenite provided the best response in the dams.

Some species have a greater ability to concentrate Se than other species. For example, Norwegian reindeer meat has more Se than beef, lamb, mutton, pork, or chicken.[22]

Vitamin E

There may be an antioxidant interaction with proinflammatory cascades involving important signal transduction elements. There may be an antiinflammatory property of compounds that could shift the TH1–TH2 type of immune balance toward a TH2-type immunity.[23]

Cows supplemented with VE had a lower rate of culling and mastitis and a reduced level of retained fetal membranes, from 6.5% to 3.0%, compared with nonsupplemented diets. There was no effect on milk yield, reproductive performance, or uterine infections.[24] The relationship between plasma VE and milk VE is too poor for milk VE to be used as a primary test for VE deficiency.[25]

VE deficiency occurs most commonly when animals are fed inferior-quality hay or straw or root crops. Cereal grains, green pasture, and well-cured fresh hay contain adequate amounts of the vitamin.

Alpha-tocopherol levels are high in green grasses and clovers, but there are wide variations in the concentrations from one area to another. The serum α-tocopherol levels are higher in calves born from cows fed grass silage than in those born from cows fed the same grass as hay. Many factors influence the α-tocopherol content of pasture and hence the animals' intake. The level of α-tocopherol in pasture declines by up to 90% as it matures. Levels as low as 0.7 mg/kg DM have been reported in dry summer pastures grazed by sheep. The α-tocopherol content of ryegrass and clover pasture ranges from 22 to 350 mg/kg DM and 90 to 210 mg/kg DM, respectively. After harvesting and storage, the α-tocopherol content of pasture and other crops may fall further, sometimes to 0. Preservation of grain with propionic acid does not prevent the decline. Thus the dietary intake of α-tocopherol by cattle and sheep may be expected to vary widely and lead to wide variations in tissue levels. The plasma VE status of horses is highest from May to August in Canada when fresh grass is being grazed and lowest when the horses are being fed harvested or stored feed during the same period. Plasma VE levels in dairy cows in the United States were higher during the summer and fall than during the winter and spring.

Outbreaks of NMD may occur in yearling cattle fed on high-moisture grain treated with propionic acid as a method of inexpensive storage and protection from fungal growth. There is a marked drop in the VE content of acid-treated grain and an increase in the levels of peroxides of fat, which is consistent with a loss of naturally occurring antioxidants such as the tocopherols (secondary VE deficiency). In these situations, the levels of Se in the feed were below 0.05 mg/kg DM, which is inadequate and emphasizes the interdependence of Se and VE. The α-tocopherol content of moist grain (barley and maize) stored for 6 months, with or without propionic acid, falls to extremely low levels compared with conventionally stored grain, in which the α-tocopherol levels usually persist over the same length of time. Selenium-deficient barley treated with sodium hydroxide to deplete it of vitamin E can be used to induce NMD when fed to yearling cattle. The disease may occur in sucking lambs with low plasma α-tocopherol levels and an adequate Se status, which indicates that the sparing effect of each nutrient may not occur over the broad spectrum of clinical deficiencies.

Polyunsaturated Fatty Acids in Diet

Diets rich in polyunsaturated fatty acids (PUFAs), such as cod liver oil, other fish oils, fishmeal used as a protein concentrate, lard, linseed oil, soybean, and corn oils, have been implicated in the production of NMD, particularly in calves fed milk replacers containing these ingredients. The disease can be reproduced experimentally in young ruminant cattle, 6 to 9 months of age, by feeding a diet low in VE and Se and adding linolenic acid. There are widespread lesions of myodegeneration of skeletal and myocardial muscles. Fresh spring grass containing a sufficient concentration of linolenic acid to equal the amount necessary to produce NMD in calves may explain the occurrence of the naturally occurring disease in the spring months. The oxidation during rancidification of the oils causes destruction of the vitamin, thus increasing the dietary requirements (a conditioned vitamin E deficiency), and the presence of myopathic agents in the oils may also contribute to the occurrence of the disease. The lack of specificity of VE in the prevention of muscular dystrophy in some circumstances is indicated by its failure and by the efficiency of Se as a preventive agent in lambs on lush legume pasture.

Supplementation with fish oil and barium selenite and its effects on carcass characteristics and muscle fatty acid of late-season lambs finished on grass or concentrate has been studied.[26] It was found that fish oil is of some help in concentrate diets but not in grass-based diets. Barium sulfate helps if there is no concentrate in the diet but is of little use if the lambs are fed on concentrate- or fish-oil-enriched diets.

Other Myopathic Agents in Diet

Not all of the myopathic agents that may be important in the development of NMD in farm animals have been identified. Unsaturated fatty acids in fish and vegetable oils may be myopathic agents in some outbreaks of NMD of calves and lambs. Lupinosis-associated myopathy in sheep is a substantial skeletal muscle myopathy encountered in weaner sheep grazing lupin stubbles infected with the fungus *Phomopsis* spp. Affected sheep have a stiff gait, walk reluctantly, stand with their back humped and their feet under the body, and have difficulty getting to their feet.

Unaccustomed Exercise

Historically, NMD occurred most commonly in rapidly growing, well-nourished beef calves 2 to 4 months of age, shortly following unaccustomed exercise. This was commonplace in countries where calves were born and raised indoors until about 6 to 8 weeks of age, when they were turned out onto new pasture in the spring of the year. This has been a standard practice in small beef herds in the United Kingdom, Europe, and North America. A similar situation applies for ewes that lambed indoors and the lambs were let out to pasture from 1 to 3 weeks of age. Thus unaccustomed activity in calves and lambs, such as running and frolicking following their turn-out onto pasture, is an important risk factor but is not necessarily a prerequisite for the disease. In lambs, the vigorous exertion associated with running and sucking may account for the peracute form of myocardial dystrophy in young lambs on deficient pastures and from deficient ewes. In older lambs up to 3 months of age, outbreaks of acute NMD and stiff-lamb disease may be associated with the driving of flocks long distances. A similar situation applies for calves that are moved long distances from calving grounds and early-spring pastures to lush summer pastures. The wandering and bellowing that occur in beef calves weaned at 6 to 8 months of age may precipitate outbreaks of subacute NMD. Degenerative myopathy of yearling cattle (feedlot cattle, housed yearling bulls, and heifer replacements) is now being recognized with increased frequency. The disease resembles subacute NMD of calves and in the United Kingdom is often seen when yearlings are turned outdoors in the spring of the year after being housed during the winter and fed poor-quality hay or straw or propionic-acid-treated grain. Unaccustomed exercise is a common precipitating factor. However, the disease has occurred in housed yearling bulls with no history of stress or unaccustomed exercise but whose diet was deficient in Se and VE.

In horses subjected to exercise, there is an increase in erythrocyte malondialdehyde, a product of peroxidation, but Se supplementation has no beneficial effect. There is inconclusive evidence that a selenium–vitamin E deficiency causes NMD in adult horses. There is no evidence that paralytic myoglobinuria and "tying-up" syndrome are a result of a deficiency of selenium and vitamin E.

Congenital Nutritional Muscular Dystrophy

Congenital NMD is rare in farm animals. Isolated cases have been reported.

Similarly, NMD can occur in calves and lambs only a few days of age, but rarely. Se readily crosses the bovine placenta, and fetal Se is always higher than the maternal status. There is no evidence that weak-calf syndrome is associated with Se deficiency. Long-term parenteral supplementation with either Se alone or in combination with VE had no effect on the incidence of weak-calf syndrome.

An investigation of aborted bovine fetuses with lesions of heart failure, specifically cardiac dilatation or hypertrophy, along with a nodular liver and ascites compared with aborted fetuses without such lesions and nonaborted fetuses from the abattoir found myocardial necrosis and mean selenium levels of 5.5 μmol/kg in the fetuses with heart lesions, 6.5 μmol/kg in the fetuses without heart lesions, and 7.5 μmol/kg selenium in the fetuses from the abattoir. This suggests that Se deficiency in bovine fetuses may cause myocardial necrosis and heart failure. Normal levels of selenium in the liver and kidney tissue of bovine fetuses derived from the abattoir were 7.5 ± 5.2 μmol/kg and 4.4 ± 1.1 μmol/kg, respectively.

In pigs, NMD has been produced experimentally on VE- and Se-deficient rations but is usually only a part of the more serious complex of mulberry heart disease and hepatosis dietetica.

Vitamin E–Selenium Deficiency Syndrome

The combination of mulberry heart disease, hepatosis dietetica, exudative diathesis, and nutritional myopathy, also known as vitamin E–selenium deficiency (VESD) syndrome, occurs in pigs, usually as a serious disease. Nutritional muscular dystrophy may also occur in pigs. The occurrence of edema in various tissues has also been suggested as a possible result of Se or VE deficiency. Impaired spermatogenesis and increased susceptibility to the effects of swine dysentery have also been suggested as responses to reduced levels of these two substances. There is a suspicion that the problems become more common as the pig grows more quickly and the requirements and demands for antioxidants are increased at the same time that the provision of fat-soluble vitamins is increasingly difficult. In addition, there is a very small difference between the therapeutic and toxic levels of Se, and Se toxicosis has occurred in an attempt to prevent Se deficiency. A more recent complication is the realization that we have been using inorganic Se to provide Se in the diet, whereas in the plant, most of the Se is organic in the form of L-selenomethionine, an Se analog of the amino acid methionine. In the pig, as in other species, Se is thought to serve as an antagonist to toxic free radicals and act in concert with other substances such as vitamin C. Little is known about Se metabolism in the pig. In the pig, there is very little transfer of fat-soluble products across the placenta, so there is very little reserve of VE in the new born pig. Immediately after birth, the young pig gets its VE from the colostrum and milk of the sow. If the sow has low body stores or is fed a ration low in VE, then the piglet will be very low in VE when it is weaned. SE and VE can substitute for each other in a limited way in the pig. In the pig, the diet has the most influence. Diets rich in polyunsaturated fatty acids, copper, vitamin A, or mycotoxins may reduce the availability of VE. As dietary vitamin A levels increase, serum and liver α-tocopherol concentrations decline, suggesting a reduced absorption and retention of α-tocopherol when weaned pigs were fed high dietary vitamin A levels. Se antagonists or crops from inherently low-soil-Se fields may also make the situation worse. In pigs, NMD has been produced experimentally on VE- and Se-deficient rations but is usually only a part of the more serious complex of mulberry heart disease and hepatosis dietetica. Microangiopathy is most common in weaned pigs and may be particularly related to VE deficiency.

There is conflicting evidence on the effect of the antioxidative vitamins C and E on the reproductive performance of sows. In some studies, increasing dietary VE in the diet during gestation may have increased the litter size and reduced the preweaning piglet mortality. A similar response has been seen following intramuscular injection of sows with VE and Se, but the injection of vitamin C has produced no improvement. A recent study has confirmed that there was no effect on the reproductive performance of sows and the growth performance of piglets when supplemented by both vitamin E and C. Vitamin E and Se given to immature gilts for flushing purposes led to the formation of fewer but larger corpora lutea after ovulation, probably as a result of the progression of a smaller number of follicles to the ovulatory stage. Vitamin E and Se increased the development of the uterus but did not influence the number of piglets at farrowing.

VESD occurs naturally in rapidly growing pigs, usually during the postweaning period (3 weeks to 4 months), particularly during the early finishing period. The lowest concentration of VE in piglets was at day 45 after farrowing, but it may be that the Se status of the newborn piglets may be more important for their health than their VE status. The first 3 to 4 weeks following the move to the finishing house is the most dangerous period for a low VE level, and it is important to remember that there is considerable individual variation. Serum VE declines after weaning, and even with VE supplementation it takes 2 to 3 days for levels to rise. There appears to be a temporary decreased absorption of the vitamin in the immediate postweaning period, and this in turn leads to the reduction of the stored vitamin E reserves. It is usually associated with diets deficient in both Se and vitamin E and those that may contain a high concentration of unsaturated fatty acids. Such diets include those containing mixtures of soybean, high-moisture corn, and cereal grains grown on soils with low levels of Se. The feeding of a basal ration of cull peas, low in Se and VE, to growing pigs can cause the typical syndrome, and low tissue levels of Se are present in pigs with spontaneously occurring hepatosis dietetica. It has been shown that feeding diets containing linseed oil reduced the VE levels in the diet but increased the skatole levels. However, there are reports of naturally occurring mulberry heart disease of pigs in Scandinavia in which the tissue levels of Se and VE are within normal ranges compared with normal pigs. In Ireland, in spite of supplementation of pig rations with VE and Se at levels higher than that necessary to prevent experimental disease, spontaneous mulberry heart disease may still occur. Affected pigs have lower tissue vitamin E levels than control pigs, which suggests an alteration in α-tocopherol metabolism unrelated to dietary Se and PUFA contents.

Natural occurrence of the disease complex in pigs is not uncommonly associated with diets containing 50% coconut meal, fish-liver-oil emulsion, fish scraps with a high content of unsaturated fatty acids, or flaxseed, which produces yellow and brown discoloration of fat preventable by the incorporation of adequate amounts of α-tocopherol or a suitable antioxidant. The quality of the dietary fat does not necessarily influence blood VE levels, but the presence of oxidized fat reduces the resistance of the red blood cells against peroxidation. The higher requirement for VE by pigs fed oxidized fat may be a result of the low VE content in such fat. It has recently been shown that the inclusion of 0.3 ppm Se to the diet of postweaning piglets resulted in better performance than non-Se-supplemented diets, irrespective of the level of VE in the ration (up to 200 ppm).

Mulberry Heart Disease

Mulberry heart disease (MHD) is the most common form of Se and VE deficiency of pigs. It occurs most commonly in rapidly growing feeder pigs (60 to 90 kg) in excellent condition being fed on a high-energy diet low in VE and Se. The true causal mechanism is not known, but it can be prevented by supplementation with VE. It can also occur when it would appear that the level in the diet and in the serum or tissues appear to be satisfactory. The diets most commonly incriminated are soybean, corn, and barley. Mean liver concentrations of VE were lower in pigs with MHD than in pigs that died of causes other than MHD. The α-tocopherol content of corn is usually low, and it is virtually absent from solvent-extracted soybean

meal. Both are low in Se. The use of high-moisture corn may further exacerbate the tocopherol deficiency. The level of PUFAs in the diet was thought to be an important etiologic factor, but this is now not considered to be a necessary prerequisite. Outbreaks of the disease may occur in which 25% of susceptible pigs are affected, and the case-mortality rate is about 90%. The disease has occurred in young piglets and in adult sows.

Hepatosis Dietetica

Hepatosis dietetica appears to be less common than mulberry heart disease, but the epidemiologic characteristics are similar. It appears to be less common because the Se levels in supplements were raised to 0.3 ppm. It affects young, rapidly growing pigs up to 3 to 4 months of age. NMD in pigs usually occurs in cases of mulberry heart disease and hepatosis dietetica, but it has occurred alone in gilts.

Selenium-Responsive Disorders

A variety of diseases have been known as selenium-responsive disorders because they respond beneficially to the strategic administration of Se. These include the following: **ill-thrift** in lambs and calves on pasture; **lowered milk production** in cows; **white-muscle disease** in lambs, calves, and kids; **lowered fertility** and **embryonic death** in sheep and cattle; **retained fetal membranes**, **metritis**, **poor uterine involution**, and **cystic ovaries** in cows; subclinical **mastitis** and **impaired immune function** in cattle; and **prematurity**, **perinatal death**, and **abortion** in cattle. Of these, only ill-thrift, lowered fertility, lowered milk production, and white-muscle disease have been reported in New Zealand.

The pathogenesis of these selenium-responsive diseases is not well understood, but it would appear that the Se deficiency is only marginal. Most investigations into selenium-responsive diseases have occurred in selenium-deficient areas in which diseases such as NMD of calves and lambs occur. The evidence that Se deficiency in breeding ewes can result in a decline in reproductive performance has not been substantiated experimentally. Reproductive performance was not affected in ewes on a selenium-depleted diet.

Selenium-responsive unthriftiness in sheep has received considerable attention in New Zealand, where the response to Se administration has been most dramatic, compared with Australia, where the syndrome has also been recognized but where the response is much smaller. The oral administration of Se to lambs in these areas results in greater bodyweight gains from weaning to 1 year of age compared with lambs not receiving Se supplementation. The mean fleece weight of selenium-treated lambs is also greater.

The diagnosis of selenium-responsive unthriftiness depends on analyses of the soil, pasture, and animal tissues for Se and response to trials of Se supplementation. A deficiency state might be encountered when the Se content of the soil is below 0.45 mg/kg, the pasture content is below 0.02 mg/kg DM, the liver content is below 21 µg/kg (0.27 µmol/kg wet weight [WW]), and wool concentrations are below 50 to 60 µg/kg (0.63 to 0.76 µmol/kg). For the blood in selenium-responsive unthriftiness of sheep, the following criteria are suggested for mean blood selenium status (µg/dL):

- Deficient = 1.0
- Doubtful = 1.1 to 1.9
- Normal = ~2.0

The GSH-PX activity is a good index of the Se status of sheep with a selenium-responsive disease. If measured on a regular basis, it can provide an indication of the Se status of grazing sheep in individual flocks. Single measurements of GSH-PX activity may fail to detect recent changes in grazing area, differences in pasture species and pasture composition, and alterations in the physiologic state of the animals.

Subclinical Selenium Insufficiency

Subclinical insufficiencies of Se in grazing ruminants are widespread over large areas of southern Australia. The plasma concentrations of affected sheep flocks are low, there are no obvious clinical signs of insufficiency in the ewes, and there are significant responses in wool production and fiber diameter to Se supplementation. The incidence of estrus and fertility is not affected by Se supplementation. Live weights at birth, in midlactation, and at weaning were increased in lambs born to selenium-supplemented and crossbred ewes and in lambs born as singletons. Clean fleece weight at 10 months of age was increased by 9.5% and fiber diameter by 0.3 µm in lambs born to ewes that had received supplementary Se. Differences in fleece weight and live weight were not detected at 22 months, suggesting that subclinical Se insufficiency in early life did not permanently impair productivity if Se status subsequently increased.

Temporal variations in glutathione peroxidase activity in sheep can be used to identify seasons of the year with the highest risk of Se deficiency. In the Mediterranean area, lambs born in the spring/summer are at higher risk of selenium-deficiency related diseases. Lambs born in autumn/winter are from ewes gestating during the summer, when supplementation with cereal grains is provided.

Se is a component of type I iodothyronine deiodinase, which catalyzes the extrathyroidal conversion of thyroxine (T4) to the more active tri-iodothyronine (T3). Sheep grazing pastures low in Se frequently have higher circulating T4 and lower circulating T3 concentrations than sheep receiving Se supplementations.

When ewes grazing pastures low in Se were supplemented with thiocyanate (to cause iodine insufficiency), iodide, and Se, there was no evidence of clinical deficiencies. Growth rates of lambs were not affected by the thiocyanate of their dams during midpregnancy, but plasma T3 and T4 concentrations were depressed in ewes receiving thiocyanate. The iodide supplementation increased thyroid hormone concentrations in ewes but depressed plasma T3 concentrations in lambs. Supplementation of sheep grazing pastures low in Se with both Se and thyroid hormones improved wool characteristics, live-weight gain, and blood Se, but there was no evidence of an interaction between the Se and the hormones. Thus it seems unlikely that the decline in the quantity of T3 produced, or of T4 utilized for T3 production, in selenium-deficient sheep is responsible for the observed differences in the productivity of selenium-deficient and supplemented sheep. The thyroids have a major role in regulating thermogenesis, and lambs born to ewes supplemented with iodide tend to have higher rectal temperatures during cold stress. The thermoregulatory ability of the perinatal lamb is not adversely affected by subclinical Se deficiency.

In a survey of the status of VE and Se of the livers of cull ewes and market lambs raised in Ontario, Se was present at marginal levels in 3.3% of cull ewe samples and in 43% of market lamb samples. VE was low to deficient in 10% of cull ewe samples and in 90% of market lamb samples. In cull ewes, there was a strong relationship between Se and VE. A large percentage of samples with marginal Se values had adequate VE, which may indicate that the sheep had access to high levels of VE but received inadequate levels of supplement containing Se.

An evaluation of the trace mineral status of beef cows in Ontario found that 96% of cull cows were deficient in blood Se. Based on analysis of serum samples from cattle in Iowa and Wisconsin, subclinical Se deficiency is common in the cattle population. The serum levels may be adequate for reproductive performance but marginal for optimal resistance to mastitis or for adequate transfer of selenium to the calf.

In moose in northwestern Minnesota, declining numbers of moose have been associated with low trace elements, particularly copper and selenium.[27]

Reproductive Performance

The roles of reactive oxygen species in female reproduction have been reviewed,[28] and nutritional management is important.[29] The published information on the effects of VE and Se deficiency or of dietary supplementation with one or the other or both on reproductive performance in farm animals is conflicting and controversial. Reproductive performance is complex and dependent on the interaction of many factors. Reproductive inefficiency is likewise complex, and it is

difficult to isolate one factor, such as a deficiency of VE or Se, as a cause of reproductive inefficiency. Conversely, it is difficult to prove that supplementation with these nutrients will ensure optimum reproductive performance. The roles of cellular reactive oxygen species, oxidative stress, and antioxidants in the outcome of pregnancy have been reviewed.[30] Many vitamins and trace elements have a dual role in mammals in that they (a) control or are involved in the metabolic processes and/or gene expression and (b) spend most of their time in trapping radical oxygen species. Any deficiencies will produce high rates of radical oxygen species production.[31]

Pigs

Selenium and vitamin E improve the in vitro maturation, fertilization, and growth to blastocysts of porcine oocytes.[32]

Sheep

The evidence about the effect of Se and VE deficiency on reproductive performance in sheep is conflicting. Observations in the 1960s concluded that Se deficiency caused embryonic deaths 20 to 30 days after fertilization in ewes. But Se supplementation of ewes that were low or marginal in Se status did not improve reproductive performance. Experimental studies using selenium-deficient diets in ewes have been unable to find any adverse effects of Se depletion on ewe conception rates, embryonic mortality, or numbers of lambs born. The parenteral administration of Se to pregnant ewes between 15 and 35 days after mating resulted in a reduced embryonic survival rate and is not recommended during the first month of pregnancy.

Cattle

VE supplementation can have significant effects on the health and some aspects of fertility in lactating dairy cows. VE supplementation of dairy cows has its most beneficial effect of reducing the incidence of mastitis when used at rates of at least 1000 IU per day during the dry period and early lactation. The primary effect of VE supplementation is on the immune system. The importance of Se and VE for the maintenance of optimum reproductive performance is not clear. The IM injection of dairy cattle at 3 weeks prepartum did not have any effect on average days to first estrus or first service, average days to conception, services per conception, or number of uterine infusions required. The prepartum IM injection of VE and Se at 3 weeks prepartum increased the percentage of cows pregnant to first service, reduced the number of services per conception, decreased the incidence of retained placenta, and reduced the interval from calving to conception. In a randomized field trial in a large dairy herd in the United States, oral supplementation of pregnant first-calf dairy heifers with Se using a commercially available sustained-release intraruminal selenium bolus increased blood Se concentrations in treated animals at 30 days after treatment until after calving. However, based on data analyzed at midlactation and late lactation, there were no differences between treated and control groups in somatic cell count, days not pregnant, total milk production, or times bred. The use of an intraruminal pellet of Se at two different levels in dairy herds in New Zealand was evaluated in yearling heifers. The recommended dose was effective in elevating whole-blood GSH-PX activity and Se concentrations to over 10 times those of control animals. Milk production was increased, and there was a trend toward decreased somatic cell counts. There were no differences in calving-first-service or calving-conception intervals, or in the percentage of animals pregnant to first or all services. In other observations, there was an improvement in first-service conception rate and significantly higher blood levels of GSH-PX following the treatment of dairy cows with oral Se pellets. The inconsistent results obtained following the use of Se and VE in pregnant cows may be related to the Se status of the animals; in some herds the blood levels are marginal, and in others the levels are within the normal range.

Winter-fed lactating Norwegian dairy cows were found to have an adequate plasma levels of VE and marginal to adequate levels of blood Se. Silage was the most important source of VE, and selenium-supplemented commercial concentrates were the most important source of selenium. No significant differences in VE or Se status were found between cows with or without recorded treatments of mastitis, parturient paresis, or reproductive abnormalities.

Retained Fetal Placenta

A high incidence (more than 10%) of retained fetal membranes has been associated with marginal levels of plasma Se compared with herds without a problem. In some cases, the incidence could be reduced to below 10% by the injection of pregnant cattle with Se and VE at approximately 3 weeks prepartum, whereas in other studies similar prepartum injections neither reduced the incidence nor improved reproductive performance. A single injection of Se 3 weeks prepartum can reduce the number of days postpartum required for the uterus to reach minimum size and reduce the incidence of metritis and cystic ovaries during the early postpartum period. The parenteral administration of a single injection of 3000 mg VE prepartum to dairy cows of all ages decreased the incidence of retained placenta and metritis to 6.4% and 3.9%, respectively, in the treated group, compared with 12.5% and 8.8% in the control group. The injection, 20 days prepartum, of 50 mg of Se and 680 IU of VE reduced the incidence of retained fetal membranes in one series, but it did not have this effect in another series. The plasma Se concentration at parturition ranged from 0.02 to 0.05 ppm in control cows, in which there was an incidence of 51% retained membranes, and from 0.08 to 0.1 ppm in treated cows, in which the incidence was reduced to 9%. A dietary level of 0.1 mg/kg DM Se is recommended to minimize the incidence of the problem. The complex nature of the etiology of retained fetal membranes also requires a well-designed experimental trial to account for all of the possible factors involved. In a study in Croatia, where the soils are generally deficient, it was found that there is a high level of retained fetal membranes in cattle associated with low levels of Se and VE.[33] VE supplementation during the dry period has reduced the risk of retained fetal membranes, and it is said that the synthetic forms of VE are more effective in this regard.[34]

Mammary Gland Function

One of the techniques for protection against mastitis is to increase the immunity of the bovine mammary gland. Se affects the innate and adaptive immune mechanisms of the mammary gland.[35] VE also reduces the incidence of mastitis.[36] VE supplementation was shown to have an adverse effect on the occurrence of clinical and subclinical mastitis in high doses. The level at dry-off of 14.5 mu mol/L was a risk factor for clinical mastitis. It is therefore necessary to assess the exact level at which VE affects udder health.

In buffaloes, Se helps to combat mastitis because it increases neutrophil phagocytosis and antioxidant levels during acute mastitis in riverine buffaloes.[37]

Transport Stress

VE, Se, and vitamins A and D have been shown to prevent lipid peroxidation and oxidative stress associated with long-term transportation stress in cattle.[38]

Resistance to Infectious Disease

Several trace elements, particularly copper, Se, and zinc, affect immune function, but the effects of supplementation are equivocal. However, adding VE may reduce bovine respiratory disease morbidity but have some effect on performance.[39]

Many studies have examined the role of Se and VE resistance to infectious disease. Most of the evidence is based on in vitro studies of the effects of deficiencies of Se or VE or supplementation with the nutrients on leukocyte responses to mitogens, or on the antibody responses of animals to a variety of pathogens. The status of Se and VE in an animal can alter antibody response, phagocytic function, lymphocyte response, and resistance to infectious disease. The deficiency of VE or Se reduces neutrophil function during the periparturient period. Se and iodine administration in prepartum cows may enhance the calf immune system.[40] The administration of VE and Se during the dry

period can influence mammary gland health and milk cell counts in dairy ewes. In general, a deficiency of Se results in immunosuppression, and supplementation with low doses of Se augments immunologic functions.

A deficiency of Se has been shown to inhibit the following:

- Resistance to microbial and viral infections
- Neutrophil function
- Antibody production
- Proliferation of T and B lymphocytes in response to mitogens
- Cytodestruction of T lymphocytes and natural killer lymphocytes

VE and Se have interactive effects on lymphocyte responses to experimental antigens.

VE supplementation of transport-stressed feedlot cattle is associated with reduced serum acute-phase protein concentrations compared with control animals. Supplementation of the diet of cattle arriving in the feedlot with VE had beneficial effects on humoral immune response and recovery from respiratory disease.

The parenteral administration of Se and VE during pregnancy in dairy cows has a positive effect on the increase of Se and VE concentrations in blood, increase of Se and immunoglobulin concentrations in colostrum, and increase of T3 concentration in blood on the day of parturition. In addition, there was a trend toward a decreased incidence of clinical mastitis.

Neutrophil Function

Se deficiency can affect the function of polymorphonuclear neutrophils (PMNs), which are associated with physiologic changes in GSH-PX levels. In calves on an experimental selenium-deficient diet, the oxygen consumption and the activities of GSH-PX were lower than normal in neutrophils. The feeding of 80 to 120 mg of Se/kg of mineral mixture provided ad libitum was shown to be an effective method of increasing blood Se in a group of cattle and to optimize the humoral antibody response experimentally. It is suggested that blood Se levels over 100 µg/L are necessary to maintain optimum immunocompetence in growing beef cattle. In selenium-deficient goats, the production of leukotriene B_4, a product of neutrophil arachidonic acid lipoxygenation and a potent chemotactic and chemokinetic stimulus for neutrophils, is decreased, resulting in dysfunction of the neutrophils. A deficiency of Se in pregnant sows impairs neutrophil function, and VE deficiency impairs function of both neutrophils and lymphocytes, which may result in increased susceptibility of their piglets to infectious diseases. It is suggested that selenium supplementation be maintained at 0.3 mg/kg of the diet.

Neutrophils from postparturient dairy cows with higher levels of Se have greater potential to kill microbes, and cattle with greater superoxide production may have higher milk production. VE is a fat-soluble membrane antioxidant that enhances the functional efficiency of neutrophils by protecting them from oxidative damage following intracellular killing of ingested bacteria. Peripartum immunosuppression in dairy cows is multifactorial but is associated with endocrine changes and decreased intake of critical nutrients. Decreased phagocytosis and intracellular killing by neutrophils occurs in parallel with decreased dry matter intake and decreased circulating VE. Because neutrophils are the primary mechanism of uterine defense and mammary health, the role of VE on the health of dairy cows during the transition period has been examined. Compared with control cows given a placebo, the parenteral administration of VE 1 week prepartum had no effect on the incidence of retained placenta, clinical mastitis, metritis, endometritis, ketosis, displaced abomasum, or lameness. However, there was a decreased incidence of retained placenta in cows with marginal pretreatment VE status. An increase in α-tocopherol of 1 µg/mL in the last week prepartum reduced the risk of retained placenta by 20%. In addition, serum nonesterified fatty acid concentration greater than or equal to 0.5 mEq/L tended to increase the risk of retained placenta by 80%, and in the last week prepartum, a 100 ng/mL increase in serum retinol was associated with a 60% decrease in the risk of early-lactation clinical mastitis.

Immune Response

The effects of Se deficiency and supplementation on the immune response of cattle to experimental infection with the infectious bovine rhinotracheitis virus and sheep to parainfluenza-3 virus indicate that a deficiency can affect the humoral response and that supplementation enhances the response. The administration of Se either alone or in combination with VE can improve the production of antibodies against *E. coli* in dairy cows. Pigs fed a deficient diet develop an impaired cell-mediated immunity as measured by lymphocyte response to mitogenic stimulations. Supplementation of the diets of young pigs with Se levels above those required for normal growth have increased the humoral response, but not in sows. The wide variations in antibody responses that occur in these experiments indicate that there is a complex relationship between the Se status of the host, humoral immune responses, and protective immunity. The concept of using selenium supplementation to enhance antibody responses in sheep to vaccines is probably unfounded. However, the administration of sodium selenite to sheep vaccinated against enzootic abortion (*Chlamydophila abortus*) increased the antibody response, but not when given with vitamin E. The Se sources provided to mares may influence the immune function of foals at 1 month of age.[41] In sheep with footrot, an improved immune response is found after a higher blood serum Se response is found.[42]

Experimentally, VE can stimulate the immune defense mechanisms in laboratory animals and cattle. In most cases, the immunostimulatory effects of additional VE are associated with supplementation in excess of levels required for normal growth. The parenteral administration to calves of 1400 mg of VE weekly increases their serum VE concentrations and lymphocyte stimulation indices. Similarly, in growing pigs, a serum VE concentration above 3 mg/L is necessary to achieve a significant response of the lymphocytes to stimulation with mitogens.

The administration of a daily 2500 IU RRR-alpha-tocopherol to pregnant mares stimulated maternal IgG and IgM production in colostrum and enhanced VE and IgM status in foals.[43]

General Resistance

These changes may render selenium-deficient animals more susceptible to infectious disease, but there is no available evidence to indicate that naturally occurring deficiencies are associated with an increase in the incidence or severity of infectious diseases. Neutrophils from selenium-deficient animals lose some ability to phagocytose certain organisms, but how relevant this observation is in naturally occurring infections is unclear. Field studies of the incidence and occurrence of pneumonia in housed calves found that Se status was not a risk factor.

Transfer of Selenium and Vitamin E to the Fetus, Colostrum, and Milk

Selenium

In sheep, Se is transferred across the placenta to the fetus, and maternal Se status during gestation is positively associated with fetal and newborn lamb Se status. Supplementation of gestating ewes with Se will improve the Se status of the lambs at birth. Supplementing ewes with VE and Se during pregnancy increased the weight of lambs at weaning by about 2 kg above those on a marginal level of Se., and organic Se produced better lamb viability.[44] However, after birth, the Se of the lamb is depleted quickly, by about 18 days after birth. Thus continued intake of Se by the lamb is necessary to maintain normal Se status during the postnatal period. The colostrum of ewes contains higher levels of Se than ewe milk. The Se content of ewe's milk decreases rapidly after parturition, reaching a stable level by 1 week postpartum. Supplementation of ewes during lactation results in higher milk Se concentration and higher blood Se in lambs. Supplementation of ewes has been shown to prevent nutritional myodegeneration in nursing lambs in selenium-deficient flocks.

There is a highly significant relationship between blood Se of cattle and milk Se concentration. As in sheep, in cattle, Se is

transferred across the placenta to the fetus and across the mammary barrier into the colostrum and milk.

Pigs

The maternal intake of Se affects fetal liver Se, and newborn piglets have lower liver Se concentrations compared with their dams, regardless of Se intake of sows during gestation. Thus compared with cattle and sheep, the relatively high concentration of Se needed in the diets of young rapidly growing piglets may be partially a function of limited placental transport or hepatic deposition of Se and may explain why the piglet is more susceptible to Se deficiency than the sow.

Vitamin E

The transfer of VE across the placenta to the fetus in sheep and cattle is limited. Plasma levels of VE in the fetus and in newborn lambs (before ingestion of colostrum) are lower than in the ewe. VE supplementation of the ewe in late gestation results in insignificant increases of the serum VE in the lamb. However, supplementation of the ewe in the last month of pregnancy increases the VE content of colostrum and milk. Colostrum of the ewe is a rich source of VE for the neonatal lamb, containing 5 to 11 times more VE than milk at 1 week postpartum. The parenteral administration of sodium selenite to ewes at lambing increases the VE content of milk of ewes over the first 5 weeks of lactation, indicating a potential positive effect of Se repletion on VE transfer to milk.

Neonatal Morbidity and Mortality

Based on some preliminary observations of the Se content of hair samples of young calves, higher Se levels in newborn calves may have some protective effect against morbidity as a result of neonatal disease. Similarly, neonatal piglets with high blood levels of GSH-PX activity may be more resistant to infectious diseases or other causes of neonatal mortality. Administration of VE and Se to dairy cows in late pregnancy resulted in the production of increased quantities of colostrum, and the calves had increased quantities of GSH-PX at birth and 28 days of age, but the improved Se status did not provide any improvement in passive immunity or growth.

Supplementing Se to beef cows grazing selenium-deficient pastures with a salt mineral mix containing 120 mg selenium/kg of mix increased the Se status of the cows and increased the serum IgG concentration, or enhanced transfer of IgG from serum to colostrum, and increased the Se status of the calves. The parenteral administration of 0.1 mg Se and 1 mg of vitamin E/kg BW at midgestation did not affect the production of systemic or colostral antibodies. Supplementation of dairy cows at dry-off with Se at 3 mg/d as selenite via an intraruminal bolus resulted in sufficient transfer of Se to meet a target concentration of more than 2.2 μg of selenium/g of liver DM in newborn calves. Milk Se is a useful indicator of animal and herd Se status.[45]

Mastitis

There is some evidence that a dietary deficiency of VE may be associated with an increased incidence of mastitis in dairy cattle. An increased incidence of mastitis during the early stages of lactation coincides with the lowest plasma concentration of VE. Supplementation of the diet of dairy cows beginning 4 weeks before and continuing for up to 8 weeks after parturition with vitamin E at 3000 IU/cow per day, combined with an injection of 5000 IU 1 week before parturition, prevented the suppression of blood neutrophil and macrophage function during the early postpartum period compared with controls. The VE prevented the suppression of blood neutrophils during the postpartum period. Cows in both the treated and control groups were fed diets containing Se at 0.3 ppm of total dry matter. When Se status in dairy cows is marginal, plasma concentrations of α-tocopherol should be at least 3 μg/mL. Cows receiving a dietary supplement of about 1000 IU/d of VE had 30% less clinical mastitis than did cows receiving a supplement of 100 IU/d of VE. The reduction was 88% when cows were fed 4000 IU/d of VE during the last 14 days of the dry period.

The Se status of dairy cows may also have an effect on the prevalence of mastitis and mammary gland health. Dairy herds with low somatic cell counts had significantly higher mean blood GSH-PX and higher whole-blood concentrations of Se than in herds with high somatic cell counts. The prevalence of infection caused by *Streptococcus agalactiae* and *Staphylococcus aureus* was higher in herds with the high somatic cell counts compared with those with the low somatic cell counts. This suggests that phagocytic function in the mammary gland may be decreased by a marginal Se deficiency. In a survey of cattle in herds in Switzerland, those with chronic mastitis had lower serum levels of Se than healthy control herds. Experimental coliform mastitis in cattle is much more severe in selenium-deficient animals than selenium-adequate animals. The severity was in part a result of the increased concentrations of eicosanoids.

Milk neutrophils from cows fed a selenium-deficient diet have significantly reduced capacity to kill ingested *E. coli* and *S. aureus,* compared with cells from cows fed a selenium-supplemented diet. However, other experimental results are not as convincing.

In pasture-based heifers injected with barium sulfate before calving and fed diets with 1.3 or 2.5 mg of Se/d precalving and during lactation, respectively, there was no clinical mastitis observed in the first month of lactation.[46] Se deficiency may predispose to mastitis in sheep, and examination of the Se status may indicate which ewes may develop ovine mastitis.[47]

Lambs supplemented with Se were also able to deal with oxidative stress generated from *H. contortus* infections by the provision of higher GSH-Px levels.[48]

Blood Abnormalities

In young cattle from areas where NMD is endemic, and particularly at the end of winter housing, the erythrocytes have an increased susceptibility to hemolysis following exposure to hypotonic saline. During clinical and subclinical white-muscle disease in calves, there is a significant increase in both the osmotic and the peroxidative hemolysis of the erythrocytes. This defect is thought to be the result of alterations in the integrity of cell membranes, of which tocopherols are an essential component. Abnormalities of the bone marrow associated with VE deficiency in sheep have been described, and abnormal hematologic responses have been described in young, rapidly growing pigs on an experimental SE- and VE-deficient diet. VE deficiency in sheep results in increased hemolytic susceptibility of erythrocytes, which may provide a basis for a single functional test for VE deficiency in sheep.

Anemia characterized by a decreased packed cell volume, decreased hemoglobin concentration, and Heinz-body formation has been observed in cattle grazing on grass grown on peaty muck soils in the Florida everglades. Se supplementation corrected the anemia, prevented Heinz-body formation, increased the body weight of cows and calves, and elevated blood Se. In a study of supplementation,[49] it was found that the Se levels stabilized in the liver and plasma by 56 to 112 days, whereas the whole-blood and red blood cell (RBC) concentrations were still increasing through 224 days of supplementation, regardless of the form of supplemental Se.

In lambs with WMD, there was a significant increase in serum total sialic acid (TSA) and lipid-bound sialic acid (LBSA), together with a significant decrease in serum Se and VE concentrations. Within 1 month of treatment, the changes were reversed.[50]

Equine Nutritional Myopathy

In areas of severely Se-deficient soil, such as the Pacific Northwest of the United States, there is the possibility of Se deficiency myopathy; this can occur in horses of any age, but more usually it occurs in foals, most commonly up to 2 weeks of age. VE deficiency occurs in horses that eat marginal- or poor-quality grass hay with no access to pasture and no VE supplementation. Affected foals are born to deficient mares. They are weak at birth or shortly after. They may become recumbent but are generally bright and alert. The weakness of the tongue and pharyngeal muscles makes it difficult to suckle. The

affected horses are usually stabled, and the condition occurs mostly in late winter or early spring; in the very deficient Northwest, it can occur at any time of the year. The temporal or masseter muscles are often predisposed, with swelling and stiffness of these muscles and impaired mastication. There may be dysphagia and impaired prehension of food. There is often general weakness and a stiff, short-strided gait. The muscles may be pale, and the most severely affected muscles are those that do the most work. Often this means the neck muscles during attempts to suckle. The gross appearance depends on the duration of the condition and may involve the heart. In animals that die, there are often areas of severe necrosis. In the more subacute cases there are areas of repair and regeneration together with new areas of necrosis. In these animals diagnosis is based on the geographic area, history, clinical signs, increased levels of CK and AST, and gross and histologic lesions.

Fatal myocardial degeneration in an adult Quarter horse with Vitamin E deficiency but normal Se has been described.[51] There were pale and firm foci in the heart.

Congenital white-muscle disease also occurs in deer calves.[52]

Equine Degenerative Myeloencephalopathy

Equine degenerative myeloencephalopathy, also sometimes called neuronal dystrophy, is seen pure and mixed breeds of horses. It has also been seen in zebras and in Morgan and Haflinger horses. Clinically, it is a symmetric spasticity with ataxia and paresis of the limbs.

Equine degenerative myeloencephalopathy, which may have an inherited basis, has been associated with VE deficiency. The VE status is low in some affected horses, and supplementation with the vitamin was associated with a marked reduction in the incidence of the disease. In some premises affected with the condition, the administration of VE reduced the incidence. On the other hand, however, serum VE and blood GSH-PX activities determined in horses with histologically confirmed diagnosis of the disease compared with age-matched controls failed to reveal any differences, and the findings did not support a possible role for VE deficiency as a cause. Foals sired by a stallion with degenerative myeloencephalopathy and with neurologic deficits consistent with the disease during their first year of life had lower plasma levels of α-tocopherol when the levels were determined serially beginning at 6 weeks to 10 months of age than did age-matched controls. Absorption tests with VE revealed that the lower α-tocopherol levels were not attributable to an absorption defect. The lesions are usually microscopic and are found as axonal degeneration in the spinal cord, with the dorsal spinocerebellar tracts in the lateral funiculi and some areas of the ventral funiculi severely affected. Myelin loss is secondary to axonal loss. In the brain, there are eosinophilic spheroids in the brainstem nuclei.

Equine Motor Neuron Disease

Equine motor neuron disease is a neurodegenerative disease of the somatic lower motor neurons resulting in a syndrome of diffuse neuromuscular disease in the adult horse. Case-control studies found the mean plasma VE concentrations in affected horses were lower than that of control horses. Adult horses are affected with the risk peaking at 16 years of age. In addition to the role of VE depletion, other individual and farm-level factors contribute to the risk of developing the disease.

Generalized Steatitis

Steatitis in farm animals and other species may be associated with VE and/or Se deficiency. Most cases in horses have involved nursing or recently weaned foals. Generalized steatitis in the foal has been described as either generalized cachexia as a result of steatitis alone or as a primary myopathy or myositis, with steatitis of secondary importance. The terms used have included steatitis, generalized steatitis, fat necrosis, yellow-fat disease, polymyositis, and muscular dystrophy. The relationships between steatitis and VE and Se deficiency in the horse are not clear, and there may not be any. Many more clinical cases must be examined in detail before a cause–effect relationship can be considered.

PATHOGENESIS

Dietary Se, sulfur-containing amino acids, and VE act synergistically to protect tissues from oxidative damage. GSH-PX, which is selenium dependent, functions by detoxifying lipid peroxides and reducing them to nontoxic hydroxy fatty acids. Vitamin E prevents fatty acid hydroperoxide formation. High levels of PUFAs in the diet increase the requirements for VE, and with an inadequate level of Se in the diet, tissue oxidation occurs, resulting in degeneration and necrosis of cells. VE protects cellular membranes from lipoperoxidation, especially membranes rich in unsaturated lipids, such as mitochondric, endoplasmic reticulum, and plasma membranes. Thus dietary PUFAs are not a prerequisite for the disease. Diets low in Se and/or VE do not provide sufficient protection against the "physiological" lipoperoxidation that occurs normally at the cellular level.

The relative importance of Se, VE, and sulfur-containing amino acids in providing protection in each of the known diseases caused by their deficiency is not clearly understood. Se has a sparing effect on VE and is an efficient prophylactic against muscular dystrophy of calves and lambs at pasture, but it does not prevent muscular dystrophy in calves fed on a diet containing cod liver oil. The current understanding of the biochemical function of Se and its relation to VE and the mechanisms of action of Se and VE in protection of biological membranes have been reviewed.

Nutritional Muscular Dystrophy

A simplified integrated concept of the pathogenesis of the NMD would be as follows. Diets deficient in Se and/VE permit widespread tissue lipoperoxidation, leading to hyaline degeneration and calcification of muscle fibers. One of the earliest changes in experimental Se deficiency in lambs is the abnormal retention of calcium in muscle fibers undergoing dystrophy, and Se supplementation prevents the retention of calcium. Unaccustomed exercise can accelerate the oxidative process and precipitate clinical disease. Muscle degeneration allows the release of enzymes, such as lactate dehydrogenase, aldolase, and creatine phosphokinase, the last of which is of paramount importance in diagnosis. Degeneration of skeletal muscle is rapidly and successively followed by invasion of phagocytes and regeneration. In myocardial muscle, replacement fibrosis is the rule.

In calves, lambs, and foals, the major muscles involved are skeletal, myocardial, and diaphragmatic. The myocardial and diaphragmatic forms of the disease occur most commonly in young calves, lambs, and foals, resulting in acute heart failure, respiratory distress, and rapid death, often in spite of treatment. The skeletal form of the disease occurs more commonly in older calves, yearling cattle, and older foals and results in weakness and recumbency; it is usually less severe and responds to treatment. The biceps femoris muscle is particularly susceptible in calves, and muscle biopsy is a reliable diagnostic aid.

In foals with NMD, there is a higher proportion of type IIC fibers and a lower proportion of type I and IIA fibers than in healthy foals. The type IIC fibers are found in fetal muscle and are undifferentiated and still under development. During the recovery period, fibers of types I, IIA, and IIB increase and the proportion of type IIC fibers decreases. A normal fiber type composition is present in most surviving foals 1 to 2 months after the onset of the disease.

Acute NMD results in the liberation of myoglobin into the blood, which results in myoglobinuria. This is more common in horses, older calves, and yearling cattle than in young calves, whose muscles have a lower concentration of myoglobin. Hence, the tendency to myoglobinuria will vary depending on the species and age of animal involved.

Subclinical Selenium Insufficiency

Se deficiency affects thyroid hormone metabolism and may explain the cause of ill-thrift. The conversion of the iodine-containing hormone thyroxine (T4) to the

more potent triiodothyronine (T3) is impaired in animals with low Se status, and iodothyronine deiodinase is a selenoprotein that mediates this conversion.

VESD Syndrome and Others

The pathogenesis of mulberry heart disease, hepatosis dietetica, exudative diathesis, and muscular dystrophy of pigs is not yet clear. VE and Se are necessary to prevent widespread degeneration and necrosis of tissues, especially the liver, the heart, skeletal muscle, and blood vessels. Se and VE deficiency in pigs results in massive hepatic necrosis (hepatosis dietetica), degenerative myopathy of cardiac and skeletal muscles, edema, microangiopathy, and yellowish discoloration of adipose tissue. Myocardial and hepatic calcium concentrations are increased in pigs with mulberry heart disease. In addition, there may be esophagogastric ulceration, but it is uncertain whether or not this lesion is caused by a Se and/or VE deficiency. Anemia has also occurred and has been attributed to a block in bone-marrow maturation, resulting in inadequate erythropoiesis, hemolysis, or both. However, there is no firm evidence that anemia is a feature of Se and VE deficiency in pigs. The entire spectrum of lesions has been reproduced experimentally in pigs with natural or purified diets deficient in Se and VE or in which an antagonist was added to inactivate VE or Se. However, in some studies, the Se content of tissues of pigs that died from mulberry heart disease was similar to that of control pigs without the disease.

The extensive tissue destruction in pigs may account for the sudden-death nature of the complex (mulberry heart disease and hepatosis dietetica) and the muscle stiffness that occurs in some feeder pigs and sows of farrowing time with muscular dystrophy. The tissue degeneration is associated with marked increases in serum enzymes related to the tissue involved. An indirect correlation between VE intake and peroxide hemolysis in pigs on a deficient diet suggests that lipoperoxidation is the ultimate biochemical defect in pigs and that VE and Se are protective.

It is thought now that the disease is associated with the lack of balance between free-radical generation and scavenging of these radicals that is called oxidative stress. Scavengers include superoxide dismutase, glutathione peroxidase, vitamin C, and vitamin E. Se is included because it is a component of glutathione peroxidase. Deficiency of these scavengers can lead to cellular injury and death.

In these pigs, there are other complicating factors that may make the condition multifactorial. These include stress, increased iron tissue concentrations, increased calcium and decreased magnesium concentrations, and diets containing corn oil, PUFAs, aflatoxins, excess vitamin A, or dried distiller grains. Individual animals may also have a genetic predisposition.

CLINICAL FINDINGS

Nutritional muscular dystrophy is frequently diagnosed in cattle in Europe, but diagnosis based on samples is the only way to confirm the diagnosis because the clinical signs are rarely pathognomonic.[53]

Acute Enzootic Muscular Dystrophy

Affected animals may collapse and die suddenly after exercise without any other premonitory signs. The excitement associated with the hand-feeding of dairy calves may precipitate peracute death. In calves under close observation, a sudden onset of dullness and severe respiratory distress, accompanied by a frothy or blood-stained nasal discharge, may be observed in some cases. Affected calves, lambs, and foals are usually in lateral recumbency and may be unable to assume sternal recumbency even when assisted. When picked up and assisted to stand, they feel and appear limp. However, their neurologic reflexes are normal. Their eyesight and mental attitude are normal, and they are usually thirsty and can swallow unless the tongue is affected. The heart rate is usually increased up to 150 to 200/min and often with arrhythmia, the respiratory rate is increased up to 60 to 72/min, and loud breath sounds are audible over the entire lung fields. The temperature is usually normal or slightly elevated. Affected animals commonly die 6 to 12 hours after the onset of signs, in spite of therapy. Outbreaks of the disease occur in calves and lambs in which up to 15% of susceptible animals may develop the acute form and the case-fatality approaches 100%.

Subacute Enzootic Muscular Dystrophy

Subacute enzootic muscular dystrophy is the most common form in rapidly growing calves, often referred to as "white-muscle disease" and, in young lambs, "stiff-lamb disease." Affected animals may be found in sternal recumbency and be unable to stand, but some make an attempt to stand (Fig. 15-12). If they are standing, the obvious signs are stiffness, trembling of the limbs, weakness, and, in most cases, an inability to stand for more than a few minutes. The gait in calves is accompanied by rotating movements of the hocks and in lambs by a stiff, goose-stepping gait. Muscle tremor is evident if the animal is forced to stand for more than a few minutes. On palpation the dorsolumbar, gluteal, and shoulder muscle masses may be symmetrically enlarged and firmer than normal (although this may be difficult to detect). Most affected animals retain their appetite and will suck if held up to the dam or eat if hand-fed. Major involvement of the diaphragm and intercostal muscles causes dyspnea with labored and abdominal-type respiration. The temperature is usually in the normal range, but there may be a transient fever (41° C; 105° F) as a result of the effects of myoglobinemia and pain. The heart rate may be elevated, but there are usually no rhythmic irregularities. Following treatment, affected animals usually respond in a few days, and within 3 to 5 days they are able to stand and walk unassisted. In sheep with stiff-lamb disease, there were heart arrhythmias resulting from myocardial degeneration. In these lambs with low VE and Se, there were seven different arrhythmias detected.[54]

Fig. 15-12 **Subacute enzootic muscular dystrophy in a recently weaned Merino lamb. The weanling is bright, alert, and responsive, with a good appetite, but it is unable to stand for more than a few seconds.**

In alpacas grazing the same pastures as sheep, it was found that the sheep had higher blood Se levels but the alpacas had higher plasma Se levels.[55]

In some cases, the upper borders of the scapulae protrude above the vertebral column and are widely separated from the thorax. This has been called the "flying scapula" and has occurred in outbreaks in heifers from 18 to 24 months of age within a few days to 3 weeks after being turned out in the spring following loose-housing conditions throughout the winter.[56] The abnormality is a result of bilateral rupture of the serratus ventralis muscles and has also been reported in a red deer. Occasionally, the toes are spread, and there is relaxation of carpal and metacarpal joints or knuckling at the fetlocks and standing on tip-toe, inability to raise the head, difficulty in swallowing, inability to use the tongue, and relaxation of abdominal muscles. Choking may occur when the animals attempt to drink. In "paralytic myoglobinuria" of yearling cattle, there is usually a history of recent turning out on pasture following winter housing. Clinical signs occur within 1 week and consist of stiffness, recumbency, myoglobinuria, hyperpnea, and dyspnea. Severe cases may die within a few days, and some are found dead without premonitory signs. In rare cases, lethargy, anorexia, diarrhea, and weakness are the first clinical abnormalities recognized, followed by recumbency and myoglobinuria.

Congenital muscular dystrophy has been described in a newborn calf. The calf was still recumbent 13 hours after birth and had increased serum creatine kinase and decreased serum VE and Se levels. Recovery occurred following supportive therapy and VE and Se administration.

Subcapsular liver rupture in lambs has been associated with VE deficiency in lambs, usually those under 4 weeks of age. Affected lambs collapse suddenly, become limp, and die within a few minutes or several hours after the onset of weakness.

In **foals, muscular dystrophy** occurs most commonly during the first few months of life and is common in the first week. The usual clinical findings are failure to suck, recumbency, difficulty in rising, and unsteadiness and trembling when forced to stand. The temperature is usually normal, but commonly there is polypnea and tachycardia. The disease in foals may be characterized by an acute, fulminant syndrome, which is rapidly fatal, or a subacute syndrome characterized by profound muscular weakness. Failure of passive transfer, aspiration pneumonia, and stunting are frequent complications. In the subacute form, mortality rates may range from 30% to 45%.

In **adult horses with muscular dystrophy**, a stiff gait, myoglobinuria, depression, inability to eat, holding the head down low, and edema of the head and neck are common. The horse may be presented initially with clinical signs of colic.

In **pigs, muscular dystrophy** is not commonly recognized clinically because it is part of the more serious disease complex of mulberry heart disease and hepatosis dietetica. However, in outbreaks of this complex, sucking piglets, feeder pigs, and sows after farrowing may exhibit an uncoordinated, staggering gait suggestive of muscular dystrophy.

Subclinical nutritional muscular dystrophy occurs in apparently normal animals in herds at the time clinical cases are present. The serum activity of creatine kinase may be elevated in susceptible animals for several days before the onset of clinical signs; following treatment with VE and Se the serum enzyme activity returns to normal. Grossly abnormal electrocardiograms occur in some animals and may be detectable before clinical signs are evident.

Juvenile mortality in captive lesser kudu was reported at Basle Zoo as a result primarily of WMD caused by a diet deficient in both VE and Se.[57]

Vitamin E/Selenium Deficiency in Pigs

In pigs the total antioxidant pool is the important feature because Se and ascorbic acid are sparing for vitamin C and alpha-tocopherol.[58] Usually, they occur separately, but rarely MHD and HD occur together; even more rarely, you may find that there is NMD as well. There is a suspicion that the occurrence of two or more together has recently become more common, but this in fact may be a result of the greater awareness of both conditions. Two or more conditions require supplementation with both VE and Se.

Mulberry Heart Disease

MHD is usually seen in pigs from a few weeks to 4 months of age. The incidence of the disease is generally low. These pigs are nearly always the best of the group, and it may be that this rate of growth increases the demand for VE and Se. Nearly always the animals are found dead, so clinical signs are not often seen. Death usually results from arrhythmias associated with the myocardial necrosis.

More than one pig may be found dead. When seen alive, animals show severe dyspnea, cyanosis, and recumbency, and forced walking can cause immediate death. In some outbreaks, about 25% of pigs will show a slight inappetence and inactivity; these are probably in the subclinical stages of the disease. The stress of movement, inclement weather, or transportation will precipitate further acute deaths. The temperature is usually normal, the heart rate is rapid, and irregularities may be detectable. The feces are usually normal.

Hepatosis Dietetica

In hepatosis dietetica, most pigs are found dead. Very few cases show other signs. In occasional cases, before death there will be dyspnea, severe depression, vomiting, staggering, diarrhea, and a state of collapse. Some pigs are icteric. Outbreaks also occur similar to the pattern in mulberry heart disease. Muscular dystrophy is an almost consistent necropsy finding in both mulberry heart disease and hepatosis dietetica but is usually not recognized clinically because of the seriousness of the two latter diseases. Clinical muscular dystrophy has been described in gilts at 11 months of age. About 48 hours after farrowing, there was muscular weakness, muscular tremors, and shaking. This was followed by collapse, dyspnea, and cyanosis. There were no liver or heart lesions. In experimental Se and VE deficiency in young, rapidly growing pigs, a subtle stiffness occurred along with a significant increase in the creatinine phosphatase (CPK) and serum glutamic-oxaloacetic transaminase (SGOT) values.

CLINICAL PATHOLOGY

Myopathy

Plasma Creatine Kinase

Plasma creatine kinase (CK) is the most commonly used laboratory aid in the diagnosis of NMD. The enzyme is highly specific for cardiac and skeletal muscle and is released into the blood following unaccustomed exercise and myodegeneration. In cattle and sheep, its half-life is 2 to 4 hours, and plasma levels characteristically decline quickly unless there is continued myodegeneration but remain a good guide to the previous occurrence of muscle damage for a period of about 3 days. The normal plasma levels of CK (IU/L) are as follows: sheep, 52 ± 10; cattle, 26 ± 5; horses, 58 ± 6; and pigs, 226 ± 43. In cattle and sheep with NMD, the CK levels will be increased, usually above 1000 IU/L and commonly to 5000 to 10,000 IU/L, and not uncommonly even higher. Following turn-out of housed cattle onto pasture, the CK levels will increase up to 5000 IU/L within a few days. The CK levels will usually return to normal levels within a few days following successful treatment. Persistent high levels suggest that muscle degeneration is still progressive or has occurred within the last 2 days. Measurement of plasma CK activity could be used to monitor recovery of animals treated for nutritional myopathy.

Aspartate Aminotransferase

Aspartate aminotransferase (AST) activity is also an indicator of muscle damage, but it is not as reliable as the CK because increased AST levels may also indicate liver damage. The AST activity remains elevated for 3 to 10 days because of a much longer half-life than CK. In acute cases, levels of 300 to 900 IU/L in calves and 2000 to 3000 IU/L in lambs have been observed. In normal animals of

these species, serum levels are usually less than 100 IU/L.

The magnitude of the increase in AST and CK is directly proportional to the extent of muscle damage. Both are elevated initially; an elevated AST and declining CK would suggest that muscle degeneration is no longer active. The levels of both enzymes will be increased slightly in animals that have just been turned out and subjected to unaccustomed exercise, horses in training, and in animals with ischemic necrosis of muscle as a result of recumbency caused by diseases other than muscular dystrophy. However, in acute muscular dystrophy, the levels are usually markedly elevated.

Selenium Status

Although information on the critical levels of Se in soil and plants is accumulating gradually, the estimations are difficult and expensive. Most field diagnoses are made on the basis of clinicopathologic findings, the response to treatment, and control procedures using selenium. The existence of NMD is accepted as presumptive evidence of Se deficiency, which can now be confirmed by analyses of GHS-PX and the concentrations of Se in soil, feed samples, and animal tissues. Tentative critical levels of the element are as follows:

- **Forages and grains**: A content of 0.1 mg/kg DM is considered adequate.
- **Soil**: Soils containing less than 0.5 mg/kg are likely to yield crops inadequate in selenium concentration.
- **Animal tissues, blood, and milk**: The concentrations of Se in various tissues are reliable indicators of the Se status of the animal. There is a positive correlation between the Se content of feed and the Se content of the tissues and blood of animals ingesting that feed, and the values fluctuate with the dietary intake of the element.

Three tests can be used to assess Se status in cattle and sheep: serum and whole-blood Se and glutathione peroxidase activity. Serum Se responds more rapidly to the administration of Se than whole-blood Se. There is a similar delay in glutathione peroxidase activity to Se supplementation. Blood or serum Se status is most consistently measured at the herd level. Interlaboratory differences in thresholds for deficiency exist, and results should be considered based on laboratory-specific guidelines.

The recommended blood Se reference ranges for New Zealand livestock have been used in several publications.

Reference ranges for Se and VE in serum, blood, and liver of sheep and goats in the United States are available.

Selenium Status in Horses

In New Zealand, the reference ranges for blood used for Se status in horses are as follows: adequate, greater than 1,600 nmol/L (128 ng/mL); marginal, 450 to 1,600 nmol/L (36 to 128 ng/mL); and deficient, less than 450 nmol/L (36 ng/mL).

Kidney Cortex and Liver

Normal liver Se concentrations range from 1.2 to 2.0 µg/g DM, regardless of species or age. Levels of 3.5 to 5.3 µg/g (44 to 67 nmol/g) DM in the kidney cortex and 0.90 to 1.75 µg/g (11 to 22 nmol/g) DM in the liver of cattle are indicative of adequate Se. Levels of 0.6 to 1.4 µg/g (8 to 18 nmol/g) in the kidney cortex and 0.07 to 0.60 µg/g (0.9 to 8 nmol/g) in the liver represent a deficient state.

The Se content of bovine fetal liver samples collected at an abattoir contained 0.77 µg/mL WW and 0.13 µg/mL WW, from dairy breeds and beef breeds of cattle, respectively. Mean liver Se levels from aborted bovine fetuses with myocardial lesions were 5.5 µmol/kg, 6.5 µmol/kg in fetuses without myocardial lesions, and 7.5 µmol/kg in fetuses from the abattoir, which suggests that Se deficiency may be the cause of abortion.

Blood and Milk

Blood and milk levels of Se are used as indicators of Se status in cattle and the effect of dietary supplementation. Serum Se values increase gradually with age from starting ranges for neonates of 50 to 80 ng/mL for calves and sheep and 70 to 90 for foals and pigs. Expected or normal values for adults are in the ranges of 70 to 100 for cattle, 120 to 150 for sheep, 130 to 160 for horses, and 180 to 220 for pigs.

Dams of affected calves have levels of 1.7 ng/mL (22 nmol/L) in blood and 4.9 ng/mL (62 nmol/L) in milk; their calves have blood levels of 5 to 8 ng/mL (63 to 102 nmol/L). Normal selenium-supplemented cows have 19 to 48 ng/mL (241 to 609 nmol/L) in blood and 10 to 20 ng/mL (127 to 253 nmol/L) in milk, and their calves have blood levels of 33 to 61 ng/mL (419 to 774 nmol/L). Mean Se concentrations in the blood of normal mares are 26 to 27 ng/mL (329 to 342 nmol/L). In Thoroughbred horses, Se concentrations in serum range from 39.5 to 118.5 mg/mL (40 to 160 ng/mL; 0.5 to 2.0 µmol/L), and there are significant differences between various stables of horses.

Bulk-Tank Milk

The bulk-tank milk Se levels are closely related to the mean herd blood and milk levels and have the potential to be a low-cost, noninvasive means of evaluating herd Se levels to determine Se deficiency in the dairy herd. Bulk-tank Se concentrations are an accurate reflection of the herd Se status over the range of Se intakes typical of dairy herds in an area.

Glutathione Peroxidase

There is a direct relationship between the GSH-PX activity of the blood and the Se levels of the blood and tissues of cattle, sheep, horses, and pigs. The normal Se status of cattle is represented by whole-blood Se concentration of 100 ng/mL (1270 nmol/L) and blood GSH-PX activity of approximately 30 mU/mg hemoglobin.

There is a high positive relationship ($r = 0.87$ to 0.958) between blood GSH-PX activity and blood Se concentrations in cattle. Blood Se levels less than 50 ng/mL are considered as selenium-deficient, levels between 50 and 100 ng/mL (126.6 nmol/L) are marginal, and those greater than 100 ng/mL are adequate. Comparable whole-blood levels of GSH-PX are deficient if less than 30 mU/mg hemoglobin, marginal if 30 to 60 mU/mg, and adequate if greater than 60 mU/mg hemoglobin. There is some evidence of variation in GSH-PX activities between breeds of sheep; levels may also decrease with increasing age. Low levels in some breeds of sheep may also be a reflection of adaptation to low Se intake because of low levels of Se in the soil and forages.

The GSH-PX activity is a sensitive indicator of the level of dietary Se intake and the response to the oral or parenteral administration of Se. Because Se is incorporated into erythrocyte GSH-PX only during erythropoiesis, an increase in enzyme activity of the blood will not occur for 4 to 6 weeks following administration of Se. Plasma GSH-PX will rise more quickly and will continue to increase curvilinearly with increasing dietary Se levels because it is not dependent on incorporation of the Se into the erythrocytes. The liver and Se concentration and serum GSH-PX activity may respond to changes in dietary Se more rapidly than either whole-blood Se or erythrocyte GSH-PX activity. The response in GSH-PX activity may depend on the Se status of the animals at the time when Se administered. Larger increases in the enzyme activity occur in selenium-deficient animals. The GSH-PX activity in foals reflects the amount of Se given to the mare during pregnancy.

The sandwich ELISA is a simplified method for the estimation of GSH-PX activity and Se concentration in bovine blood and can be used for rapid screening of the Se status of a large number of cattle. The GSH-PX activity of whole-blood samples has been used to assess the Se status of cattle in the Czech Republic.

The GSH-PX activity can be determined rapidly using a spot test, which is semiquantitative and can place a group of samples from the same herd or flock into one of three blood Se categories: deficient, low marginal, and marginal adequate. A commercial testing kit known as the Ransel Kit is now available. Because of the instability of GSH-PX plasma, GSH-PX activity in sheep, cattle, and pigs should be measured in fresh plasma or stored at –20° C (–4° F). For absolute measurements, it is suggested that pig plasma GSH-PX activity be measured

immediately after separation from the blood cells or be assayed within 24 hours under specified laboratory conditions.

Vitamin E Status

VE occurs in nature as a mixture of tocopherols in varying proportions. They vary widely in their biological activity so that chemical determination of total tocopherols is of much less value than biological assay. Tocopherol levels in blood and liver provide good information on the VE status of the animal. However, because of the difficulty of the laboratory assays of tocopherols, they are not commonly done, and insufficient reliable data are available. Analysis of liver from clinically normal animals on pasture reveals a mean α-tocopherol level of 20 mg/kg WW for cattle and 6 mg/kg WW for sheep. The corresponding ranges were 6.0 to 53 mg/kg WW for cattle and 1.8 to 17 mg/kg WW in sheep. The critical level below which signs of deficiency may be expected are 5 mg/kg WW for cattle and 2 mg/kg WW for sheep. Tocopherol levels in the serum of less than 2 mg/L in cattle and sheep are considered to be critical levels below which deficiency diseases may occur. However, if the diet contains adequate quantities of Se, but not an excessive quantity of PUFAs, animals may thrive on low levels of serum tocopherols. In growing pigs, the serum VE levels are between 2 and 3 mg/L. In summary, there are insufficient reliable data available on the VE status on animals with NMD to be of diagnostic value.

The mean plasma VE level in clinically normal horses of various ages and breeds was 2.8 µg/mL. The optimal method for storing equine blood before α-tocopherol analysis is in an upright position in the refrigerator for up to 72 hours. If a longer period is needed, the serum or plasma should be separated, blanketed with nitrogen gas, and frozen in the smallest possible vial; the α-tocopherol in these samples will be stable at –16° C (3° F) for at least 3 months.

A summary of the GSH-PX activity, tocopherol levels, and Se levels in blood and body tissues of animals deficient in Se appears in Table 15-7. Normal values are also tabulated for comparison. Both the abnormal and normal values should be considered as guidelines for diagnosis because of the wide variations in levels between groups of animals. The level of dietary Se may fluctuate considerably, which may account for variations in GSH-PX. Se reference ranges to determine Se status of sheep and cattle in New Zealand are shown in Table 15-8.

In the early stages of the subclinical form of NMD in lambs, there may be a decrease in serum Se and glutathione peroxidase activity and an increase in the activity of aspartate aminotransferase (AST), creatine kinase (CK), and lactate dehydrogenase (LDH) compared with healthy lambs. The LDH-isoenzyme activity is useful for detection of subclinical forms of NMD because of significant increases in the activity of the LDH_5-muscle fraction.

Table 15-7 Glutathione peroxidase (GSH-PX) activity and selenium concentration in blood and body tissues of animals deficient in selenium

Species	Clinical state or degree of deficiency	Erythrocyte GSH-PX activity µmol/min at 37° C/g hemoglobin	Serum selenium (µg/mL)	Liver selenium (µg/g DM)
Cattle	Normal or adequate	19.0–36.0	0.08–0.30	0.90–1.75
	Marginal	10.0–19.0	0.03–0.077	0.45–0.90
	Deficient	0.2–10.0	0.002–0.025	0.07–0.60
Sheep	Normal or adequate	60–180	0.08–0.50	0.90–3.50
	Marginal	8–30	0.03–0.05	0.52–0.90
	Deficient	2–7	0.006–0.03	0.02–0.35
Horse	Adequate	30–150	0.14–0.25	1.05–3.50
	Deficient	8–30	0.008–0.55	0.14–0.70
Pigs	Adequate	100–200	0.12–0.30	1.40–2.80
	Deficient	<50	0.005–0.60	0.10–0.35

Table 15-8 Selenium reference range to determine selenium status of sheep and cattle in New Zealand

	Deficient	Marginal	Adequate
Sheep			
Blood selenium (nmol/L)	<130	130–250	>250
Liver selenium (nmol/kg fresh tissue)	<250	250–450	>450
Cattle			
Blood selenium (nmol/L)	<130	130–250	>250
Liver selenium (nmol/kg fresh tissue)	<600	600–850	>850
Serum selenium (nmol/L)	<85	85–140	>250
Blood glutathione peroxidase (Ku/L –25°C)	<0.5	0.5–2.0	>2.0

Farmed Red Deer

Reference range data for liver and blood selenium in red deer are limited. White-muscle disease has occurred in young deer with blood and liver Se concentrations of 84 to 140 nmol/L and 240 to 500 nmol/kg fresh tissue, respectively. No growth-rate response to Se supplementation occurred in 1-year-old deer when blood Se concentrations were less than 130 nmol/L, the range in which a growth rate response would be expected in sheep.

Pigs

An increase in the activity of several plasma enzymes occurs in Se and VE deficiencies of pigs. The measurement of AST, CPK, LDH, and isocitrate dehydrogenase can be used to detect the onset of degeneration of skeletal and myocardial muscles and liver. However, these are not commonly used for diagnostic purposes because of the acuteness of the illness. The determination of the levels of Se in feed supplies, tissues, and blood of affected pigs is much more useful as an aid to diagnosis and for guidelines for supplementation of the diet.

In Se–VE deficiency in pigs, serum Se values of less than 2.5 ng/mL (3.2 nmol/L), hepatic Se of less than 0.10 mg/kg (1.3 µmol/kg), plasma α-tocopherol values of less than 0.40 µg/mL, and hepatic α-tocopherol concentrations of less than 0.75 µg/g of tissue are common. In a recent study, the VE level was less than 2 ppm in 25% of pigs with gross and microscopic lesions of MHD. In a recent study, results suggested that supplementation with a surfeit level of VE reduced the response to endotoxin (i.e., a reduced response to the peak levels of IL-6).

The diagnostic criteria for the VESD complex in pigs in New Zealand indicate that liver VE concentrations greater than 10 µmol/kg are adequate, with less than 2.5 µmol/kg associated with deficiency. Corresponding estimates for serum VE are greater than 2.5 µmol/L and less than 0.8 µmol/L, respectively. Liver Se concentrations of greater than 2200 nmol/kg are adequate, with 1100 to 2200 nmol/kg being in the marginal range and less than 1100 nmol/kg being deficient. Deficiency levels for blood are in the range of 400 to 1500 nmol/L. These values must be interpreted along with the concentration of PUFAs in the diet.

There is a close relationship between blood VE and resistance of erythrocytes against lipid peroxidation. The

supplementation of the diet of pigs with VE will increase both the serum levels of VE and the resistance of the erythrocytes to lipid peroxidation.

NECROPSY FINDINGS

The gross appearance of the muscle lesions is quite constant, but the distribution of affected muscles varies widely in different animals. Affected groups of skeletal muscle are bilaterally symmetric and contain localized white or gray areas of degeneration and necrosis. These areas may be in streaks, involving a large group of muscle fibers that run through the center of the apparently normal muscle or as a peripheral boundary around a core of normal muscle. In the diaphragm, the distribution of damaged bundles gives the tissue a radially striated appearance. The affected muscle is friable and edematous and may be mineralized. Secondary pneumonia often occurs in cases where the muscles of the throat and chest are affected. In cases with myocardial involvement, white areas of degeneration are visible, particularly under the endocardium of the left ventricle in calves and of both ventricles in lambs. The lesions may extend to involve the interventricular septum and papillary muscles and have a gritty character consistent with mineralization. Pulmonary congestion and edema is common.

Histologically, the muscle lesions in all species are **noninflammatory**. Hyaline degeneration is followed by coagulation necrosis and variable degrees of mineralization.

Other than a variable degree of muscular atrophy, gross lesions are not seen in horses with **equine motor neuron disease**. Confirmation of the diagnosis relies on histologic identification of characteristic degeneration and loss of motor neurons of the spinal cord ventral horns. However, a very strong presumptive diagnosis can be achieved by microscopic confirmation of neurogenic atrophy in the sacrocaudalis dorsalis muscle or axonal degeneration in the spinal accessory nerve.

A generalized **steatitis** has been described in newborn foals less than 2 months of age. The microscopic appearance of this yellow–brown fat consists of necrotic fat infiltrated by neutrophils, macrophages, and giant cells. Steatitis and nodular panniculitis have also been reported in a 3-year-old VE–Se-deficient mare.

In **mulberry heart disease**, the carcass is in good condition. All body cavities contain excessive amounts of fluid and shreds of fibrin. In the peritoneal cavity, the fibrin is often in the form of a lacy net covering all the viscera. The liver is enlarged, appears mottled, and has a characteristic nutmeg appearance on the cut surface. The lungs are edematous, and excessive fluid in the pleural cavities is accompanied by collapse of the ventral lung field. The pericardial sac is filled with gelatinous fluid interlaced with bands of fibrin. Beneath the epicardium and endocardium are multiple hemorrhages of various sizes. Usually, this hemorrhage is more severe on the right side of the heart. This gives the heart the typical mottled appearance, which is caused by areas of necrosis and areas of hemorrhage.

Histologically, the characteristic lesion is widespread myocardial congestion, hemorrhage, and myofiber degeneration. Multiple fibrinous microthrombi are within the myocardial capillaries, and occasionally degenerative changes are visible in the walls of small arterioles in many organs, including the heart. Malacia of cerebral white matter or, more rarely, the molecular layer of the cerebellum may occur and is attributable to microvascular damage. Microscopic lesions consistent with dietary microangiopathy may also be found in arterioles and capillaries of the heart, kidneys, liver, stomach, intestine, mesentery, skeletal muscle, and skin. It should be stressed that in some cases, the disease course is so rapid that morphologic changes are not discernible in the myocardial cells. Because it can be extremely difficult to distinguish mulberry heart disease from *S. suis* septicemia histologically, it is prudent to also attempt bacteriologic culture when attempting to confirm the diagnosis.

In **hepatosis dietetica,** the liver is swollen and turgid and has a mottled to mosaic-like appearance throughout its lobes. Many of the lobules are distended and reddish in color. There is in fact an irregular distribution of hepatic necrosis and hemorrhage. The gall bladder may be edematous, and there may also be myocardial necrosis and pulmonary edema. Typically, the disease course is so rapid that jaundice does not develop. Histologically, there is a distinct lobular distribution of hemorrhage, degeneration, and necrosis.

In **NMD** of pigs, the lesions are often only visible at the microscopic level and consist of areas of bilaterally distributed areas of muscular degeneration. The changes include hyalinization, loss of striations, and fragmentation of myofibers. The sections are difficult to cut because of the presence of calcium in the myocytes. A mild degree of NMD may accompany some cases of hepatosis dietetica.

Samples for Confirmation of Diagnosis

- **Toxicology**—50 g liver (ASSAY [Se] [VE])
- **Histology**—formalin-fixed skeletal muscle (multiple sites), heart (both left and right ventricular walls), and brain (including cerebral hemisphere) (LM). It may require special stains to show the presence of calcium in the sections. In biopsies from medial gluteal muscles using a Bergstrom needle, there were ragged red fibers of type I and IIA. Muscle fiber atrophy and subsarcolemmal aggregates in type I and IIA fibers were also found. More severely affected horses had inflammatory infiltrate, collagen proliferation, phagocytosis, necrosis, and calcification.[59]
- **Bacteriology** (for mulberry heart disease only)—heart, liver, swab from pericardial sac (CULT)

DIFFERENTIAL DIAGNOSIS

Nutritional muscular dystrophy (NMD)
NMD is most common in young rapidly growing animals fed a ration deficient in selenium and vitamin E or whose dams were on a deficient, unsupplemented ration throughout the winter months. Characteristically, the disease is sudden in onset, and several animals are affected initially or within a few days, particularly following unaccustomed exercise. In the acute form, generalized weakness and a state of collapse are common. In the subacute form, the major clinical findings are stiffness in walking, long periods of recumbency or total recumbency, inability to stand, a normal mental attitude and appetite, and no abnormal neurologic findings to account for the recumbency. The creatine phosphokinase (CPK) levels are markedly elevated.

Calves and yearlings
Acute enzootic muscular dystrophy in calves with myocardial involvement must be differentiated from other diseases causing generalized weakness, toxemia, and shock. These include the following:

- **Septicemias**: *Haemophilus* septicemia resulting in weakness, recumbency, and fever
- **Pneumonia**: Pneumonic pasteurellosis causing dyspnea, toxemia, fever, and weakness

Subacute enzootic muscular dystrophy, in which skeletal muscle lesions predominate, must be differentiated from other diseases of young calves and yearlings characterized clinically by paresis and paralysis. The subacute form is more common in yearlings and young cattle and is characterized by recumbency, with other body systems being within relatively normal ranges. The other diseases include the following:

- **Musculoskeletal diseases**—polyarthritis, traumatic or infectious myopathies (blackleg), osteodystrophy and fractures of long bones
- **Diseases of the nervous system**—spinal cord compression, *Hemophilus* meningoencephalitis and myelitis, organophosphatic insecticide poisoning
- **Diseases of the digestive tract**—carbohydrate engorgement resulting in lactic acidosis, shock, dehydration, and weakness

Lambs and kids
In lambs with "stiff-lamb" disease, there is stiffness and a stilted gait, affected animals

Continued

prefer recumbency, and they are bright and alert and will suck the ewe if assisted. The serum levels of CPK and serum glutamic-oxaloacetic transaminase (SGOT) are also markedly elevated. Differentiation may be necessary from enzootic ataxia and swayback, but in these two diseases, stiffness is not characteristic, but rather, weakness and paresis.

Foals

In foals, NMD must be differentiated from acute diseases of the musculoskeletal and nervous system causing abnormal gait, weakness, and recumbency. They include the following:

- Polyarthritis
- Meningitis
- Traumatic injury to the spinal cord

Mulberry heart disease

Mulberry heart disease must be differentiated from other common causes of sudden death in pigs in which the diagnosis is made at necropsy:

- Acute septicemias attributable to salmonellosis, erysipelas, pasteurellosis, and anthrax
- Porcine stress syndrome
- Gut edema
- Intestinal volvulus, heat exhaustion, suffocation during transportation

TREATMENT

Because of the overlapping functions of Se and VE and because it is not always possible to know the relative etiologic importance of one nutrient or the other in causing some of the acute conditions already described, it is recommended that a combined mixture of selenium and α-tocopherol be used in treatment. α-Tocopherol is the most potent form of the tocopherols and is available in a number of pharmaceutical forms, which also vary in their biological activity. It has become necessary to express the unitage of VE in terms of international units of biological activity (1 IU:1 mg synthetic racemic α-tocopherol acetate; natural D-α-tocopherol acetate 1 mg: 1 IU and natural D-α-tocopherol 1 mg: 0.92 IU). It is also obvious that we need to know how to use organic Se (Se-enriched yeast) because this is likely to be much more valuable as a supplement than sodium selenite as a component of the 30+ selenoproteins.

In cattle, a blend of ammonium chloride, VE, and Se is recommended for the treatment of retained fetal membranes.[60]

Organic selenium (Se-enriched yeast) is a strategy to increase the benefits of the replacement of sodium selenite.[61] Se-enriched yeast increases milk selenium at parturition and weaning.[62]

Nutritional Muscular Dystrophy

For treatment of NMD in calves, lambs, and foals, a mixture containing 3 mg Se (as sodium or potassium selenite) and 150 IU/mL of DL-α-tocopherol acetate, given IM at 2 mL/45 kg BW, is recommended. One treatment is usually sufficient. Animals with severe myocardial involvement will usually not respond to treatment, and the case-mortality rate is about 90%. However, all in-contact animals in the herd (calves, lambs, and foals) should be treated prophylactically with the same dose of Se and VE. They should be handled carefully during treatment to avoid precipitating acute muscular dystrophy. Animals with subacute skeletal muscular dystrophy will usually begin to improve by 3 days following treatment and may be able to stand and walk unassisted within 1 week.

Animals sometimes do not respond to either VE or Se or treatment with both.

Supplementation of lambs with Se had no significant effect on performance and blood hematology, but it increased blood G-Th-P and serum T3 but decreased serum T4 compared with nonsupplemented lambs. Se-enriched yeast significantly improved the disgestibility.[63] In outbreaks of mulberry heart disease, hepatosis dietetica, and related Se- and VE-deficiency diseases in pigs, all clinically affected pigs and all pigs at risk should be treated individually with a combination of Se/VE parenterally, at first to prevent any further sudden deaths. It can then be followed by oral administration.

CONTROL

It is necessary to adapt production systems to take into account changes in climatic systems, which can alter the feeding constituents and increase vitamin and mineral requirements and alter the balance between gestation and sources of stress.[31]

Se status is now associated with improved immune function, arthropathy, and cardiomyopathy. Most important, it protects against oxidative stress and aids in regulation of thyroid hormone metabolism.[64]

The control and prevention of the major diseases caused by Se and VE deficiencies can generally be accomplished by the provision of both nutrients to susceptible animals fed on deficient rations.

Provide Selenium and Vitamin E

Over the years, both the VE levels and Se levels in the diets have increased but particularly the former. This is in response to the more rapid growth rates of pigs but also the realization that pigs are coping with many more oxidative disease states. Outdoor pigs usually have sufficient levels of both unless the soil is Se deficient. A recent study from China has suggested that dietary zinc at 85 mg/kg, Se at 0.40 mg/kg, and vitamin E at 45 IU/kg is appropriate for crossbred sows.

Although Se alone is protective against a greater spectrum of diseases than is VE, there are situations in which VE is more protective. Both Se and VE should be provided when the diets are deficient in both nutrients, but this may not apply in every situation. Most of the emphasis has been on Se supplementation at the expense of VE, which is more expensive and less stable. Most injectable VE and Se preparations are adequate in Se but insufficient in VE.

There have been several attempts to supplement weaner pigs with a VE preparation. Besides individual injections, it is possible to supplement weaner pigs with water supplementation. Pigs will usually drink even if they are not eating. A recent study showed that the supplementation of drinking water with high doses of VE (150 mg of DL-α-tocopherol acetate) was effective in maintaining serum VE levels over the weaning period. This was even true when the intake of food over the weaning period was very low (it can be as low as 0.2 to 0.3 kg) and there was a temporary malabsorption in the intestine. It takes about 100 IU/L of water to provide a good VE blood serum value.

Maternal Transfer to Newborn

Treatment with organic and inorganic Se improves the growth rate, humoral immune response, and antioxidant status of the lambs.[65] Se supplementation in cattle and ewes is associated with increased embryo production, higher fetal mass, and reduced levels of retained placenta. There is a complex relationship between supplementation (source of Se, time, length of time, presence of interfering elements, and the diet feeding regime). A 79-mg Se pill to dairy cows 3 weeks before expected calving date significantly elevated blood Se levels in cows after calving.[66] Nearly always, calf VE levels are lower than cow VE levels.[67]

Diseases caused by Se deficiency are preventable by the administration of Se to the dam during pregnancy or directly to the young, rapidly growing animal. Se is transported across the placenta and provides protection for the neonate. Oral supplementation with Se in beef cattle will provide enough to maintain blood levels in the dam and for adequate transfer to the fetus, which can sequester Se when the levels are low in the dam. The colostrum of selenium-supplemented cattle also contains an adequate amount of Se to prevent severe selenium-deficiency diseases. However, by 7 days after parturition, the levels in milk may be inadequate to maintain adequate serum levels in calves. The strategic administration of Se and VE before the expected occurrence of the disease is also a reliable method of preventing the disease.

Selenium Is Potentially Toxic

Selenium toxicosis is seen as a chronic problem (alkali disease) or as an acute selenosis (blind staggers). In a study of Se toxicity in lambs, it was found that sodium selenite administration led to decreased VE

levels in the liver, but selenomethionine (organic Se) did not.[68] This study suggests that the chemical form of the ingested Se must be known to interpret tissue, blood, and serum concentrations. It can be associated with severe depression, dyspnea, congested mucous membranes, watery diarrhea, and colic spasms,[69] and high levels of Se can be found in heart muscle, liver, and kidney. Chronic selenosis has also been described in camels.[70]

Because Se is toxic, any treatment and control program using it must be carefully monitored. Se injected into or fed to animals concentrates in liver, skeletal muscle, kidney, and other tissues, and withdrawal periods before slaughter must be allowed. There is some concern that Se may be a carcinogen for humans. The only tissues that appear likely to consistently accumulate more than 3 to 4 mg/kg of Se are the kidney and liver, and these are very unlikely to constitute more than a very small part of the human diet. There have been no reports of untoward effects of Se on human health when it has been used at nutritional levels in food-producing animals. The incorporation of Se into commercially prepared feeds for some classes of cattle and pigs has been approved in some countries. A recent case in Norway showed the hazards of Se contamination in the case of an iron supplement. Se toxicosis has been fairly regularly reported. Se toxicosis in pigs seen as progressive apathy, paralysis, and sudden death has been described.[71]

Pigs that are deficient may be more susceptible to other diseases. Pigs with NMD often have the appearance of pneumonic pigs because the diaphragm is weak and the pigs are dyspneic.

Deficient and small pigs may be more susceptible to the effects of iron, and when this is given by injection there may be large numbers of dead piglets as a result of iron toxicity. In these cases, the heart lesions resemble those of MHD.

In a recent case of Se toxicosis in sheep associated with excessive sodium selenite in commercial supplement,[72] there were hemorrhages throughout the lung lobes and edema. Toxicity is greater than 250 umol/kg DM, and in these sheep the levels were 325 to 400 umol/kg DM. Se-accumulating plants are thought not to occur in the United Kingdom, and these sheep were thought to have been given free-access minerals from bags with 7628 to 8771 ppm of selenium.

Selenium in Milk Supplies

The use of Se in the diet of lactating dairy cows has caused concern about possible adulteration of milk supplies. However, the addition of Se to the diets of lactating dairy cows at levels that are protective against the deficiency diseases does not result in levels in the milk that are hazardous for human consumption. The feeding of excessive quantities of Se to dairy cattle would cause toxicity before levels became toxic for humans. Se supplementation to colostrum increased the IgG amounts and Se concentration in blood plasma in newborn calves.[73]

Dietary Requirement of Selenium

The dietary requirement of Se for both ruminants and nonruminants is 0.1 mg/kg DM of the element in the diet. There may be Nutritionally important differences in the Se status between the same feeds grown in different regions and between different feeds within a region. Even within a region featuring high Se concentrations, some feeds may contain levels of Se below the 0.1 mg/kg minimum requirement for livestock. Thus an Se analysis of feeds appears necessary to supplement livestock appropriately. Some geographic areas are known to be deficient in Se, and the feeds grown in these areas must be supplemented with Se and VE on a continuous basis. Some reports indicate that surveys have found that dairy producers are providing insufficient supplementary Se in the ration to meet the recommended Se intake for lactating dairy cows. Long-term administration of organic Se in the form of Se yeast provides higher blood and tissue concentrations than repeated parenteral administration of recommended therapeutic doses of inorganic Se.

Grass-based diets elevate precursors of VE and vitamin A. Argentinian beef contains more α -tocopherols, beta carotene, ascorbic acid, and glutathione than feedlot beef.[74]

There is an improvement in the preventative antioxidant systems of cows fed Se-enriched yeast.[75]

Avoidance of high-sulfate diets is desirable, but provision of adequate Se overcomes the sulfate effect.

Glutathione Peroxidase Activity

Whole-blood GSH-PX activity is a way of monitoring Se status but is not as reliable in pigs as in sheep and cattle. Levels of the enzyme increased significantly over a 12-week period when beef cattle were receiving organic or inorganic Se. Levels were higher in the group receiving organic Se. It was shown that combinations of Se injections and supplementation could help maintain Se and GSH-Px blood status in beef cattle heifers.[76]

Pigs

In growing pigs, both Se and vitamin E at 30 IU/kg DM of feed are necessary for the prevention of the diseases caused by diets deficient in vitamin E and Se. Supplementation of the diet of the sow will result in an adequate transfer to the piglets. Satisfactory protection of the diseases of pigs caused by VE/Se deficiency depends on the correct balance between Se, α-tocopherol, and PUFAs in the diet and the presence of a suitable antioxidant to conserve the α-tocopherol.

Different Methods of Supplementation

The prevention of the major diseases caused by Se and VE deficiencies can be achieved by different methods, including the following:

- Dietary supplementation in the feed or water supplies
- Individual parenteral injections
- Oral administration
- Pasture top dressing

The method used will depend on the circumstances of the farm, the ease of administration, the cost, the labor available, the severity of the deficiency that exists, and whether or not the animals are being dosed regularly for other diseases, such as parasitism. The subcutaneous injection of barium selenate, the administration of an intraruminal pellet, and the addition of Se to the water supply were compared in cattle; each method was effective for periods ranging from 4 to 12 months.

Dietary Supplementation

The inclusion of Se and VE in the feed supplies or salt and mineral mixes has been generally successful in preventing the major diseases caused by deficiencies of these two nutrients. The currently available data do not support the use of supplemental injections of VE for beef cattle because the benefits are greater when VE is fed.[77]

Selenium Dose

Individual Injections

Injections of Se and VE have been used successfully for prevention, particularly in circumstances where the diet cannot be easily supplemented. Following the IM injections of sodium selenite into calves, lambs, and piglets, the Se concentration of the tissues, particularly the liver, increases and then declines to reach preinjection levels in 23 days in calves and 14 days in lambs and piglets. Adequate sources of vitamin E also must be provided. Injectable preparations of Se and VE are usually adequate in Se and deficient in VE, and it may not be possible to correct a marginal deficiency of VE in pregnant beef cattle, for example, by IM injection of a Se and VE preparation that contains an inadequate concentration of VE. The current label dose of injectable Se, 0.055 mg Se/kg BW, which is therapeutically adequate for NMD, is not sufficient for long-term Se supplementation of cattle on a Se-deficient diet. Copper and Se supplementation by parenteral administration can be combined when both deficiencies are present.

Subcutaneous Injections

Cattle and Sheep. A slow-release preparation of barium selenate for SC injection is now available for use in cattle and sheep. An SC injection of 1 mg selenium/kg BW to ewes 3 weeks before breeding elevated the Se level in milk during lactation and increased the Se concentration and GSH-PX activity

in the blood of the lambs during the period when they are at greatest risk from selenium-deficiency diseases. At a dose of 1 mg selenium/kg BW to pregnant ewes, the GSH-PX activity is increased and maintained at adequate levels for up to 5 months. There is adequate transfer of Se to the lambs, providing protection for up to 12 weeks of age, which covers the period when lambs are at greatest risk. A dose of 1.2 mg selenium/kg BW provided adequate Se status for as long as two consecutive lambing seasons. Barium selenate at 1 mg selenium/kg BW SC provides protection in young sheep for at least 3 months and is not associated with risk of Se toxicity or unacceptable residues of Se in tissues other than the site of injection. A dose of 1 mg selenium/kg BW (barium selenate) to cattle SC increased the GSH-PX activity within 4 weeks and was maintained at high levels for up to 5 months.

Pigs. The SC injection of barium selenate of pregnant sows at 0.5 to 1.0 mg selenium/kg BW resulted in a significant difference in GSH-PX activity in the piglets from treated sows compared with untreated controls. The SC injection of barium selenate at 2.5 mg selenium/kg BW into pigs weighing 20 kg also maintained blood levels of selenium and GSH-PX activity during the most rapid growing period. The relative safety of barium selenate is a result of its slow rate of release from the site of injection. By comparison, when Se is administered as a soluble salt, such as sodium selenite, acute toxicity may occur at doses of 0.45 mg selenium/kg BW. Treatment with barium selenate increases the concentration of Se in blood, liver, and muscle and persists for at least 4 months. One disadvantage of barium selenate is that a large residue persists at the site of injection for long periods. The use of sodium selenite also increases tissue and blood concentrations of Se, but they begin to decline by 23 days. The bovine liver rapidly removes approximately 40% of injected Se salts (soluble) from the systemic plasma, binds it to a plasma component, and releases it back into circulation within 1 hour of injection.

Farmed Red Deer. A long-acting barium selenate given subcutaneously to red deer on pasture, at 0.5, 1.0, or 2.0 mg Se/kg BW, elevated blood Se concentrations from 105 nmol/L preinjection for at least 377 days, with peak levels of 1894, 1395, and 818 nmol/L for high, medium, and low doses, respectively. Pastures contained 10 to 30 mg Se/kg DM. There was no significant difference in growth rate between treated and control deer. The preparation produced fewer and less severe SC tissue reactions than previous preparations. Young, rapidly growing deer seem less sensitive to Se deficiency, as measured by weight gain, than sheep and cattle, suggesting that reference ranges for those species are not appropriate for deer.

Oral Selenium and Anthelmintics

Oral dosing using sodium selenite is sometimes combined with the administration of anthelmintics and vaccinations. The dose should approximate 0.044 mg/kg BW. A routine program in a severely deficient area comprises three doses of 5 mg of selenium (11 mg sodium selenite) each to ewes, one before mating, one at midpregnancy, and one 3 weeks before lambing, along with four doses to the lambs. The first dose to lambs (of 1 mg) is given at docking and the others (2 mg each) at weaning and then at 3-month intervals. A 100-day controlled release anthelmintic capsule containing 13.9 mg of selenium will protect lambs from Se deficiency for at least 180 days.

Both Se and cobalt can be incorporated into an anthelmintic program. The levels of GSH-PX activity may be monitored on a regular basis following the drenching with Se and provide a good indication of Se availability and the Se status of grazing sheep.

Pasture Top Dressing

The application of sodium selenate as a top dressing to pasture is now practiced and permitted in some countries. Top dressing at the approved rate of 10 g selenium/ha is effective for 12 months and has a toxicity margin of safety of about 20 times. Sodium selenate is now used in preference to sodium selenite because only about one-fifth is required to raise the pasture level of Se to the same concentrations provided by sodium selenite. Top dressing of severely deficient pumice soils in New Zealand prevented deficiency for at least 12 months, sheep were protected against white-muscle disease in sheep, and reproduction performance and weight gains were improved. It is recommended that sodium selenate be applied annually to all selenium-deficient soils at the rate of 10 g selenium/ha added to the superphosphate fertilizer or as prills of sodium selenate alone. Top dressing is an economical alternative to individual animal dosing, particularly in severely deficient areas with a high stocking rate. At the approved rate, no adverse effects are anticipated for human or animal health or for the environment. Se-enriched fertilizer increases the Se level of hay to a level that is recommended for horses (0.1 mg/kg DM).[78]

Muscular Dystrophy

Under most conditions, NMD of calves and lambs can be prevented by providing Se and VE in the diets of the cow or ewe during pregnancy at 0.1 mg/kg DM of actual Se and α-tocopherol at 1 g/d per cow and 75 mg/d per ewe. If possible, the supplementation should be continued during lactation to provide a continuous source of Se to the calves and lambs. Under some conditions the level of 0.1 mg/kg DM may be inadequate. In some circumstances, the optimal Se concentration in the feed is considerably higher than 0.1 mg/kg DM, and levels up to 1.0 mg/kg DM in the feed result in increases in GSH-PX activity, which may be beneficial; however, the cost-effectiveness has not been determined. Pregnant ewes being fed on alfalfa hay may require selenium at a level of up to 0.2 mg/kg DM to prevent white-muscle disease in their lambs. Young, rapidly growing cattle, particularly beef cattle, likely to receive hay and straw deficient in Se and those that are fed high-moisture grain should receive a supplement of Se at the rate of 0.1 mg/kg DM and α-tocopherol at 150 mg/d per head. If selenium-supplemented concentrates are used as part of a feeding program for dairy cows, it is not necessary to provide additional Se by parenteral injection.

Lambs are born with a low serum level of VE, but the concentration increases rapidly after the ingestion of colostrum. Supplementation of pregnant ewes with α-tocopherol, either as a single IM dose (500 mg 2 weeks before lambing) or orally (150 mg daily during 3 to 4 weeks before lambing) results in a marked increase in the levels of the vitamin in the serum and colostrum. The VE concentration in colostrum was 5 to 11 times higher than in milk 1 week after lambing.

VE supplementation of the feed of weaner sheep by oral drench or feed additive is effective in increasing plasma α-tocopherol concentrations. This is the most practical method for housed sheep and prevents subclinical myopathy. The IM oily injection was slow to increase plasma levels of tocopherols and did not prevent myopathy in grazing experiments. VE supplements have no beneficial effects on wool quality or quantity in grazing sheep, and unless certain flocks are susceptible to VE deficiency myopathy, it is not recommended.

Beef Cattle and Sheep

Salt–Mineral Mixture

NMD can be prevented in unweaned beef calves and lambs by the inclusion of Se (14.8 mg/kg) and VE (2700 IU/kg) in the mineral supplement provided ad libitum to the pregnant cows and ewes on a selenium-deficient ration during the latter two-thirds of gestation and for the first month of lactation. Under most conditions this will provide Se at 0.1 mg/kg DM in the diet.

The provision of **sodium selenite in a salt–mineral mixture** to provide 90 mg of selenium/kg salt–mineral mixture on a year-round basis, even under range conditions, increased GSH-PX activity levels into normal ranges in beef cows for 3 months when fed to extremely deficient animals. Calves of these cows had increased weaning weights and decreased incidence of infectious diseases, but the trial was uncontrolled. The provision of 30 mg selenium/kg salt–mineral mixture was insufficient to raise the GSH-PX activity levels to normal ranges. Peak blood

selenium levels were achieved in weaned beef calves supplemented with 80 and 160 mg selenium/kg in free-choice salt–mineral mixtures for a period of 108 days. In some jurisdictions, it may be necessary for the veterinarian to prescribe a supplement containing higher levels than those permitted by legislation. A level of 25 mg/kg selenium of a salt–mineral mixture provided ad libitum for sheep will result in sufficient levels of Se in the dam's blood and milk to prevent Se deficiency diseases. Each ewe must consume from 8 to 12 g of the salt–mineral mixture per day.

Se deficiency in grazing and forage-fed cattle is widespread in the United States and other countries. Calves may be severely depleted of Se and selenium-dependent glutathione peroxidase but exhibit no clinical signs of deficiency unless they are subjected to an oxidant or other types of stress. Nursing beef calves may be at risk of Se deficiency if their dams are not supplemented with Se. Even when sodium selenite is used in a free-choice mineral supplement designed to deliver 2 mg of Se daily, calves are still at risk for Se deficiency for up to 90 days. Se supplementation of pregnant beef cows with seleno-yeast in a free-choice mineral mixture increased the whole-blood Se and GSH-PX activity of both cows and calves and was much superior to sodium selenite.

In some parts of the world, it is recommended that animals be allowed to graze saltbrush, which produces a higher quality of sheep and goat meat with less fat, more lean meat, and higher VE levels.[79]

The supplementation of beef cattle in late gestation with oral VE, 1000 IU/head per day, influenced the VE status of cows that calved in late winter to a greater extent than that of cows calving in late summer because of the high VE content in the pasture-based summer diet. Calves from supplemented cows had higher serum VE levels than calves from unsupplemented cows. Winter-born calves from supplemented Hereford cows had heavier 205-day adjusted weaning weights than did winter-born calves from unsupplemented cows. Supplementation did not affect vitamin E or IgG concentrations in cows that calved in late summer, and it did not affect calf growth.

Dairy Cattle

Selenium

The legal commercial Se supplementation of complete rations for dairy cattle in the United States has been increased from 0.1 to 0.3 mg/kg DM of complete feed. At this rate, a lactating cow consuming 20 kg of DM/d would consume about 6 mg supplemental selenium in addition to that naturally present in the feedstuffs. Current recommendations indicate that Se intake for lactating and gestating dairy cattle should range from 5 to 7 mg/d for adequate concentrations in serum or plasma that would range from 70 to 100 ng of selenium/mL serum. Such supplementation should result in improved Se status of the newborn, improved concentration of Se in colostrum, and improved health of the calves. The effects of Se supplementation in dairy cattle on reproductive performance is equivocal. Some studies over a period of two lactations revealed no effect on reproductive performance, whereas others report an improvement in dairy cattle in a district considered to be marginally deficient in selenium. Intakes of inorganic Se as sodium selenite in amounts of 50 mg/d for 90 days or 100 mg/d for 28 days by adult dairy cows (10 to 30 times the nutritional requirement) did not cause any health problems. The toxic dose for cattle ranges from 0.25 to 0.5 mg/kg BW.

Milk replacers for dairy calves should contain a suitable antioxidant and be supplemented with 300 IU/kg DM of α-tocopherol acetate at the rate of 0.1 mg/kg DM of the milk replacer.

Vitamin E

Dietary or parenteral supplementation of VE to dairy cows during the peripartum period has consistently improved the function of neutrophils and macrophages. However, the effects of supplementation of dry dairy cows with VE in the feed or parenteral administration of VE before parturition on the incidence of disease have been variable. The amount of supplemental VE fed per day during the prepartum period has ranged from 1000 to 3000 IU/day. Feeding 1000 IU/day of supplemental VE to dry cows when adequate Se was supplemented reduced the incidence of retained placenta. The prepartum subcutaneous injection of dairy cows with 3000 IU of VE, 1 week before expected calving, had no significant effect on the incidence of retained placenta, clinical mastitis, metritis, endometritis, ketosis, displaced abomasum, or lameness. VE administered to cows with marginal pretreatment VE status had a reduced risk of retained placenta. In cows with adequate serum VE, there was no reduction in the incidence of any disease.

Based on health and immune function in cows, plasma concentrations of α-tocopherol in peripartum cows should be approximately 3 μg/mL. To maintain these blood values, dry cows and heifers fed stored forages during the last 60 days of gestation require approximately 1.6 IU of supplemental vitamin E/kg BW (approximately 80 IU/kg DMI). Increased intake of VE of cows and heifers during the prepartum period also increases the VE in colostrum. Milk is not a major source of VE, but colostrum contains high concentrations of α-tocopherol (3 to 6 μg/mL). To reduce the incidence of mastitis in lactating cows being fed stored forages, the recommendation for VE is 0.8 IU/kg BW (approximately 20 IU/kg DMI). When fresh forage is fed, there is less need for supplemental VE. The intake of polyunsaturated fatty acids increases the VE requirement, and additional VE may be required when protected unsaturated fats are fed. VE supplementation increases the response to vaccination,[80] and supplementation to pregnant and lactating ewes blunts the immune suppression that make take place over the parturition period. High levels of copper given to sheep during the final 3 weeks of pregnancy has a negative effect on the serum VE concentrations at 72 hours postpartum.[81] High levels of iodine in late pregnancy also seem to preprogram ewes to low VE levels from colostrum,[82] and therefore the presence of NMD in the neonate should be checked.

Although Se alone is protective against a greater spectrum of diseases than is VE, there are situations in which VE is more protective. Both Se and VE should be provided when the diets are deficient in both nutrients, but this may not apply in every situation. NMD can occur in ruminants with VE deficiency and an adequate Se status. Most of the emphasis has been on Se supplementation at the expense of VE, which is more costly and less stable. Most injectable VE and Se preparations are adequate in Se but insufficient in VE.

Selenium-Responsive Reproductive Performance and Growth

Sheep

In situations of Se deficiency, reproductive performance of ewes may be improved by Se or Se/Ve supplementation. Survival of lambs and live weights at birth and at weaning may be increased by Se supplementation. Single injections of Se before mating and lambing had no significant effects on estrus, fertility, prolificacy, and the number of lambs born and reared to 28 days in 2-year-old ewes. Two consecutive injections of Se (before mating and lambing) significantly increased the incidence of estrus, fertility, and lamb body weight at 28 days and daily weight gains for 28 days in 3-year-old ewes compared with controls. The injection of Se/VE did not significantly improve reproductive performance in 2- or 3-year-old ewes in the flock not considered Se deficient. Injected VE and Se can improve semen characteristics and reproductive performance of rams during the hot season.[83]

Weak-Calf Syndrome

The parenteral injection of Se and iodine to pregnant cattle in Ireland did not significantly reduce the incidence of the weak-calf syndrome, which is often attributed to a Se deficiency.

Pigs

The injection of Se (0.06 mg/kg BW) into piglets under 1 week of age, repeated at weaning time and into the sow 3 weeks before farrowing, will be effective. The minimum lethal dose of Se for piglets is 0.9 mg/kg BW, which provides a reasonably

wide range of safety. A high concentration of Se in the diet of pregnant sows in the last half of gestation has been associated with hemorrhagic lesions on the claws of newborn piglets.

Horses

Little information is available on the need of horses for Se, but the optimum intake is 6 mg/week or 2.4 µg/kg BW daily. The oral supplementation of 1 mg selenium/d increases blood Se concentrations above levels associated with myodegeneration in horses and foals. In New Zealand, for horses on pasture, the injection of barium selenate, at a dose of 0.5 mg Se/kg BW, aseptically at a deep intramuscular site was efficacious in correcting the Se status of mares grazing pasture with a Se content of 0.01 to 0.07 mg/kg DM. Some local swelling will occur.

To ensure nutritional adequacy and to have an adequate safety margin, adult Standardbred horses should receive 600 to 1800 mg DL-α-tocopherol daily in their feed. The parenteral administration of VE and Se to mares in late pregnancy and to their foals beginning at birth will increase blood Se to adequate levels. In selenium-deficient areas or when mares are fed selenium-deficient hay, prepartum injections of Se/VE are indicated, followed by intermittent injection of the foals or supplementation of the diet with Se at 0.1 mg/kg DM.

Intraruminal Selenium Pellets

Sheep

Intraruminal Se pellets, similar to those used in cobalt deficiency, have produced satisfactory blood levels of Se for up to 4 years in ewes at pasture. A satisfactory pellet is composed of 0.5 g elemental Se and finely divided metallic iron. The technique is efficient, but not completely, because of wide variations between animals in the absorption rate of the Se. The average delivery of Se is 1 mg/d, and there is no danger of toxicity. In sheep grazing selenium-deficient pastures, the ruminal pellets increase the Se status and weight gains compared with controls. About 15% of treated sheep reject the pellets within 12 months, and in varying degrees the pellets acquire deposits of calcium phosphate. Sheep fed pellets recovered from sheep have low selenium levels, which suggests a low release of Se from pellets that have been in the rumen of other sheep for several months. The peak levels of Se occur 3 months after administration; there is a rapid decline in activity between 5 and 13 months. Sustained-released boluses containing sodium selenite, cobalt sulfate, potassium iodide, manganese sulfate, zinc oxide, sulfate, and vitamins A, D, and E have also been formulated to provide long-term maintenance of Se levels.

A soluble glass bolus containing zinc, cobalt, and Se administered to ram lambs increased the Se status of the animals and increased sperm motility, percentage of live sperm, and sperm responding to hypo-osmotic swelling test (an assay to determine plasma membrane permeability).

High-density compressed pellets containing both sodium selenite and cobalt carbonate have been developed for cattle and sheep. The sheep pellet weighs 6 g and contains 276 mg Se and 765 mg Co. A 6-g bolus given to ewes before mating resulted in improved lambing performance, an increase in the percentage of twin lambs.

Cattle

A Se pellet containing 10% selenium and 90% iron grit is available for cattle and will maintain plasma Se and GSH-PX activity above the critical level for up to 2 years. When given to beef cows in the last 3 months of pregnancy, the Se levels in milk were found to be higher than in controls, and the Se status of the calves was sufficient to prevent NMD. The use of these pellets at 2, 3, and 4 times the recommended dose in growing cattle weighing 300 to 350 kg did not cause toxicosis, and the Se levels in the tissues at slaughter were not a risk for humans.

Use of the intraruminal Se pellets in dairy cattle in New Zealand resulted in improved growth and milk production in herds where the Se status was below the adequate range, but there was no effect on udder health and reproductive performance.

High-density compressed pellets containing both sodium selenite and cobalt carbonate have been developed for cattle and sheep. For cattle, the pellets weigh 18 g and contain 4.6% selenium and 12.75% cobalt (828 mg Se and 2295 mg Co). In both beef cows and growing cattle, the boluses increased blood glutathione peroxidase activity for at least 1 year.

A sustained-release intrareticular bolus is an osmotic pump designed to release 3 mg selenium into the reticulo-rumen. It is intended to provide Se supplementation for 120 days in grown heifers and pregnant beef cattle.

A soluble glass bolus containing zinc, copper, and Se resulted in an increased antibody response.[84]

Selenium Toxicity and Residues

Selenium intoxication can occur following the administration of toxic amounts of an Se salt. The use of selenium selenite instead of sodium selenate and giving a dose of 5 times the intended dose resulted in a high mortality within several hours after administration. Animals deficient in Se are more susceptible to Se toxicosis than those that are selenium-adequate. The pharmacokinetics of Se toxicity in sheep given selenium selenite parenterally has been examined. When oral preparations of Se and monensin are given concurrently as part of a routine dietary management practice, there is greater risk of Se intoxication than if the Se is given alone. Administration of monensin sodium at a constant, safe dosage enhanced the toxicity of Se, as demonstrated by increased severity of the signs of intoxication, fatalities, and tissue Se concentrations and intensified gross, histopathologic, and biochemical changes. There is some concern about Se supplementation of beef cattle being a potential source of contamination for nearby aquatic systems, but there is no evidence that this has occurred.

Selenium Responsiveness

The response to Se supplementation is proportional to the degree of deficiency, and supplementation of animals that have adequate Se intakes is unlikely to significantly improve growth rate. In New Zealand, for selenium-deficient lambs, the potential for a growth response to Se supplementation is strongly related to blood Se concentration. Economically significant live-weight gains of greater than 10 g/d can occur when initial blood Se concentrations are less than 130 nmol/L. This is the basis for the development of reference curves using blood Se concentration to diagnose Se deficiency and predict growth responses to lambs.

Although many methods of supplementation of Se are efficacious, they can differ widely in their cost and convenience of administration. The objective of any micronutrient supplementation program should be to optimize the return on investment. The least-cost option that provides adequate supplementation for the required period should be recommended initially.

Veterinarians are the professionals in the best position to offer advice on cost-effectiveness supplementation. To retain this position, they must provide sound recommendations based on micronutrient analysis of animal tissue and defensible reference ranges that are supported by production response data. Monitoring micronutrient status in animal tissue should be encouraged to ensure that regulatory requirements are met and that deficiency and excessive use are avoided. Circumvention of veterinary involvement in the diagnosis and treatment of micronutrient supplementation can lead to greater use of supplements when not indicated, higher costs to farmers, and low cost-to-benefit ratios for the industry

Depot and bolus preparations have revolutionized the treatment of deficiencies of cattle and sheep that are grazed extensively where there is little opportunity for frequent administration. The relatively short duration of a single drench or injection of Se salts such as sodium selenite should be noted. The use of fertilizer applications is gaining widespread acceptance on farms with high stocking rates.

MASSETER MYONECROSIS

Degeneration of the masseter muscles causes dysphagia and trismus in adult horses and Miniature horses.[1] The disease is associated with abnormally low serum or blood concentrations of vitamin E or selenium in some affected horses, and ingestion of tetrachlorvinphos, an organophosphate, was associated with the disease in Miniature horses.[1,2] Muscles of locomotion and cardiac muscle can be affected in addition to disease of the masseter muscle. Clinical signs include acute onset of dysphagia, trismus, salivation, and swelling of the masseter muscles. These can progress to weight loss, gait abnormalities, atrophy of the masseter muscle, teeth grinding or quidding of feed, and unexpected death. Ultrasonography of the masseter muscles reveals hyperechoic lesions with patchy blurring of the fascia, indicative of inflammation and edema.[3] There is electrocardiographic and echocardiographic evidence of myocardial disease in some horses. These signs include tachycardia (after resolution of hypovolemia and pain) with supraventricular and ventricular extrasystole and diminished left ventricular systolic (decreased ejection fraction and fractional shortening) and diastolic function (increased isovolumic relaxation time).[3]

Horses with extensive involvement of other muscles can have myoglobinuria. Signs of dysphagia and trismus are related to dysfunction of the masseter muscle.[4] Gait abnormalities are related to disease in muscles of locomotion, and unexpected death is probably a result of the cardiac lesions. Serum activity of creatine kinase and aspartate aminotransferase is elevated in acute cases. Serum concentrations of troponin are elevated in horses with involvement of the myocardium.[3] Necropsy examination reveals diffuse swelling, muscle pallor, and white streaking of masseter muscle in acutely affected animals. Lesions are also detected in muscles of locomotion and myocardium in some horses. Chronic cases have atrophy of affected muscle. Histologic changes include swelling, fragmentation and loss of striations of myocytes in acute cases, and degenerating fibers replaced by fibrosis in chronic cases. Treatment is symptomatic, and affected horses can require enteral or parenteral delivery of nutrients. Vitamin E and selenium status should be determined and supplements administered if indicated. Prevention should focus on ensuring that horses in geographic regions in which vitamin E or selenium are deficient in feeds are supplemented with these micronutrients.

SPORADIC EXERTIONAL RHABDOMYOLYSIS IN HORSES (AZOTURIA, TYING-UP)

The disease discussed here is that of sporadic acute exertional rhabdomyolysis that occurs as a single event in a horse and does not have a tendency to recur. The recurrent disease is discussed toward the end of this chapter under "Congenital/Inherited Musculoskeletal Disease."

ETIOLOGY

The etiology of most cases of *sporadic* acute exertional rhabdomyolysis is unknown, although suggested causes include hypothyroidism, sodium or potassium deficiency, viral infection, high-carbohydrate diets, and abnormalities in metabolic function. The most common cause is performing exercise

of unaccustomed intensity or duration, which can result in metabolic exhaustion and hyperthermia. However, the disease is not always associated with severe exertion or hyperthermia, and it can occur with as little exercise as slow draft work or turn-out to pasture after stabling. An important contributing factor is a prolonged period (days to weeks) of rest in a horse previously accustomed to regular exercise. The disease occurs in young horses as a result of vitamin E/selenium deficiency, although this is an uncommon cause in adult horses.

Rhabdomyolysis not associated with exercise occurs during general anesthesia maintained by inhalation of halothane in horses of a specific genotype or in horses at pasture in Europe. Rhabdomyolysis also occurs in horses with *S. equi* infection (strangles).

Recurrent exertional rhabdomyolysis is a recognized syndrome in Thoroughbred horses and is dealt with separately.

It is likely that most cases of sporadic exertional rhabdomyolysis are a result of a combination of predisposing factors, with the disease precipitated by a bout of exercise. The difficulty in detecting the presence of predisposing factors contributes to the sporadic nature of the disease.

EPIDEMIOLOGY

The sporadic disease is almost always associated with exercise that is either enforced, as with horses in training or competition, or spontaneous, as with young horses turned out to pasture after a prolonged period of stabling.[1] Clinical signs occur in horses within minutes to hours of the cessation of exercise, although signs can be apparent in horses during prolonged exercise. The epidemiology of the sporadic disease has not been well defined, in contrast to that of recurrent exertional rhabdomyolysis, and the subsequent discussion includes some of the epidemiology of each because it is not always possible to determine whether one episode of exertional rhabdomyolysis is the only occurrence in that animal or will reoccur.

Interpretation of reports of prevalence and risk factors for exertional rhabdomyolysis is difficult because studies to date have mostly not differentiated between the recurrent exertional rhabdomyolysis of Thoroughbreds, polysaccharide storage myopathy of Quarter horses and related breeds, and the sporadic disease in other breeds. The **incidence** or 1-year period prevalence of exertional rhabdomyolysis is as follows: 1.5% in ponies in Australia; 4.9% in Thoroughbred racehorses in the United States, Australia, and Great Britain; 6.1% in National Hunt Thoroughbreds in Great Britain; 4% to 5% in 2- to 3-year-old Thoroughbreds in the United Kingdom;[2] and up to 13.5% in polo ponies in the United States and Great Britain. Polo, racing, rodeo, Western, and show jumping are all associated with a high period prevalence (>5% per annum) of exertional rhabdomyolysis.

Risk factors for exertional rhabdomyolysis include exercise, breed and use, and sex. Overall, horses that exercise are approximately 10 times more likely to develop the disease than are sedentary horses, and among breed/use groups, polo horses are approximately 3 times more likely to develop the disease than are horses used for racing. Horses used for racing are more likely to have episodes of the disease than are horses used for pleasure riding or "other" uses, although racing and breed (Thoroughbred or Standardbred) are confounding factors. Female racehorses are three times more likely to have episodes of exertional rhabdomyolysis than are male (intact or castrated) racehorses, and young female Thoroughbreds are at greatest risk. Among National Hunt horses in Great Britain, females are 24 times as likely to have an episode of the disease as are males. Female polo ponies are not more likely to develop the disease. Thoroughbred racehorses and polo ponies, but not National Hunt horses, with a nervous or "flighty" temperament are more likely to experience episodes of the disease. Other apparent risk factors include a rest day before hard exercise, feeding greater than 4.5 kg of grain per day, lameness, playing polo at a level for which the horse is not fit, and playing early in the season.

The disease occurs repeatedly in 74% of affected Thoroughbred racehorses in Great Britain and in 20% of affected polo ponies.

The disease is of considerable **economic impact** because of its frequent occurrence in athletic horses, recurrent nature, and need to rest affected horses. On average, affected Thoroughbred racehorses cannot train for 6 days after an episode, and approximately two-thirds of affected horses are unable to race because of the disease. Polo ponies lose an average of 7 days of training after an episode of exertional rhabdomyolysis. The effect of the loss of training days for each episode is magnified because of the recurrent nature of the disease in a large proportion of affected horses. Approximately 6% of the wastage of Thoroughbred racehorses in Australia is attributable to exertional rhabdomyolysis.

PATHOGENESIS

The disease is a result of dysfunction and death of myocytes with subsequent release of cellular constituents, including the enzymes creatine kinase, aspartate aminotransferase and carbonic anhydrase, and myoglobin. The proximate cause of myocyte death is uncertain, but it is not related to accumulation of lactic acid, as previously supposed. Proposed mechanisms include oxidant injury to cells as a result of increased oxidant formation during exercise or inadequate antioxidant activity. Apart from horses deficient in vitamin E and/or selenium, which are rare, there is no indication that oxidant injury is a common cause of rhabdomyolysis in horses.

Cell death is likely linked to abnormal accumulation of calcium in intracellular fluids secondary to deranged energy and/or membrane function. Necrosis of myocytes causes pain and inflammation in the muscle, with infiltration of inflammatory cells. Healing and regeneration of myocytes occurs over a period of weeks in the absence of further episodes of myonecrosis.

Release of cellular constituents results in electrolyte abnormalities, primarily hypochloremic metabolic alkalosis, a systemic inflammatory response, and pigmenturia. Severely affected horses can have metabolic acidosis. Myoglobin and possibly other cell constituents are nephrotoxic, and acute renal failure can develop as a result of myoglobinuric nephrosis. Pain and loss of muscle function cause a stilted, short-stepping gait.

CLINICAL FINDINGS

The clinical findings are variable and range from poor performance to recumbency and death. Signs can be mild and resolve spontaneously within 24 hours or be severe and progressive.

Clinical findings are very similar to those observed in horses with sporadic acute exertional rhabdomyolysis that occurs as a single event in a horse (see earlier section in this chapter), except that clinical signs recur. The most common presentation of recurrent exertional rhabdomyolysis is a horse that does not perform to expectation and displays a stiff or short-stepping gait that can be mistaken for lower leg lameness. The horse might be reluctant to move when placed in its stall, be apprehensive and anorexic, paw, and frequently shift its weight. More severely affected horses can be unable to continue to exercise, have **hard and painful muscles** (usually gluteal muscles), sweat excessively, tremble or have widespread muscle fasciculations, be apprehensive, refuse to walk, and have elevated heart and respiratory rates. Affected horses can be hyperthermic, especially soon after exercise. Signs consistent with abdominal pain are present in many severely affected horses. Deep-red urine (myoglobinuria) occurs but is not a consistent finding. Severely affected horses are often recumbent.

CLINICAL PATHOLOGY

Mildly affected or apparently nonaffected horses have moderate increases in **serum creatine kinase** (CK) (20,000 to 50,000 IU/L), **aspartate aminotransferase** (AST), and **lactate dehydrogenase** (LDH) activity. Severely affected horses have large increases in CK (>100,000 IU/L) and other muscle-derived enzymes. Serum CK and AST activities peak approximately 5 to 6 and 24 hours after exercise, respectively, and in the absence of further muscle damage, serum AST might not return to normal levels for 7 to 10 days. The half-life of CK activity in serum is

approximately 12 hours, and serum CK declines rapidly in the absence of continuing muscle damage. The persistence of increased AST activity, compared with CK, is useful in identifying affected horses days or weeks after the episode.

Serum myoglobin concentrations increase markedly during exercise in affected horses and decline within 24 to 48 hours. Serum carbonic anhydrase III activity is increased in horses with exertional rhabdomyolysis.

Severely affected horses are often **hyponatremic** (<130 mEq/L), **hyperkalemic** (>5.5 mEq/L), **hypochloremic** (<90 mEq/L), azotemic (increased serum urea nitrogen and creatinine concentrations), and **acidotic** or **alkalotic**. Hemoconcentration (hematocrit > 50%, 0.5 L/L) and increased serum total protein concentration (>80 g/L) indicative of dehydration are common. Serum bicarbonate concentration can be falsely markedly elevated in animals with severe rhabdomyolysis because of cellular constituents released from damaged muscle that interfere with the analytical method when automated clinical chemistry analyzers are used. **Myoglobinuria** is detectable either grossly or on chemical analysis and should be differentiated from hemoglobinuria or hematuria. Measurement of **urinary excretion of electrolytes**, although popular in the past, is of no use in diagnosing, treating, or preventing exertional rhabdomyolysis.

Muscle biopsy during the acute or convalescent stages reveals myonecrosis of type II (fast-twitch, oxidative) fibers, mild myositis, and fibrosis.

NECROPSY FINDINGS

Horses dying of exertional rhabdomyolysis have widespread degeneration of striated muscle, principally the muscles of exertion, but often involving the diaphragm and heart. Affected muscles tend to be dark and swollen but may have a pale, streaked appearance. The kidneys are swollen and have dark-brown medullary streaks. Dark-brown urine is present in the bladder. Histologic examination reveals widespread necrosis and hyaline degeneration of predominantly type II (fast-twitch, oxidative) fibers. In horses with recurrent disease, there may be evidence of myofiber regeneration. Myoglobinuric nephrosis is present in severely affected horses.

Samples for Postmortem Confirmation of Diagnosis

- Formalin-fixed kidney and affected muscle for light microscopic examination

DIAGNOSTIC CONFIRMATION

Biochemical confirmation of muscle damage by demonstration of increased serum CK or AST activity, in conjunction with appropriate clinical signs, provides the diagnosis.

DIFFERENTIAL DIAGNOSIS

- Muscle cramping induced by ear tick (*Otobius megnini*)
- Polysaccharide storage myopathy of Quarter horses and related breeds
- Emerging or newly recognized myopathies, such a vacuolar myopathy in Warmbloods[3]
- Ionophore intoxication (monensin, lasalocid, salinomycin, narasin, maduramicin)
- Infection by *Anaplasma phagocytophilum*[4]
- Equine lower motor neurone disease (acute form)
- White snake root (*Eupatorium rugosum*) or rayless goldenrod (*Isocoma pluriflora*)
- Hyperkalemic periodic paralysis
- Laminitis
- Colic
- Pleuritis
- Aorto-iliac thrombosis

TREATMENT

The treatment chosen depends on the severity of the disease. The **general principles** are rest; correction of dehydration and electrolyte abnormalities; prevention of complications, including nephrosis and laminitis; and provision of analgesia.

Mildly affected horses (heart rate < 60 bpm, normal rectal temperature and respiratory rate, no dehydration) may be treated with rest and phenylbutazone (2.2 mg/kg, orally or IV every 12 hours for 2 to 4 days). Horses should be given mild exercise with incremental increases in workload as soon as they no longer have signs of muscle pain. Access to water should be unrestricted.

Severely affected horses (heart rate > 60 bpm, rectal temperature > 39° C [102° F], 8% to 10% dehydrated, reluctant or unable to walk) should not be exercised, including walking back to the stable, unless it is unavoidable. Isotonic, polyionic **fluids**, such as lactated Ringer's solution, should be administered IV to severely affected horses to correct any hypovolemia and to ensure a mild diuresis to prevent myoglobinuric nephropathy. Less severely affected horses can be treated by administration of fluids by nasogastric intubation (4 to 6 L every 2 to 3 hours). Although it has been recommended that urine should be alkalinized by administration of mannitol and sodium bicarbonate (1.3% solution IV, or 50 to 100 g of sodium bicarbonate orally every 12 hours) to minimize the nephrotoxicity of myoglobin, this therapy is not effective in humans at risk of myoglobinuric nephrosis. Affected horses should not be given diuretics (e.g., furosemide) except if they are anuric or oliguric after correction of hypovolemia.

Phenylbutazone (2.2 to 4.4 mg/kg, IV or orally, every 12 to 24 hours), **flunixin meglumine** (1 mg/kg IV every 8 hours), or **ketoprofen** (2.2 mg/kg IV every 12 hours) should be given to provide **analgesia**. **Mild sedation** (acepromazine 0.02 to 0.04 mg/kg IM, or xylazine, 0.1 mg/kg IM, both with butorphanol, 0.01 to 0.02 mg/kg) may decrease muscle pain and anxiety. Tranquilizers with vasodilatory activity, such as acepromazine, should only be given to horses that are well hydrated. **Muscle relaxants**, such as methocarbamol, are often used but have no demonstrated efficacy.

Recumbent horses should be deeply bedded and repositioned by rolling every 2 to 4 hours. Severely affected horses should not be forced to stand.

CONTROL

Prevention of the sporadic, idiopathic disease centers on ensuring that horses are fed a balanced ration with adequate levels of vitamin E, selenium, and electrolytes and have a regular and consistent program of exercise. Despite lack of clear evidence for a widespread role for **vitamin E or selenium deficiency** in exertional rhabdomyolysis, horses are often supplemented with 1 IU/kg vitamin E and 2.5 µg/kg selenium daily in the feed. Care should be taken not to induce selenium toxicosis.

Sodium bicarbonate (up to 0.5 to 1.0 g/kg BW daily in the ration) and other electrolytes are often added to the feed of affected horses, but their efficacy is not documented. **Phenytoin** has proven useful in the treatment of recurrent rhabdomyolysis. It is administered at a dose rate of 6 to 8 mg/kg, orally, every 12 hours, and the dose is adjusted depending on the degree of sedation produced (a reduced dose should be used if the horse becomes sedated) or lack of effect on serum CK or AST activity. Phenytoin can be administered to horses for months. **Dimethylglycine, altrenogest, and progesterone** are all used on occasion in horses with recurrent rhabdomyolysis, but again, without demonstrated efficacy.

The feeding of high-fat, low-soluble-carbohydrate diets is useful in the prevention of recurrent exertional rhabdomyolysis in Thoroughbred horses and polysaccharide storage myopathy in Quarter horses. The usefulness of this practice in preventing sporadic, idiopathic exertional rhabdomyolysis has not been demonstrated.

DIETARY DEFICIENCY OF PHOSPHORUS, CALCIUM, AND VITAMIN D AND IMBALANCE OF THE CALCIUM:PHOSPHORUS RATIO

A dietary deficiency or disturbance in the metabolism of calcium, phosphorus, or vitamin D, including imbalance of the calcium:phosphorus ratio, is the principal cause of the **osteodystrophies,** which can occur in a number of forms:

- **Osteomalacia**—a reduction in the strength of bones secondary to defective bone mineralization typically caused by inadequate or imbalanced levels of available phosphate and calcium, vitamin D deficiency, or because of excessive resorption of calcium from the bone, such as is caused by hyperparathyroidism. There is a reduction in the mineral:matrix ratio in bone in that there is less mineral than expected for the bone mass. The disease is histologically evident as increased osteoid (unmineralized matrix).
- **Osteoporosis**—a reduction in bone mass, with associated increased risk of fracture, in which there is a proportionate reduction in both the mineral and the matrix (protein, osteoid) content of bone. The remaining bone is essentially normal but is insufficient in quantity. The disease is typically evident as thin bone cortices on sectioning or radiographic examination.
- **Rickets**—a disease caused by vitamin D deficiency, resulting in aberrant calcium and phosphorus metabolism, that affects young animals and is characterized osteomalacia. Affected animals are described as "rachitic."

Osteodystrophia fibrosa—also referred to osteitis fibrosa (incorrectly, because this is not an inflammatory condition) or fibrous osteodystrophy. A form of osteomalacia in which mineralized bone is replaced by unmineralized fibrotic tissue under the influence of prolonged hyperparathyroidism, secondary to a high phosphorus:low calcium ratio in feed in horses, calcium deficiency in pigs, or chronic renal disease in some species.

The etiology and pathogenesis of these disorders is discussed in more detail in the sections of this text dealing with those diseases. It is important to note that the interrelations of calcium, phosphorus, and vitamin D metabolism are complex, and the importance of these and related factors (age, overall nutritional status, other mineral deficiencies or excesses) in clinical disease is often very difficult to define.

In an attempt to simplify this situation, the diseases in this section are covered in the following order:

Calcium deficiency (hypocalcicosis)
- Primary: an absolute deficiency in the diet
- Secondary: when the deficiency is conditioned by some other factor, principally an excess intake of phosphorus

Phosphorus deficiency (hypophosphatosis)
- Primary: an absolute deficiency in the diet
- Secondary: when the deficiency is conditioned by some other factor; although in general terms an excessive intake of calcium could be such a factor, specific instances of this situation are lacking

Vitamin D deficiency (hypovitaminosis-D)
- Primary: an absolute deficiency intake of the vitamin
- Secondary: when the deficiency is conditioned by other factors of which excess carotene intake is the best known.

In different countries with varying climates, soil types, and methods of husbandry, these individual deficiencies are of varying importance. For instance, in South Africa, northern Australia, and North America, the most common of the deficiencies just listed is that of phosphorus deficiency; vitamin D deficiency is uncommon. In Great Britain, Europe, and parts of North America, a deficiency of vitamin D can also be of major importance.[1,2] Animals are housed indoors for much of the year, they are exposed to little ultraviolet irradiation, and their forage may contain little vitamin D. Under such conditions, the absolute and relative amounts of calcium and phosphorus in the diet need to be greater than in other areas if vitamin D deficiency is to be avoided. In New Zealand, where much lush pasture and cereal grazing are used for feed, the vitamin D status is reduced not only by poor solar irradiation of the animal and plant sterols, but in addition, an antivitamin D factor is present in the diet, possibly in the form of carotene.

Now that the gross errors of management with respect to calcium and phosphorus and vitamin D are largely avoided, more interest is devoted to the marginal errors; in these, diagnosis is not nearly so easy, and the deficiency can be evident only at particular times of the year. The conduct of a response trial in which part of the herd is treated is difficult unless they are hand-fed daily; there are no suitable reticular retention pellets or long-term injections of calcium or phosphorus because the daily requirement is so high. Two methods suggest themselves:

1. Analysis of ash content of samples of spongy bone from the tuber coxae
2. The metabolic profile method

The latter program may have some value as a monitoring and diagnostic weapon in the fields of metabolic disease, nutritional deficiency, and nutritional excesses.

Absorption and Metabolism of Calcium and Phosphorus

In ruminants, dietary calcium is absorbed by the small intestine according to body needs, whereas in equids there is greater obligatory absorption of calcium, and it is less dependent on vitamin D (and its metabolites) than in ruminants.[3,4] Whereas young animals with high growth requirements absorb and retain calcium in direct relation to intake over a wide range of intakes, adult male ruminants, irrespective of intake, absorb only enough calcium to replace that lost by excretion into urine and intestine, retaining none of it. Calcium absorption is increased in adult animals during periods of high demand, such as pregnancy and lactation, or after a period of calcium deficiency, but a substantial loss of body stores of calcium appears to be necessary before this increase occurs. The dietary factors influencing the efficiency of absorption of calcium include the nature of the diet, the absolute and relative amounts of calcium and phosphorus present in the diet, and the presence of interfering substances. The calcium in milk is virtually all available for absorption, but the calcium in forage-containing diets has an availability of only about 50%. The addition of grain to an all-forage diet markedly improves the availability of the calcium.

Phosphorus is absorbed by young animals from both milk and forage-containing diets with a high availability (80% to 100%), but the availability is much lower (50% to 60%) in adult animals. Horses fed diets containing adequate amounts of calcium and phosphorus absorb 50% to 65% of the calcium and slightly less than 50% of the phosphorus present in a variety of feedstuffs. In grains, 50% to 65% of the phosphorus is in the phytate form, which is utilizable by ruminants, but not as efficiently by nonruminants such as the horse and pig. An average availability of 70% has been assumed for phosphorus in early-weaning diets for young pigs, and a value of 50% is assumed for practical cereal-based feeds as supplied to growing pigs, sows, and boars.

The metabolism of calcium and phosphorus is influenced by the parathyroid hormone, calcitonin, and vitamin D (Fig. 15-13), although there are important differences in calcium homeostasis between ruminants and equids.[5-8] For instance, equids have much lower serum vitamin D concentrations, greater absorption of calcium by the small intestine (duodenum), and greater renal excretion of calcium than do ruminants.[4,8,9] In all mammalian species, parathyroid hormone is secreted in response to hypocalcemia and stimulates the conversion of 25-dihydroxycholecalciferol to 1,25-dihydroxycholecalciferol (1,25-DHCC). Parathyroid hormone and 1,25-DHCC together stimulate bone resorption, and 1,25-DHCC alone stimulates active intestinal absorption of calcium.[10] Calcium enters the blood from bone and intestine, and when the

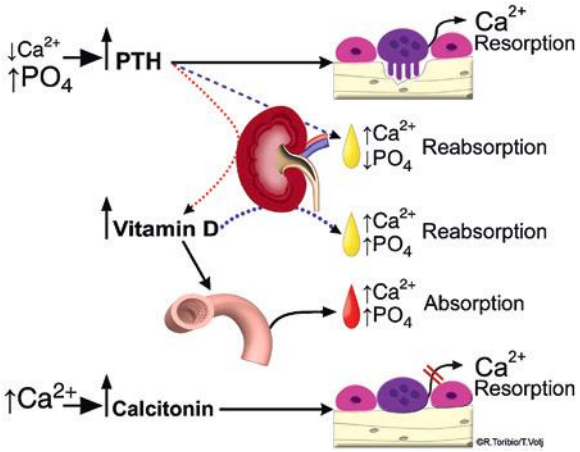

Fig. 15-13 Calcium and phosphate homeostasis. A decrease in extracellular Ca^{2+} concentrations or an increase in phosphate (PO_4) concentrations leads to a parathyroid hormone (PTH) release from the parathyroid gland, which in turn increases renal reabsorption of Ca^{2+}, renal activation of vitamin D, urinary PO_4 excretion, and bone resorption. In turn, vitamin D increases intestinal absorption and renal reabsorption of Ca^{2+} and PO_4. An increase in Ca^{2+} concentration stimulates the thyroid gland to secrete calcitonin to inhibit osteoclastic bone resorption. (Courtesy of Ramiro E. Toribio, DVM, MS, PhD, and Tim Vojt, Columbus, OH; Reproduced with permission.[8])

serum calcium level increases above normal, parathyroid hormone is inhibited and calcitonin secretion stimulated. The increased calcitonin concentration blocks bone resorption, and the decreased parathyroid hormone concentration depresses calcium absorption. Most calcium absorption occurs in the small intestine, with equids absorbing a greater proportion of dietary calcium than ruminants.[5] Detailed descriptions of the physiology of calcium metabolism are available in the section "Milk Fever (Hypocalcemia)" and in reviews.[6]

CALCIUM DEFICIENCY

Calcium deficiency can be primary or secondary, but in both cases, the end result is a type of osteodystrophy, with the specific disease depending largely on the species and age of the animals affected.

SYNOPSIS

Etiology Primary dietary deficiency of calcium is uncommon. Secondary calcium deficiency can be induced by marginal calcium intake and high phosphorus intake.

Epidemiology Sporadic. Not common if diets adequate.

Signs Poor growth and dentition. Tetany can occur in lactating ewes. Inappetence, stiffness, fracture of long bones. Specific diseases include rickets, osteomalacia, and osteodystrophia fibrosa.

Clinical pathology Serum calcium and phosphorus. Radiography.

Necropsy findings Osteoporosis; low ash content of bone.

Diagnostic confirmation Histology of bone and bone ash analyses.

Differential diagnosis list See differential diagnosis of each specific disease.

Treatment Calcium salts parenterally (for tetany) and orally (for prolonged correction of deficiency).

Control Adequate calcium and phosphorus levels in diet.

ETIOLOGY

A primary deficiency attributable to a lack of calcium in the diet is uncommon, although a secondary deficiency attributable to a marginal calcium intake aggravated by a high phosphorus intake is not uncommon. In ponies, such a diet depresses intestinal absorption and retention of calcium in the body, and the resorption of calcium from bones is increased as a result of hyperparathyroidism (secondary nutritional hyperparathyroidism—see discussion of osteodystrophia fibrosa later in this section). Hypoparathyroidism, either primary or secondary to renal disease, reduces intestinal and renal reabsorption of calcium and causes seizures and muscle fasciculation.[1-3]

EPIDEMIOLOGY

Calcium deficiency is a sporadic disease occurring in particular groups of animals rather than in geographically limited areas. Although death does not usually occur, there can be considerable loss of function and disabling lesions of bones or joints.

Horses in training, cattle being fitted for shows, and valuable stud sheep are often fed artificial diets containing cereal or grass hays that contain little calcium and grains that have a high content of phosphorus. The secondary calcium deficiency that occurs in these circumstances is often accompanied by a vitamin D deficiency because of the tendency to keep animals confined indoors. Pigs are often fed heavy concentrate rations with insufficient calcium supplement. Dairy cattle can occasionally be fed similarly imbalanced diets, the effects of which are exaggerated by high milk production.

There are no well-established records of calcium deficiency in grazing cattle, but there are records of low calcium intake in feedlots accompanied by clinical osteodystrophy. There is also a well-recognized field occurrence of calcium deficiency in young sheep in southeast Australia. Outbreaks can affect many sheep and are usually seen in winter and spring, following exercise or temporary starvation. In most outbreaks, the characteristic osteoporosis results from a long-term deprivation of food as a result of poor pasture growth. Occasional outbreaks occur on green oats used for grazing. The calcium intake in some cases is as low as 3 to 5 g/week in contrast to the requirement of 3 to 5 g/d. Sheep in the Kalahari Desert develop osteoporosis as a result of low calcium intake and low-grade fluorosis.[4] Goats deficient in calcium, phosphorus, and vitamin D develop osteoporosis.[5] Copper deficiency is associated with osteoporosis in young sheep.

High protein intake and rapid growth have been suggested as contributory factors in the development of skeletal problems in young horses (developmental orthopedic disease [DOD]). The cause of DOD in young horses is multifactorial and related to mineral imbalances in the diet, genetic predisposition,[6] trauma, and maternal[7] and foal nutritional status. For instance, wither height at 30 days of age, age of the mare, breed, regularity of exercise, Ca/P level in the mare and foal rations, group size in pasture, and the type and frequency of handling were identified as risk factors for DOD in foals in France.[8] Although excessive energy intake is sometimes blamed, a concentration of dietary protein of 20%, which is significantly above the National Research Council (NRC) recommended level of 14%, is neither helpful nor harmful to growing horses. The high protein intake did not affect the rate of growth, height, and circumference of cannon bones compared with horses receiving the lower 14% diet. The high-protein diet did not

result in hypercalciuria and did not affect calcium absorption or calcium retention.

In females there is likely to be a cycle of changes in calcium balance, with a negative balance occurring in late pregnancy and early lactation and a positive balance in late lactation and early pregnancy and when lactation has ceased. The negative balance in late pregnancy is in spite of a naturally occurring increased absorption of calcium from the intestine at that time, at least in ewes.

PATHOGENESIS

The main physiologic functions of calcium are the formation of bone and milk, participation in the clotting of blood, and the maintenance of neuromuscular excitability. In the development of osteodystrophies, dental defects, and tetany, the role of calcium is well understood; however, the relation between deficiency of the element and lack of appetite, poor growth, loss of condition, infertility, and reduced milk flow is not readily apparent. The disinclination of the animals to move about and graze and poor dental development may contribute to these effects.

Experimentally, feeding young lambs a diet low in calcium and phosphorus for 12 weeks results in soft and pliable ribs with thickening of the costochondral junctions, reduction in feed intake by about 34%, significant changes in plasma calcium and phosphorus concentrations, and changes in dry matter digestibility. Feeding repletion diets results in complete remineralization of rib bones but only partial remineralization of the metatarsal bones.

Nutritional factors other than calcium, phosphorus, and vitamin D can be important in the production of osteodystrophies, which also occur in copper deficiency, fluorosis,[4] and chronic lead poisoning. Vitamin A is also essential for the development of bones, particularly those of the cranium.

CLINICAL FINDINGS

The clinical findings, apart from the specific syndromes described later, are less marked in adults than in young animals, in which there is decreased rate or cessation of growth and dental maldevelopment. The latter is characterized by deformity of the gums, poor development of the incisors, failure of permanent teeth to erupt for periods of up to 27 months, and abnormal wear of the permanent teeth as a result of defective development of dentine and enamel, occurring principally in sheep.

A calcium deficiency can occur in lactating ewes and sucking lambs, whose metabolic requirements for calcium are higher than in dry and pregnant sheep. There is a profound fall in serum calcium. Tetany and hyperirritability do not usually accompany hypocalcemia in these circumstances, probably because it develops slowly. However, exercise and fasting often precipitate tetanic seizures and parturient paresis in such sheep. This is typical of the disease as it occurs in young sheep in southeast Australia. Attention is drawn to the presence of the disease by the occurrence of tetany, convulsions, and paresis, but the important signs are ill-thrift and failure to respond to anthelmintics. Serum calcium levels will be as low as 5.6 mg/dL (1.4 mmol/L). There is lameness, but fractures are not common even though the bones are soft. A simple method for assessing this softness is compression of the frontal bones of the skull with the thumbs. In affected sheep, the bones can be felt to fluctuate.

Pigs fed on heavy concentrate rations may develop a hypocalcemic tetany, which responds to treatment with calcium salts. Tetany may also occur in young, rapidly growing cattle in the same circumstances.

Inappetence, stiffness, tendency of bones to fracture, disinclination to stand, difficult parturition, reduced milk flow, loss of condition, and reduced fertility are all nonspecific signs recorded in adults.

SPECIFIC SYNDROMES

Primary Calcium Deficiency

No specific syndromes are recorded, although the complex relationship between overall nutrition, including concentration or amount of calcium in the diet, and bone development should be noted.

Secondary Calcium Deficiency

Rickets, osteomalacia, osteoporosis, osteodystrophia fibrosa of the horse, goat, and pig and degenerative arthropathy of cattle are the common syndromes in which secondary calcium deficiency is one of the specific causative factors.[5] In sheep, rickets is seldom recognized, but there are marked dental abnormalities. Rickets has been produced experimentally in lambs by feeding a diet low in calcium. There is an inherited form of rickets in Corriedale sheep.[9-11]

CLINICAL PATHOLOGY

Because of the effect of the other factors listed previously on body constituents, examination of specimens from living animals may give little indication of the primary cause of the disturbance. For example, hypocalcemia need not indicate a low dietary intake of calcium. Data on serum calcium and phosphorus concentrations and plasma alkaline phosphatase activity, radiographical examination of bones, and balance studies of calcium and phosphorus retention are all of value in determining the presence of osteodystrophic disease, but determination of the initial causative factor will still depend on analysis of feedstuffs and comparison with known standard requirements. Serum calcium concentration can be within the normal range in most cases, although calcium deficiency is followed, at least in sheep, by a marked fall in serum calcium levels to as low as 3.5 mg/dL (0.87 mmol/L). In an uncomplicated nutritional deficiency of calcium in sheep, there is only a slight reduction in the radiopacity of bone, in contrast to sheep with a low phosphorus and vitamin D status, which show marked osteoporosis. The response to dietary supplementation with calcium is also of diagnostic value.

NECROPSY FINDINGS

True primary calcium deficiency is extremely rare, but when it does occur, severe osteoporosis and parathyroid gland hypertrophy are the significant findings. The cortical bone is thinned, and the metaphyseal trabeculae appear reduced in size and number. The ash content of the bone is low because the bone is resorbed before it is properly mineralized.

Calcium deficiency secondary to other nutritional factors is common and typically induces the form of osteodystrophy known as osteodystrophia fibrosa (see subsequent description). In most instances, the confirmation of a diagnosis of hypocalcinosis at necropsy includes an analysis of the diet for calcium, phosphorus, and vitamin D content.

Samples for Confirmation of Diagnosis

- **Toxicology**—long bone (ASSAY [ash]); feed (ASSAY [Ca] [P] [Vit D])
- **Histology**—formalin-fixed section of long bone (including metaphysis), parathyroid (LM)

DIFFERENTIAL DIAGNOSIS

A diagnosis of calcium deficiency depends on proof that the diet is, either absolutely or relatively, insufficient in calcium, that the lesions and signs observed are characteristic, and that the provision of calcium in the diet alleviates the condition. The diseases that may be confused with calcium deficiency are described under the diagnosis of each of the specific disease entities.

The close similarity between the dental defects in severe calcium deficiency of sheep and those occurring in chronic fluorosis may necessitate quantitative estimates of fluorine in the teeth or bone to determine the cause.

TREATMENT

The response to treatment is rapid, and the preparations and doses recommended here are effective as treatment. Parenteral injections of calcium salts are advisable when tetany is present. When animals have been exposed to dietary depletion of calcium and phosphorus over a period of time, it is necessary to supplement the diet with calcium and phosphorus during dietary mineral repletion.

CONTROL

The provision of adequate calcium in the diet, the reduction of phosphorus intake where it

is excessive, and the provision of adequate vitamin D are the essentials of both treatment and prevention. Some examples of estimated minimum daily requirements for calcium, phosphorus, and vitamin D are set out in Table 15-9. These are estimated minimum requirements and may need to be increased by a safety factor of 10% to allow for variation in individual animal requirements, the biological availability of nutrients in the feedstuffs, and the effect which total amount of feed intake has on absolute intake of minerals. For example, the use of a complete pig ration on a restricted basis may require that the concentration of both calcium and phosphorus be increased for that ration to deliver the actual total quantity of calcium and phosphorus necessary to meet a particular requirement for growth, pregnancy, or lactation. The information in Table 15-9 is presented as a guideline. When investigating a nutritional problem of formulating rations, it is recommended that the most recently available publications on the nutrient requirements of domestic animals be consulted.

Ground limestone is most commonly used to supplement the calcium in the ration, but it should be prepared from calcite and not from dolomite. Variations in availability of the calcium in this product occur with variations in particle size, with a finely ground preparation being superior in this respect. Bone meal and dicalcium phosphate are more expensive, and the additional phosphorus may be a disadvantage if the calcium:phosphorus ratio is very wide. Alfalfa, clover, and molasses are also good sources of calcium but vary in their content. The optimum calcium:phosphorus ratio is within the range of 2:1 to 1:1. In cattle, absorption of both elements is better at the 2:1 ratio. For optimum protection against the development of urolithiasis in sheep, a ratio of 2 to 2.5 calcium to 1 phosphorus is recommended.

The dustiness of powdered limestone can be overcome by dampening the feed or adding the powder mixed in molasses. Addition to salt or a mineral mixture is subject to the usual disadvantage that not all animals partake of it readily when it is provided in a free-choice manner, but this method of supplementation is often necessary in pastured animals. High-producing dairy cows should receive the mineral mixture in their ration and have access to it in boxes or in blocks.

PHOSPHORUS DEFICIENCY

SYNOPSIS

Etiology Usually a primary deficiency in the diet; may be conditioned by vitamin D deficiency.

Epidemiology Primary phosphorus (P) deficiency occurs in arid regions with low phosphorus content in soil. Most commonly chronic, but transient and acute P deficiency thought to occur in lactating dairy cattle in early lactation. Occurs under range conditions in beef cattle and sheep. Occurs in pigs not supplemented with sufficient phosphorus.

Signs Feed intake depression and anorexia are most commonly encountered sign with chronic P deficiency. Young animals grow slowly and develop rickets. Adults develop osteomalacia, unthriftiness, weight loss, reduced feed consumption, reluctance to move, leggy appearance, and fractures. Impaired milk production, growth rate, and fertility, presumably from energy and nutrient deficiency as a result of feed-intake depression. Recumbency and acute intravascular hemolysis (postparturient hemoglobinuria) in high-producing cows in early lactation have empirically been associated with hypophosphatemia and P depletion.

Clinical pathology Serum inorganic phosphorus. Phosphorus content of diet.

Necropsy findings Rickets and osteomalacia; lack of mineralization of bones.

Diagnostic confirmation Radiography of long bones, histology of bone lesions; bone ash analyses.

Differential diagnosis Those diseases resembling rickets and osteomalacia. Milk fever and downer cow syndrome in periparturient recumbent cattle. Other disorders associated with intravascular hemolysis in cases of periparturient hemoglobinuria.

Treatment Phosphate salts orally or intravenously, vitamin D.

Control Supplement diets with adequate phosphorus, calcium, and vitamin D.

ETIOLOGY

Phosphorus (P) deficiency occurs predominantly in arid regions of the world with low P content in soil. Phosphorus deficiency is encountered whenever the daily dietary P intake is insufficient to cover the requirements for maintenance and production and the organism has to recur to the mobilization of bone P. Under most circumstances P deficiency is chronic, and signs and symptoms associated with it occur after dietary P deprivation over months to years.

In dairy cattle, a rather acute and transient period of P deficiency is thought to occur in the first days to weeks of lactation and has been associated with recumbency and acute intravascular hemolysis in early-lactating cows. Rations with marginal P content in combination with low feed intake around calving are thought to result in inadequate P intake to cover for the suddenly increasing P requirements for milk production at the onset of lactation. The assumption that the commonly observed periparturient hypophosphatemia is an indicator for P depletion is, however, under contentious debate, and the clinical relevance of subnormal plasma inorganic phosphorus (Pi) levels in affected cows is uncertain.[1] Pronounced hypophosphatemia is also seen around parturition in mastectomized cattle, which don't produce any milk. Furthermore, even severe hypophosphatemia is often seen in healthy fresh cows not showing any clinical signs or symptoms.[1]

EPIDEMIOLOGY

Geographic Occurrence

Chronic P deficiency has a distinct geographic distribution depending largely upon the P content of the parent rock from which the soils of the area are derived, but also upon the influence of other factors, such as excessive calcium, aluminum, or iron, which reduce the availability of P to plants. Large areas of grazing land in many countries are of little value for livestock production without P supplementation. In New Zealand, for example, where fertilization of pasture with superphosphate has been practiced for many years, P deficiency may still occur in dairy herds because of inadequate maintenance of application over several years. Animals in affected areas mature slowly and are inefficient breeders, and additional losses as a result of botulism and defects and injuries of bones may occur. Apart from areas in which frank P deficiency is seen, it is probable that in many other areas a mild degree of deficiency is a limiting factor in the production of meat, milk, and wool.

Heavy leaching by rain and constant removal by cropping contribute to P deficiency in the soil, and the low P levels of the plant cover may be further diminished by drought conditions. Pastures deficient in P are classically also deficient in protein.

Cattle

The earliest report of naturally occurring P deficiency in grazing cattle was at Armoedsvlakte in the Northern Cape of South Africa. The disease was called **aphosphorosis,** and animals with the disease demonstrated a depraved appetite characterized by the desire to eat wood, bones, rocks, and other such materials, a behavior known as **pica**. In severely affected regions, cattle often died from botulism from eating bones from old carcasses contaminated with *Clostridium botulinum* toxin. In advanced states of aphosphorosis, animals developed bone malformations that were associated with stiffness in

Table 15-9 Examples of estimated daily requirements of calcium, phosphorus, and vitamin D

Species, kg body weight, and function	Calcium (g/animal)	Phosphorus (g/animal)	Vitamin D
Dairy cattle			
Growing heifers (large breeds)			300 IU/kg dry matter (DM) intake
159	15	12	
300	24	18	
400	26	20	
Growing heifers (small breeds)			
100	9	7	
200	15	11

Pig			
Growing pigs (10- to 100-kg live weight)	0.65	0.50	200 IU/kg ration
Breeding pigs (gilts, sows, boars)	0.75	0.50	275 IU/kg ration

the forelegs, with a characteristic lameness referred to as "styfsiekte" in South Africa, "creeps" in Texas, and "pegleg" in Australia.

A survey of the mineral status of bones of cattle at abattoirs in western New South Wales, Australia, found evidence of osteodystrophy based on ash density. They represented cattle attempting to grow in a poor season, often female, in poor body-fat condition, light in body weight, and mostly from red soils known to be deficient in P.

Cattle constantly grazing pasture in the southern hemisphere appear to require somewhat less P in the diet (0.20% is probably adequate) than do higher-producing, partly housed livestock. The dietary requirements of P recommended by the NRC for beef cows weighing 450 kg may exceed the basic requirements. Over a period of several gestations, a daily allowance of 12 g of P per day per animal was deemed to be adequate for beef cows. Cattle given a P-deficient diet did not develop detectable signs of P deficiency until after 6 months of deprivation of this mineral.[2]

Hypophosphatemia in periparturient dairy cows is widespread, affecting at least 10% of fresh dairy cows, and it is often interpreted as a sign of dietary P deficiency in the periparturient period.[1,3,4] Hypophosphatemia in early lactation has been associated with syndromes such as postparturient hemoglobinuria, a form of intravascular hemolysis that is thought to be caused by increased fragility of red blood cell in P-deficient states and postparturient recumbency that is not responsive to intravenous treatment with calcium salts.[1,5]

Sheep and Horses

Sheep and horses at pasture are much less susceptible to the osteodystrophy of P deficiency than are cattle, and their failure to thrive on P-deficient pasture is probably attributable in part to the low protein content of the pasture. In fact, there has been no clear demonstration of a naturally occurring P deficiency in sheep.

There is some limited evidence that the plasma inorganic phosphorus (Pi) levels in Thoroughbred racehorses may be related to certain feeding regimens and to racing performance. Horses fed cubed or pelleted dietary supplement have plasma Pi concentrations consistently below an accepted mean of 1.03 mmol/L (3.2 mg/dL). It is suggested that a rapid rate of passage of the ingesta may affect P absorption. Other observations indicate that some of the best track performers had significantly lower plasma Pi concentrations compared with some of the worst performers.

Pigs

A primary deficiency can occur in pigs kept in confinement and not provided with sufficient dietary P. Lactating sows are more commonly affected than growing pigs. In some situations, in the cereal grains, the phytate levels are so high and phytase levels so low that rickets and osteomalacia are common in the pig population.

Secondary Phosphorus Deficiency

Secondary P deficiency is the result of hyperparathyroidism or vitamin D deficiency. This is of minor importance compared with the primary P deficiency. A deficiency of vitamin D is not necessary for the development of osteodystrophy, although with suboptimal P intakes deficiency of this vitamin becomes critical. Excessive intake of calcium does not necessarily result in secondary P deficiency, although it may cause a reduction in weight gains, probably as a result of interference with digestion, and may contribute to the development of P deficiency when the intake is marginal. The presence of phytic acid in plant tissues, which renders phytate-P unavailable to nonruminant species, is a major consideration in pigs but of only minor importance in ruminants, except that increasing intakes of calcium may reduce the availability of phytate-P even for ruminants. Rock phosphates containing large amounts of iron and aluminum have been shown to be of no value to sheep as a source of P. A high intake of magnesium, such as that likely to occur when magnesite is fed to prevent lactation tetany, may cause hypophosphatemia if the P intake of dairy cows is already low.

PATHOGENESIS

Of the body P, 80% to 85% is located in the skeleton, where it is deposited in a metabolically inert form together with calcium as hydroxyapatite. Hydroxyapatite is the compound that provides bone with its characteristic structural rigidity and stability. Bone P also functions as an important P reservoir that can be mobilized when body requirements temporarily exceed dietary intake. The remainder of the body P is available as dissolved P that is either encountered as inorganic phosphate (Pi) or forming part of organic molecules such as phospholipids, phosphocreatine, different adenosine molecules, or various carbohydrate metabolites. Phosphorus is a predominantly intracellular mineral, of which only small amounts are located in the extracellular space. Phosphorus bound in phospholipid molecules is essential for the structural stability of cell membranes that are composed of these phospholipids. The availability of soluble Pi in the intracellular space is essential for a plethora of biochemical reactions, especially those concerned with energy metabolism and transfer. Phosphorus furthermore functions as a buffer in rumen fluid, urine, and the intracellular space. Rumen microbes that are of critical importance for ruminant nutrition are inherently dependent of adequate P supply, which is not only provided by feed but also by the salivary glands, which produce large amounts of saliva rich in P.

Inadequate dietary P supply will result in the mobilization of hydroxyapatite, from which will release P together with calcium. Prolonged P deficiency is therefore associated with abnormal development of bone tissue, known as osteodystrophy.

Experimentally, female beef cattle fed diets containing less than 6 g of P/day developed an insidious complex syndrome characterized by weight loss, rough hair coat, abnormal stance, and lameness. Spontaneous fractures occurred in the vertebrae, pelvis, and ribs. Some affected bones were severely demineralized, and the cortical surfaces were porous, chalky white, soft, and fragile. The osteoid tissue was not properly mineralized.

Experimental dietary P depletion in cattle results in a rapid and marked decline in serum Pi. When markedly P deficient diets are fed over months, affected animals develop an avid appetite for old bones. The long-term signs include decreased weight gain in growing animals or loss of body condition in adult animals, feed-intake depression, reduced bone density as determined by radiography, and reduced bone weight, which are consistent with osteodystrophy. Serum Pi concentrations tend to increase despite of ongoing dietary P deprivation with activation of counterregulatory mechanisms that are reflected in increased plasma 1,25-dihydroxyvitamin D, reduced plasma concentrations of parathyroid hormone, and increased renal calcium excretion.

Muscle weakness to the point of recumbency is thought to be another symptom of P depletion, particularly in early-lactating dairy cows. The proposed underlying mechanism is a deficiency of Pi that may result in decreased concentration of phosphorylated molecules such as phosphocreatine and adenosine triphosphate (ATP) that are essential for energy storage on a cellular level. It has been proposed that it is through a depletion of these energy-storing molecules that P deficiency may result in muscle weakness and recumbency in periparturient cattle.[6] Nevertheless, it should be noted that disturbed muscle function has only been associated with hypophosphatemia in fresh cows but is not a common feature of chronic P deprivation in cattle. Doubts about the causative association between P deficiency and recumbency in cattle have furthermore been raised because of the impossibility of experimentally inducing recumbency through dietary P depletion in cattle and because of the variable response to treatment with P salts in recumbent hypophosphatemic cows.[1]

A decline of the intracellular ATP concentration, this time of red blood cells, is the presumed mechanism behind intravascular hemolysis observed in fresh cows with postparturient hemoglobinuria (see also the discussion of postparturient hemoglobinuria). Red blood cells (RBCs) require ATP to maintain their osmotic stability. A

decrease of the ATP concentration in P depleted human RBCs to 15% of normal values resulted in increased osmotic fragility of erythrocytes that was associated with intravascular hemolysis. In cattle, hypophosphatemia has been reported in many but not all cases of postparturient hemoglobinuria, and response to treatment with phosphate salts is variable.[5,7] In a recently published study in which dairy cows were fed a ration over 40% deficient for several weeks, the plasma Pi concentration dropped by over 60% within days, whereas the Pi concentration of RBCs and their osmotic resistance remained unchanged.[7] The authors concluded that dietary P depletion causing pronounced hypophosphatemia is not generally associated with intracellular P depletion of RBCs or increased osmotic fragility, and that the plasma Pi concentration is an unsuitable indicator for the intracellular P content of RBCs.[7]

Decreased fertility was historically one of the predominant symptoms associated with P deficiency in cattle. Because there is no known mechanism through which P deficiency would directly affect fertility and because P depletion is commonly associated with feed-intake depression, weight loss, and decreased milk production along with reproductive failure, it is more likely that poor fertility is a result of a negative energy and nutrient balance rather than a specific effect of P on a (yet undetermined) reproductive function.

The pathophysiologic effects of low dietary P in pigs have been examined. Determination of the serum concentrations of parathyroid hormone, 1,25-$(OH)_2$ D, and osteocalcin were monitored in Romanian Landrace pigs originating from herds with dietary P deficiency. Serum Pi concentrations were negatively correlated with those of 1,25-$(OH)_2$ D. In lactating animals and sucklings, the linear relationships were not present. Serum Pi concentrations positively correlated with those of PTH, and 1,25-$(OH)_2$ D concentrations were negatively correlated. The serum concentrations of 1,25-$(OH)_2$ D and osteocalcin were positively correlated. Milk P concentrations ranging from 3.1 to 7.5 mmol/L were correlated positively with urinary Pi concentrations ranging from 0.3 to 11.4 mmol/L. In conclusion, similar to other species, P homeostasis is achieved in pigs by feedback mechanisms between P, PTH, and 1,25-$(OH)_2$ D, and osteocalcin production is induced by 1,25-$(OH)_2$ D.

CLINICAL FINDINGS

A plethora of clinical signs and conditions, such as unthriftiness, anorexia, pica, impaired growth and fertility, muscle weakness, lameness, recumbency, intravascular hemolysis, osteomalacia, and many more, have been associated with P deficiency in ruminants and other species.

Primary P deficiency is common only in cattle and is associated with chronic dietary P deprivation. In the experimental production of P deficiency in beef or dairy cattle, several months to years on a P-deficient diet are necessary before clinical signs develop.

Young animals grow slowly and develop rickets. In adults there is an initial subclinical stage followed by osteomalacia. In ruminants of all ages, a reduction in voluntary feed intake is a first sign of P deficiency and is the basis of most of the general systemic symptoms to follow, which are retarded growth, weight loss, low milk yield, and reduced fertility. For example, in severe P deficiency in range beef cattle, the calving percentage has been known to drop from 70% to 20%. The development and wear of teeth are not greatly affected, in contrast with the severe dental abnormalities that occur in a nutritional deficiency of calcium. However, malocclusion may result from poor mineralization and resulting weakness of the mandible. More advanced stages of P deficiency occurring in severely P-deficient regions are associated with reluctance to move, abnormal stance, and increased incidence of bone fractures. The animals have a leggy appearance with a narrow chest and small girth, the pelvis is small, and the bones are fine and break easily. The chest is slab-sided as a result of weakness of the ribs, and the hair coat is rough and lacking in pigment. In areas of severe deficiency, the mortality rate may be high as a result of starvation, especially during periods of drought when deficiencies of P, protein, and vitamin A are severe. Osteophagia is common and may be accompanied by a high incidence of botulism.

Cows in late pregnancy often become recumbent, and although they continue to eat, they are unable to rise. Such animals present a real problem in drought seasons because many animals in the area may be affected at the same time. Parenteral injections of P salts are ineffective, and the only treatment that may be of benefit is to terminate the pregnancy by the administration of corticosteroids or by cesarean section.

A more acute form of P deficiency is thought to occur in the first days to weeks of lactation in mature, high-yielding dairy cows. Hypophosphatemia in these animals has been associated with periparturient recumbency that is unresponsive to IV treatment with calcium salts. Affected animals are recumbent but mentally alert, with normal or only slightly decreased feed intake. They continue making attempts to stand and tend to creep around.

Another condition associated with P depletion and hypophosphatemia in dairy cattle in early lactation is postparturient hemoglobinuria. The disorder affects individual mature animals in the first days to weeks of lactation and is characterized by massive intravascular hemolysis, resulting in the excretion of large amounts of hemoglobin in urine (see also the discussion of postparturient hemoglobinuria).[7]

Although sheep and horses in P-deficient areas do not develop clinically apparent osteodystrophy, they are often of poor stature and unthrifty and may develop perverted appetites. An association between low serum or plasma Pi and infertility in mares has been suggested, but the evidence is not conclusive. The principal sign in affected sows is posterior paralysis.

CLINICAL PATHOLOGY

Serum Phosphorus

The concentration of serum or plasma Pi is the most commonly used parameter to assess the P status of an individual animal independent of the species. Although the serum Pi concentration reflects the short-term dietary P supply and the body's P pool size reasonably well, it is less suited to diagnose chronic P deficiency because compensatory mobilization of P reserves from bone tend to increase the Pi concentration in serum or plasma, thereby masking P depletion at least partially. Marked individual and diurnal fluctuations of the serum Pi concentration further complicate the interpretation of this parameter on an individual animal basis.[1]

Serum Pi levels are affected by such factors as age, milk yield, stage of pregnancy, breed, dietary P content, time of sample collection relative to feeding, and the blood vessel from which the blood sample is collected. Rapid and pronounced changes of the serum Pi level in the range of 10% to 30% can occur as a result of sudden shifts of P from the extracellular to the intracellular space, for instance, after strenuous physical exercise or oral or parenteral administration of carbohydrates.[1] Hypophosphatemia diagnosed in one single sample collected from one animal is therefore an unreliable indicator for the P status of that individual or a group of animals. The diagnostic value of the serum P concentration is complicated by the fact that clinical signs are not consistently observed with a certain degree of hypophosphatemia. For instance, serum Pi levels below 0.6 mmol/L (1.9 mg/dL) in cattle have been associated with intravascular hemolysis and recumbency, whereas even lower concentrations are often measured in healthy dairy cows.[1] To obtain comparable results it is advisable to collect blood from the same blood vessel at standardized times relative to feeding.

Reference ranges for cattle given in the literature are 1.4 to 2.6 mmol/L (4.0 to 8.0 mg/dL) and 1.9 to 2.6 mmol/L (6.0 to 8.0 mg/dL) for adult and growing animals, respectively. The reference ranges for sheep and goats are 1.6 to 2.4 mmol/L (5.0 to 7.3 mg/dL) and 1.3 to 3.0 mmol/L (4.2 to 9.1 mg/dL), respectively. Juvenile and growing individuals have higher serum Pi because of enhanced intestinal Pi uptake,

presumably to provide sufficient Pi for adequate bone mineralization. The reference ranges for serum Pi for horses and swine are 1.0 to 1.8 mmol/L (3.1 to 5.6 mg/dL) and 2.1 to 3.3 mmol/L (6.5 to 10.2 mg/dL) respectively.

Dietary Phosphorus Content

Estimating the dietary P content is among the most reliable methods to estimate the P status of one or several animals, provided the feed intake can also be quantified. For pastured cattle, estimation of the dietary P content based on the P content in soil has been proposed. A P content in soil above 8 ppm was not associated with any signs of P deficiency, whereas negative effects on feed intake, growth, and fertility became apparent in cattle pastured for prolonged periods on soils with a P content between 7 and 8 ppm. Signs became more prominent in animals kept on soils with a P content between 4 and 6 ppm and were most severe on soils with a P content below 4 ppm.

The association between dietary P intake and the concentrations of P in feces has been explored in several studies. Although the effect of the dietary P content on the intestinal absorption rate of P is well established, neither rumen fluid samples nor fecal grab samples were found to reliably identify P depleted animals. Specifically, when P-depleted animals show feed-intake depression, a clinical sign often associated with P deficiency, fecal output decreases. This can translate into unchanged or even increased fecal P, although the total fecal P output is decreased.[1]

Bone Ash Concentrations

Determination of total bone ash concentrations and bone calcium and P concentrations from a sample of rib can provide useful diagnostic information and comparison to normal values. Nonetheless the bone P content is slow to respond to changes in dietary P supply, which means that the nutritional history has a strong impact on the mineral content of fresh bone. The P content in fresh bone is considered an excellent indicator for the body P reserves, but not for the current dietary P supply or the P pool size. Because obtaining bone biopsies is impractical under field conditions, determination of bone P content is largely restricted to postmortem examination or research.[1]

NECROPSY FINDINGS

The necropsy findings are those of the specific diseases, rickets, and osteomalacia.

DIFFERENTIAL DIAGNOSIS

A diagnosis of phosphorus (P) deficiency depends on evidence that the diet is lacking in P and that the lesions and signs are typical of those caused by P deficiency and can be arrested or reverted by the administration of P. Differentiation from those diseases that may resemble rickets and osteomalacia is dealt with under those headings.

Milk fever and downer cow syndrome in periparturient recumbent cattle.

Other disorders associated with intravascular hemolysis in cases of periparturient hemoglobinuria.

TREATMENT

For P supplementation in ruminants, either oral or parenteral treatment has been proposed. For metabolism and cell function, the organism requires P as inorganic phosphate (PO_4). Accordingly, P must be supplemented in a form that either contains phosphate or as a compound that can be hydrolysed to phosphate. Most pharmaceutical products containing P and labeled for parenteral administration in animals contain phosphite (Po_2), hypophosphite (PO_3), or organic P compounds such as toldimfos (dimethylamino-methylphenyl-phosphinate) or butafosfan (butylamino-methylethyl-phosphoric acid), which the body does not appear to convert to phosphate. These compounds must thus be considered to be unsuitable for P supplementation.

The preparation of a custom-made solution either with 300 mL of distilled water containing 30 g of NaH_2PO_4 or 500 mL of deionized water containing 90 g of $Na_2HPO_4 \times 12H_2O$, which are to be administered intravenously as a single dose to an adult cow, have been proposed in the literature (both equivalent to approximately 8 g of P) but are extra-label treatments. Both solutions are only suitable for IV administration, and their effect on the plasma Pi concentration is short lived, lasting for less than 2 hours when administered as an IV bolus.

Because of the rapid and sustained effect of orally administered P salts, this treatment route is preferred over the parenteral treatment. Oral administration of monosodiumdihydrogen phosphate (300 g) or monopotassium dihydrogen phosphate (250 g), both providing approximately 60 g of P, were found to increase the plasma Pi concentration in hypophosphatemic dairy cows within 3 to 4 hours of treatment and for at least 12 hours.[8] Monocalcium phosphate (250 g, also equivalent to approximately 60 g P) was less effective than monosodium phosphate and monopotassium phosphate, but more effective than dicalcium phosphate.[8,9]

TREATMENT AND CONTROL

Treatment

Cattle:

Monosodium dihydrogen phosphate (36 g NaH_2PO_4 dihydrate in 300 mL distilled water IV as single dose) (R-2)

Disodium monohydrogen phosphate (90 g $Na_2HPO_4 \times 12\ H_20$ in 500 distilled water IV as single dose) (R-2)

Monosodium dihydrogen phosphate (300 g NaH_2PO_4 PO q12h for 1 to 3 days) (R-1)

Monopotassium dihydrogen phosphate (250 g KH_2PO_4 PO q12h for 1 to 3 days) (R-2)

Monocalcium dihydrogen phosphate (250 g $Ca\ [HPO_4]_2$ PO q12h for 1 to 3 days) (R-2)

Dicalcium monohydrogen phosphate (300 g $CaHPO_4 \times 2H_20$ PO q12h for 1 to 3 days) (R-3)

Monosodium dihydrogen phosphate IM or SC (R-3)

Disodium monohydrogen phosphate IM or SC (R-3)

Butafosfan (butylamino-methylethyl-phosphoric acid) (R-3)

Toldimfos (dimethylamino-methylphenyl-phosphinate) (R-3)

Control

Bone meal, calcium-phosphate salts, sodium-phosphate salts, and sodium-pyrophosphate may be provided in supplementary feed or by allowing free access to their mixtures with salt.

Fertilization of P-deficient pastures with phosphate.

CONTROL

Phosphorus deficiencies in grazing livestock can be prevented by direct treatment of the animal through supplementing the diet or the water supply, or indirectly by approximate fertilizer treatment of the soils. Hand-fed animals are supplemented with P in their diets.

Phosphorus Requirements

Cattle

The P requirements for cattle in various stages of the production cycle have varied widely worldwide. Estimates of daily P requirements for cattle have been adjusted over the past decades based on evidence indicating that the digestibility of dietary P has been underestimated in the past, particularly in ruminants.[10] Apparent P requirements can vary for a variety of reasons: differences among breeds of cattle, P availability in the feed, whether animals are pen fed or free grazing, possible interactions between nutrients, and the effects of disease and parasitism.

Dairy Cattle

There is widespread belief among producers and consultants that reproductive performance in dairy cows can be improved by feeding P above recommended levels. The current NRC recommendations for early-lactation (90 days in milk) diets are 0.36% P (DM basis) for cows milking 45 kg/d and 0.35% P for cows milking 35 kg/d. The NRC

recommends up to 0.42% dietary P for the highest-producing cows during the first few weeks of lactation.[10]

Several studies indicate that dietary P at 0.38 to 0.40% is sufficient for high producing dairy cows. Depending on feed ingredients, this concentration of P can be obtained with no or minimum supplementation with P of a standard North American or European dairy cow ration. Negative effects on milk yield and feed intake were observed in dairy cows fed ration with a dietary P content below 0.31% of feed dry matter over several months.[1] Cows conserve P when fed diets low in P by reducing P excretion in feces.

The transition period from late gestation to lactation presents a particular challenge for the mechanisms regulating the P homeostasis. In the last weeks of gestation, the dietary P content is often limited to reduce the risk of periparturient paresis.[10] With the onset of lactation, daily P requirements increase suddenly while daily feed intake is at a nadir. This situation may indeed result in a transiently negative P balance during the first days of lactation, which is likely to contribute to the commonly encountered hypophosphatemia in fresh cows. However, the mechanisms driving this periparturient hypophosphatemia are not well understood, and the degree of P depletion in affected cows has never been examined in detail, but has rather just been extrapolated from the observed declines in plasma Pi levels.[1] Hypophosphatemia shortly after calving is an unreliable indicator for P depletion because this decline in plasma Pi levels has not only been attributed to P losses through the mammary gland but also to hormone-induced compartmental shifts of P from the extracellular to the intracellular space.[1]

It is deemed unlikely that increasing the amount of dietary P in late pregnancy and early lactation will be able to prevent periparturient hypophosphatemia because this imbalance seems to occur secondary to hypocalcemia.[10]

Environmental Implications of Phosphorus Feeding of Livestock

In the European Union and the United States, environmental pollution with P from cattle manure has received increased attention over the past decades, and incentives with the objective to reduce the P content in ruminant fecal material have been implemented in many countries.

Ideally, P is recycled into the soil/plant/animal system, from which only the P incorporated into the animal system escapes. In a sustainable dairy farming system, the amount of P expelled in the form of manure must be limited to the amount that crops need for maximum growth. However, because of high livestock intensities and excessive amounts of P in feed, overapplication of P from manure occurs, leading to P accumulation in the soil and finally leaching, thus causing eutrophication of surface waters. Reducing the dietary P intake of cattle has been identified as an effective way to reduce the amount of P in manure and thereby contain environmental pollution with P.

The current recommendations for dairy cattle from the NRC are to provide phosphorus at 0.32% to 0.42% of dry matter intake.[10] These are lower than the previous recommendation of 0.5% of dry matter intake. Based on calculation of P losses and the true absorption coefficient using data on saliva production, saliva P content, and the efficiency of P absorption, the P requirement recommended for dairy cows in the Netherlands are as follows: P requirement (g/d per 600-kg cow) = 19 + 1.43 × 1 kg milk. This recommendation is up to 22% lower than the current recommendation for high-yielding dairy cows used in the United Kingdom.

Surveys in the United States revealed that dairy diets contain approximately 0.45% to 0.50% P (DM basis), an amount that is about 20% in excess of estimated requirements. A reduction of the dietary P content by 20% was estimated to result in a 25% to 30% reduction in the P content of manure and a similar reduction in the amount of land required to accommodate the manure. Phosphorus is the most expensive nutrient in typical mineral–vitamin formulations for dairy cattle. Feeding a diet containing 0.45% P versus one containing 0.55% would save about $0.05/cow daily; for a 100 cows over 1 year, this would save about $1825.00.

Simulation models of the long-term effects of changes in feeding, cropping, and other production strategies on P loading and the economics of 100-cow and 800-cow dairy farms in southeastern New York found that the most easily implemented change was to reduce the supplemented mineral P fed to that required to meet the current NRC recommended amounts, which would provide an annual increase in farm profit of about $22.00 per cow.

The overfeeding of P has important environmental implications. Phosphorus excretion increases linearly as P intake is increased above the requirement. Once P requirements are met, all of the excess dietary P is excreted in the feces. This excess P accumulates in the environment, primarily by the recycling of manure to land as fertilizer for crop production. The surface runoff of this excess P promotes the eutrophication of surface waters (eutrophication is the accidental or deliberate promotion of excessive growth of one kind of organism to the disadvantage of other organisms in the ecosystem). Therefore, close monitoring of P inputs in the livestock industry is important to reduce the risk of eutrophication of lakes and streams. Reducing dietary intake closer to the requirement will require frequent and accurate feed analysis, quantification of dry matter intake, and ration management to ensure that formulated diets are mixed and delivered to the cows properly. Phosphorus reduction will be achieved by precision of feeding of dairy cattle. Portable and rapid tests are now available to determine the level of P in dairy cattle manure. These hand-held tools can yield real-time measurements of dissolved P and total P in manure.

The effects of feeding low amounts of P to high-yielding dairy cows have been examined extensively in numerous studies.[10] Lactating dairy cows were fed diets containing 67%, 80%, and 100%, respectively, of the P requirements recommended by the Dutch Committee on Mineral Nutrition for a period of 21 months. Nearly 5 months after the beginning of the feeding trial, the milk yield and milk lactose content of the 67% group decreased significantly. It was concluded that rations for high-yielding dairy cows should not have a P content lower than 3.0 g/kg (or 0.3%) DM. The P supply with the 80% ration was considered to be just sufficient.

The supplementation of dietary P above levels recommended by the NRC (0.38% considered adequate or 0.48% excessive) did not improve duration or intensity of estrus in dairy cows. Large lactation studies have shown that feeding P in excess of 0.37% of diet DM, which corresponds closely to the NRC P requirements, did not affect milk production, milk composition, or animal health. Digestion studies and P retention data also support the NRC recommendations.[10]

Beef Cattle

There has been a notable lack of research into the P requirements of grazing beef cattle of various age groups and under varying soil and forage conditions, which has created considerable confusion and disagreement about the P requirements. The effects of P fertilizer on forage P levels and seasonal changes in P concentration are well understood, but the availability of P in different forage species, at different stages of maturity, and grown under different management schemes and environmental conditions is not well understood.

The details of the phosphorus requirements for beef cattle of various age groups are available in the NRC publication *Nutrient Requirements of Beef Cattle*, which was updated in 2000.[2]

Feedlot Cattle

The P requirement of finishing feedlot calves is less than 0.16% of diet DM or 14.2 g/d. Typical grain-based feedlot cattle diets do not require supplementation of inorganic mineral P to meet P requirements. Plasma P, performance, and bone characteristics indicate that P requirements are less than the predicted requirements and should be modified. Supplementation of mineral P in finishing diets is an unnecessary economic and environmental cost for beef feedlot producers and should be discontinued.

Pigs

The estimated dietary P requirements for maximum growth and feed efficiency of pigs at 3 to 5, 5 to 10, 10 to 20, 20 to 50, 50 to 80, and 80 to 120 kg, as a percentage of diet (90% DM) are 0.70%, 0.65%, 0.60%, 0.50%, 0.45%, and 0.40%, respectively. The form in which P exists in natural feedstuffs influences the efficiency of its utilization. In cereal grains, grain byproducts, and oilseed meals, about 60% to 75% of the P is organically bound in the form of phytate, which is poorly available to nonruminant species. The biological availability of P in cereal grains is variable, ranging from less than 15% in corn to approximately 50% in wheat, which has naturally occurring phytase enzyme. The P in inorganic phosphorus supplements also varies in bioavailability. The P in ammonia, calcium, and sodium phosphates is highly available.

Phosphorus Supplementation

Bone meal, calcium-phosphate salts, sodium-phosphate salts, and sodium-pyrophosphate may be provided in supplementary feed or by allowing free access to their mixtures with salt or more complicated mineral mixtures. The availability of the phosphorus in feed supplements varies, and this needs to be taken into consideration when compounding rations. For cattle, mineral sources with the highest absorption coefficients for P are monosodium dihydrogen phosphate (absorption coefficient 0.9), ammonium phosphates and monocalcium phosphate (absorption coefficient 0.80), followed by dicalcium phosphate (absorption coefficient 0.75).[10] The relative biological values for young pigs in terms of phosphorus are as follows: dicalcium phosphate or rock phosphate, 83%; steamed bone meal, 56%; and colloidal clay or soft phosphate, 34%. It is suggested that in deficient areas adult dry cattle and calves up to 150 kg BW should receive 225 g bone meal/week, growing stock over 150 kg BW 350 g/week, and lactating cows 1 kg weekly, but experience in particular areas may indicate the need for varying these amounts. The top dressing of pasture with superphosphate is an adequate method of correcting the deficiency and has the advantage of increasing the bulk and protein yield of the pasture, but it is often impractical under the conditions in which the disease occurs.

The addition of phosphate to drinking water is a much more satisfactory method, provided the chemical can be added by an automatic dispenser to water piped into troughs. Adding chemicals to fixed tanks introduces errors in concentration, excessive stimulation of algal growth, and precipitation in hard waters. Monosodium dihydrogen phosphate (monosodium orthophosphate) is the favorite additive and is usually added at the rate of 10 to 20 g/20 L of water. Superphosphate may be used instead but is not suitable for dispensers, must be added in larger quantities (50 g/20 L), and may contain excess fluorine. A reasonably effective and practical method favored by Australian dairy farmers is the provision of a supplement referred to as "super juice." Plain superphosphate at a rate of 2.5 kg in 40 L of water is mixed and stirred vigorously in a barrel. When it has settled for a day, the "super juice" is ready for use and is administered by skimming off the supernatant and sprinkling 100 to 200 mL on the feed of each cow.

VITAMIN D DEFICIENCY

SYNOPSIS

Etiology Deficiency of preformed vitamin D and, less commonly, insufficient exposure to ultraviolet solar irradiation.

Epidemiology Uncommon because diets are supplemented. Occurs in animals in countries with relative lack of UV irradiation, especially in winter months; animals raised indoors for long periods. Can occur in young grazing animals in winter months. The is marked species variation in susceptibility to effects of vitamin D deficiency.

Signs Reduced productivity; poor weight gain; reduced reproductive performance. Rickets in young animals (see that topic); osteomalacia in adults.

Clinical pathology Serum calcium and phosphorus. Plasma vitamin D.

Necropsy findings Lack of mineralization of bone.

Diagnostic confirmation Histology of bone lesions.

Differential diagnosis list See rickets and osteomalacia.

Treatment Administer vitamin D parenterally and oral calcium and phosphates.

Control Supplement diets with vitamin D. Injections of vitamin D when oral supplementation not possible.

Vitamin D deficiency is usually caused by insufficient solar irradiation of animals or their feed, or inadequate concentrations of vitamin D in rations of housed animals, and is manifested by poor appetite and growth and in advanced cases by osteodystrophy (rickets or osteomalacia).

ETIOLOGY

A lack of ultraviolet solar irradiation of the skin, coupled with a deficiency of preformed vitamin D complex in the diet, leads to a deficiency of vitamin D in tissues.

EPIDEMIOLOGY

Although the effects of clinically apparent vitamin D deficiency have been largely eliminated by improved nutrition, the subclinical effects have received little attention. For example, retarded growth in young sheep in New Zealand and southern Australia during winter months is corrected or prevented by vitamin D administration.

However, general realization of the importance of this subclinical vitamin D deficiency in limiting productivity of livestock has come only in recent years. This is partly a result of the complexity of the relations between calcium, phosphorus, and vitamin D and their common association with protein and other deficiencies in the diet. Much work remains to be done before these individual dietary essentials can be assessed in their correct economic perspective.

Vitamin D is available to animals from either or both of isomerization of 7-dehydrocholesterol (7-DHC) in the skin to vitamin D_3 during exposure to ultraviolet light or ingestion of vitamin D_2 or D_3 in the diet.[1]

Ultraviolet Irradiation

The intensity of ultraviolet light that reaches the skin of the animal depends on latitude and altitude. The lack of ultraviolet irradiation becomes important as distance from the

equator increases and the sun's rays are filtered and refracted by an increasing depth of the earth's atmosphere. Cloudy, overcast skies, smoke-laden atmospheres, and winter months exacerbate the lack of irradiation. When the incidence angle of sun striking the skin is less than 35 degrees, as occurs during winter at latitudes of 31 degrees or higher, there is insufficient penetration of ultraviolet light to convert 7-DHC to previtamin D_3.[1] Reduced grazing time of cattle during summer at higher latitudes (56 degrees) is linearly associated with serum vitamin D concentrations.[2] The production of vitamin D_3 by dairy cows is directly correlated with the amount of skin exposed to ultraviolet radiation, and blanketing cows reduces vitamin D_3 production.[3]

The effects of poor irradiation are felt first by animals with dark skin (particularly pigs and some breeds of cattle) or heavy coats (particularly sheep), by rapidly growing animals, and by those that are housed indoors for long periods. The concentration of plasma vitamin D_3 recorded in grazing sheep varies widely throughout the year. During the winter months in the United Kingdom, the levels in sheep fall below what is considered optimal, whereas in the summer months, the levels are more than adequate. There is a marked difference in vitamin D status between sheep with a long fleece and those that have been recently shorn, especially in periods of maximum sunlight. The higher blood levels of vitamin D in the latter group are probably a result of their greater exposure to sunlight. Pigs reared under intensive farming conditions and animals being prepared for shows are susceptible especially if the diet is marginal or deficient in vitamin D.[4]

Dietary Vitamin D

The importance of dietary sources of preformed vitamin D must not be underestimated. Irradiated plant sterols with antirachitic potency occur in the dead leaves of growing plants. Variation in the vitamin D content of hay can occur with different methods of curing. Exposure to irradiation by sunlight for long periods causes a marked increase in antirachitic potency of the cut fodder, whereas modern hay-making technique with its emphasis on rapid curing tends to keep vitamin D levels at a minimum. Grass ensilage also contains very little vitamin D.

Based on a survey of the concentrations of vitamin D in the serum of horses in the United Kingdom, the levels may be low. In the absence of a dietary supplement containing vitamin D, the concentrations of 25-OH D_2 and 25-OH D_3 are, respectively, a reflection of the absorption of vitamin D_2 from the diet and of biosynthesis of vitamin D_3.

Information on the vitamin D requirements of housed dairy cattle is incomplete and contradictory. It appears, however, that in some instances natural feedstuffs provide less-than-adequate amounts of the vitamin for optimum reproductive performance in high-producing cows.

Grazing Animals

The grazing of animals, especially in winter and on lush green feed including cereal crops, leads to a high incidence of rickets in the young. An antivitamin D factor is suspected because calcium, phosphorus, and vitamin D intakes are usually normal, but the condition can be prevented by the administration of calciferol. Carotene, which is present in large quantities in this type of feed, has been shown to have antivitamin D potency, but the existence of a further rachitogenic substance seems probable. The rachitogenic potency of this green feed varies widely according to the stage of growth and virtually disappears when flowering commences. Experimental overdosing with vitamin A causes a marked retardation of bone growth in calves. Such overdosing can occur when diets are supplemented with the vitamin and may produce clinical effects.

Exposure of animals to solar radiation is important in metabolism of vitamin D, with previtamin D_3 formed in the skin. Skin pigmentation—specifically, melanin—influences the amount of ultraviolet exposure needed to produce vitamin D_3. A longer time in sunlight is required for maximum previtamin D_3 formation in dark-skinned animals.[1]

The importance of vitamin D to animals is now well recognized, and supplementation of the diet where necessary is usually performed by the livestock owner. Occasional outbreaks of vitamin D deficiency are experienced in intensive systems where animals are housed and in areas where specific local problems are encountered (e.g., rickets in sheep on green cereal pasture in New Zealand).

Animal Risk Factors

Most herbivores efficiently produce vitamin D_3 in the skin, and shorn sheep have higher concentrations of vitamin D_3 than do unshorn sheep.[1] However, New World camelids are particularly susceptible to vitamin D deficiency, likely as a result of their heavy fleece and evolution in the Andes and attendant exposure to high levels of solar radiation. Movement to lower altitudes, higher latitudes, or housing denies them access to the required amount of sunlight.[1,5-7] Inherited rickets in Corriedale sheep is caused by excessive vitamin D catabolism as a result of overexpression of the gene for 25-hydroxyvitamin D3-24-hydroxylase, the enzyme responsible for catabolism of vitamin D.[8,9] The disease occurs in housed fattening pigs, likely as a result of errors in feed formulation resulting in vitamin D deficiency.[4]

Foals have lower serum vitamin D concentrations than do adult horses.[10]

PATHOGENESIS

Vitamin D is a complex of substances with antirachitogenic activity. Increasingly in human medicine, vitamin D is recognized as also having important roles in immune function and resistance to neoplasia and cardiovascular disease.[11,12] The important components are as follows:

- Vitamin D_3 (cholecalciferol) is produced from its precursor 7-dehydrocholesterol in mammalian skin by natural irradiation with ultraviolet light (270 to 315 nm) over the course of 3 days.[1]
- Vitamin D_2 is present in certain plants, such as sun-cured hay, as a result of conversion of ergosterol to vitamin D_2 by ultraviolet light. Vitamin D_2 is present in and is produced by ultraviolet irradiation of plant sterols.
- Vitamin D_4 and D_5 occur naturally in the oils of some fish.

Vitamin D produced in the skin or ingested with the diet and absorbed by the small intestine is transported to the liver. In the liver, 25-hydroxycholecalciferol is produced, which is then transported to the kidney, where at least two additional derivatives are formed by 1-α-hydroxylase. One is 1,25-dihydroxycholecalciferol (DHCC), and the other is 24,25-DHCC. Under conditions of calcium need or calcium deprivation, the form predominantly produced by the kidney is 1,25-DHCC. At present, it seems likely that 1,25-DHCC is the metabolic form of vitamin D most active in eliciting intestinal calcium transport and absorption and is at least the closest known metabolite to the form of vitamin D functioning in bone mineralization. The metabolite also functions in regulating the absorption and metabolism of the phosphate ion and especially its loss from the kidney. A deficiency of the metabolite may occur in animals with renal disease, resulting in decreased absorption of calcium and phosphorus, decreased mineralization of bone, and excessive losses of the minerals through the kidney. A deficiency of vitamin D per se is governed in its importance by the calcium and phosphorus status of the animal.

Because of the necessity for the conversion of vitamin D to the active metabolites, there is a lag period of 2 to 4 days following the administration of the vitamin parenterally before a significant effect on calcium and phosphorus absorption can occur. The use of synthetic analogs of the active metabolites such as 1-α-hydroxycholecalciferol (an analog of 1,25-DHCC) can increase the plasma concentration of calcium and phosphorus within 12 hours following administration and has been recommended for the control of parturient paresis in cattle.

Maternal Status

Maternal vitamin D status is important in determining neonatal plasma calcium concentration. There is a significant correlation between maternal and neonatal calf plasma

concentrations of 25-OH D_2, 25-OH D_3, 24,25-$(OH)_2$ D_2, 24,25-$(OH)_2$ D_3, and 25,26-$(OH)_2$ D_3. This indicates that the vitamin D metabolite status of the neonate is primarily dependent on the 25-OH D status of the dam. The maternal serum concentrations of calcium, phosphorus, and magnesium do not determine concentrations of these minerals found in the newborn calf. The ability of the placenta to maintain elevated plasma calcium or phosphorus in the fetus is partially dependent on maternal 1,25-$(OH)_2$ D status. Parenteral cholecalciferol treatment of sows before parturition is an effective method of supplementing neonatal piglets with cholecalciferol via the sow's milk and its metabolite via placenta transport.

Calcium : Phosphorus Ratio

When the calcium : phosphorus ratio is wider than the optimum (1 : 1 to 2 : 1), vitamin D requirements for good calcium and phosphorus retention and bone mineralization are increased. A minor degree of vitamin D deficiency in an environment supplying an imbalance of calcium and phosphorus might well lead to disease, whereas the same degree of vitamin deficiency with a normal calcium and phosphorus intake could go unsuspected. For example, in growing pigs, vitamin D supplementation is not essential provided calcium and phosphorus intakes are rigidly controlled, but under practical circumstances, this may not be possible.

The minor functions of the vitamin include maintenance of efficiency of food utilization and a calorigenic action, with the metabolic rate being depressed when the vitamin is deficient. These actions are probably the basis for the reduced growth rate and productivity in vitamin D deficiency. Some evidence suggests that vitamin D may have a role in the immune system. Local production of 1,25-$(OH)_2$ D by monocytes may be important in immune function, particularly in the parturient dairy cow.

Other Roles for Vitamin D

Vitamin D is now recognized in humans to have important roles in immune function, cancer, and cardiovascular disease as a result of a diverse range of biological actions, including induction of cell differentiation, inhibition of cell growth, immunomodulation, and control of hormonal systems. In addition, 1,25-dihydroxyvitamin D (calcitriol), through the vitamin D receptor, has an immunoregulatory role in both the innate and adaptive immune systems and exerts pleiotropic effects on numerous tissues.[12]

CLINICAL FINDINGS

The most important effect of lack of vitamin D in farm animals is reduced productivity. A decrease in appetite and efficiency of food utilization cause poor weight gains in growing stock and poor productivity in adults. Reproductive efficiency is also reduced, and the overall effect on the animal economy can be severe. The underlying mechanisms are unclear but could be related to the recently recognized pleiotropic effects of vitamin D (calcitriol).

In the late stages, lameness, which is most noticeable in the forelegs, is accompanied in young animals by bending of the long bones and enlargement of the joints. This latter stage of clinical rickets may occur simultaneously with cases of osteomalacia in adults. An adequate intake of vitamin D appears to be necessary for the maintenance of fertility in cattle, particularly if the phosphorus intake is low. In one study in dairy cattle, the first ovulation after parturition was advanced significantly in vitamin D-supplemented cows.

CLINICAL PATHOLOGY

Serum Calcium and Phosphorus

A pronounced hypophosphatemia occurs in the early stages and is followed some months later by a fall in serum calcium. Plasma alkaline phosphatase levels are usually elevated. The blood picture quickly returns to normal with treatment, often several months before the animal is clinically normal. Typical figures for beef cattle kept indoors are serum calcium 8.7 mg/dL (10.8 normal), 2.2 mmol/L (2.7 normal); serum inorganic phosphate 4.3 mg/dL (6.3 normal), 1.1 mmol/L (1.6 normal); and alkaline phosphatase 5.7 units (2.75 normal).

Plasma Vitamin D

The normal ranges of plasma concentrations of vitamin D and its metabolites in the farm animal species are now available and can be used to monitor the response of the administration of vitamin D parenterally or orally in sheep. The serum concentrations of vitamin D in the horse have been determined.[10]

NECROPSY FINDINGS

The pathologic changes in young animals are those of rickets, whereas in older animals there is osteomalacia. In all ages, a variable amount of osteodystrophia fibrosa may develop, and distinction of the origin of these osteodystrophies based on only gross and microscopic examination is impractical. A review of management factors and a nutritional analysis of the feed are essential. The samples for confirmation of the diagnosis at necropsy are as per calcium deficiency.

DIFFERENTIAL DIAGNOSIS

A diagnosis of vitamin D deficiency depends on evidence of the probable occurrence of the deficiency and response of the animal when vitamin D is provided. Differentiation from clinically similar syndromes is discussed under the specific osteodystrophies.

TREATMENT

It is usual to administer vitamin D in the dose rates set out under "Control." Affected animals should also receive adequate calcium and phosphorus in the diet.

CONTROL

Supplementation

The administration of supplementary vitamin D to animals by adding it to the diet or by injection is necessary only when exposure to sunlight or the provision of a natural ration containing adequate amounts of vitamin D is impractical.

A total daily intake of 7 to 12 IU/kg BW is optimal. Sun-dried hay is a good source, but green fodders are generally deficient in vitamin D. Fish liver oils are high in vitamin D, but they are subject to deterioration on storage, particularly with regard to vitamin A. They have the added disadvantages of losing their vitamin A and D content in premixed feed, of destroying vitamin E in these feeds when they become rancid, and of seriously reducing the butterfat content of milk. Stable water-soluble vitamin A and D preparations do not suffer from these disadvantages. Irradiated dry yeast is probably a simpler and cheaper method of supplying vitamin D in mixed grain feeds.

Stable water-soluble preparations of vitamin D are now available and are commonly added to the rations of animals being fed concentrate rations. The classes of livestock that usually need dietary supplementation include the following:

- Calves raised indoors on milk replacers
- Pigs raised indoors on grain rations
- Beef cattle receiving poor-quality roughage during the winter months
- Cattle raised indoors for prolonged periods and not receiving sun-cured forage containing adequate levels of vitamin D—these include calves raised as herd replacements, yearling cattle fed concentrate rations, bulls in artificial insemination centers, and purebred bulls maintained indoors on farms.
- Feedlot lambs fed grain rations during the winter months or under totally covered confinement
- Young, rapidly growing horses raised indoors or outdoors on rations that may not contain adequate concentrations of calcium and phosphorus—this may be a problem in rapidly growing, well-muscled horses receiving a high level of grain.

Because there is limited storage of vitamin D in the body, compared with the storage of vitamin A, it is recommended that daily dietary supplementation be provided when possible for optimum effect.

Injection

In situations where dietary supplementation is not possible, the use of single IM injections of vitamin D_2 (calciferol) in oil will protect

ruminants for 3 to 6 months. A dose of 11,000 units/kg BW is recommended and should maintain an adequate vitamin D status for 3 to 6 months.

In mature nonpregnant sheep weighing about 50 kg, a single IM injection of 6000 IU/kg body weight produced concentrations of 25-hydroxyvitamin D_3 at adequate levels for 3 months. The parenteral administration of vitamin D_3 results in both higher tissue and plasma levels of vitamin D_3 than does oral administration, and IV administration produces higher plasma levels than does IM injection. The timing of the injection should be selected so that the vitamin D status of the ewe is adequate at the time of lambing. The vitamin D_3 status of lambs can be increased by the parenteral administration of the vitamin to the pregnant ewe. Dosing pregnant ewes with 300,000 IU of vitamin D_3 in a rapidly available form, approximately 2 months before lambing, provides a safe means of increasing the vitamin D status of the ewe and the newborn lambs by preventing seasonally low concentrations of 25-hydroxyvitamin D_3. In adult sheep, there is a wide margin of safety between the recommended requirement and the toxic oral dose, which provides ample scope for safe supplementation if such is desirable. In adult sheep given 20 times the recommended requirements for 16 weeks, there was no evidence of pathologic calcification. Oral dosing with 30 to 45 units/kg BW is adequate, provided treatment can be given daily. Massive oral doses can also be used to give long-term effects (e.g., a single dose of 2 million units is an effective preventive for 2 months in lambs). Excessive doses may cause toxicity, with signs of drowsiness, muscle weakness, fragility of bones, and calcification in the walls of blood vessels. The latter finding has been recorded in cattle receiving 10 million units/d and in unthrifty lambs receiving a single dose of 1 million units, although larger doses are tolerated by healthy lambs.

VITAMIN D INTOXICATION

Vitamin D intoxication has occurred in cattle, horses, alpacas and llamas, and pigs after the parenteral or oral administration of excessive quantities of the vitamin. It also occurs in horses, cattle, and sheep after ingestion of hay or silage containing large amounts of *Trisetum flavescens* (yellow oat grass).[1,2]

In cattle, large parenteral doses of vitamin D_3 (15 to 17 million IU) result in prolonged hypercalcemia, hyperphosphatemia, and large increases in plasma concentrations of vitamin D_3 and its metabolites. Clinical signs of toxicosis occur within 2 to 3 weeks and include marked anorexia, loss of body weight, dyspnea, tachycardia, loud heart sounds, weakness, recumbency, torticollis, fever, and a high case-fatality rate. Pregnant cows 1 month before parturition are more susceptible than nonpregnant cows.

Hypercalcemia and hypervitaminosis D occurred in 17-day-old lambs being fed a milk replacer. The vitamin D content of the milk replacer was not excessive; there was no explanation for the abnormalities in the lamb, which recovered when the milk replacer was changed. Serum concentrations of calcium were high at 23.61 mg/dL and 23.09, respectively, in the two lambs.

Accidental vitamin D_3 toxicosis has occurred in horses fed a grain diet that supplied 12,000 to 13,000 IU/kg BW of vitamin D_3 daily for 30 days, equivalent to about 1 million IU vitamin D_3/kg of feed. Clinical findings included anorexia, stiffness, loss of body weight, polyuria, and polydipsia. There was also evidence of hyposthenuria, aciduria, soft tissue mineralization, and fractures of the ribs. Calcification of the endocardium and the walls of large blood vessels are characteristic.

Vitamin D intoxication occurs in pigs, usually as a result of errors in mixing of rations, and can result in polydipsia, polyuria, and weight loss.[3] Severe toxicosis in pigs occurs at a daily oral dose of 50,000 to 70,000 IU/kg BW. Signs include a sudden onset of anorexia, vomiting, diarrhea, dyspnea, apathy, aphonia, emaciation, and death. Clinical signs are commonly observed within 2 days after consumption of the feed containing excessive vitamin D. At necropsy, hemorrhagic gastritis and mild interstitial pneumonia are commonly present. Arteriosclerosis with calcification of the heart base vessels may also be visible macroscopically in poisoned cattle. Osteoporosis with multiple fractures has been observed in subacute to chronic hypervitaminosis D in pigs. Histologically, there is widespread soft tissue mineralization, with a predilection for the lung and gastric mucosa, and elastin-rich tissue, such as blood vessels. Changes in bone vary with the duration of exposure to toxic levels of the vitamin.

Research notes development of vitamin D intoxication in New World camelid cria supplemented with vitamin supplements that provided doses of 4000 to 13,000 IU/kg per day over several days.[4] The recommended dose of vitamin D to crias is a single parenteral dose of 1000 to 2000 IU/kg BW every 7 to 11 weeks.[4] Clinical signs of intoxication in the supplemented crias included weakness and inappetence. There was azotemia, hypercalcemia, and hyperphosphatemia.[4] Treatment was for acute renal failure.

Assay of the various metabolites of vitamin D in tissues is difficult. The diagnosis is therefore usually confirmed by correlating microscopic changes with a history of exposure to toxic levels of vitamin D.

Samples for Confirmation of Diagnosis

- **Toxicology**—500 g of suspect feed (ASSAY [Vit D])
- **Histology**—formalin-fixed lung, stomach/abomasum, proximal aorta, lung, bone (LM)

RICKETS

SYNOPSIS

Etiology Deficiencies of any or combination of phosphorus and vitamin D, and less commonly calcium. Inherited forms are recognized in sheep and pigs.

Epidemiology Young, rapidly growing animals. No longer common. In calves on phosphorus-deficient diets (range or housed). In grazing lambs as a result of lack of solar irradiation. Rare in foals and pigs.

Signs Stiff gait and lameness, enlargement of ends of long bones, curvature of long bones, prolonged periods of recumbency. Delayed dentition.

Clinical pathology Elevated alkaline phosphatase; low serum calcium and phosphorus. Lack of density of bone radiographically.

Necropsy findings Abnormal bones and teeth. Bone shafts are soft, epiphyses enlarged. Ratio of bone ash to organic matter is decreased.

Diagnostic confirmation Histology of bone, especially epiphyses.

Differential diagnosis list
- Epiphysitis
- Congenital and acquired abnormalities
- Infectious synovitis

Treatment Vitamin D injections; calcium and phosphate orally.

Control Supplement deficient diets with calcium, phosphorus, and vitamin D.

Rickets is a disease of young growing animals caused by impaired mineralization of physeal and epiphyseal cartilage during endochondral ossification and of newly formed osteoid.[1] Osteomalacia is the failure of calcification of osteoid in adult animals (i.e., after closure of the growth plate). The essential lesion is a failure of provisional calcification with persistence of hypertrophic cartilage and enlargement of the epiphyses of long bones and the costochondral junctions (so-called "rachitic rosary" of humans). The poorly mineralized bones are susceptible to fracture, compression, or both.

ETIOLOGY

Rickets is caused by an absolute or relative deficiency of any or a combination of calcium, phosphorus, or vitamin D in young growing animals. The effects of the deficiency are also exacerbated by a rapid growth rate.

An inherited form of rickets has been described in pigs. It is indistinguishable from rickets caused by nutritional inadequacy. The inherited form of the disease in Corriedale sheep is associated with increased expression of the gene for 25-hydroxyvitamin D3-24-hydroxylase, the enzyme responsible for catabolism of vitamin D.[2,3]

EPIDEMIOLOGY

Clinical rickets is not as important economically as the subclinical stages of the various dietary deficiencies that produce it. The provision of diets adequate and properly balanced with respect to calcium and phosphorus and sufficient exposure to sunlight are mandatory in good livestock production. Rickets is no longer a common disease because these requirements are widely recognized, but the incidence can be high in extreme environments, including purely exploitative range grazing, intensive feeding in fattening units, and heavy dependence on lush grazing, especially in winter months.

Rickets is a disease of young, rapidly growing animals and occurs naturally under the following conditions.

Calves

Primary phosphorus deficiency in phosphorus-deficient range areas and vitamin D deficiency in calves housed for long periods are the common circumstances. Vitamin D deficiency is the most common form of rickets in cattle raised indoors for prolonged periods in Europe and North America. Grazing animals may also develop vitamin D deficiency rickets at latitudes where solar irradiation during winter is insufficient to promote adequate dermal photobiosynthesis of vitamin D_3 from 7-dihydrocholesterol. Rickets has occurred in yearling steers in New Zealand wintered on swede (*Brassica napus*) crop deficient in phosphorus.

In young, rapidly growing cattle raised intensively indoors, a combined deficiency of calcium, phosphorus, and vitamin D can result in leg weakness characterized by stiffness, reluctance to move, and retarded growth. In some cases, rupture of the Achilles tendon and spontaneous fracture can occur. The Achilles tendon may rupture at the insertion of, or proximal to, the calcaneus.

Lambs

Lambs are less susceptible to primary phosphorus deficiency than cattle, but rickets does occur under the same conditions. Green cereal grazing and, to a lesser extent, pasturing on lush ryegrass during winter months may cause a high incidence of rickets in lambs; this is considered to be a secondary vitamin D deficiency. An outbreak of vitamin D–deficiency rickets involving 50% of lambs aged 6 to 12 months grazing new grass and rape occurred during the early winter months in Scotland. In the South Island of New Zealand, where winter levels of solar irradiation are low, rickets occurs in hoggets grazing green oats, or other green crops, which have been shown to contain high levels of rachitogenic carotenes. The disease occurs in sheep flocks in northern England, likely for similar reasons to the disease occurring in New Zealand.[4] A vitamin D–responsive rickets has occurred in twin lambs at 3 to 4 weeks of age.

Pigs

Rickets in young pigs occurs in intensive fattening units.[5] The cause is assumed to imbalances or mixing errors resulting in feed that contains excessive phosphate (high-cereal diets), or vitamin D and calcium deficiencies.

Foals

Rickets is uncommon in foals under natural conditions, although it has been produced experimentally.

New World Camelids

Llamas and alpacas are particularly susceptible to rickets secondary to vitamin D deficiency,[6-9] a consequence of them evolving at high altitudes with consequent high exposure to solar radiation. Movement to lower altitudes, where the increased atmospheric depth reduces solar radiation, or indoor housing, reduces the opportunity for dermal production of vitamin D.

PATHOGENESIS

Dietary deficiencies of calcium, phosphorus, and vitamin D result in defective mineralization of the osteoid and cartilaginous matrix of developing bone. There is persistence and continued growth of hypertrophic epiphyseal cartilage, increasing the width of the epiphyseal plate. Poorly calcified spicules of diaphyseal bone and epiphyseal cartilage yield to normal stresses, resulting in bowing of long bones and broadening of the epiphyses, with apparent enlargement of the joints. Rapidly growing animals on an otherwise good diet will be first affected because of their higher requirement of the specific nutrients.

CLINICAL FINDINGS

The subclinical effects of the particular deficiency disease will be apparent in the group of animals affected and have been described in the earlier general section. Clinical rickets is characterized by the following:

- Stiffness in the gait
- Enlargement of the limb joints, especially in the forelegs
- Enlargement of the costochondral junctions
- Long bones showing abnormal curvature, usually forward and outward at the carpus, in sheep and cattle
- Lameness and a tendency to lie down for long periods

Outbreaks affecting 50% of a group of lambs have been described. Arching of the back and contraction, often to the point of virtual collapse, of the pelvis occur, and there is an increased tendency for bones to fracture.

Eruption of the teeth is delayed and irregular, and the teeth are poorly calcified, with pitting, grooving, and pigmentation. They are often badly aligned and wear rapidly and unevenly. These dental abnormalities, together with thickening and softness of the jaw bones, may make it impossible for severely affected calves and lambs to close their mouths. As a consequence, the tongue protrudes, and there is drooling of saliva and difficulty in feeding. In less severely affected animals, dental malocclusion may be a significant occurrence. Severe deformity of the chest may result in dyspnea and chronic ruminal tympany. In the final stages, the animal shows hypersensitivity, tetany, and recumbency and eventually dies of inanition.

CLINICAL PATHOLOGY

The plasma alkaline phosphatase activity is commonly elevated, but serum calcium and phosphorus levels depend on the causative factor. If phosphorus or vitamin D deficiencies are the cause, the serum phosphorus level will usually be below the normal lower limit of 3 mg/dL. The serum concentrations of 25-hydroxyvitamin D_3 and 25-hydroxyvitamin D_2 are markedly decreased in vitamin D–deficient rickets compared with the normal values of greater than 5 ng/mL. Serum vitamin D concentrations as low as 0.4 ng/mL have been reported in lambs with vitamin D–responsive rickets. Serum calcium levels will be low only in the final stages. In leg weakness of young, rapidly growing cattle, the serum concentration of 25-hydroxyvitamin D may be nondetectable,

and the serum levels of calcium and inorganic phosphorus may be low.

Radiographic examination of bones and joints is one of the most valuable aids in the detection of rickets. Rachitic bones have a characteristic lack of density compared with normal bones. The ends of long bones have a "woolly" or "moth-eaten" appearance and have a concave or flat, instead of the normal convex, contour. Surgical removal of a small piece of costochondral junction for histologic examination has been used extensively in experimental work and should be applicable in field diagnosis.

NECROPSY FINDINGS

Apart from general poorness of condition, the necropsy findings are restricted to abnormal bones and teeth. The bone shafts are softer and larger in diameter, in part because of the subperiosteal deposition of osteoid tissue. The joints are enlarged, and on cutting, the epiphyseal cartilage can be seen to be thicker than usual. Histologic examination of the epiphysis is desirable for final diagnosis. In sheep, the best results are obtained from an examination of the distal cartilages of the metacarpal and metatarsal bones.

A valuable diagnostic aid is the ratio of ash to organic matter in the bones. Normally the ratio is 3 parts of ash to 2 of organic matter, but in rachitic bone this may be depressed to 1:2, or to 1:3 in extreme cases. A reduction below 45% of the bone weight as ash also suggests osteodystrophy. Because of the difficulty encountered in repeating the results of bone ash determinations, a standardized method has been devised in which the ash content of green bone is determined, using either the metacarpus or metatarsus and the ash content related to the age of the animal, as expressed by the length of the bone. Although normal standards are available only for pigs, the method suggests itself as being highly suitable for all species.

Samples for Confirmation of Diagnosis

- **Toxicology**—long bone (ASSAY [ash]); 500 g feed (ASSAY [Ca] [P] [Vit D])
- **Histology**—formalin-fixed long bone (including growth plate) (LM)

DIFFERENTIAL DIAGNOSIS

Rickets occurs in young, rapidly growing animals and is characterized by stiffness of the gait and enlargement of the distal physes of the long bones, particularly noticeable on the metacarpus and metatarsus as circumscribed painful swellings. A history of a dietary deficiency of any of calcium, phosphorus, or vitamin D will support the clinical diagnosis. Radiographic evidence of widened and irregular physes suggests rickets. Copper deficiency in young cattle under 1 year of age can also result in clinical, radiographic, and pathologic findings similar to rickets. Clinically, there is an arched back, severe stiffness of gait, reluctance to move, and loss of weight. There are marked swellings of the distal aspects of metacarpus and metatarsus, and radiographically there is a widened zone of cartilage and lipping of the medial and lateral areas of the physeal plate. Copper concentration in plasma and liver are low, and there is usually dietary evidence of copper deficiency.

Epiphysitis occurs in rapidly growing yearling cattle raised and fed intensively under confinement. There is severe lameness, swelling of the distal physes, and radiographic and pathologic evidence of a necrotizing epiphysitis. The etiology is uncertain but thought to be related to the type of housing.

Congenital and acquired abnormalities of the bony skeletal system are frequent in newborn and rapidly growing foals. Rickets occurs, but only occasionally. "Epiphysitis" in young foals resembles rickets and is characterized by enlargements and abnormalities of the distal physes of the radius, tibia, third metacarpal, and metatarsal bones and the proximal extremity of the proximal phalanx. There may or may not be deviation of the limbs caused by uneven growth rates in various growth plates. The suggested causes include improper nutrition, faulty conformation and hoof growth, muscle imbalance, overweight, and compression of the growth plate. Recovery may occur spontaneously or require surgical correction.

Rickets in pigs is uncommon and the diagnosis can be difficult. The disease is usually suspected in young, rapidly growing pigs in which there is stiffness in the gait, walking on tip-toes, enlargements of the distal ends of long bones, and dietary evidence of a marginal deficiency of calcium or phosphorus. The radiographic and pathologic findings may suggest a rickets-like lesion.

Mycoplasmal synovitis and arthritis clinically resemble rickets of pigs. There is a sudden onset of stiffness of gait, habitual recumbency, a decrease in feed consumption, and enlargements of the distal aspects of the long bones, which may or may not be painful; spontaneous recovery usually occurs in 10 to 14 days. The locomotor problems in young, growing pigs raised in confinement and with limited exercise must be considered in the differential diagnosis. In performance testing stations, up to 20% of boars may be affected with leg weakness.

Rickets in lambs must be differentiated from chlamydial and erysipelas arthritis, which are readily diagnosed at necropsy.

TREATMENT AND CONTROL

Recommendations for the treatment of the individual dietary deficiencies (calcium, phosphorus, and vitamin D) are presented under their respective headings. Lesser deformities recover with suitable treatment, but gross deformities usually persist. A general improvement in appetite and condition occurs quickly and is accompanied by a return to normal blood levels of phosphorus and alkaline phosphatase. The treatment of rickets in lambs with a vitamin A, vitamin D_3, calcium borogluconate solution containing magnesium and phosphorus parenterally and supplementation of the diet with bone meal and protein resulted in a dramatic response. Recumbent animals were walking within a few days.

OSTEOMALACIA

SYNOPSIS

Etiology Absolute or relative deficiency of any one or combination of calcium, phosphorus, and vitamin D in adult animals.

Epidemiology Primarily in cattle and sheep on phosphorus-deficient diets. In feedlot animals as a result of excessive phosphorus without complementary calcium and vitamin D.

Signs Reduced productivity, licking and chewing inanimate objects, stiff gait, moderate nonspecific lameness, shifting from leg to leg, crackling sounds while walking, arched back, lying down for long periods. "Milk lameness" in high-producing dairy cows on deficient diet.

Clinical pathology Increased alkaline phosphatase, decreased serum phosphorus levels. Decreased density of long bones radiographically.

Necropsy findings Decreased density of bones; erosions of articular cartilages.

Diagnostic confirmation Histology of bones.

Differential diagnosis list
- Chronic fluorosis
- Polysynovitis and arthritis
- Spinal cord compression

Treatment As for calcium, phosphorus, and vitamin D deficiency.

Control Adequate supplementation of diet.

Osteomalacia is a disease of mature animals affecting bones in which endochondral ossification has been completed. The characteristic lesion is osteoporosis and the formation of excessive uncalcified matrix (osteoid). Lameness and pathologic fractures are the common clinical findings.

ETIOLOGY

In general, the etiology and occurrence of osteomalacia are the same as for rickets, except that the predisposing cause is not the increased requirement of growth but the drain of lactation, pregnancy, or both.

EPIDEMIOLOGY

Osteomalacia occurs in mature animals under the same conditions and in the same areas as rickets in young animals, but it is recorded less commonly. Its main occurrence is in cattle in areas seriously deficient in phosphorus. It occurs in goats.[1] It is also recorded in sheep, again in association with hypophosphatemia. In pastured animals, osteomalacia is most common in cattle, and sheep raised in the same area are less severely affected. In feedlot animals, excessive phosphorus intake without complementary calcium and vitamin D is likely as a cause, especially if the animals are kept indoors. It also occurs in sows that have recently weaned their pigs after a long lactation period (6 to 8 weeks) while on a diet deficient in calcium. A marginal deficiency of both phosphorus and vitamin D will exaggerate the condition. Intensively fed yearling cattle with inadequate mineral supplementation may be affected with spontaneous fractures of the vertebral bodies, pelvic bones, and long bones, leading to recumbency.[1] Simply handling the animals through a chute for routine activities such as tuberculin testing may precipitate the fractures.

PATHOGENESIS

Increased resorption of bone mineral to supply the needs of pregnancy, lactation, and endogenous metabolism leads to osteoporosis and weakness and deformity of the bones. Large amounts of uncalcified osteoid are deposited around the diaphyses. Pathologic fractures are commonly precipitated by sudden exercise or handling of the animal during transportation. There is evolving understanding of the role of fibroblast growth factor 23 in this disease and other diseases (rickets) associated with abnormalities in calcium, phosphorus, or vitamin D metabolism.[2]

CLINICAL FINDINGS

Ruminants

In the early stages, the signs are those of phosphorus deficiency, including lowered productivity and fertility and loss of condition. Licking and chewing of inanimate objects begins at this stage and may bring their attendant ills of oral, pharyngeal, and esophageal obstruction; traumatic reticuloperitonitis; lead poisoning; and botulism.

The signs specific to osteomalacia are those of a painful condition of the bones and joints and include a stiff gait; moderate lameness. often shifting from leg to leg; crackling sounds while walking; and an arched back. The hindlegs are most severely affected, and the hocks may be rotated inward. The animals are disinclined to move, lie down for long periods, and are unwilling to get up. The colloquial names "pegle," "creeps," "stiffs," "cripples," and "bog lame" describe the syndrome aptly. The names "milkleg" and "milk lameness" are commonly applied to the condition when it occurs in heavily milking cows. Fractures of bones and separation of tendon attachments occur frequently, often without apparent precipitating stress. In extreme cases, deformities of bones occur; when the pelvis is affected, dystocia may result. Finally, weakness leads to permanent recumbency and death from starvation.

Pigs

Affected sows are usually found recumbent and unable to rise from lateral recumbency or from the dog-sitting position. The shaft of one femur or the neck of the femur is commonly fractured. The fracture usually occurs within a few days following weaning of the pigs. The placing of the sow with other adult pigs usually results in some fighting and increased exercise, which commonly precipitates the pathologic fractures.

CLINICAL PATHOLOGY

In general, the findings are the same as those for rickets, including increased serum alkaline phosphatase and decreased serum phosphorus levels. Radiographic examination of long bones shows decreased density of bone shadow.

NECROPSY FINDINGS

It can be difficult to discern any gross changes as the epiphyses are seldom enlarged, and the altered character of cancellous bone may not be macroscopically visible. Cortical bone may be somewhat thinned, and erosions of the articular cartilages have been recorded in cattle suffering from primary phosphorus deficiency. The parathyroid glands may be enlarged. Histologically, abnormal osteoid covers trabeculae, and a degree of fibrous tissue proliferation is often evident. Analysis reveals the bones to be lighter than normal with a low ratio of ash to organic matter.

Samples for Confirmation of Diagnosis

- **Toxicology**—long bone (ASSAY [ash]); 500 g feed (ASSAY [Ca] [P] [Vit D])
- **Histology**—formalin-fixed bone, parathyroid (LM)

DIFFERENTIAL DIAGNOSIS

The occurrence of nonspecific lameness with pathologic fractures in mature animals should arouse suspicion of osteomalacia. There may be additional evidence of subnormal productivity and reproductive performance and dietary evidence of a recent deficiency of calcium, phosphorus, or vitamin D.

A similar osteoporotic disease of cattle in Japan has been ascribed to a dietary deficiency of magnesium. The cattle are on high-concentrate, low-roughage diets and have high serum calcium and alkaline phosphatase levels but a low serum magnesium level. The osteoporosis is observable at slaughter, and clinical signs observed are those of intercurrent disease, especially ketosis, milk fever, and hypomagnesemia. Reproductive and renal disorders occur concurrently.

In **cattle** it must be differentiated from **chronic fluorosis** in mature animals, but the typical mottling and pitting of the teeth and the enlargements on the shafts of the long bones are characteristic. In some areas (e.g., northern Australia) where the water supply is obtained from deep subartesian wells, the two diseases may occur concurrently. Analysis of water supplies and foodstuffs for fluorine may be necessary in doubtful cases.

In sows, **osteomalacia** with or without pathologic fractures must be differentiated from **spinal cord compression** as a result of a vertebral body abscess and chronic arthritis resulting from erysipelas.

TREATMENT AND CONTROL

Recommendations for the treatment and control of the specific nutritional deficiencies have been described under their respective headings. Some weeks will elapse before improvement occurs, and deformities of the bones are likely to be permanent.

OSTEODYSTROPHIA FIBROSA

Osteodystrophia fibrosa is similar in its pathogenesis to osteomalacia, but it differs in that soft, cellular, fibrous tissue is laid down as a result of the weakness of the bones instead of the specialized uncalcified osteoid tissue of osteomalacia.[1] It occurs in horses, goats, and pigs.[2-4] The disease occurs in large animals, principally equids, as a result of secondary nutritional hyperparathyroidism.[4] Renal hyperparathyroidism, as is widely recognized in dogs, is rare to nonexistent in equids.[1]

ETIOLOGY

A **secondary calcium deficiency resulting from excessive phosphorus feeding is the**

common cause in horses and probably also in pigs. The disease also occurs in horses grazing tropical or subtropical pastures containing buffel, pangola, setaria, kikuyu, green panic, guinea, signal, and purple pigeon grasses. These tropical grasses contain oxalate, which interferes with mineral utilization by horses by forming calcium oxalate, which renders the calcium unavailable for intestinal absorption.[4] Grasses with more than 0.5% oxalate or calcium : oxalate ratios of less than 0.5 result in a negative calcium balance and are capable of inducing hypocalcemia in horses.[4] The disease can be readily produced in horses on diets with a ratio of calcium : phosphorus of 1 : 2.9 or greater, irrespective of the total calcium intake. Calcium : phosphorus ratios of 1 : 0.9 to 1 : 1.4 have been shown to be preventive and curative. With a very low calcium intake of 2 to 3 g/d and a calcium : phosphorus ratio of 1 : 13, the disease may occur within 5 months. With a normal calcium intake of 26 g/d and a calcium : phosphorus ratio of 1 : 5, obvious signs appear in about 1 year, but shifting lameness may appear as early as 3 months.

The disease is reproducible in pigs on similar diets to those just described and also on diets low in both calcium and phosphorus. The optimum calcium : phosphorus ratio is 1.2 : 1, and the intake for pigs should be within the range of 0.6% to 1.2% of the diet.

EPIDEMIOLOGY

Osteodystrophia fibrosa is principally a disease of horses and other Equidae and to a lesser extent of pigs. It occurs in goats. Previously, among horses, those engaged in heavy city work and in racing were more likely to be affected because of the tendency to maintain these animals on unbalanced diets. Widespread adoption of use of commercial diets and recognition of the importance of correct mineral nutrition has likely decreased the importance of this disease in these animals. The disease in developed countries is now restricted to equids fed inadequate or imbalanced diets. The major occurrence is in horses fed a diet high in phosphorus and low in calcium. Such diets include cereal hays combined with heavy grain or bran feeding. Legume hays, because of their high calcium content, are preventive.

The disease may reach endemic proportions in army horses moved into new territories, whereas local horses, more used to the diet, suffer little. Although horses may be affected at any age after weaning, it is the 2-to-7-year age group that suffers most, probably because they are the group most likely to be exposed to the rations that predispose to the disease.

A novel occurrence has been recorded of an endemic form of the disease affecting large numbers of horses at pasture.[4] The dietary intake of calcium and phosphorus and their proportions were normal. The occurrence was thought to be caused by the continuous ingestion of oxalate in specific grasses: *Cenchrus ciliaris, Panicum maximum* var. *trichoglume, Setaria anceps, Brachiaria mutica,* and *Pennisetum clandestinum.*

PATHOGENESIS

Defective mineralization of bones follows the imbalance of calcium and phosphorus in the diet, and a fibrous dysplasia occurs. This may be in response to the weakness of the bones, or it may be more precisely a response to hyperparathyroidism stimulated by the excessive intake of phosphorus. The weakness of the bones predisposes to fractures and separation of muscular and tendinous attachments. Articular erosions occur commonly, and displacement of the bone marrow may cause the development of anemia.

CLINICAL FINDINGS

Horse

As in most osteodystrophies, the major losses are probably in the early stages before clinical signs appear or on diets where the aberration is marginal. In horses, a shifting lameness is characteristic of this stage of the disease, and arching of the back may sometimes occur. The horse is lame, but only mildly so, and in many cases, no physical deformity can be found by which the seat of lameness can be localized. These signs probably result from relaxation of tendon and ligaments and appear in different limbs at different times. Articular erosions may contribute to the lameness. In more advanced cases, severe injuries, including fracture and visible sprains of tendons, may occur, but these are not specific to osteodystrophia fibrosa, although their incidence is higher in affected than in normal horses. Fracture of the lumbar vertebrae while racing has been known to occur in affected horses.

The more classical picture of the disease has largely disappeared because cases are seldom permitted to progress to this advanced stage. Local swelling of the lower and alveolar margins of the mandible is followed by soft, symmetric enlargement of the facial bones, which may become swollen so that they interfere with respiration. Initially these bony swellings are firm and pyramidal and commence just above and anterior to the facial crests. The lesions are bilaterally symmetric and prevent full occlusion of the incisors. Flattening of the ribs may be apparent, and fractures and rupture or avulsion of ligaments might occur if the horse is worked. There may be obvious swelling of joints and curvature of long bones. Severe emaciation and anemia occur in the final stages.

Pigs

In pigs, the lesions and signs are similar to those in the horse, and in severe cases, pigs may be unable to rise and walk and show gross distortion of limbs and enlargement of joints and the face. In less severe cases, there is lameness, reluctance to rise, pain on standing, and bending of the limb bones, but normal facial bones and joints. With suitable treatment, the lameness disappears, but affected pigs may never attain their full size. The relationship of this disease to atrophic rhinitis is discussed under the latter heading.

Goats

An outbreak of the disease has been recorded in goats receiving a diet of wheat straw (60%) and 40% barley for 89 months. The ratio of calcium to phosphorus in the diet was 1 : 1.8. Affected goats were 9 to 10 months of age, with a history of stunted growth, lameness, diarrhea, and tongue protrusion. Clinically, there was symmetric enlargement of the face and jaws, tongue protrusion, prominent eyeballs, and tremor. The enlarged bones were firm and painful on palpation. The hindlimbs were bent outward symmetrically from the tarsal joints.

CLINICAL PATHOLOGY

There are no significant changes in blood chemistry in horses affected with severe osteodystrophia fibrosa. However, the serum calcium level will tend to be lower than normal, the serum inorganic phosphorus higher than normal, and the alkaline phosphatase activity higher than normal. The levels of diagnostic alkaline phosphatase have not been determined. Affected horses may be unable to return their serum calcium levels to normal following the infusion of a calcium salt. Radiographic examination reveals increased translucency of bones, especially of the mandibles.

NECROPSY FINDINGS

The entire skeleton is abnormal in this severe form of metabolic bone disease, but the change is most notable in the mandibular, maxillary, and nasal bones, which may appear thickened and distorted. The fleshy tissue that replaces normal cancellous bone in these sites is also present in the metaphyses of the long bones. Microscopically, there is proliferation of fibrous tissue and markedly increased osteoclast activity along thinned and abnormally oriented bony trabeculae. The parathyroid glands are enlarged. It must be remembered that osteodystrophia fibrosa is a lesion, not a disease. The pathway to this lesion usually involves a dietary imbalance in calcium and phosphorus, but the kidneys should also be examined to rule out the possibility of renal secondary hyperparathyroidism.

Samples for Confirmation of Diagnosis

- **Toxicology**—bone (ASSAY [ash]); 500 g feed (ASSAY [Ca] [P] [Vit D])
- **Histology**—formalin-fixed bone, parathyroid gland, kidney (LM)

DIFFERENTIAL DIAGNOSIS

In the early stages, the diagnosis may be difficult because of the common occurrence of traumatic injuries to horses' legs. A high incidence of lameness in a group of horses warrants examination of the ration and determination of their calcium and phosphorus status. An identical clinical picture has been described in a mare with an adenoma of the parathyroid gland. Inherited multiple exostosis has been described in the horse.

In pigs, osteodystrophia can be the result of hypovitaminosis A and experimentally as a result of manganese deficiency.

TREATMENT AND CONTROL

A ration adequately balanced with regard to calcium and phosphorus (calcium : phosphorus should be in the vicinity of 1 : 1 and not wider than 1 : 1.4) is preventive in horses, and affected animals can only be treated by correcting the existing imbalance. Even severe lesions may disappear in time with proper treatment. Cereal hay may be supplemented with alfalfa or clover hay, or finely ground limestone (30 g daily) should be fed. Dicalcium phosphate and bone meal are not as efficient because of their additional content of phosphorus.

"BOWIE" OR "BENTLEG" IN LAMBS

Bowie is a disease of lambs of unknown etiology characterized by carpus valgus, and less commonly carpus varus, resulting in a lateral displacement of the carpus and medial displacement of the hooves. The lesions differ from those of rickets. It has been observed only on unimproved range pasture in New Zealand and in South Africa. The cause is unknown, although phosphorus deficiency has been suggested. A similar syndrome has been produced by the feeding of wild parsnip (*Trachemene glaucifolia*) and, experimentally, by the feeding of a diet low in both calcium and phosphorus. There is no clear genetic component to the disease in South Africa.

Improvement of the pasture by top dressing with superphosphate and sowing-improved grasses is usually followed by disappearance of the disease. Only sucking lambs are affected, and cases occur only in the spring at a time when rickets does not occur. Up to 40% of a group of lambs can be affected without breed differences in incidence. Signs of the disease can be evident at 3 to 4 weeks of age.

The disease has also been reported from South Africa, where it occurs primarily in ram lambs and develops from as early as 3 months up to 1 year of age. There is gradual bending of the forelimbs, with the hooves turned inward and the carpal joints turned outward. Animals of the South African Mutton Merino breed had significantly higher plasma phosphorus concentrations than those of the Merino and Dohne Merino breeds. The plasma calcium : phosphorus ratio was lower in affected lambs and their ewes, and this converse ratio is thought to result in an induced plasma ionized calcium deficiency leading to improper calcification of bone.

Some tenderness of the feet and lateral curvature at the knees can be seen as early as 2 to 3 weeks of age, and marked deformity is present at 6 to 8 weeks, with maximum severity at weaning. The forelimbs are more commonly affected than the hindlimbs. Carpus varus occurs in rare cases. The sides of the feet become badly worn, and the lateral aspects of the lower parts of the limbs can be injured and be accompanied by lameness. The lambs grow well at first, but by the time of weaning, affected lambs are in poor condition because of their inability to move about and feed properly. A rather similar syndrome has been observed in young Saanen bucks, but the condition showed a tendency to recover spontaneously.

At necropsy lesions are restricted to the radius and metacarpus with medial collapse of the distal radial epiphysis and consequent carpus valgus. There is often excessive synovial fluid in the carpal joints; in the later stages, there are articular erosions. Increased deposition of osteoid is not observed.

Supplementation of the diet with phosphorus or improvement of the pasture seems to reduce the incidence of the disease. Dosing with vitamin D or providing mineral mixtures containing all trace elements is ineffective.

DEGENERATIVE JOINT DISEASE AND OSTEOARTHRITIS

Degenerative joint disease in food animals describes severe, progressive, nonseptic arthropathy in growing animals that is the result of one or more processes that lead to damage to articular cartilage and consequent osteoarthritis. The insult can be to cartilage or underlying bone as a result of metabolic, nutritional, congenital, or traumatic causes but can be difficult to identify because the insult to tissues causing the disease usually occurs weeks to months before clinical signs of disease. Degenerative joint disease can affect almost any diarthrodial joint. The most severe disease occurs when affected joints are loaded with weight.[1] The disease is well documented and researched in racehorses in which it is the end result of damage to articular cartilage.[2,3]

According to some studies, greater than 90% of steers are affected by osteoarthritis, and it is an important cause of infertility in beef bulls.[4] The disease is most often seen in the stifle joint, where the predilection sites are the medial and lateral condyles and the patellar groove. Most lesions are bilateral.[1,4,5]

Degenerative arthropathy occurs in cattle of all breeds but reaches its highest incidence as a sporadic disease of young beef bulls. The disease has been identified as hip dysplasia because of the preexisting shallow contour of the acetabulum. It is considered to be inherited as a recessive characteristic and exacerbated by rapid weight gain in young animals. The occurrence of the condition in these animals is usually associated with rearing on nurse cows, housing for long periods, provision of a ration high in cereal grains and byproducts (i.e., a high phosphorus : calcium ratio), and possibly with an inherited straight conformation of the hindlegs. Although the disease occurs in all beef breeds, there is a strong familial tendency that appears to be directly related to the rate of body-weight gain and the straightness of the hindleg. If the potential for rapid weight gain is being realized in animals being force fed, the rate of occurrence appears to be dependent on their breeding, and animals in the same herd that are allowed to run at pasture under natural conditions are either not affected or are affected at a much later age. Thus animals in a susceptible herd can show signs as early as 6 months of age if they are heavily hand-fed and raised on dairy cow foster mothers. In the same herd, signs do not appear until 1 to 2 years of age if supplementary feeding is not introduced until weaning and not until 4 years if there is no significant additional feeding.

Clinically there is a gradual onset of lameness in one or both hindlegs. The disease progresses, with the lameness becoming more severe over a period of 6 to 12 months. In some animals, there is a marked sudden change for the worse, usually related to violent muscular movements, as in breeding or fighting. In severely affected animals, the affected limb is virtually useless; on movement, distinct crepitus can often be felt and heard over the affected joints. This can be accomplished by rocking the animal from side to side or having it walk while holding the hands over the hip joints.

An additional method of examination is to place the hand in the rectum close to the hip joint while the animal is moved. Passive movement of the limb may also elicit crepitus or louder clinking or clicking sounds. The hip joints are always most severely affected, but in advanced cases, there may be moderate involvement of the stifles and minimal lesions in other joints. Affected animals lie down most of the time and are reluctant to

rise and to walk. The joints are not swollen, but in advanced cases, local atrophy of muscles may be so marked that the joints appear to be enlarged. There is a recorded occurrence in which the lesions were confined mainly to the front fetlocks.

Radiographic examination can provide confirmatory or diagnostic evidence but is restricted to facilities with equipment suited to these examinations.

At **necropsy,** the most obvious finding is extensive erosion of the articular surfaces, often penetrating to the cancellous bone, and disappearance of the normal contours of the head of the femur or the epiphyses in the stifle joint. The synovial cavity is distended, with an increased volume of brownish, turbid fluid; the joint capsule is much thickened and often contains calcified plaques. Multiple small exostoses are present on the periarticular surfaces. When the stifle is involved, the cartilaginous menisci, particularly the medial one, are very much reduced in size and may be completely absent. In cattle with severe degenerative changes in the coxofemoral joint, an acetabular osseous bulla may be present at the cranial margin of the obturator foramen.[1]

Adequate calcium, phosphorus, and vitamin D intake and a correct calcium : phosphorus ratio in the ration should be ensured. Supplementation of the ration with copper at the rate of 15 mg/kg has also been recommended for the control of a similar disease.

Degenerative joint disease of cattle is recorded on an enzootic scale in Chile and is thought to be attributable to gross nutritional deficiency. The hip and tarsal joints are the only ones affected, and clinical signs appear when animals are 8 to 12 months old. There is gross lameness and progressive emaciation. An inherited osteoarthritis is described under that heading. Sporadic cases of degenerative arthropathy, with similar signs and lesions, occur in heavy-producing, aged dairy cows and are thought to be caused by long-continued negative calcium balance. Rare cases also occur in aged beef cows but are thought to be associated with an inherited predisposition. In both instances the lesions are commonly restricted to the stifle joints.

Degenerative arthropathy of the distal interphalangeal joints and sesamoid bones occurs in calves (Fig. 15-14). Affected animals have moderate to severe lameness of one or both forelimbs but no discernible distension of the joint. Treatment is palliative, involving administration of NSAIDs (meloxicam or phenylbutazone, where permitted by regulatory authorities) or surgery.[6]

Osteoarthritis occurs in the stifle joint of dairy breed bulls. Seventy-two percent (39/54) of stifle joints and 85% (23/27) of dairy bulls 31 to 60 months of age had at least one gross lesion, and 94% of the lesions were localized to the distal end of the femur, with the patellar groove and the lateral trochlear ridge being predilection sites.

Fig. 15-14 Degenerative joint disease (arrow) affecting P2 to P3 of a calf. (Reproduced with permission.[6])

Osteoarthritis of one or both temporomandibular joints occurs in ~1.3% of Soay sheep on the island of St. Kilda, being more common in older ewes.[7] Osteoarthritis also occurs in the elbows of sheep.[8] It can be bilateral, in which case the sheep have a characteristic stance with both hindfeet placed more cranially, under the abdomen, apparently in an effort to reduce weight-bearing by the forelegs. There is no definitive treatment.[8]

MANGANESE DEFICIENCY

A dietary deficiency of manganese (Mn) can cause skeletal deformities, both congenitally and after birth, and infertility.

ETIOLOGY

A primary deficiency occurs endemically in some areas because of a geological deficiency of manganese in the local rock formations. Apart from a primary dietary deficiency of manganese, the existence of factors depressing the availability of ingested manganese is suspected. An excess of calcium and/or phosphorus in the diet increases the requirements of manganese in the diet of calves and is considered to reduce the availability of dietary manganese to cattle generally.

Congenital chondrodystrophy in calves has been associated with a manganese deficiency, and there are outbreaks of congenital skeletal defects in calves suspected to be attributable to manganese deficiency.[1-3]

EPIDEMIOLOGY

Soils containing less than 3 mg/kg of manganese are unlikely to be able to support normal fertility in cattle. In areas where manganese-responsive infertility occurs, soils on farms with infertility problems have contained less than 3 mg/kg of manganese, whereas soils on neighboring farms with no infertility problems have had levels of more than 9 mg/kg. A secondary soil deficiency is thought to occur, and one of the factors suspected of reducing the availability of manganese in the soil to plants is high alkalinity. Thus

heavy liming is associated with manganese-responsive infertility. There are three main soil types on which the disease occurs:

- Soils low in manganese, which have low output even when pH is less than 5.5
- Sandy soils, where availability starts to fall
- Heavy soils, where availability starts to fall at a pH of 7.0

Many other factors are suggested as reducing the availability of soil manganese, but the evidence is not conclusive. For example, heavy liming of soils to neutralize sulfur dioxide emissions from a neighboring smelter is thought to have reduced the manganese intake of grazing animals.

Herbage on low-manganese soils, or on marginal soils where availability is decreased (possibly even soils with normal manganese content), is low in manganese. A number of figures are given for critical levels. It is suggested that pasture containing less than 80 mg/kg of manganese is incapable of supporting normal bovine fertility, and that herbage containing less than 50 mg/kg is often associated with infertility and anestrus. The Agricultural Research Council believes that although definite figures are not available, levels of 40 mg/kg DM in the diet should be adequate. Other authors state that rations containing less than 20 mg/kg DM may cause anestrus and reduction in conception rates in cows and the production of poor-quality semen by bulls. Most pasture contains 50 to 100 mg/kg DM. Skeletal deformities in calves occur when the deficiency is much greater that just noted; for example, a diet containing more than 200 mg/kg DM is considered to be sufficient to prevent them.

Rations fed to pigs usually contain more than 20 mg/kg DM of manganese, and deficiency is unlikely unless there is interference with manganese metabolism by other substances.

There are important variations in the manganese content of seeds, an important matter in poultry nutrition. Maize and barley have the lowest content. Wheat or oats have 3 to 5 times as much, and bran and pollard are the richest natural sources, with 10 to 20 times the content of maize or wheat. Cows' milk is exceptionally low in manganese.

Diets high in iron reduce duodenal activity of manganese transporters in calves, although the clinical importance of this finding is unclear.[4]

PATHOGENESIS

Manganese plays an active role in bone-matrix formation and in the synthesis of chondroitin sulfate, which is responsible for maintaining the rigidity of connective tissue. In manganese deficiency, these are affected deleteriously, and skeletal abnormalities result. Only 1% of manganese is absorbed from the diet, and the liver removes most of it, leaving very low blood levels of the element.

CLINICAL FINDINGS

In cattle, the common syndromes in confirmed or suspected manganese deficiency are infertility, stillbirth, perinatal loss, calves with congenital limb deformities, and calves that manifest poor growth, dry coat, and loss of coat color.[2,3] The deformities include knuckling over at the fetlocks, enlarged joints, and, possibly, twisting of the legs. The bones of affected lambs are shorter and weaker than normal, and there are signs of joint pain, hopping gait, and reluctance to move.

Heifers fed a low-manganese diet (16 mg Mn per kg DM of diet) during pregnancy had impaired fetal growth and development evident as lower birth weight than calves from heifers fed 50 mg of Mn per kg DM, superior brachygnathism, unsteadiness, disproportionate dwarfism, and swollen joints.[5] A severe congenital chondrodystrophy in Charolais calves occurred on one farm. The limbs were shortened and the joints enlarged. The pregnant cows were fed on apple pulp and corn silage, both of which were low in manganese.

An outbreak of congenital skeletal malformations in Holstein calves was characterized clinically by small birth weights (average 15 kg). Abnormalities included joint laxity, doming of the foreheads, superior brachygnathia, and a dwarflike appearance as a result of the short length of the long bones. The features of the head were similar to those of the wildebeest. The majority of affected calves were dyspneic at birth, and snorting and grunting respiratory sounds were common. Affected calves failed to thrive, and most were culled because of poor performance.

A manganese-responsive infertility has been described in ewes and is well known in cattle. In cattle, it is manifested by slowness to exhibit estrus and failure to conceive, often accompanied by subnormal size of one or both ovaries. Subestrus and weak estrus have also been observed.

Functional infertility was once thought to occur in cattle on diets with calcium-to-phosphorus ratios outside the range of 1:2 to 2:1. This was not upheld on investigation but might have been correct if high calcium-to-phosphorus intakes directly reduced manganese (or copper or iodine) availability in diets marginally deficient in one or other of these elements.

In pigs, experimental diets low in manganese cause reduction in skeletal growth; muscle weakness; obesity; irregular, diminished, or absent estrus; agalactia; and resorption of fetuses or the birth of stillborn pigs. Leg weakness, bowing of the front legs, and shortening of bones also occur.

CLINICAL PATHOLOGY

The blood of normal cattle contains 18 to 19 µg/dL (3.3 to 3.5 µmol/L) of Mn, although considerably lower levels are sometimes quoted. The livers of normal cattle contain 12 mg/kg (0.21 mmol/kg) of Mn and down to 8 mg/kg (0.15 mmol/kg) in newborn calves, which also have a lower content in hair. The Mn content of hair varies with intake. The normal level is about 12 mg/kg (0.21 mmol/kg), and infertility is observed in association with levels of less than 8 mg/kg (0.15 mmol/kg). In normal cows, the Mn content of hair falls during pregnancy from normal levels of 12 mg/kg (0.21 mmol/kg) in the first month of pregnancy to 4.5 mg/kg (0.08 mmol/kg) at calving. All of these figures require much more critical evaluation than they have received before they can be used as diagnostic tests.

Although tissue manganese levels in normal animals have been described as being between 2 and 4 mg/kg (0.04 and 0.07 mmol/kg), in most tissue there appears to be more variation between tissues than this. However, tissue levels of manganese do not appear to be depressed in deficient animals, except for in the ovaries, in which levels of 0.6 mg/kg (0.01 mmol/kg) and 0.85 mg/kg (0.02 mmol/kg) are recorded in contrast to a normal level of 2 mg/kg (0.04 mmol/kg).

Thus, there is no simple, single diagnostic test permitting detection of manganese deficiency in animals. Reproductive functions, male and female, are most sensitive to manganese deficiency and are affected before possible biochemical criteria (e.g., blood and bone alkaline phosphatase, and liver arginase levels) are significantly changed. The only certain way of detecting moderate deficiency states is by measuring response to supplementation. Clinical findings in response to treatment that may provide contributory evidence of manganese deficiency are set out in the following discussion.

NECROPSY FINDINGS

In congenital chondrodystrophy in calves, the limbs are shortened, and all the joints are enlarged. Histologically, there is poor cartilage maturation with excessive amounts of rarefied cartilage matrix. The major histologic abnormality in the physes is disorderly development of the zones of cartilage hypertrophy, with reduced number and irregular arrangement of hypertrophic chondrocytes; similar but less severe changes are present in the zones of cartilage proliferation.[3] There are degenerative changes in the chondrocytes and severe reduction in the mucopolysaccharide content of all body hyaline cartilage.

TREATMENT AND CONTROL

The NRC estimated the maintenance requirement (0.002 of available Mn/kg BW) of dairy cows from dietary concentrations of Mn reported to cause Mn deficiency in cattle. Based on NRC of 2001 equations, the maintenance requirement for Mn

represents 82% of the total Mn requirement for a nonlactating, late-gestation cow and 53% for a cow producing 40 kg/d of milk. Fecal loss of endogenous Mn is assumed to comprise the entire maintenance requirement. Assuming typical dry matter intake (DMI), a diet with approximately 14 mg Mn/kg DM will meet the requirement for a 700-kg nonlactating cow during the last month of lactation. Recent research has determined that Mn intake had to equal 580 mg/d to meet the metabolic fecal Mn requirement. The corresponding dietary concentrations, assuming DMIs of 21 and 12 kg/d for lactating and dry cows, respectively, were 28 and 49 mg/kg DM. These concentrations are approximately 1.6 and 2.7 times higher than those needed to meet the Mn requirements for lactating and dry cows, respectively, as calculated using the 2001 NRC dairy nutrient requirements model. Supplementation of 50 mg of Mn/kg of DM to the control diet of heifers was sufficient to overcome any signs of Mn deficiency in calves; the control diet contained ~17 mg Mn per kg DM.[5]

For pigs, the recommended dietary intakes are 24 to 57 mg manganese per 45 kg BW. Expressed as a proportion of food intake, the recommended dietary level is 40 mg/kg DM in feed. The manganese requirements for gestation and lactation are 20 ppm of the diet.

Supplementation with high levels of manganese to cattle fed a copper-deficient diet can further impair copper absorption, with consequent reductions in the growth and health of cattle.[6]

BIOTIN (VITAMIN H) DEFICIENCY (HYPOBIOTINOSIS)

Biotin, or vitamin H, has several important biochemical functions. It is a cofactor in several enzyme systems involved in carboxylation and transcarboxylation reactions and consequently has a significant effect on carbohydrate metabolism, fatty acid synthesis, amino acid deamination, purine synthesis, and nucleic acid metabolism. Biotin is found in almost all plant and animal materials and, being required in very small quantities, is unlikely to be deficient in diets under natural conditions, especially because microbial synthesis occurs in the alimentary tract.

Cattle

Biotin is now considered a significant factor in lameness of cattle.[1-5] Biotin is important for the differentiation of epidermal cells, which are required for normal production of keratin and hoof horn tissue. Biotin also acts as a cofactor in carboxylase enzymes and is an important factor in both gluconeogenesis and fatty acid synthesis. Significant differences in the fatty acid profile of horn tissue of cattle with claw lesions have been observed. Biotin supplementation reduces clinical white-line disease, reduces horn lesions, and improves horn quality by strengthening the intercellular cementing material between keratinocytes. Improved hoof integrity in intensively managed dairy cows has occurred following biotin supplementation. However, a long period of supplementation is required before the effect of the vitamin on hoof health care is expressed. In addition, there can be improved milk production, milk composition, and cow fertility with biotin supplementation, although this finding is not consistent across studies.[6]

Biotin is synthesized in the rumen, and absolute biotin deficiency has not been recognized. However, ruminal synthesis of biotin may be compromised by acidic conditions in the rumen, which may increase the need for supplementation of biotin in the diet of high-producing dairy cows. In the dairy cow in the periparturient period and early lactation, the levels of biotin may decrease. A decrease in plasma biotin levels of dairy cows at 25 days in milk (DIM) has been noted, returning to constant levels from 100 DIM until the end of lactation. Feeding supplemental biotin at 20 g/d during the last 16 days postpartum and at 30 g/d from calving through to 70 days postpartum elevated concentrations of plasma and milk compared with cows unsupplemented with biotin. Supplemental biotin also elevated plasma glucose and lowered nonesterified fatty acids, which indicates that supplemental biotin is involved in hepatic gluconeogenesis. The triacylglycerol concentration in liver tended to decrease at a faster rate within 2 days after parturition.

Supplementation of young, extensively managed cattle with 12.5 mg of diluted powdered biotin, or a control treatment, for 40 consecutive days revealed an effect of biotin to increase average hoof growth of 11.3 +/– 0.72 mm in supplemented cattle versus 7.2 +/– 0.78 mm over the 40 days.[2] There was a positive effect of biotin supplementation on the growth of the angle and length of the dorsal hoof wall and the hoof sole length, and on resistance to wearing, in young, extensively managed cattle.[2] The supplementation of Holstein cows in the Atherton Tablelands in Australia with biotin at 20 mg/head per day resulted in improved locomotion scores compared with unsupplemented cows. In the wet summer period, the number of lame cows observed by the farmer was significantly fewer during the rainy period for the biotin-supplemented herds, and animals in the herd required fewer antibiotic treatments than unsupplemented herds. Most hoof lesions were most commonly observed in the outer claws of the hindlimb.

In a randomized control field trial on five commercial dairy farms in Gloucestershire, southwest United Kingdom, the effect of parity and duration of supplementation with oral biotin at 20 mg/d on white-line disease was studied over a period of 18 months. The incidence of white-line disease increased with increasing parity independent of biotin supplementation from 2 cases per 100 cow-years in primiparous cows to 15.5 cases per 100 cow-years in all multiparous cows, but up to 47.7 cases per 100 cow-years for cows in parities = 5. Supplementation with biotin reduced white-line disease lameness by 45% in multiparous cows down to 8.5 cases per 100 cow-years, whereas the effect of biotin supplementation in primiparous cows was not significant. A supplementation of length of at least 6 months was required to reduce the risk of white-line lameness in multiparous cows. The overall incidence rate of lameness (per 100 cows per year) was 68.9, with a range of 31.6 to 111.5 per farm. The incidence rates of the four most frequently reported causes of lameness were sole ulcer, 13.8; white-line separation, 12.7; digital dermatitis, 12.0; and interdigital necrobacillosis, 7.1 per 100 cows per year. The incidence of lameness was highly variable between farms. However, when the data from all farms were pooled, the risk of lameness caused by white-line separation in cattle supplemented with biotin was approximately 50%. Approximately 130 days of biotin supplementation is required before a significant difference in white-line lesion lameness occurs.

A controlled 14-month field trial evaluated the effect of biotin supplementation on hoof lesions, milk production, and reproductive performance of dairy cows housed in the same free-stall facility with the same environment, base diet, and management. Supplemented cows received 20 mg/d by computer feeder. The feet of a select number of cows were trimmed three times at 6-month intervals, and hoof health was evaluated. At the final hoof trimming, the incidence of sole hemorrhages was significantly higher in the control group (50%) compared with the supplemented group (24%). No cases of lameness occurred. Milk production and fat yield increased in all parities, and fertility was improved in first-calf heifers.

It is possible that biotin improves the quality of claw horn, which encourages the replacement of defective horn, improves healing, and makes it less likely for sole lesions to develop from laminitis in its early stages. The administration of biotin at 40 mg per day for 50 days to dairy cows with uncomplicated sole ulcers resulted in significant improvement in histologic horn quality of the newly formed epidermis covering the sole ulcer. Biotin supplementation at 20 mg/d

did not affect the tensile strength of the white line.

Vertical fissures, or sand cracks, are vertical cracks of the hoof that may extend across the coronary band and continue to the bearing surface of the dorsal wall of the claw. Sand cracks are common in beef cattle in western Canada. One survey, 37.5% of beef cows were affected with one or more cracks. Supplementary dietary biotin at 10 mg/head per day significantly increased serum levels of biotin and increased claw hardness compared with unsupplemented cows. After 18 months, 15% of the biotin-supplemented cows had vertical fissures compared with 35% in the unsupplemented cows.

Sheep

There is evidence from a small number of studies that biotin supplementation of the diets of sheep improves hoof health.[7]

Pigs

The principal source of biotin for the pig is the feed it receives, and feeds vary greatly in their biotin content and in the biological availability of that biotin. Diets based on cereals with a low available biotin content may provide insufficient dietary biotin for the maintenance of hoof horn integrity in pigs. The biotin content in basal diets fed to pigs has varied from 29 to 15 µg/kg available biotin, and supplementation of these diets has resulted in improvements in litter size. Continuous feeding of sulfonamides or antibiotics may induce a deficiency. An antivitamin to biotin (avidin) occurs in egg white, and biotin deficiency can be produced experimentally by feeding large quantities of uncooked egg white.

In pigs, experimental biotin deficiency is manifested by alopecia, dermatitis, and painful cracking of the soles and the walls of the hooves.

Naturally occurring outbreaks of lameness in gilts and sows associated with lesions of the soles and the walls of the hooves, which responded to biotin supplementation, have now been well described. The severe lameness and long course of convalescence have been responsible for a high rate of culling in breeding animals. In gilts fed a basal diet with a low level of biotin (32 µg available biotin/kg) from 25 kg live weight to 170 days of age, there were no significant differences in the number of lesions and claws affected compared with gilts fed a biotin-supplemented diet (350 µg available biotin/kg). However, between 170 days of age and the first weaning, the incidence of hoof lesions increased markedly. Over the next four litters, the incidence of lesions increased with the age of the sow. The predominant lesions in the foot were cracks, which occurred mainly in two associated regions: the heel/toe junction and the heel and the sidewall and adjacent white-line region of the toe. Supplementation of the diet of breeding sows with biotin at an early stage of development makes a significant contribution to the maintenance of horn integrity.[8]

Affected animals become progressively lame after being on a biotin-deficient ration for several months. Arching of the back and a haunched stance with the hindlegs positioned forward occurs initially. This posture has been described as a "kangaroo-sitting" posture. The foot pads become softer and the hoof horn less resilient. The feet are painful, and some sows will not stand for breeding. Deep fissures at the wall–sole junction may extend upward beneath the wall horn, and gaping cracks may separate the toe and heel volar surfaces. The foot pads initially show excessive wear; later, longitudinal painful cracks develop. In well-developed cases, the foot pads appear enlarged, and the cracks are obvious and covered by necrotic debris. The foot pads of the hindfeet are usually more severely affected than those of the forefeet, and the lateral digit is more frequently affected. The dewclaws also are affected by cracks and the accumulation of necrotic tissue.

Skin lesions also develop in affected gilts and sows. There is gradual alopecia, particularly over the back, the base of the tail, and the hindquarters. The hairs are more bristly than normal and break easily. The alopecia is accompanied by a dryness of the skin.

As the lesions of the feet and skin develop there is a marked drop in the serum biotin concentrations, which is considered as a sensitive index of biotin deficiency. Adequate biotin status may be indicated by serum biotin levels (ng/L) greater than 700; marginal, 600 to 700; inadequate, 400 to 600; and deficient, below 400. Compression and hardness tests made on external hoof have also been used as an indirect measure of biotin adequacy in pigs. The tests indicate that significant improvements in the strength and hardness of pig hoof horn are produced by biotin. Supplementation of the diet with biotin does not affect either horn growth or wear rates. Biotin supplementation does affect the structure of the coronary epidermis; there is an increase in the density of the horn tubules in the stratum medium, the horny squames in the stratum medium are more tightly packed, and the tubules are more clearly defined.

Reproductive performance of sows is also influenced by their biotin status. Supplementation of the diet with biotin may increase litter size, increase the number of pigs weaned, decrease the mean interval in days from weaning to service, and improve conception rate. Over a period of four parities, piglet production increased by 1.42 pigs/sow year.

Biotin Requirements

Pigs

The daily requirements of biotin for pigs have not been well defined, but certain amounts have been associated with an absence of lameness and improved reproductive performance. Basic diets for gilts contain 35 to 50 µg/kg, and the addition of 350 to 500 µg/kg is recommended. This provides a daily intake of 4.0 to 5.0 mg/sow per day. The response to dietary supplementation may take several months; therefore, supplementation should begin at weaning. The details of biotin studies in pigs, including experimental deficiency, the absorption and synthesis of biotin, biotin availability in feedstuffs, and the biotin requirements of the growing pig, are available.

Supplementation of a basal diet, calculated to contain 56 µg/kg available biotin with daily allowances of biotin at 1160 µg/sow per day in pregnancy and 2320 µg/sow per day in lactation, produced significant improvements in litter size in second- and fourth-parity sows. It is suggested that the requirement is in excess of 175 µg available biotin per 1 kg of diet. In a swine herd with a lameness problem, the supplementation of the sow's ration during pregnancy and lactation with daily intakes of biotin of 400 and 800 µg/sow per day, respectively, and the rations of the weaners and growers to 150 and 250 was effective.

Horses

The dietary supplementation of horses with 10 to 30 mg biotin/d for 6 to 9 months is considered to be effective as an aid in the treatment of weak horn hoof in horses. The hoof horn quality of more than two-thirds of the Lippizaner horses had moderate to severe changes: microcracks visible in the transition from the middle to the inner zone of the coronary horn; separation of the sole from the coronary horn in the region within the white zone. Biotin supplementation for 19 months improved horn quality. Continuous dietary supplementation with biotin at a daily dose of 20 mg is necessary to improve and maintain hoof horn quality in horses with less-than-optimum-quality hooves.

Toxic Agents Affecting the Musculoskeletal System

HYENA DISEASE OF CATTLE

Hyena disease of cattle occurs worldwide and is characterized clinically by a lateral body appearance similar to the hyena. The

cause is unknown for some cases, but sustained excessive intake of vitamin A and vitamin D_3 in young calves appears to be the most likely cause of hyena disease by suppressing differentiation and proliferation in chondrocytes and osteoblasts. This effect is clinically detectable because of **premature closure of the physis of long bones**. A small number of cases may be a result of systemic viral disease of young calves.

In some naturally occurring cases in yearlings from one large dairy herd, approximately 1% of calves were affected annually. Affected calves had received vitamins A and D_3 immediately after birth, and from birth to weaning they received the same vitamins from fresh milk, whole corn, a customized feed mix, and a milk supplement. The mean daily intake of vitamin A from birth to 6 weeks of age was approximately 80,000 IU and 6,300 IU of vitamin D_3, and progressively less vitamin A and D_3 was fed from 6 weeks until weaning at 3 months. The NRC recommendations for daily vitamin intake are 2100 IU of vitamin A at birth, increasing to 6360 IU at 2 months, and 330 IU of D_3, increasing to 990 IU over the same period. Experimentally, the IM injection of vitamins A and D (2,000,000 IU and 300,000 IU, respectively) on the first day after birth followed by 30,000 IU/kg BW added to the milk replacer daily resulted in gross lesions in the proximal tibial growth plates in 3 weeks. Excessive amounts of vitamin D_3 appear to promote the primary effect of vitamin A on premature closure of the physis. For example, daily administration of vitamin A (30,000 IU/kg BW) in milk replacer fed to lambs resulted in premature closure of the distal growth plate in the femur and proximal growth plate in the tibia, but clinical signs of hyena disease were not detected.[1]

The premature closure of the growth plates of the long bones results in a marked dissimilarity in growth and development between the forequarters and the hindquarters, the latter being comparatively underdeveloped. This gives the animal the classic contours of the hyena, and this resemblance is heightened by a crest of thick, stiff bristles along the back in the midline. An aggressive attitude also develops. Affected calves are normal at birth and only develop the abnormality at 5 to 6 months of age. The femur and tibia are shorter in affected than in normal animals. There are accompanying difficulties of locomotion, with a tendency to fall sideways, and to frequently adopt a position of lateral recumbency. The gait is described as "bunny-hopping."

German Simmental, Charolais, Black Pied, German Holstein–Friesian, and German Red Pied cattle have been involved. Genetic analysis appears to indicate that the disease is inherited as a simple recessive trait with incomplete penetrance, but this is obviously not so in some herds.

The lesion is a chondrodystrophy affecting particularly the long bones and the lumbar vertebrae. Gross examination and radiography of the longitudinal slabs of the humeri, tibias, and femurs reveal focal to almost complete closure of the physes, with physes subjected to compression being more severely affected more than those subjected to tension.

CALCINOGENIC GLYCOSIDE POISONING (ENZOOTIC CALCINOSIS)

SYNOPSIS

Etiology Ingestion of calcinogenic glycosides in a few specific poisonous plants.

Epidemiology Enzootic disease in all species in regions where toxic plants occur.

Clinical pathology Elevated blood calcium and phosphorus concentration; tissue calcification visible on x-ray.

Lesions Calcification of all tissues; degenerative arthritis in all limb joints.

Diagnostic confirmation Identification of specific plant.

Treatment None.

Control Remove and keep animals away from toxic plants.

ETIOLOGY

Calcinogenic glycosides occur in very small quantities in plant leaves. The aglycone (nonsugar) radical is a vitamin D_3 sterol, a 1,25-$(OH)_2D_3$-like compound. Hydrolysis of the glycoside releases the vitamin D_3 analog, causing the development of calcification of soft tissues, similar to hypervitaminosis D. The plants in which these glycosides have been identified are *Solanum malacoxylon* (i.e., *S. glaucophyllum, S. glaucum, S. glaucescens, S. glaucumfrutescens*), *Nierembergia veitchii,* and *Cestrum diurnum* (wild jessamine).[1]

Other plants in which the presence of calcinogenic glycosides is suspected are *Stenotaphrum secundatum* (crab grass) in Jamaica, *S. linnaeanum* (= *S. hermannii, S. sodomaeum*; apple of Sodom), *S. torvum* (devil's fig), and *Trisetum flavescens* (yellow or golden oat grass) in Europe.[1,2]

The plants are weeds of pasture and are readily eaten by livestock, especially in drought years when other forage is scarce.[2] The glycosides are very stable and resist drying and storage for periods of longer than a year. Heating reduces the toxicity of *Solanum malacoxylon* significantly but has little effect on that of *Trisetum flavescens.*

EPIDEMIOLOGY

Occurrence

Enzootic calcinosis and its causative plants occur in most countries. The disease associated with *Solanum* spp. occurs in tropical and subtropical regions, including Africa, Argentina, Brazil, Cuba, Papua New Guinea, the West Indies, and Hawaii. *Cestrum diurnum* poisoning occurs in the far southern United States, especially Florida, Texas, and California. Tentative diagnoses have been made in India and Israel. In Jamaica the disease is known as "Manchester wasting disease," in Hawaii as "naalehu," and in South America as "espichamento" or "enteque seco."

In Austria and Germany, *T. flavescens* is a common component of alpine pasture and is associated with the onset of signs about 18 months after cattle are put onto the infested pasture. Resident cattle show clinical signs at about 3 years of age. The grass is most toxic when it is young, and the clinical signs are worse when the cattle are at pasture.

Risk Factors

Animal Risk Factors

Both sexes and all ages of all animal species are affected—ruminants most commonly, horses less so. Pigs and sucking lambs are least susceptible.

PATHOGENESIS

The glycoside ingested in the plant is hydrolyzed by rumen microbes, intestinal mucosal enzymes, and bone cells to form the vitamin D_3 analog.[2] Absorption of the active substance results in a dramatic increase in the uptake of calcium from the diet. Blood levels of calcium are markedly increased, and this is followed by deposition of calcium in soft tissues. The mode of action of the glycoside is similar to that of 1,25-dihydroxycholecalciferol.

CLINICAL FINDINGS

The disease is chronic and may persist for several years. It is characterized by wasting, reluctance to walk, a stiff gait, constant shifting of the weight from foot to foot, and a disinclination to get up or to lie down.[1,2] Forced exercise is associated with severe distress; some animals may become aggressive. Affected animals stand for long periods with the back arched and the legs stiffly extended. Calcification of blood vessels may be palpable, for example, during rectal examination. Cardiac murmurs are audible. Clinical signs subside if the animals are removed from the causative feed, but resorption of calcium

deposits in tissues is minimal even years after removal from the affected pastures. Animals left on the toxic pasture eventually become recumbent and die. Fetuses may be affected.

CLINICAL PATHOLOGY

Serum concentrations of calcium and phosphorus increase by 20% to 25%, with increases of up to 3.4 mmol/L of calcium and 4 mmol/L of phosphorus.[2] Tissue calcification should be detectable radiologically. Anemia is common in animals poisoned by *Solanum malacoxylon.*

NECROPSY FINDINGS

Nonspecific emaciation, anasarca, and ascites are common. Calcification of all blood vessels, including the aorta and coronary arteries, and of the endocardium, is the most readily visible, characteristic lesion. Calcification is also present in the pleura; the lung parenchyma, which is usually emphysematous; in most other viscera; and in tendons and ligaments.[3] Degenerative arthritis occurs in the limb joints.

DIFFERENTIAL DIAGNOSIS

The history, clinical findings, and discovery of specific toxic plants will provide diagnostic confirmation. Repeated overdosing with vitamin D, by injection or administration in compounded feeds, replicates the clinical and necropsy findings.

TREATMENT AND CONTROL

No practicable treatment is available. Careful management of affected pasture in Europe has been shown to significantly reduce the losses as a result of the disease.

HYPOGLYCIN A INTOXICATION OF HORSES (ATYPICAL MYOPATHY [MYOGLOBINURIA] IN GRAZING HORSES)

Hypoglycin A intoxication of horses is a syndrome of acute myoglobinuria occurring in horses at pasture in Great Britain, Ireland, Europe, North America, and, possibly, Australia and New Zealand.[1-6] The disease is caused by ingestion of seeds of the maple trees *Acer negundo* (box elder) in the United States and *Acer pseudoplantanus* in Europe.[6-8] The toxic compound is hypoglycin A (L-a-amino-methylenecyclopropylpropionic acid), which is metabolized to methylenecyclopropylacetic acid (MCPA). MCPA can be detected in the blood of affected horses[9] and is a potent inhibitor of multiple acyl-CoA dehydrogenases causing a specific abnormal pattern of accumulation of blood acylcarnitines and urine organic acids.[7] This pattern was recognized in affected horses before the causative agent was identified.[5]

The potential of other maple trees (*Acer palmatum* [Japanese maple], *A. saccharum* [sugar maple], *A. spicatum* [mountain maple], and possibly others) to cause this disease is unknown, although these species contain, or likely contain, hypoglycin A.[10]

The disease has a strong seasonal distribution, with most, but not all, cases occurring in autumn.[1,4,11,12] Occurrence of the disease is sporadic but usually affects more than one animal in a band of equids. Horses, ponies, and zebras have been affected.[11] Localized outbreaks involving large numbers of horses are reported.[11] Risk of the disease in Europe increases with increasing time at pasture, presence of wood or dead leaves in the pasture, lack of supplemental feeding, and presence of trees.[11,12] Wind speed and speed of wind gusts is greater immediately preceding outbreaks of the disease than at other times.[7]

There does not appear to be a breed or sex predilection to development of the disease. Younger horses might be at greater risk of the disease, but this could simply reflect the age distribution of horses at pasture in areas in which the disease occurs. Atypical myopathy occurs almost exclusively in horses at pasture and is not associated with enforced exercise.

The case-fatality rate is usually 60% to 70% but can be much higher.[11] Prognosis is directly related to the severity of clinical signs, such as tachycardia, tachypnea, recumbency, sweating, anorexia, and dyspnea.[13]

Clinical signs are those characteristic of acute rhabdomyolysis and include an abrupt onset of stiffness and reluctance to move. Affected horses might be noticed to be depressed or have reduced activity for 1 to 2 days before onset of clinical signs.[11] Horses can be affected up to 4 days after being removed from pasture.[11] Progression to lateral recumbency is rapid, occurring within hours of the initial onset of signs. Recumbency is often the first indication of this disease observed in horses at pasture. Horses forced to stand have tremors and difficulty walking. Lumbar and gluteal muscles can be firm. Affected horses are tachycardic and tachypneic. Respiratory distress, presumably secondary to degeneration of intercostal muscle and the diaphragm, is common in recumbent horses in the terminal stages of the disease. There is discolored urine (pigmenturia). There are abnormal ventricular arrhythmias and impaired myocardial function, which can persist for at least 10 weeks in affected horses.[14] Affected horses usually die or are euthanized within 24 to 72 hours of onset of clinical signs.[11]

Serum biochemical abnormalities include massively increased serum activities of creatine kinase, lactate dehydrogenase, and aspartate aminotransferase. Serum concentrations of troponin T, a marker of myocardial damage, are above normal in most affected horses. Serum concentrations of vitamin E and/or selenium and red cell activity of glutathione peroxidase are not consistently abnormally low. Serum concentrations of acylcarnitines are abnormal, with elevations of concentrations of short-, medium-, and long-chain compounds.[6,7] Urine concentrations of ethylmalonic acid, methylsuccinic acid, lactic acid, adipic acid, butyrlglycine, isovalerylglycine, and hexanoglycine are increased in affected horses.[7]

The acid–base status of affected horses is a mixture of respiratory alkalosis, lactic acidosis, and strong iron difference (SIDm) alkalosis.[15] Abnormalities in serum sodium, potassium, and chloride concentrations are usually small.[15]

Necropsy examination does not reliably reveal gross evidence of muscle disease, although there can be swelling, edema, and localized hemorrhage into muscles. There are hemorrhagic or pale areas in the ventricular myocardium of some horses. Histologic examination reveals the presence of widespread degeneration of myocytes, without inflammation, in muscles of locomotion and respiration. Within a muscle group, some fibers are severely affected, whereas other neighboring fibers are apparently normal. The ventricular myocardium has lesions of muscle degeneration in some horses. Myoglobinuric nephrosis is a consistent finding in horses that die spontaneously or are euthanized in the terminal stages of the disease.

Definitive diagnosis is based on the presence of clinical signs of muscle disease, large elevations in serum activity of muscle-derived enzymes, and necropsy examination.

Treatment is supportive because there is no definitive antidote for hypoglycin A.[16,17] Affected and at-risk horses should be removed from the pasture and prevented from eating more seeds of *A. negundo* or *A. pseudoplantanus.* Consideration should be given to administering activated charcoal to reduce absorption of further toxin from the gastrointestinal tract (500 g per 500-kg horse, orally). Some affected horses are in pain and should be administered analgesics. Hydration and electrolyte and acid: base balance should be maintained.

Administration of antioxidants and muscle relaxants is recommended but is without objective evidence of efficacy.[16,17]

Control centers around preventing horses and ponies from eating the seeds (samaras) of *Acer negundo* or *A. pseudoplantanus*. The seeds can be blown into pastures from trees bordering the pasture—consistent with wind speeds being higher immediately preceding outbreaks than at times when the disease did not occur.[7]

PLANT POISONINGS WITH KNOWN TOXINS

AMINOPROPIONITRILE

3-Aminopropionitrile is a poisonous substance found in *Lathyrus* spp. (wild peas), for example, *Lathyrus hirsutus* (wild winter pea), sometimes sown with grasses to provide early-spring grazing. Signs of toxicity in cattle grazing mature plants bearing seed pods consist of salivation, sawhorse stance, head held low, continuous head and ear movements, trance-like gaze, diminished responsiveness, reluctance to move, pain in the feet causing lameness, sitting with the feet under the body, and a marked disinclination to rise. Other signs include lameness, stumbling gait, recumbency, and paddling convulsions. The signs are exacerbated by driving or other stimulation. Necropsy findings are limited to nonspecific lesions such as pulmonary congestion.

PLANT POISONINGS WITH SUSPECTED OR UNIDENTIFIED TOXINS

JUGLONE

Juglone, a poisonous resinoid found in the shavings of *Juglans nigra* (black walnut tree), has been suspected as being associated with lameness and edema of the lower limbs in horses bedded on the shavings, but juglone is present in the bark and leaves, not the heartwood from which the shavings are made. The lesions are produced by an increase in local capillary blood pressure.

A similar syndrome is associated with *Berteroa incana* (hoary alyssum). Swelling of the distal limbs and fever are consistent signs associated with ingestion of this plant. Signs appear 18 to 36 hours after ingestion of the plant and disappear 2 to 4 days after the plant is removed. Abortions have been reported but may be secondary to the high fever. An alternative syndrome of severe gastroenteritis plus intravascular hemolysis is also recorded in horses fed hay contaminated by *Berteroa incana*.

MYOPATHY—WITH GAIT INCOORDINATION, RECUMBENCY, ELEVATED CPK

- *Karwinskia humboldtiana*—coyotillo
- Small amounts of *Senna* (= *Cassia*) spp. ingested over a long period are associated with skeletal muscle myopathy and/or paralysis. In *Senna occidentalis* poisoning in horses and goats, the early signs are anorexia and diarrhea followed by hyperpnea, tachycardia, ataxia, staggering, and recumbency. At autopsy there is a fatal cardiomyopathy. The muscle lesion is accompanied by marked elevations of SGOT and CPK levels. Similarly, in pigs, early diarrhea may be followed by lateral recumbency and skeletal muscle myopathy.

ALUMINUM TOXICOSIS

Aluminum is one of the potentially toxic elements introduced into the diets of animals by the deposition of soluble salts in acid rain, powder particles in factory effluent, accidental dosing, or absorption by plants.

Case reports in large animals are rare, and most of the toxicologic information comes from human data or investigational studies using rats, mice, and rabbits. Frank et al. reported polioencephalomalacia associated with elevated aluminum levels in Simmental calves,[1] and Easterwood et al. reported phosphine gas generation in horses accidentally receiving aluminum phosphide in their feed.[2] It should be pointed out that the toxin associated with aluminum phosphide intoxication is the toxic gas phosphine and not aluminum.

Absorption of aluminum is poor following oral, dermal, and inhalation exposure. Following absorption, it is distributed to other tissues, with the highest concentration in the bone.[3] Chronic exposure to aluminum results in sequestration in the bone, from which it is slowly released. Aluminum readily crosses the blood–brain barrier and placental barrier, resulting in neurotoxicity and developmental toxicity.[4,5] Excretion is through the urine, with very little bile and fecal excretion.[3]

Clinical signs depend on specific organs, but deposition in the bone is associated with osteoarthritis and anemia. Other organs affected include the heart (myocardial infarction), brain (cognitive dysfunction and other neurotoxic effects), liver, and kidney.

There is no treatment, and diagnosis depends on finding aluminum in the liver and kidney. Aluminum levels of 6 to 11 ppm in the liver and 4 to 5 ppm in the kidney of sheep and cattle are considered toxic amounts.

FLUORIDE TOXICOSIS

SYNOPSIS

Etiology Toxic amounts of fluoride are found in water (naturally or contaminated), soil, and plants contaminated by industry pollution, mineral mixes with excessive fluoride, and older insecticides, anthelmintics, and rodenticides containing sodium fluoride, sodium fluorosilicate, and sodium fluoroacetate. Fluoroacetate may also be found in several plant species, such as *Dichapentalum* spp., *Gastrolobium* spp. *Oxylobium* spp., and others.

Epidemiology Most often associated with continuous ingestion of small but toxic amounts of fluoride in the diet or drinking water.

Clinical pathology Elevated serum and urine levels of fluoride; elevated serum levels of Ca, BUN, and ALP in some cases.

Lesions

Live animals: Dental fluorosis—mottling and erosion of permanent teeth. Osteofluorosis with lameness and unthriftiness.

Postmortem: Osteoporosis; widespread exostoses. Dental enamel and dentin hypoplasia.

Diagnostic confirmation Fluoride assay of forage, soil, or water; blood and urine of affected animals; bones and teeth at necropsy.

Treatment Primarily supportive; activated charcoal is not recommended; oral calcium, magnesium, or aluminum to bind fluoride in gastrointestinal tract.

Control Good nutritional plane; keep young animals off and rotate stock if water or forage contaminated; keep fluoride in feed less than 2%; use of aluminum salts in feed of questionable efficacy.

ETIOLOGY

Fluoride is present in some concentration in almost all animal feed and water sources, so exposure not only occurs but continues throughout the lifetime. Both acute and chronic poisoning occur. Acute toxicosis in large animals is very rare and generally occurs after exposure to an older commercial product, such as sodium fluoride, sodium fluorosilicate, or sodium fluoroacetate, or to volcanic ash.[1,2] Chronic toxicosis is associated with the ingestion of high-fluoride-containing rock salt phosphate supplements, fluoride-contaminated forage or soil, and water either naturally containing excess fluoride or that has been contaminated with fluoride.[3-6] The severity of the poisoning depends on the amount ingested, the solubility of the fluoride compound, the species, diet, and the animal's age.[1,7] Death losses are rare and restricted largely to acute poisoning, with the major losses taking the form of unthriftiness associated with chronic fluorosis.

EPIDEMIOLOGY

Occurrence

Fluoride intoxication has been observed in most countries, usually in association with specific natural or industrial hazards. In Europe and Great Britain, losses are greatest on summer grazing of pastures contaminated by industrial fumes, including dust from factories converting rock phosphate to superphosphate and effluent from aluminum smelters. Iceland and parts of the southern Andes Mountains are extensively affected by contamination from volcanic ash. Drinking water from deep wells, industrial contamination of pasture, and the feeding of fluoride-bearing phosphatic supplements are the common associations in North America. Deep wells also are an important source in Australia and South America. In Africa the important association is the feeding of phosphatic rock supplements.

In experimentally induced fluorosis in cattle, mottling of the tooth enamel occurs at intakes of 27 mg/kg in the diet, but there is no pitting until levels of 49 mg/kg are fed. Bony lesions are slight at intakes of 27 mg/kg, moderate at 49 mg/kg, and marked at 93 mg/kg, and milk production in dairy cows is thought not to be affected by intakes of 50 mg/kg of fluoride in the diet until about the fourth lactation. A more recent view is that the existing tolerance level for dairy cows of 40 mg/kg is too high and will lead to serious loss of production and some dental fluorosis in high-producing cows.[1]

Risk Factors

Animal Risk Factors

Host factors are age and species. Daily intakes of 0.5 to 1.7 mg/kg BW of fluoride as sodium fluoride produce dental lesions in growing animals without affecting general well-being. Intakes equal to twice these amounts are consumed by adult animals without ill effect. In heifers a continuous intake of 1.5 mg/kg BW per day is sufficient to be associated with severe dental fluorosis without affecting growth rate or reproductive function. However, extensive osteofluorosis and periods of severe lameness will occur. The fluoride content of the bones of newborn calves depends on the dam's intake of fluoride in the last 3 to 4 months of pregnancy and not on her own bone composition.

Most recorded occurrences of fluorosis are in cattle. Sheep are less susceptible than cattle, and it is rarely reported in horses. A continuous intake of 1 mg/kg BW is the maximum safe limit for ruminants; an intake of 2 mg/kg BW produces clinical signs. In pigs an intake of 1 mg/kg BW added fluoride for long periods has no deleterious effect.

Fetal effects are small. The current view is that placental passage is infinitesimal in amount, but historically, cases of neonatal dental fluorosis have been identified in cattle.[3] Fluoride does not occur in significant quantities in the milk or colostrum of poisoned cows.[1]

Environmental Risk Factors

Fluoride occurs naturally in rocks, particularly in association with phosphate, and these rocks, the soils derived from them, and the surface water leaching through the soils may contain toxic quantities of fluoride. In such areas the soil content of fluoride may be as high as 2000 to 4000 mg/kg, even up to 12,000 mg/kg, and the levels in water up to 8.7 mg/kg; soil fluoride varies in its solubility from 10% to 20%. Levels of fluoride likely to be toxic to animals are not usually encountered in natural circumstances; interference by humans is necessary in most instances to increase fluoride ingestion above the critical level.

Contamination from industrial factories by smoke, vapor, or dust may produce pasture containing 20 to 50 mg/kg of fluoride. Factories producing aluminum by the electrolytic process, iron and steel with fluoride-containing fluxes, superphosphate, glazed bricks, copper, glass, and enamels are likely to be potent sources and may be associated with toxic levels of contamination as far as 14 km downwind from the factory. Dust from factories manufacturing superphosphate from rock phosphate may contain as much as 3.3% fluoride. Industrial plants engaged in the calcining of ironstone have also been incriminated as sources of fluoride.

Contamination by effluent is a complex problem because of variation in the form of the contaminating compound. Grass can absorb and retain gaseous fluoride from the ambient air, but physical deposit of liquids and dust is the critical form of contamination.[5,6] Two of the common effluent substances are hydrofluoric acid and silicon tetrafluoride, both of which are as toxic as sodium fluoride, and dental lesions occur in 100% of young ruminants on an intake of 14 to 16 mg/kg DM of these substances. Severe cases occur on pasture or hay containing more than 25 mg/kg DM, and similar lesions develop much more rapidly on pasture containing 98 mg/kg DMr. Fluoracetamide is also known to be a toxic factory effluent.

Dust and gases from volcanic eruptions may also be associated with acute fatal fluoride intoxication in the period immediately after the eruption, and contamination of pasture may be sufficient to be associated with subsequent chronic intoxication in animals eating the herbage, although the fluoride content of the contaminated materials decreases very rapidly if rain falls. Iceland is particularly afflicted with fluoride intoxication deriving from this source.

Top dressing of pasture with phosphatic limestone is commonly associated with fluorosis. Most phosphatic limestones, particularly those from North Africa, are rich in fluoride (0.9% to 1.4%). Nonphosphatic limestones contain insignificant amounts.

Supplementary Feeding of Phosphates

The common occurrence of phosphorus deficiency in animals has led to the search for cheap phosphatic materials suitable for animal feeding. Rock phosphates are commonly used, and many deposits contain dangerous amounts of fluoride (3% to 4%).[8] The fluoride content of the mineral can be reduced, but the cost encourages the use of marginally safe material.

The major occurrence of water-borne fluoride intoxication is from water obtained from deep wells or artesian bores. The available data suggest that although minor tooth lesions occur at 5 mg/kg of fluoride, it is not until levels of 10 mg/kg are exceeded that excessive tooth wear occurs and the nutrition of the animal is impaired. More serious systemic effects do not occur until the water contains 30 mg/kg.

Miscellaneous sources of fluoride include the ingestion of superphosphate itself, but a

supernatant liquid of a suspension of the fertilizer will contain no fluoride. Some wood preservatives may contain large quantities of fluoride, which may be associated with acute poisoning in some circumstances.

Farm Risk Factors

Animals that are housed in the winter and grazed only during the summer and fall on pasture contaminated by factory effluent may show considerable clinical improvement in clinical signs during the winter and an annual recrudescence of signs when the animals are outside.[9]

Human Risk Factors

Although it is possible for animal tissues to contain amounts of fluoride in excess of permissible amounts, this is not usually so in chronic fluorosis. The fluoride content of milk in these circumstances is below that permitted in fluoridated drinking water (1 mg/L).

PATHOGENESIS

Absorption from the gastrointestinal (GI) tract depends on the form ingested, with soluble forms such as sodium fluoride being more bioavailable than fluoride found in contaminated feed, soil, or water. Once absorbed, fluoride is distributed throughout the body, primarily to bone and teeth. Excretion is renal.[10]

Acute intoxication, as a result of the ingestion of large amounts of soluble fluorides (e.g., sodium fluoride), occurs rapidly, with signs appearing 30 to 60 minutes after ingestion. The mechanism of action is unknown but may be attributable to the development of hydrofluoric acid in the GI tract, onset of systemic hypocalcemia, decreased Na/K ATPase activity, or the inhibition of glycolysis.[10]

Chronic ingestion results in the deposition of fluoride in the bones and/or teeth of affected animals.[7] Deposition in bone occurs throughout life but in teeth only in the formative stages.[1,7] In bones, fluorides alter mineralization, crystal structure, and remodeling of bone by replacing hydroxyl groups in the hydroxyapatite of the bone crystalline structure. The degree of deposition varies, being greatest on the periosteal surface of the long bones where exostoses commonly develop. These bony changes are often referred to as skeletal fluorosis or osteofluorosis.

During tooth formation, fluorides inhibit the action of ameloblasts and odontoblasts, resulting in failure of the developing tooth to accept minerals. Thus tooth lesions occur only if the intake is high before the teeth have erupted, but bone lesions occur at any stage.

When the tissue levels of fluoride are moderate, characteristic lesions as a result of hypoplasia of enamel appear in the teeth. During this time the fluoride levels in bone can increase slowly without appreciable bone changes. The facility of storage in bone explains the long latent period that occurs in animals subjected to chronic intoxication. Lesions generally begin on the medial side of the proximal metatarsal bones and expand to include the mandibles, metacarpal bones, and ribs. Abnormalities, once they occur, result in lameness and are generally symmetric and bilateral.[1] At very high levels the storage capacity of bone and teeth is exceeded, and blood and urine levels rise. The bone lesions of osteomalacia and osteoporosis, with accompanying pathologic fractures, are associated with excessive mobilization of calcium and phosphorus to compensate for their increased urinary excretion in conjunction with fluoride.

The kidney is the primary tissue affected, but other tissues in which degenerative changes may occur are the bone marrow, adrenal glands, heart muscle, and central nervous system.[2,10,11] A severe anemia may rarely occur as a result of toxic depression of bone-marrow activity, although this is not a constant or expected sign.

CLINICAL FINDINGS

Acute Intoxication

The syndrome includes dyspnea, complete anorexia, vomiting, and diarrhea in pigs and ruminal stasis with constipation or diarrhea in ruminants.[1,2] Vomiting acts as a protective mechanism, and toxic doses in pigs may be eliminated in this way without the development of other signs. Nervous signs are characteristic and include ataxia, muscle tremors and weakness, a startled expression, pupillary dilatation, hyperesthesia, and constant chewing. Tetany, convulsions, and collapse and death follow within a few hours.

Chronic Intoxication

Because of the distinct clinical separation between animals with dental lesions and those that have, in addition, signs of lameness and general ill-health, it is customary to refer to two forms of the disease: dental fluorosis and osteofluorosis. Lesions of the teeth and bones are characteristic, and the signs are largely referable to these lesions. Tooth changes are the earliest and most diagnostic sign but may not produce clinical effects until other signs have developed.[12] Consequently, they are often missed until other clinical findings suggest that the teeth be examined.

Dental Fluorosis

The permanent teeth exposed to intoxication before eruption will be affected and perhaps those of animals exposed in utero. The earliest and mildest sign is mottling with the appearance of pigmented (very light yellow, green, brown, or black) spots or bands arranged horizontally across the teeth. Occasional vertical bands may be seen where pigment is deposited along enamel fissures. Mottling and staining occur on incisors and cheek teeth and are not evident when the affected tooth erupts, and in fact they may not appear until some months later. The cheek teeth are usually more dramatically affected than the incisors but are very difficult to examine clinically. If the period of exposure to intoxication has been limited only some of the teeth may be affected, but the defects will always be bilateral.

Mottling may not progress any further, but if the intoxication has been sufficiently severe, defective calcification of the enamel leads to accelerated attrition or erosion of the teeth, usually in the same teeth as the mottling. The mottled areas become pits, and the teeth are brittle and break and wear easily and unevenly. Patterns of accelerated attrition are dependent on the chronologic occurrence of the intoxication and the eruption time of the teeth. Uneven and rapid wear of the cheek teeth makes proper mastication impossible. Infection of the dental alveoli and shedding of teeth commonly follow. The painful condition of the teeth and inability to prehend and masticate seriously reduce the food intake and are associated with poor growth in the young and unthriftiness and acetonemia in adults. Affected cattle may lap cold drinking water to avoid the discomfort occasioned by normal drinking. Eruption of the teeth may be abnormal, resulting in irregular alignment.

A standard for the classification of fluorosis has been proposed based on the degree of mottling, pitting, and rate of wear of the teeth. The effects of dental mottling, pitting, and excessive wear of incisors can be used to estimate the exposure periods of cattle during odontogenesis. The additional clinically apparent abnormalities include delayed eruption of permanent incisor teeth, necrosis of alveolar bone resulting in recession of bone and gingiva, oblique eruption of permanent teeth, hypoplasia of teeth, wide spaces between teeth, and rapid development of any dental lesions.

Osteofluorosis

Lameness most marked in the loins, hip joints, and hindlimbs and unthriftiness in animals of any age are the signs usually observed first.[11,12] The occurrence of hip lameness or fractures of the third phalanx on a herd scale in cattle is thought to be diagnostic of fluorosis. Pain is evinced on pressure over limb bones and particularly over the bulbs of the heels. The bones may be palpably and visibly enlarged. This is most readily observed in the mandible, sternum, metacarpal, and metatarsal bones and the phalanges. This overall thickness may be subsequently replaced by well-defined exostoses. The bones are subject to easy fracture. These well-defined lesions occur only in advanced cases and are often accompanied by extensive tooth lesions in young animals. In addition to the cases affected by

generalized lameness, there are cases that show a sudden onset of very severe lameness, usually in a forelimb, associated with transverse fracture of the third phalanx.

Other Effects

Reproduction, milk yield, and wool growth are not usually considered to be adversely affected except indirectly by the reduced food intake. Severely lame animals may have lowered reproductive performance indirectly as a result of physical dysfunction that interferes with mating.

Additional signs, including diarrhea and anestrus and other forms of infertility in cattle, diarrhea in sheep, and polydipsia and polyuria in pigs, are recorded in the naturally occurring disease but cannot be considered as constant or pathognomonic. Horses with chronic fluorosis have lameness; dental lesions, including excessive molar abrasion; and hyperostotic lesions of the metatarsus, metacarpus, mandible, and ribs.

CLINICAL PATHOLOGY

Normal cattle have blood levels of up to 0.2 mg fluoride per mg/dL of blood and 2 to 6 mg/kg in urine. Cattle on fluoride intakes sufficient to cause intoxication may have blood levels of 0.6 mg/dL and urine levels of 16 to 68 mg/kg, although blood levels are often normal. Such high levels may not be an indication of high intakes immediately preceding the examination because heavy deposits in bones may be associated with abnormally high blood and urine fluoride levels for some months after the intake has been reduced to normal. Urine levels should be corrected to a specific gravity of 1.040. Serum calcium may be low or normal, phosphorus levels are usually normal, and there is a significant correlation between the amount of fluoride fed and the concentration of alkaline phosphatase in the serum.[2,12] The increase in phosphatase activity is probably related to the abnormal formation of bone and may be 3 to 7 times the normal level.

Radiographic changes of bones containing more than 4000 mg/kg of fluoride include increased density or abnormal porosity, periosteal feathering and thickening, increased trabeculation, thickening of the compact bone, and narrowing of the marrow cavity. Spontaneous rib fractures show incomplete union. Good data are available for fluoride concentrations in rib bones, and estimations of fluoride content in biopsy samples of ribs have been used in the clinicopathologic study of the disease. Samples of tail bone and the spongiosa of the tuber coxae have also been used for these purposes.

NECROPSY FINDINGS

Severe gastroenteritis is present in acute poisoning, and there may be degenerative changes in the renal tubular epithelium. In chronic fluorosis the bones have a chalky, white appearance; are brittle; and have either local or disseminated exostoses, particularly along the diaphyses. Intraarticular structures are not primarily affected, although there may be some spurring and bridging of the joints. Histologically, there is defective and irregular calcification of newly formed trabecular bone and active periosteal bone formation. Hypoplasia of the enamel and dentin are consistent physical and histologic defects in the teeth of affected young animals. Young animals may also develop thickened growth plates and widened metaphyses that are grossly similar to rachitic changes. Degenerative changes in kidney, liver, heart muscle, adrenal glands, and central nervous system have been reported in severe cases. Degeneration of the bone marrow and consequent aplastic anemia also occur.

Chemical examination of necropsy specimens is valuable in the diagnosis because the fluoride content of bones from poisoned animals is greatly increased. Levels of up to 1200 mg/kg of bone on a dry, fat-free basis are observed in normal animals but may be increased up to 3000 mg/kg in animals exposed to fluoride and showing only mottling of the teeth. Animals showing severe clinical signs have levels greater than 4000 mg/kg of bone on a dry, fat-free basis; after prolonged heavy feeding, levels may be as high as 1.04%. Care must be taken in selecting the bone samples because of the great variation in the concentration of fluoride that occurs between different bones. Good data are available for comparison between metacarpal, metatarsal, rib, pelvic, and mandibular bones and antlers of deer. Mandibles usually show the greatest concentrations; in the long bones, the distal and proximal quarters are more sensitive indicators than the center half.

Diagnostic confirmation depends on fluoride assay of forage, soil, or water; blood and urine of affected animals; and bones and teeth at necropsy.

Samples for Confirmation of Diagnosis

- **Toxicology**—mandible/metacarpal/metatarsal, rib, vertebrae for evidence of osteofluorosis; urine from affected animals for evidence of recent exposure (ASSAY [F])
- **Histology**—formalin-fixed metacarpal/metatarsal/mandible (LM)

DIFFERENTIAL DIAGNOSIS

ACUTE:

- Heavy metal toxicosis
- Nephrotoxic mycotoxicosis
- Oak (*Quercus* spp.) toxicosis
- Plant toxins (*Amaranthus* spp., *Isotropis* spp., *Lantana* spp.)

Chronic:

- Chronic selenium toxicosis
- Degenerative joint disease/osteoarthritis
- Enzootic calcinosis
- Ephemeral fever in cattle
- Nutritional deficiency of phosphorus
- Nutritional deficiency of vitamin D
- Osteodystrophia fibrosa in horses
- White-muscle disease

TREATMENT

Treatment, apart from removing the animals from the source of fluoride, is largely impractical and supportive in nature. In acute ingestions, most animals die before there is time for treatment. With chronic ingestions, no improvement in dental or osseous lesions can be anticipated, but there may be amelioration of the other clinical signs. Activated charcoal is not recommended because fluoride does not bind well to it. Calcium, magnesium, or aluminum may be used to bind hydrofluoric acid produced in the stomach, and because of their insolubility they are safe even in large quantities.[13,14] Intravenous calcium should be used if hypocalcemia or tetany are present.

CONTROL

- Where fluoride levels are marginal, careful husbandry, including the watering of young growing stock on fluoride-free supplies, permitting only adults to be watered on the dangerous supplies, and rotating the animals between safe and dangerous waters at 3-month intervals, may make it possible to utilize land areas otherwise unsuitable for stock raising. In some areas, dairy herds may have to be maintained by the purchase of replacements rather than by the rearing of young stock. In areas where long-term ingestion of fluoride is likely to occur, the aim should be to provide a diet of less than 50 mg/kg of the total diet of dairy cows. Adequate calcium and defluorinated phosphorus intakes should be ensured because these reduce bone storage of fluoride.
- Phosphate feed supplements should contain no more than 0.2% fluoride for milking or breeding cattle or 0.3% for slaughter cattle, and they should not comprise more than 2% of the grain ration if the fluoride content is of this order. Some deposits of rock phosphate have much higher contents of fluoride than others, and commercial defluorination makes these toxic deposits safe for animal feeding.
- Bone meal in some areas may contain excessive quantities of fluoride and should be checked for its fluoride content.
- Water from deep wells and artesian bores should be assayed for fluoride content before use. The fluoride content of drinking water can be reduced (from 10 to 0.95 mg/kg) by adding freshly

slaked lime to the water; 500 to 1000 mg/kg should be added, and the water must be allowed to settle for 6 days. The method requires the use of large storage tanks.
- Aluminum salts are the principal substances used to detoxicate food and water. They are unpalatable and relatively ineffective, reducing the accumulation of fluoride in bone by only 20% to 30%, and are thus referred to as "alleviators." Extensive field trials of aluminum as an alleviator have not justified its use as a practicable control measure in average circumstances.

Congenital Defects of Muscles, Bones, and Joints

Defects of the musculoskeletal system are among the most common congenital abnormalities in farm animals. In cattle, 476 such defects are listed. Many of them are lethal, and most of the remainder are life-threatening because of interference with grazing or the prehension of food. Many of them occur in combinations, and thus single defects are uncommon. For example, most axial skeletal defects and cleft palates occur in calves that already have arthrogryposis.

Because of the very large volume of literature involved it is not possible to deal with all the recorded defects here, and the text is limited to those defects that are thought to be of general importance. Whether or not they are inherited or have an environmental cause is often not known, and thus an etiologic classification is not very effective—nor is an anatomic or pathologic classification, so we are reduced to a classification based on abnormal function.

WEAKNESS OF SKELETAL MUSCLES

A number of sporadic myopathies are recorded in cattle and sheep. Causes have not been determined in most of them. Splayleg in pigs has been well described and occurs in most countries.

CONGENITAL HYPERPLASIA OF MYOFIBER

There is only one identified state of congenital hyperplasia; it is the inherited form of doppelender, double muscling, or culard of cattle, described under "Myofiber hyperplasia." The principal cause of the bulging muscles is an increase in the number of myofibers in the muscle.

OBVIOUS ABSENCE OR DEFORMITY OF SPECIFIC PARTS OF THE MUSCULOSKELETAL SYSTEM

Some of these defects are inherited and include the following:
- Achondroplastic dwarfism, inherited miniature calves, bulldog calves
- Umbilical or scrotal hernia, cryptorchidism
- Tail deformity (kinking), taillessness
- Reduced phalanges, including hemimelia (individual bones missing), amputates (entire limbs missing), vestigial limbs (all parts present but limbs miniaturized)—amputates in outbreak form are recorded in cattle and produced experimentally by irradiation injury of sows, cows, and ewes during early pregnancy
- Inherited arachnomyelia (spidery limbs) of calves
- Congenital thickleg of pigs, osteopetrosis of calves, muscular hypertrophy of calves
- Cyclopean deformity—the inherited form is associated with prolonged gestation. The toxic form associated with ingestion of *Veratrum californicum*.
- Displaced molar teeth, mandibular prognathism—agnathia in lambs takes a variety of forms, including complete absence of the lower jaw and tongue.

FIXATION OF JOINTS

Because arthrogryposis, which has been used to convey the description of joint fixation, strictly means fixation in flexion, the term **congenital articular rigidity** has been introduced. The immobilization of the joint may be attributable to lack of extensibility of muscles, tendons, ligaments, or other tissues around the joint; to deformity of articular surfaces; or, theoretically, to fusion between the bones at the articular surface. Muscle contracture, which is the principal cause of joint fixation, has been produced experimentally and occurs naturally as a result of primary muscle atrophy or of atrophy resulting from denervation. Articular surface deformity is usually associated with gross deformity of the limb bones and is usually identifiable, but the principal problem in the diagnosis of congenital articular rigidity is to determine what the pathogenesis might have been and, beyond that, what was the specific cause.

Congenital fixation of joints can be caused by some well-known entities, as follows.

Cattle
- Hereditary congenital articular rigidity (HCAR) with cleft palate in Charolais
- HCAR with normal palates in Friesians, Danish Reds, Swedish, Shorthorns
- Inherited arthrogryposis
- Inherited multiple-tendon contracture
- Sporadic cases of congenital joint deformity as described for foals
- Inherited multiple ankylosis of Holstein–Friesian cattle
- Environmentally induced congenital articular rigidity caused by the following:
  - Intrauterine infection with Akabane virus
  - Ingestion of lupins
  - Ingestion of *Astragalus* and *Oxytropis* spp. (locoweeds)
  - Sorghum, Johnson grass, Sudan grass
  - Dietary deficiency of manganese

Sheep and Goats
- Inherited congenital articular rigidity in Merino sheep
- Infection with Akabane virus
- Infection with Schmallenberg virus
- Poisonous plants as for cattle
- Poisoning with parbendazole and cambendazole.

Foals
- **"Contracted" foals** having congenital axial and appendicular contractures of joints have been report in the United States; the cause unknown, but it is not thought to be inherited. Deformities include torticollis, scoliosis, and thinning of ventral abdominal wall, sometimes accompanied by eventration, asymmetry of the skull, and flexion contracture in distal limb joints.
- **Congenital articular rigidity** also occurs in foals from mares fed on hybrid Sudan grass pastures.

- **Sporadic cases of congenital joint deformity** occur in foals and calves. They are manifested usually by excessive flexion of the metacarpophalangeal joints, causing affected animals to "knuckle" at the fetlocks and sometimes walk on the anterior aspect of the pastern. A similar defect occurs in the hindlegs. Many mild cases recover spontaneously, but surgical treatment may be required in badly affected animals. The cause in these sporadic cases in unknown, and necropsy examination fails to reveal lesions other than excessive flexion of the joints caused by shortening of the flexor tendons. Rarely such fixations are associated with spina bifida or absence of ventral horn cells of the spinal cord.

Piglets

- Inherited congenital articular rigidity
- Nutritional deficiency of vitamin A
- Poisonous plants, hemlock (*Conium maculatum*), *Prunus serotina,* Jimson weed (*Datura stramonium*), tobacco wastes

CONGENITAL ARTHROGRYPOSIS AND HYDRANENCEPHALY, AKABANE DISEASE, CACHE VALLEY VIRUS DISEASE, SCHMALLENBERG VIRUS

SYNOPSIS

Etiology Akabane virus in the Simbu serogroup of *Orthobunyavirus,* Cache Valley virus in the Bunyamwera serogroup of *Orthobunyavirus,* Schmallenberg virus in the Simbu serogroup of *Orthobunyavirus.*

Epidemiology Transmission by hematophagous insects. Outbreaks occur when cattle or sheep are infected in early pregnancy.

Clinical findings Teratogenic pathogen that results in abortions, stillbirths, and birth of calves (Akabane virus, Schmallenberg virus) and lambs or kids (Cache Valley virus, Schmallenberg virus) with skeletal deformities and neurologic disorders (arthrogryposis-hydranencephaly syndrome).

Necropsy findings Necrotizing nonsuppurative encephalomyelitis and polymyositis. Arthrogryposis and hydranencephaly.

Control Vaccination or exposure of breeding females to natural infection before pregnancy.

ETIOLOGY

Akabane virus and Cache Valley viruses are both members of the genus *Orthobunyavirus* in the family Bunyaviridae, with Akabane virus and Schmallenberg virus being members of the Simbu serogroup of the genus *Orthobunyavirus* and Cache Valley virus being a member of the Bunyamwera serogroup of the genus *Orthobunyavirus.* There are a large number of members of the *Orthobunyavirus* genus, and several can produce clinically inapparent infections in ruminants, but Akabane virus and Cache Valley virus produce fetal disease when they infect the dam in early pregnancy. There are subtypes of these viruses.

Other *Bunyavirus* that have been associated with natural or experimentally produced fetal disease in ruminants include the following:

- Simbu serogroup—Aino and Peaton viruses
- Bunyamwera serogroup—Main Drain viruses
- California serogroup—LaCrosse and San Angelo viruses

Antibodies to the related, but as far as is known nonpathogenic, Australian Douglas virus and Tinaroo virus have been detected in cattle, sheep, goat, buffalo and deer.

EPIDEMIOLOGY

Occurrence

Akabane

Serologic studies suggest that infection occurs in cattle, sheep, goats, horses, donkeys, camels, pigs, and buffaloes, but disease occurs only in calves, lambs, and goat kids.

The disease is most common in calves and has been recorded as the cause of epizootics of abortion, stillbirths, and congenital malformation in calves, with high attack rates in affected herds in two north–south geographic bands. The first band extends from Japan/Korea through Taiwan to Australia.[1,2] The second band extends from the Middle East to South Africa. Congenital disease in lambs is less common but is recorded in Israel and Australia. The virus has also been isolated from insect vectors in Africa and is the probable cause of the "rigid lamb syndrome" in Zimbabwe.

Serologic surveys suggest widespread distribution of the virus in the Middle East, Asia and South East Asia, and in parts of Africa. Whereas infection in adult cattle is common in endemic areas, reports of clinical disease are rare, but neurologic disease associated with infection in cattle 2 to 7 years of age has been observed. Akabane viruses have been divided genetically into four groups (I to IV), with group I being further divided into two subgroups (Ia, Ib).[1,3,4] Genogroup Ia strains are found primarily in Japan and Taiwan and appear to have a stronger neurovirulence than genogroup II strains that have been isolated from Japan and Korea. Genogroup Ib strains have been isolated in Japan and Israel. Genogroup III strains have been isolated from Queensland in Australia, whereas a strain isolated in Kenya represents genogroup IV.[1,3,4]

Cache Valley

There is serologic evidence that infection occurs in sheep, goats, horses, cattle, pigs, and several wildlife species but clinical disease is recorded only in sheep. The disease in sheep is recorded as an occasional epizootic in flocks in North America. Cache Valley virus is one of the more common *Orthobunyaviruses* in North America and has been isolated from mosquito pools collected in 22 states and several provinces in Canada and Mexico and also in Central and South America. Cache Valley is an agricultural valley in northern Utah and southeast Idaho in the United States.

Schmallenberg

A new disease in dairy cattle was identified in autumn 2011 in northwest Germany and the Netherlands. Viral genome sequences were identified in pooled blood from three affected sick dairy cows from a farm near Schmallenberg in northwest Germany, hence the name Schmallenberg virus (SBV). Serologic studies indicate that SBV was not present in domestic ruminants in northern Europe before 2011, and that the epizootics constituted introduction of the new virus into a susceptible population. Genomic studies indicate that SBV belongs to the species Sathuperi and may represent the ancestor of the reassortant Shamonda virus.

Antibodies against SBV have been identified in roe deer, red deer, European fallow deer, mouflons, bison, New World camelids, and wild boar in northern and west-central Europe.[5]

Aino and Shamonda

Aino virus is present and thought to be a cause of disease in Australia, Japan, and Israel. Serologic studies in Australia show a similar distribution in cattle to Akabane but at a lower prevalence, and clinical disease is much less common than with Akabane virus. Aino virus and Shamonda virus can induce congenital malformations in sheep and goats.

Source of Infection

The viruses are maintained through a cycle involving vectors, in which there is probably transovarial transmission, and a susceptible vertebrate population. Replication occurs in both vertebrate and insect populations.

Akabane

Viremia in cattle is short-lived, lasting 1 to 9 days, and long-term carriers are not thought to occur. Herbivores appear essential to the vector–virus–host cycle, and there is serologic evidence of infection in cattle, sheep, goats, camels, horses, and buffaloes. In endemic areas, breeding females are infected before their first pregnancy, and therefore clinical signs are not observed in their offspring. Clinical signs occur at the north and south end of the two bands, where weather

effects determine expansion of vectors out of the endemic region. This accounts for intermittent "outbreaks" of congenitally affected calves in southern Australia, Japan, and Korea.

In Australia, transmission is by the bites of midges *Culicoides brevitarsis* and *C. nebeculosus.* The virus has been isolated from *C. brevitarsis,* and this is probably the major vector; serologic data in Australia show that most identified infections are within the known habitat of *C. brevitarsis.* Vertical infection occurs, but introduction of the virus into the bovine uterus in semen causes no developmental defects. Ruminants do not become persistently infected.

The vectors for Akabane disease in Japan and Korea are *C. brevitarsis, Culicoides oxystoma, Aedes vexans,* and *Culex tritaeniorhynchus.*

Cache Valley

The Cache Valley virus has been isolated predominantly from mosquitoes. The primary amplifying vertebrate hosts are unknown, but white-tailed deer are suspected to play a role as a disease reservoir.[6]

Schmallenberg

Biting midges, including *C. dewulfi, C. chiopterus,* and *C. obsoletus* complex are thought to be important vectors for SBV transmission in Belgium and Denmark and presumably contiguous countries.

Aino

Aino virus has been isolated from mosquitoes and midges, including *C. brevitarsis.* Serologic studies show antibody in cattle, sheep, goats, and buffalo but not camels, dogs, or horses.

Host and Environmental Risk Factors

The seasonal and geographic pattern of epizootics of abortions and premature births are determined by the distribution of vectors and the availability of susceptible ruminant populations in early pregnancy. Global warming is thought to be contributing to extension of vectors into geographic regions north and south of the typical infection belts and therefore disease epidemics.[1,3,7]

Akabane

In the north of Australia, *C. brevitarsis* is active throughout the year, cattle are infected with Akabane virus before their first pregnancy, and disease does not occur. Epizootics occur in southern Australia when *C. brevitarsis* extends its range of distribution, probably by wind-borne spread from the north, to infect immunologically naive herds. Abortions and premature births commence in the autumn, with clinical cases of arthrogryposis and hydranencephaly occurring in midwinter.

Wind-borne introduction of *Culicoides* spp. is also postulated as the means of introduction of infection in Israel. The movement of immunologically naive pregnant cattle into an enzootic area can be the result in severe outbreaks in those herds.

The disease is likely to disappear for intervals of 5 to 10 years, until there is combination of a susceptible population and a heavy vector population. Occurrences of the disease are also dependent on the presence of susceptible early-pregnant females at the time that the vectors are plentiful. These conditions are provided by a series of years of drought in an enzootic area, so that there are no insect vectors, no infection, and no immunization activity of prepubescent females, followed by a wet season when the vectors are plentiful.

Cache Valley

Outbreaks occur after a long period of drought and winter frosts reducing the population of mosquito vectors and resulting in populations of seronegative ewes. Mating in the summer appears to be a major risk factor, allowing sheep to be in the susceptible stage of pregnancy during the vector season. Many outbreaks are in areas that interface between suburban and rural environments.

Schmallenberg

Retrospective analysis of stored serum samples indicates that SBV was introduced into Europe in spring or early summer of 2011, probably first along the border of the Netherlands with northwest Germany. It is interesting to note that SBV emerged in the same region of Europe in 2011 as did bluetongue strain 8 in 2006.

Experimental Reproduction

Disease has been reproduced by inoculation into early-pregnant cattle, sheep, and goats.

Zoonotic Implications

Bunyavirus infections occur in humans from bites from infected insect vectors.

PATHOGENESIS

Akabane

Viremia occurs in the dam for 2 to 4 days, with an antibody peak 4 to 5 days after the viremia and a subsequent secondary rise. The dam is unaffected, but there is a focal viral persistence in cotyledons and subsequent viremia in the fetus.

Inflammatory and degenerative lesions occur in the central nervous system, but tissue tropism and damage are determined by the age of the fetus and its ability to mount an immune response. Three forms, or principal manifestations, of the disease in an affected herd are described. The first is arthrogryposis occurring in calves infected at an older age than others (fetus infected at 105 to 174 days of pregnancy). The second is arthrogryposis accompanied by hydranencephaly. The third is hydranencephaly only (infected between days 76 and 104 of pregnancy).

With arthrogryposis, there is almost complete absence of ventral horn cells in the spinal cord and an accompanying neurotropic failure of muscle development. Contracture of the joints results. The hydranencephaly is manifested by a partial or complete failure of development of the cerebral cortex. The brainstem and cerebellum are usually normal.

Several other manifestations have been described. They include prearthrogryposis groups of calves with incoordination and a mild to moderate nonsuppurative encephalitis, along with other calves with flaccid paralysis and active secondary demyelination in motor areas of the spinal cord. Some calves are unable to stand and have thickened dorsal cranial bones, hydranencephaly involving anterior and midbrainstem, and a diminutive cerebellum. The infection with Akabane virus is also credited with causing abortion, stillbirth, and premature birth. There are reports from Japan and South Korea where encephalomyelitis as a result of Akabane virus is thought to have been acquired after birth,[2,8] and experimental inoculation of young calves with the Iriki variant of Akabane virus has induced encephalitis.

Lesions produced in **lambs** by experimental inoculation of the ewes during early pregnancy (days 32 to 36) include skeletal muscle atrophy and degeneration, and inflammatory and degenerative lesions in the cerebrum; the lesions in the central nervous system vary from porencephaly to hydranencephaly. There are also brachygnathism, scoliosis, hypoplasia of the lungs, agenesis or hypoplasia of the spinal cord, and arthrogryposis. Lesions are also present in fetuses of ewes inoculated between 29 and 45 days of gestation.

Cache Valley

Ovine fetuses are susceptible to the teratogenic effects between 28 and 48 days of gestation.[9] Destructive lesions occur in the central nervous system, but infection of fetal membranes with a reduction in the volume of amniotic fluid and constriction by membranes around the fetus are thought to contribute to the occurrence of arthrogryposis.

Schmallenberg

The acute phase of infection in adult ruminants produces a viremia of 5 to 6 days in duration.[10] In utero infection of the lamb appears to be determined by the absence or presence of a functional blood–brain barrier, explaining the window for experiment infection of 28 to 50 days (placentomes are initially present on day 28; the blood–brain barrier becomes functional on day 50 of gestation).

Arthrogryposis is secondary to transplacental infection resulting in abnormal development of motor neurons of the ventral horn

of the fetal spinal cord. This results in hypoplasia of the limb musculature, neurogenic muscle atrophy, and subsequent fixation (ankyloses) of the joints.

CLINICAL FINDINGS

Akabane

Infection in adult cattle is most commonly clinically inapparent, unless there is dystocia, but neurologic disease manifests with hypersensitivity, tremor, and ataxia has been recorded. In calves, the two syndromes, arthrogryposis and hydranencephaly, occur separately—arthrogryposis in the early stages of the outbreak and hydranencephaly at the end. Cases of calves with both defects occur in the middle of the outbreak. In some outbreaks, only one of the manifestations of the disease is seen.

Calves with arthrogryposis almost always are the subjects of difficult birth requiring physical assistance. They are small and significantly underweight, but they are fully mature in terms of teeth eruption and hair coat and hoof development. They are unable to rise, stand, or walk. One or more limbs is fixed at the joints; there is a congenital articular rigidity. The limb is usually fixed in flexion, but it may be in extension. The joint becomes freely movable if the tendons around it are severed; that is, there is no abnormality of the articular surface. The muscles of affected limbs are severely wasted. Kyphosis or scoliosis are common.

Calves with hydranencephaly have no difficulty rising and walking. The major defects are a lack of intelligence and blindness. They will suck if put onto the teat, but if this is not done, they stand and vocalize and have no apparent dam-seeking reflex. A few calves have microencephaly and are more severely affected. They are dummies, very uncoordinated in gait, and unable to stand properly, and they move erratically when stimulated. These cases appear at the very end of the outbreak.

In addition to the skeletal and neurologic diseases, cases of abortion, stillbirth, and premature birth are also regarded as being associated with Akabane virus infection in cows. They are usually recorded at the beginning of the outbreak before the neurologic defects occur.

Cache Valley

Affected flocks have a higher rate of stillbirth and mummified fetuses. Congenital malformations in liveborn lambs include arthrogryposis of one or more limbs, scoliosis, and torticollis, and neurologic signs are similar to those seen in calves with Akabane disease.

Schmallenberg

Adult cattle exhibit clinical signs of decreased milk production and fever, and some have diarrhea, with the duration of illness ranging from 1 to 6 days. Clinical disease has not been reported in sheep or goats.

Embryonic deaths, abortions, stillbirths, and arthrogryposis–hydranencephalopathy syndrome in newborn lambs and kids are the most common clinical abnormalities observed following infection of pregnant ewes and does. These abnormalities in lambs and kids are almost identical to those produced by Akabane virus in calves. Teratogenic effects were also observed in cattle, but at a much lower rate than in sheep and goats. A presumptive diagnosis of SBV teratogenicity is made in lambs, kids, and calves in Europe if stillbirth, premature or mummified fetuses, or abnormal neonates present with two or more of the following abnormalities: arthrogryposis, hydranencephaly, torticollis, scoliosis, kyphosis, brachygnathia inferior, muscle atrophy, joint malformations, ataxia, paresis, behavioral abnormalities, or blindness.

CLINICAL PATHOLOGY

The presence of specific antibody in fetal sera or the precolostral sera of neonates is diagnostic, but its absence does not exclude the diagnosis if infection precedes the development of immunologic competence. Precolostral sera from several animals should be tested, and most cases are positive at high titer. A rising titer with paired samples from the dam, or a high titer in the serum of surviving neonates, is suggestive of recent infection but not confirmatory for disease. Serologic tests include microneutralization, hemagglutination inhibition, agar gel immunodiffusion (AGID), and an ELISA test.

Virus can be detected using real-time RT-PCR and culture in specific cell lines. RT-qPCR testing of blood is of reduced value because the period of viremia is short, but brainstem material provides the best tissue for testing teratogenic fetuses.[11] A humoral immune response mounted by the fetus can clear SBV from the fetus during gestation; consequently, SBV antibody testing of fetal heart blood or dam blood should be combined with RT-PCR testing of brainstem tissue for confirmation of SBV infection.[11,12]

NECROPSY FINDINGS

The primary lesions with Akabane, Cache Valley, and Schmallenberg infections in the fetus are a **necrotizing nonsuppurative encephalomyelitis and polymyositis**.

In calves and lambs with arthrogryposis, there is severe muscle atrophy, fixation of joints by tendon contracture, and normal articular surfaces. The joints are easily released by cutting the surrounding tendons. Histologically, there may be almost complete absence of ventral horn cells in the spinal cord. This lesion may be localized to one segment of the cord, and viral antigen may be demonstrated via immunohistochemistry.

In calves and lambs with hydranencephaly, the cerebral hemispheres are completely absent, and the vacant space is filled with fluid enclosed by the normal meninges. In a few cases the lesions will be limited to porencephaly. In most, the brainstem and cerebellum lack cavitations, but diminution of their size may be recorded.

Samples for Confirmation of Diagnosis

- **Virology**—2 mL fetal heart blood and maternal serum for serology performed using ELISA[13]
- **Histology**—brain, spinal cord, muscle (LM, IHC)

DIFFERENTIAL DIAGNOSIS

Akabane virus disease in calves, Cache Valley virus disease in lambs and kids, and Schmallenberg virus disease in calves, lambs, and kids, because they are manifest epidemiologically and are well-defined and easily recognizable entities. Differentials include the following:

- Lupine-induced arthrogryposis in calves
- Manganese deficiency in calves
- Heritable forms of arthrogryposis and/or micrencephaly
- Fetal infection with bluetongue virus, Rift Valley fever virus, or pestivirus

Cattle in Japan may also produce hydranencephalic calves, which are recumbent, opisthotonic, and unable to suckle at birth, when infected during pregnancy by the Chuzan virus. The virus, a member of the Polyam subgroup of orbiviruses, is transmitted by *Culicoides oxystoma*.

In Africa, infection with flaviviruses, including West Nile, Banzi, and AR5189, also causes abortion, stillbirth, and congenital brain malformations.

TREATMENT AND CONTROL

No treatment is contemplated because affected calves, lambs, and kids are not viable and cannot be humanely kept alive.

Vector control is not possible with current knowledge, and vaccination provides the most effective method of control.

Killed vaccines for Akabane virus have proved very effective against natural exposure and are available in Japan and Australia. Japanese data suggest vaccines should include genogroup Ia strains because these strains have a stronger neurovirulence,[14] and vaccine failures has been attributed to antigenic variation among Akabane virus strains.[15] Vaccination requires two inoculations before pregnancy and an annual booster. Maternally derived antibodies against Akabane virus appear to last 4 to 5 months in colostrum-fed calves, and they last slightly longer in beef calves than dairy calves,[16] possibly as a result of a higher colostral titer in beef calf colostrum as a result of smaller colostral volumes. The economics of annual vaccination against Akabane virus is dictated by the risk of disease in regions subject to periodic outbreaks of disease.

Vaccines are not commercially available for Cache Valley virus.

Killed vaccines are commercially available for Schmallenberg virus in the United Kingdom and France, but they have not been widely used. Vaccination of calves with a commercially available Japanese vaccine against Akabane virus, Aino virus, and Chuzan virus did not provide cross-protection against SBV.[17] Preliminary data on a small number of vaccinated sheep suggest that protection against detectable viremia is provided after one injection of a SBV vaccine.[18] Early lambing flocks and pedigree flocks have been more likely to employ vaccination in the United Kingdom.[19] The seroprevalence in ranges widely from herd to herd, and determination of seroprevalence within a herd could be used to guide the decision regarding the need to vaccinate. Individual blood testing is not practical in this regard, and for cattle, determining the titer of a bulk-tank milk sample does not provide a sufficiently accurate test of herd seroprevalence.[20] Maternally derived antibodies against SBV last at least 2 years in adult cattle after natural infection and 5 months in their colostrum-fed calves;[21] on this basis, an initial vaccination series could start at 6 months of age if indicated.

Spread of SBV infection from farm to farm appears to be primarily a result of vector movements on the wind, and thus application of animal movement restrictions, including a total animal movement ban, is likely to have little impact on farm-to-farm transmission of infection.[22] In the Schmallenberg virus outbreak in Europe, cattle that had access to pasture for grazing in 2011 were 2.6 times more likely to delivered malformed calves than cattle that were housed inside.[23] Specific control measures may not be economically indicated in cattle because the decrease in milk production is mild and transient, non-SBV-associated mortality in adult cattle has been reported, and the incidence of fetal abnormalities is low.[24] Housing sheep to minimize contact with midges has been shown to decrease seroprevalence within a flock. The seroprevalence in the endemic area is lower in goat herds than sheep flocks; this has been attributed to differences in housing, with goats being more likely to be kept indoors with decreased exposure to midges. The use of insecticides or repellants on pregnant ewes and does is not likely to be efficacious, but experimental data are lacking. Changing the timing of lambing and kidding so that the second month of gestation occurs during cold ambient temperatures when midges are not active will theoretically decrease the incidence of teratogenic effects resulting from SBV. This recommendation has been supported by epidemiologically studies indicating lower odds of SBV-induced fetal malformations in sheep flocks that started breeding in October versus August.[25]

A number of European countries, including Germany, France, and the Netherlands, made it mandatory to report the birth of malformed lambs, kids, and calves on farms seropositive for SBV. The numbers of abnormal lambs, kids, and calves born decreased in 2013 and 2014, most likely because of the development of herd immunity and high seroprevalence. Reemergence and spread of SBV within Europe is considered likely.

HYPERMOBILITY OF JOINTS

- This is recorded as an inherited defect in Jersey cattle. Affected animals are unable to rise or stand because of the lack of fixation of limb joints. The joints and limbs are usually all affected simultaneously and are so flexible that the limbs can be tied in knots. Causes include the following:
  - Inherited joint hypermobility in Jersey cattle
  - Heredity in Holstein–Friesian cattle, which also have pink teeth as a result of absence of enamel
  - In inherited congenital defects of collagen formation, including dermatosparaxis, hyperelastosis cutis, and Ehlers–Danlos syndrome in cattle
  - Sporadically in newborn animals

Inherited Diseases of Muscles

GLYCOGEN STORAGE DISEASES

A number of glycogen storage diseases have been detected in large animal species. The glycogen storage diseases discussed here are those that result in accumulation of abnormal concentrations of glycogen in muscle, either within lysosomes or within myocytes. These diseases include polysaccharide storage myopathy (glycogen storage disease type I) in various breeds of horses and as a result of a mutation in the gene encoding the enzyme glycogen synthase (addressed in detail later in the discussion of other inherited myopathies of the horse), glucosidase deficiency (glycogen storage disease type II) in sheep and cattle, and glycogen phosphorylase deficiency (glycogen storage disease type V) in sheep and cattle. Glycogen storage disease types II and V are discussed in the following sections.

GENERALIZED GLYCOGENOSIS (GLYCOGEN STORAGE DISEASE TYPE II)

Generalized glycogenosis is a glycogen storage disease. Glycogen storage disease type II (GSD II; generalized glycogenosis), which resembles Pompe's disease in humans, occurs in Corriedale sheep, Shorthorn, and Brahman beef cattle, and it is caused by mutant alleles of the glucosidase alpha acid (GAA), creating a loss of function. Glucosidase is a lysosomal enzyme catabolizing glycogen to glucose. The heredity is autosomal recessive. In Brahman cattle, the glycogenosis is caused by two mutations; the mutation in exon 7 is a dinucleotide deletion (c.1057_1058delTA) causing frameshift, and the mutation in exon 13 is the cytosine-to-thymine transition (c.1783C>T) coding for stop codons in exons 8 and 13, respectively.[1] The mutation in exon 9 (c.1351C>T) reduces glucosidase activity, and MspI polymorphism is a silent mutation in exon 16 (c.2223G>A). In Shorthorn cattle, glycogenosis type II is caused by a single mutation that is a deletion (c.2454_2455delCA). The genetic abnormality was not detected in a survey of Charolais, Czech Spotted (Czech Simmental), Belgian Blue, Limousine, Blonde d'Aquitaine, Aberdeen Angus, and Beef Simmental sires reared in the Czech Republic, although the number of animals tested was small for some breeds (Czech Simmental, 62; Charolais, 34; Belgian Blue, 6; Limousine, 4; Blonde d'Aquitaine, 4; Beef Simmental, 2; and Aberdeen Angus, 1).[1]

In Brahman cattle, there is a common mutation affecting many Australian Brahmans and a less common one affecting descendants of one imported bull. In addition, a third mutation is associated with significantly reduced α-glucosidase activity, but not sufficient to cause clinical disease in the homozygous state.

Clinical signs include poor growth, muscle weakness, incoordination of gait, and difficulty in rising. The animals become permanently recumbent. The disease is identified as a lysosomal storage disease, with lesions present in skeletal and cardiac muscle and central nervous tissue. During the course of the disease there is progressive muscular damage and acute degeneration of muscle fibers in the terminal stage. Affected Brahman calves die at 8 to 9 months of age and British breed cattle at over 1 year. Only histopathologic lesions are evident and include extensive vacuolation and accumulations of granular material in affected tissues. Among the biochemical lesions are greatly diminished α-glucosidase activity in liver and muscle and a correspondingly high level of glycogen. Animals in affected herds are divisible into normal heterozygotes and homozygotes on the basis of α-1,4-glucosidase activity in lymphocytes or in muscle, especially the semitendinosus muscle.

Genotyping methods using hair root and blood samples to test Shorthorn cattle for generalized glycogenosis are available, and PCR assays have been developed to genotype Brahman cattle for loss-of-function alleles within the acidic α-glucosidase gene.

GLYCOGEN STORAGE DISEASE TYPE V (MUSCLE GLYCOGEN PHOSPHORYLASE DEFICIENCY)

Glycogen storage disease Type V (akin to McArdle's disease in humans) has been recorded in Charolais cattle in North America and Merino sheep in Australia.[1] Type V is inherited as an autosomal-recessive trait, and the mutation in sheep has been identified as an adenine-for-guanine substitution at the intron 19 3′ splice site, with subsequent lack of myophosphorylase activity.[2] There is mildly elevated muscle glycogen concentration and elevated serum creatine and aspartate aminotransferase activity. Severely affected animals can develop rhabdomyolysis, which may be accompanied by myoglobinuria.

In Charolais cattle, glycogen storage disease type V is usually seen in calves at several weeks or months of age and is associated with exercise intolerance or reduced capacity for exercise. Calves lag behind their dam or herd and may become temporarily recumbent for several minutes; with continuous exercise there are further periods of collapse and recumbency, which can become prolonged. Not all homozygous animals are clinically affected if they are allowed to "pace their exercise," and some animals have been known to breed despite muscle weakness.

The disease in Merino sheep is associated with exercise intolerance and increased concentrations of glycogen in muscle.[1,2]

A PCR restriction fragment length polymorphism test has been used to identify heterozygous individuals in a Charolais herd in New Zealand that were otherwise normal. Using a similar test, a Blonde d'Aquitaine crossbred calf with a double-muscled phenotype and suspected of having myophosphorylase deficiency based on clinical findings of brown-colored transparent urine after exercise, pain, and elevated creatine kinase was considered negative. The gene maps to chromosome 29.[3]

INHERITED DIAPHRAGMATIC MUSCLE DYSTROPHY

Inherited diaphragmatic muscle dystrophy is an inherited defect in diaphragmatic muscle of Meuse–Rhine–Yssel and Holstein–Friesian cattle appearing in adults and characterized by anorexia, decreased rumination, and eructation leading to recurrent bloat, dyspnea, abdominal respiration, nostril dilatation, and death from asphyxia after a course of several weeks. The disease is a result of a mutation involving one of the genes for heat shock protein 70 (HSP70), resulting in markedly reduced HSP70 concentrations in muscle of affected animals.[1] Loss of HSP70 function causes accumulation of glycogen phosphorylase enzyme protein in muscle. Necropsy lesions comprise degenerative changes in diaphragmatic and thoracic muscles.

CONGENITAL MYASTHENIA GRAVIS

Congenital myasthenic syndrome occurs in Brahman cattle in South Africa and is reported in a Hereford heifer in the United States. Affected Brahman calves develop progressive muscular weakness, beginning at birth and up to 3 to 4 weeks of age. Within 1 week they are unable to stand without assistance. Some calves are able to stand and walk for 30 to 45 minutes before collapsing, but they are still able to suck their dams. The calves remain alert and continue sucking but may collapse after 20 to 60 seconds. The weakness becomes progressively worse, and affected calves are usually euthanized. Hematology and serum biochemistry are normal, and muscle biopsies do not reveal any abnormalities.

The disease was traced to two founder animals as the most likely original carriers. Pedigree analysis revealed no ancestors common to all known carriers, but rather that the mutation had been introduced at least twice into the South African Brahman population, probably via animals imported from the United States.[1]

The underlying defect is a homozygous 20-base-pair (bp) deletion in the gene, muscular acetylcholine receptor (bov*CHRNE*), coding for the subunit of the nAChR at the neuromuscular junction. A PCR-based DNA test, using blood or semen, has been developed and validated. The test makes it possible to differentiate rapidly and accurately between homozygous wild-type, heterozygous, and homozygous affected animals. Overall prevalence of carriers among 1453 animals tested in South Africa was 0.97% (0.50% to 1.68%, 95% confidence interval). Heterozygosity for the CHRNE 470del20 mutation is associated with a 13.3-kg increase in adjusted 600-day body weight, providing evidence of a selective advantage for carrier animals and an explanation of the relatively high prevalence of the disease.[1]

The disease in a Hereford heifer was characterized as recurrent recumbency and upper eyelid ptosis. Both recumbency and ptosis resolved within 1 minute of IV administration of edrophonium (0.1 mg/kg) and persisted for up to 48 hours.[2] The heifer was first examined at 7 months of age and was slaughtered at 11 months of age.

BOVINE FAMILIAL DEGENERATIVE NEUROMUSCULAR DISEASE

Bovine familial degenerative neuromuscular disease has been reported as occurring in Gelbveih cattle in several separate beef herds in the United States. Affected animals are 4 to 20 months of age, and the case-fatality rate is 100%. Clinical findings include ataxia, weakness, and terminal recumbency. Gross and histologic muscle lesions were indicative of nutritional muscular dystrophy with no myocardial lesions. Acute to chronic lesions in most large skeletal muscle groups consist of degeneration, necrosis, regeneration, fibrosis, and atrophy. Fibrinoid necrosis of arterioles is a common feature in multiple tissues. Lesions in the spinal cord white matter and peripheral nerves consisted of degeneration of the dorsal columns and axons, respectively. Chronic

interstitial nephritis with fibrosis, hyaline droplet change, and tubular epithelial vacuolar change were most severe in older calves. Vitamin E levels were abnormally low in most affected calves. Pedigree analysis found a common ancestry for all but one of the affected calves. It is hypothesized that a hereditary metabolic defect, possibly involving antioxidant metabolism, may be the causative factor.

INHERITED UMBILICAL HERNIA

Umbilical hernias in cattle have been considered to be inherited defects for many years, but the evidence is uncertain.

Umbilical hernias are commonly identified in dairy heifers. In 18 commercial dairy herds in New York, 15% of heifer calves had umbilical hernias during the first 3 months of age. The economic costs of umbilical hernias include the cost of medical and surgical treatment and the loss in value for breeding animals.

It has been generally accepted that umbilical hernias may be inherited in a dominant or recessive mode. Some studies have found the risk of hernias was higher in some breeds, with the incidence being much higher in Holstein cattle than other breeds such as Angus, Ayrshire, Brown Swiss, Charolais, Guernsey, Hereford, Jersey, and Shorthorn. However, aspects other than genetic factors may be important. For example, many veterinarians have observed that umbilical infections commonly lead to umbilical hernia by slowing closure of the umbilicus. It is unlikely that the responsible genes are sex-linked, in spite of the apparent greater incidence in females. Umbilical hernias in Holstein–Friesian cattle can also be conditioned by a dominant character with incomplete penetrance or be caused by environmental factors. In a case-control study to determine risk factors associated with identification of an umbilical hernia during the first 2 months after birth in Holstein heifers, the sire and umbilical infection were associated with risk of a hernia. Heifers born to sires with = 3 progeny with an umbilical hernia were 2.31 times as likely to develop a hernia as were heifers born to sires with = 2 progeny with an umbilical hernia. Heifers with umbilical infection were 5.65 times as likely to develop a hernia as were heifers without umbilical infection. Attributable proportion analysis found that the frequency of umbilical hernias in Holstein heifers with umbilical infection would have been reduced by 82% if umbilical infection had been prevented.

The risk factors for congenital umbilical hernias in German Fleckvieh calves offered for sale at livestock markets were examined. An umbilical hernia was defined as a palpable opening in the abdominal wall of the umbilical region greater than 1.5 cm, even if no hernia had developed. Inflammation, abscesses, or fistulae were excluded. Data from 53,105 calves were collected from 77 livestock markets over a 2-year period. The overall incidence of congenital hernia was 1.8%. The analyses found significant effects for sex of calf, birth type, age of calf at examination, market place and date, sire line, sire, and frequency of affected herdmate calves in male calves. The incidence was 2.2% in males and 1.5% in females. The calves varied from 3 to 8 weeks of age. The diameter of hernial openings was between 1.5 and 9 cm, with 47% of affected calves with a hernia measuring greater than 3 cm. A significantly higher incidence occurred in twin or triplet calves. Shorter gestation periods increased the risk of hernias linearly by a factor of 1.3% for 10 days. There were differences in the incidence of hernias according to sire lines, but the heritability estimates were low, varying from $h = 0.04$ (>100 progeny) or $h = 0.05$ (>25 or 50 progeny). However, analysis of the data found no evidence for a monogenic autosomal-recessive inheritance. The analyses indicated that the incidence of congenital umbilical hernia observed could not be explained by one autosomal-recessive gene locus; it seems much more likely that more than one gene locus is involved, or a mixed multifactorial monogenic mode of inheritance may be the underlying genetic mechanism. It is suggested that the incidence of congenital umbilical hernias could be reduced if all breeding bulls are examined as calves and a veterinary certificate confirms a closed umbilical ring.

Breeders should be aware of the implications of congenital hernias, and, thus, congenital hernia should get more attention in the selection process of young sires.

Breeding studies and genotyping using the Canadian Holstein bull Glenhapton Enhancer have provided evidence that Enhancer is the carrier of a major dominant or codominant gene with partial penetrance for umbilical hernia. Five sons of Enhancer produced progeny with greater than 10% frequency of umbilical hernia, whereas the progeny of three sons had less than 3% frequency umbilical hernia. Genotyping of grand-progeny found significant differences in paternal allele frequencies between the affected and unaffected progeny groups for a marker BMS1591 on bovine chromosome 8(BTA8). The umbilical hernia–associated paternal allele originated from Enhancer.

MYOFIBER HYPERPLASIA (DOUBLE MUSCLING, DOPPELENDER, CULARD)

EPIDEMIOLOGY

Myofiber hyperplasia is an inherited condition characterized by an increased bulk of skeletal muscles as a result of the presence of a greater-than-normal number of muscle fibers that occurs in Charolais, Belgian Blue (Fig. 15-15), Piedmont, and South Devon breeds. The condition is recorded only rarely in sheep (Texel breed).[1] Pietrain pigs (see following discussion) exhibit many of the characteristics of double-muscled cattle, including large muscle mass and susceptibility to stress.

The condition in Belgian Blue cattle is attributable to a mutation in the MSTN gene that regulates myostatin production.[1-3] Inhibition of myostatin, through a loss-of-function mutation, results in increases in muscle fiber number and muscle mass. The disease in Belgian Blue cattle, and presumably in other breeds of cattle and sheep,

Fig. 15-15 Myofiber hyperplasia in a Belgian Blue cow.

is transmitted as an autosomal-recessive characteristic. A similar mutation in Thoroughbred horses is associated with superior sprint (<1600 m) racing performance.[4,5] The mutation has been induced experimentally in Meishan pigs.[6]

The mutation of MSTN was "fixed" in the Belgian Blue breed in the 1990s as a result of strong selection pressure for the double-muscle phenotype.[2] Subsequent continued selection pressure has resulted in increases in frequency of other haplotypes favoring increased lean muscle mass, resulting in a polygenic basis for the current phenotype. Selection of the phenotype is currently limited because of the occurrence of crooked-tail syndrome (see section on Inherited Taillessness and Tail Deformity later in this chapter) in animals homozygous for the MRC2 gene, which encodes protein Endo180. Animals heterozygous for the MRC2 mutation do not have crooked-tail syndrome and have enhanced muscularity.[7]

CLINICAL FINDINGS

Severely affected cattle show a marked increase in muscle mass most readily observed in the hindquarters, loin, and shoulder; an increase in the muscle : bone ratio; and a decrease in body fat.[8] Affected calves demonstrate above-average weight gains during the first year of life if well fed and managed, although mature size is somewhat reduced. Well-marked grooves along the intramuscular septa in the hindquarters are a distinguishing feature, as is an apparent forward positioning of the tail head. Macroglossia, prognathism, and a tendency toward muscular dystrophy and rickets have been observed in affected calves. Electrocardiographic abnormalities have been reported. The condition often gives rise to dystocia and the need for frequent caesarian section to deliver viable calves.[9] There is also a very high incidence of Elso heel in affected cattle, and this interferes greatly with their economic value. Other associated defects are brachygnathia, deviation of the incisor arch, and, in Belgian Blue and White cattle, greater susceptibility than normal to laryngitis and bronchopneumonia.

CLINICAL PATHOLOGY

Blood lactate is increased, as is susceptibility to stress. These findings are interpreted as being indicators of cell-membrane fragility, which is also manifested by fragility of the erythrocytes.

NECROPSY FINDINGS

The skin is thinner than normal, and the muscle mass is characterized by a disproportionate number of glycolytic anaerobic fibers.

INHERITED SPLAYED DIGITS

Recorded only in Jersey cattle, this defect appears to be conditioned by an inherited gene, most likely a monogenic autosomal-recessive gene. Lameness becomes apparent at 2 to 4 months of age, with the toes becoming increasingly widely spread and the toes themselves misshapen. Walking and standing are painful, especially on the front feet, so that some animals graze and walk on their knees. Affected animals either lie down increasingly or stay standing for very long periods. The apparent abnormality is a defect of the muscles and ligaments holding the phalanges together.

INHERITED PROGRESSIVE MUSCULAR DYSTROPHY

Inherited progressive muscular dystrophy is a primary skeletal muscle disease of sheep with a strong probability of having a genetic mode of transmission. It is recorded in Merino flocks in Australia and is characterized by a gradually progressive failure to flex the joints of the hindlimbs commencing at 3 to 4 weeks of age. Eventually the limbs are rigid at all times, and running becomes impossible. The forelimbs and the head and neck are normal. Affected sheep are easily detected when they are 1 year old and will have mobility problems by the time they are 2 to 3 years old. At necropsy there are pale areas in skeletal muscle and sometimes the muscles of the diaphragm in those sheep that have a tendency to bloat. The histopathology and histochemistry of the muscle lesions are comparable with those of inherited muscle atrophies in humans.

PSEUDOMYOTONIA OF CATTLE, CONGENITAL MUSCULAR DYSTONIA-1

SYNOPSIS

Etiology Pseudomyotonia (PMT) and congenital muscular dystonia-1 (CMD1) are caused by dysfunctional sarcoplasmic reticulum Ca^{2+}-ATPase (SERCA1) that is caused by a mutation in the ATP2A1 gene that encodes SERCA1.

Epidemiology PMT is predominantly observed in Italian beef cattle breeds; CMD1 has only been reported in Belgian Blue cattle.

Clinical findings Increased resting muscle tone; exercise-induced, transient muscle stiffness that resolves within seconds to minutes and may result in adaptation of a sawhorse-type posture or flipping over. Congenital, nonprogressive. Animals with PMT can reach adult age; calves with CMD1 die in the first weeks of life.

Diagnostic confirmation Genome analysis to identify gene mutation.

Treatment None available.

Control Check parents of confirmed cases for presence of gene defect and exclude from future breeding. In population with high prevalence of gene defect, test breeding bulls for gene defect.

ETIOLOGY

Pseudomyotonia (PMT) of cattle is a congenital muscular condition similar to Brody's disease in humans that is clinically indistinguishable from myotonia.[1,2] Congenital muscular dystonia-1 (CMD1) is a condition thus far only reported in Belgian Blue calves that is clinically distinct from PMT.[3] The underlying cause for both conditions was determined to be a malfunction of the **sarcoplasmic reticulum Ca^{2+}-ATPase isoform 1 (SERCA1)** as a result of a **missense mutation in the ATP2A1 gene** that encodes SERCA1.[1,2] It is inherited in an autosomal-recessive manner.[4]

EPIDEMIOLOGY

Bovine congenital pseudomyotonia has been described in Italian Chianina and Romagnola cattle and as a single case in a Dutch Improved Red and White crossbreed calf.[1,5] Congenital muscular dystonia in contrast has only been described in Belgian Blue cattle.[3] Two distinct point mutations in the ATP2A1 gene have been identified, with one consistently occurring in Italian cattle breeds and one identified in Belgian Blue and in one Dutch Improved Red and White crossbreed calf.[4] Although the mutation described in Italian breeds has only be associated with PMT, the mutation observed in Belgian Blue calves, and thus generally associated with CMD1, was also found in the single animal, where it presented clinically as PMT.[1,5]

The incidence of CMD in Belgian Blue calves, which comprises CMD1 but also the clinically similar but etiologically different condition CMD2, has been given as 0.1% to 0.2%.[3] The prevalence of the PMT gene defect in the Italian Chianina sire population used for artificial insemination was 13.6% for the period between 2007 and 2011, and the prevalence in the male progeny selected for a performance testing program was 13.4%.[6]

PATHOGENESIS

PMT and CMD1 are both caused by a malfunction of the **sarcoplasmic reticulum Ca^{2+}-ATPase isoform 1 (SERCA1)**.[1,5] In normal skeletal muscle fibers, contraction

and relaxation are determined by Ca^{2+} interaction with contractile proteins. Ca^{2+} is normally stored in the lumen of the sarcoplasmic reticulum, and its release into the cellular cytoplasm induces muscle contraction. At the end of a contraction cycle, SERCA1 proteins pump excessive Ca^{2+} ions back from the cytoplasm into the sarcoplasmic reticulum to initiate relaxation. Impaired function of SERCA1 delays the removal of Ca^{2+} from the cytosol of muscle fibers, thereby prolonging the contractile phase.[5]

CLINICAL FINDINGS

Although PMT and CMD1 are caused by the same gene defect, the clinical presentation of both conditions differs markedly.

Congenital Muscular Dystonia Type 1 (CMD1)

CMD1 is a fatal congenital and nonprogressive condition of Belgian Blue calves.[3] The disease is characterized by exercise-induced pronounced episodes of generalized muscle contractures. During such episodes the affected calf has stiffened limbs and is unable to move or may even flip over with the extremities extended. Impaired swallowing has also been reported, and affected calves usually die in the first weeks of life as a result of respiratory complications.[3]

Pseudomyotonia (PMT)

PMT in cattle is a congenital and nonprogressive disease characterized by a generally increased muscle tone and exercise induced episodes of generalized muscle stiffness. Affected animals are reported to have a stiff or clumsy gait from birth on, and forcing them to move faster than at their own pace will trigger an episode of transient muscle contracture lasting from 20 seconds to over 1 minute. During this episode the animal is unable to move as a result of rigidity of the limbs. It either adopts a saw-horse type posture or may even flip over with all of the limbs extended. After a variable time period lasting from a few seconds to over a minute, the muscle contracture resolves progressively and the animal returns to its normal behavior. Although affected animals are often thought to have a neurologic affliction, the condition is purely a muscular disorder and is not associated with any neurologic deficiencies. In contrast to CMD1, animals with PMT can reach adult age.[5]

CLINICAL PATHOLOGY

Clinically, the condition is indistinguishable from myotonia, a chloride channel disorder, occurring incidentally in cattle as consequence of a spontaneous mutation in the ClCN1 gene (see also "Myotonia of Goats"). Percussing large muscle bellies either with the fingers or a percussion hammer will fail to produce local muscle fasciculation (**percussion myotonia**) in calves with PMT or CMD1, which would be characteristic for myotonia. **Electromyographic examination** is unremarkable, which also allows for differentiation of the condition from myotonia.[1,5]

Genome analysis to confirm the presence of a mutation in the **ATP2A1 gene** is required to make the definitive diagnosis. DNA analysis is also required to rule out congenital myotonia type 2 (CMD2) in Belgian Blue cattle, which is caused by a nonsense mutation in the gene encoding the inhibitory glycine receptor.[3]

TREATMENT

There is currently no specific treatment available.

NECROPSY FINDINGS

Necropsy examination has been not reported to yield remarkable findings.

CONTROL

With the condition being inherited in an autosomal-recessive manner, it has been recommended to test parents of a calf confirmed with PMT or CMD1 for the presence of the gene defect. Parent animals recessively carrying the gene defect are clinically healthy but should not be used for breeding. For populations with high prevalence of the gene defect, it is advisable to systematically check breeding bulls for the presence of the mutations before using their semen for breeding.[6]

OVINE HUMPYBACK

Ovine humpyback is probably a form of heat stroke that affects Merino wethers in western Queensland (Australia). It is characterized by a stiff, short gait when sheep are forced to walk for about a kilometer. The sheep stops walking and adopts an arched-back posture, and the body temperature is significantly elevated. Blood samples reveal a low number of lymphocytes. The condition occurs predominantly in summer, when sheep are in full wool, and the hyperthermia and ataxia disappear when sheep are shorn. Environmental temperatures at the time of the greatest prevalence of the disease are commonly 40° C (104 F).

MYOTONIA OF GOATS (FAINTING GOATS)

SYNOPSIS

Etiology Chloride channel disorder caused by a gene mutation affecting the ClCN-1 gene.

Epidemiology Myotonia of goats is the characteristic trait of an uncommon American goat breed, the fainting goat.

Clinical findings Increased resting muscle tone; transient muscle stiffness after startling the animal that resolves within seconds to minutes and may result in adaptation of a sawhorse-type position or flipping over. Congenital, nonprogressive.

Diagnostic confirmation Muscle percussion, electromyography, genetic analysis to identify gene mutation.

Treatment Not treated.

Control Not applicable.

ETIOLOGY

Myotonia of goats describes an inherited condition that is characterized by an abnormal delay in muscle relaxation following voluntary forceful muscle contraction.[1] The underlying cause is a structural and functional defect of the **skeletal muscle chloride channel 1 (ClC1)** that is essential to restore and maintain the membrane potential of muscle cells at the resting level. A missense mutation of the ClCN1 gene encoding the skeletal muscle C1C1 in so-called fainting goats has been identified and has been associated with decreased muscle chloride conductance resulting from a decreased number of functional chloride channels on muscle cell membranes.[2]

Anecdotal evidence suggests that the myotonic goat phenotype is transmitted as an autosomal-dominant trait, although many herds have been inbred, resulting in clinical presentation reminiscent of human recessive generalized myotonia (or Becker myotonia) with recessive inheritance.[1]

Historically the fainting goats played an important role in the process of unraveling the etiology and pathophysiology of congenital myotonia, a condition also affecting humans and other species.[2]

EPIDEMIOLOGY

Occurrence

Myotonia in goats was first reported in the 1880s in Tennessee, United States, where several does and one buck with signs of nervousness and stiffness appear to have been introduced by a transient farm worker.[3] Since then, the progeny of these animals have become established in the area. These goats, which are now a recognized breed, **the fainting goat,** became popular in the region as shepherds used them to protect their flocks from predators. During a predator attack, the

fainting goat would become startled and develop a characteristic episode of muscle stiffness, making it an easy prey, while the rest of the flock would be able to make an escape.

Currently there are two strains of this breed, which is indigenous to the United States. The original strain in Tennessee and the eastern part of the United States consists of smaller animals, whereas fainting goats found in and around Texas have been selectively bred for the meat market and are larger and heavy rumped, with a deep chest. The Livestock Breed Conservancy has this goat breed listed as a conservation priority livestock breed, with an estimated world population below 10,000 head.[4]

Economic Importance

Myotonic goats are considered a rare breed. Although historically their main purpose appears to have been to serve as prey animals to protect flocks from predators, this use has fallen out of practice. Today the main purposes are meat production and amusement. Myotonia is generally accompanied by muscle fiber hypertrophy, yielding greater muscle mass, less body fat, and higher bone-to-meat ratio than other breeds. Frequently this breed is kept as pet for its fainting spells for the owners' amusement, which has led to ethical concerns about breeding animals with this gene defect.

PATHOGENESIS

The missense mutation in the ClCN1 gene results in the transcription into a faulty chloride channel 1 protein that reduces the sarcolemmal chloride conductance. With normal chloride conductance across muscular cell membranes, chloride moves in and out of the cell until the intracellular concentration is adjusted to set the chloride equilibrium potential equal to the resting potential. The function of chloride is to rapidly return the membrane potential of the contracted and thus depolarized cell to the resting membrane potential, thereby allowing muscle relaxation. A reduced number of functional chloride channels on the sarcolemmal membrane reduces the velocity with which the membrane potential can be returned to the resting level, which has two important consequences: (1) a lower electrical stimulus is required to trigger an action potential, resulting in increased excitability the muscle cell; and (2) after initial depolarization, the membrane potential very slowly returns to a normal resting membrane potential. Until the resting membrane potential is reached, the actual membrane potential is closer to the threshold voltage needed to trigger a new action potential, which can result in spontaneous action potentials that are not triggered by neuromuscular transmission. Such autonomous action potentials will cause persistent muscle contraction and delayed muscle relaxation after an initial voluntary muscle activity, which are characteristic for myotonia.[1,5]

CLINICAL FINDINGS

The congenital condition that is characterized by a delay in muscle relaxation following an initial voluntary contraction is present from birth and is nonprogressive. Although affected goats are referred to as fainting goats, the condition is a purely muscular disorder and not associated with any neurologic deficits. The severity can vary from very mild to severe, and it appears that goats are able to adjust to the condition with age. Myotonia is not associated with pain.

A typical presentation is a slightly to moderately increased resting muscle tone that may result in a clumsy or stiff gait in animals with severe myotonia. Myotonic episodes and muscular stiffness can be triggered by startling the animal and thereby inducing a forceful initial movement. Because of delayed muscle relaxation, initially contracted muscles remain tensed for a period of between 10 seconds and 1 minute or longer and relax progressively thereafter. During this prolonged phase of muscle contraction, animals may either remain in a sawhorse-type position or may flip over with extended, stiffened limbs. Once muscle contraction resolves, the animal returns to normal attitude and behavior.

CLINICAL PATHOLOGY

The presentation is characteristic, with animals being affected from birth by inducible myotonic episodes. Clinically the diagnosis can be supported by percussing large muscle bellies either with the fingers or a percussion hammer. In myotonic animals, muscle percussion triggers local muscle fasciculation (**percussion myotonia**) that lingers for several seconds. **Electromyographic examination** reveals increased insertional activity when inserting myography needles into muscle tissue and continued high-frequency discharges that outlast normal motor unit responses by several seconds.

To confirm the diagnosis, DNA analysis to confirm the presence of mutation in the ClCN1 gene is required.[6]

NECROPSY FINDINGS

Necropsy examination is not usually undertaken for diagnostic purposes.

MYOTONIA CONGENITA AND MYOTONIC DYSTROPHY

Myotonia is the prolonged contraction of muscle as a result of delayed relaxation. It can be present soon after birth or develop as a progressive disease.

The **congenital** form in horses (New Forest ponies),[1] goats, and Murrah buffalo is an inherited disorder of muscle membrane hyperexcitability caused by mutations in the voltage-gated chloride channel gene CLCN1. The mutation reduces sarcolemmal chloride conductance and delays relaxation of the muscle.[1,2] It is transmitted as an autosomal-recessive trait in ponies.[1] The disease is evident as generalised myotonia evident soon after birth. The disease is not progressive, but there is not treatment. Control is based on breeding programs.

The disease in horses **myotonia dystrophia** is evident as increased muscle tone, increased muscle bulk or muscle atrophy, stilted gait, and weakness.[3] Electromyographic examination reveals the classic myotonic discharges. Affected horses can have testicular atrophy and cataracts. The disease is progressive. There are no characteristic changes in blood or serum. Muscle biopsy demonstrates dystrophic changes, with variations in fiber size and fiber-type grouping. There is no effective treatment, and control is through avoidance of breeding of affected animals.

RECURRENT EXERTIONAL RHABDOMYOLYSIS IN THOROUGHBRED AND STANDARDBRED HORSES

ETIOLOGY

Recurrent exertional rhabdomyolysis is a recognized syndrome in Thoroughbred, Standardbred, and Arabian racehorses. A genetic basis is considered likely, with heritability of 0.42,[1] but has not been demonstrated. Genome-wide scans and linkage analyses map candidate genes to the genomic region between UCDEQ41 and TKY499 on ECA12 (*Equus caballus* chromosome 12) or regions on ECA16 or ECA 20.[1,2] The differences between the two studies, with one mapping to ECA16[2] and the other to ECA12 and ECA20,[1] might be attributable to the

study of different populations of horses (North America vs. Japan), phenotyping (disease classification), or laboratory techniques. The RYR1, CACNA1S, and ATP2A1 genes are not linked to recurrent exertional rhabdomyolysis in Thoroughbreds,[3] nor do affected Standardbred horses have the GSY1 mutation identified as a cause of polysaccharide storage myopathy in Quarter horses, draft horses, and other breeds.[4] Mutations in genes expressing monocarboxylate transporter 1 and CD147 are not associated with the disease.[5]

Recurrent exertional rhabdomyolysis in Thoroughbreds is likely to be a complex genetic disease resulting from one or more genes having a major effect, with expression affected by modifying genes, environment, or sex.[2,6]

EPIDEMIOLOGY

Interpretation of reports of prevalence and risk factors for exertional rhabdomyolysis are imprecise because of difficulties in distinguishing the disease from other causes of rhabdomyolysis, including the sporadic disease. The **incidence** or 1-year period prevalence of exertional rhabdomyolysis is as follows: 4.9% in Thoroughbred racehorses in the United States, Australia, and Great Britain; 6.1% in National Hunt Thoroughbreds in Great Britain; and 4% to 5% in 2- to 3-year-old Thoroughbreds in the United Kingdom.[7] The annual incidence in Standardbred racehorses in Sweden is 6.4 (95% CI 4.6% to 8.2%) per 100 horses.[4] Annual incidence in 22 Standardbred training yards in Sweden ranged from 1.7 to 20 cases per 100 horses.[4]

Risk factors for recurrent exertional rhabdomyolysis include exercise and sex. Female racehorses are 3 times more likely to have episodes of exertional rhabdomyolysis than are male (intact or castrated) racehorses, and young female Thoroughbreds are at greatest risk. Among 2- to 4-year-old Thoroughbreds in the United Kingdom, 76% to 78% of occurrences of "tying-up" are in females, and female Standardbreds in Sweden are 7 times more likely (95% CI 2.1 to 23.4) to be affected by the disease than are males.[4] Among National Hunt horses in Great Britain, females are 24 times as likely to have an episode of the disease as are males. Thoroughbred racehorses and Standardbred horses (odds ration [OR] 7.9, 95% CI 2.3 to 27)[4], but not National Hunt horses, with a nervous or "flighty" temperament are more likely to experience episodes of the disease.[8]

The disease occurs repeatedly in 74% of affected Thoroughbred racehorses in Great Britain and in 20% of affected polo ponies.

The disease is of considerable **economic impact** because of its frequent occurrence in athletic horses, its recurrent nature, and the need to rest affected horses.[8] On average, affected Thoroughbred racehorses cannot train for 6 days, and Standardbreds for 7 days, after an episode,[4,8] and approximately two-thirds of affected horses are unable to race because of the disease. The effect of the loss of training days for each episode is magnified because of the recurrent nature of the disease in a large proportion of affected horses. Approximately 6% of the wastage of Thoroughbred racehorses in Australia is attributable to exertional rhabdomyolysis.

Interestingly, Standardbred horses in the United Kingdom with recurrent exertional rhabdomyolysis have enhanced performance.[4]

PATHOGENESIS

The cellular defect has not been identified and fully explicated. Muscle from affected horses has abnormal contraction and relaxation kinetics and is hypersensitive to exposure to caffeine in vitro, but connection with development of the disease is unclear. Affected French Trotters have a characteristic micro-RNA profile in muscle, although this might represent a response to muscle damage rather than the mi-RNA's involvement in development of the disease.[9]

The disease is attributable to dysfunction and death of myocytes with subsequent release of cellular constituents, including the enzymes creatine kinase, aspartate aminotransferase, and carbonic anhydrase, and myoglobin. The proximate cause of myocyte death is uncertain, but it is not related to accumulation of lactic acid.

Cell death is likely linked to abnormal accumulation of calcium in intracellular fluids secondary to deranged energy and/or membrane function. Necrosis of myocytes causes pain and inflammation in the muscle, with infiltration of inflammatory cells. Healing and regeneration of myocytes occurs over a period of weeks in the absence of further episodes of myonecrosis.

Release of cellular constituents results in electrolyte abnormalities, primarily a hypochloremic metabolic alkalosis, a systemic inflammatory response, and pigmenturia. Severely affected horses can have a metabolic acidosis. Myoglobin, and possibly other cell constituents, is nephrotoxic, and acute renal failure can develop as a result of myoglobinuric nephrosis. Pain and loss of muscle function cause a stilted, short-stepping gait.

CLINICAL FINDINGS

The clinical findings are variable and range from poor performance through classic signs of muscle pain, stiffness, and reluctance to move, to recumbency and death, although the latter are rare with recurrent exertional rhabdomyolysis. Most affected horses have more than one episode of the disease each year while in training, and some can have numerous episnodes (up to 20).[4,8]

The most common presentation is of a horse that does not perform to expectation and displays a stiff or **short-stepping gait** that can be mistaken for lower leg lameness. The horse might be reluctant to move when placed in its stall, be apprehensive and anorexic, paw, and frequently shift its weight. More severely affected horses can be unable to continue to exercise, have **hard and painful muscles** (usually gluteal muscles), sweat excessively, tremble or have widespread muscle fasciculations, be apprehensive, refuse to walk, and have elevated heart and respiratory rates. Affected horses can be hyperthermic, especially soon after exercise. Signs consistent with abdominal pain are present in many severely affected horses. Deep-red urine (myoglobinuria) occurs but is not a consistent finding. Severely affected horses are often recumbent.

Among affected Standardbred horses, clinical signs are evident in 98% of horses within 1 hour of exercise. Clinical signs include stiffness in all cases (44), sweating (86%), pain or evident distress (43%), swollen or firm gluteal muscles (23%), and recumbency (2%).[4]

CLINICAL PATHOLOGY

Mildly affected or apparently nonaffected horses have moderate increases in **serum creatine kinase** (CK) (20,000 to 50,000 IU/L), **aspartate aminotransferase** (AST), and **lactate dehydrogenase** (LDH) activity. Severely affected horses have large increases in CK (>100,000 IU/L) and other muscle-derived enzymes. Serum CK and AST activities peak approximately 5 to 6 and 24 hours after exercise, respectively, and in the absence of further muscle damage, serum AST might not return to normal levels for 7 to 10 days. The half-life of CK activity in serum is approximately 2 hours, and in the absence of continuing muscle damage, serum CK declines rapidly. The persistence of increased AST activity, compared with CK, is useful in identifying affected horses days or weeks after the episode.[8]

Serum myoglobin concentrations increase markedly during exercise in affected horses and decline within 24 to 48 hours. Serum carbonic anhydrase III activity is increased in horses with exertional rhabdomyolysis.[8]

Severely affected horses are often **hyponatremic** (<130 mEq/L), **hyperkalemic** (>5.5 mEq/L), **hypochloremic** (<90 mEq/L), azotemic (increased serum urea nitrogen and creatinine concentrations), and **acidotic** or **alkalotic**. Hemoconcentration (hematocrit > 50%, 0.5 L/L) and increased serum total protein concentration (>80 g/L) indicative of dehydration are common. Serum bicarbonate concentration can be falsely markedly elevated in animals with severe rhabdomyolysis because of cellular constituents released from damaged muscle that interfere with the analytical method when automated clinical chemistry analyzers are used. **Myoglobinuria** is detectable either grossly or on chemical analysis and should be differentiated from hemoglobinuria or hematuria.

Measurement of **urinary excretion of electrolytes**, although popular in the past, is of no use in diagnosing, treating, or preventing exertional rhabdomyolysis.

Muscle biopsy during the acute or convalescent stages reveals myonecrosis of type II (fast-twitch, oxidative) fibers, mild myositis, and fibrosis.

NECROPSY FINDINGS

Horses dying of exertional rhabdomyolysis have widespread degeneration of striated muscle, principally the muscles of exertion, but often involving the diaphragm and heart. Affected muscles tend to be dark and swollen but may have a pale, streaked appearance. The kidneys are swollen and have dark-brown medullary streaks. Dark-brown urine is present in the bladder. Histologic examination reveals widespread necrosis and hyaline degeneration of predominantly type II (fast-twitch, oxidative) fibers. In horses with recurrent disease, there may be evidence of myofiber regeneration. Myoglobinuric nephrosis is present in severely affected horses.

Samples for Postmortem Confirmation of Diagnosis

- Formalin-fixed kidney and affected muscle for light microscopic examination (LM)

DIAGNOSTIC CONFIRMATION

Biochemical confirmation of muscle damage by demonstration of increased serum CK or AST activity, in conjunction with appropriate clinical signs, provides the diagnosis.

DIFFERENTIAL DIAGNOSIS (See Table 15-2)

- Muscle cramping induced by ear tick (*Otobius megnini*)
- Ionophore intoxication (monensin, lasalocid, salinomycin, narasin, maduramicin)
- Infection by *Anaplasma phagocytophilum*[10]
- White snake root (*Eupatorium rugosum*) or rayless goldenrod (*Isocoma Pluriflora*),
- Laminitis
- Colic
- Pleuritis
- Aorto-iliac thrombosis

TREATMENT AND CONTROL

TREATMENT OF RECURRENT EXERTIONAL RHABDOMYOLYSIS IN THOROUGHBRED AND STANDARDBRED HORSES

Treatment of Acute disease

- Nonsteroidal antiinflammatory drugs—phenylbutazone (2.2 to 4.4 mg/kg IV or PO q12–24h) or **ketoprofen** (2.2 mg/kg IV every 12 h) (R-1)
- Rest (R-1)
- Fluid therapy—as needed (R-1)
- Acepromazine or similar sedatives (R-2)
- Furosemide (R-3)

Control

- Consistent exercise schedule (R-1)
- Dietary modifications (R-1)
- Dantrolene sodium (R-2)
- Phenytoin (R-3)

The treatment chosen depends on the severity of the disease. The **general principles** are rest; correction of dehydration and electrolyte abnormalities; prevention of complications, including nephrosis and laminitis; and provision of analgesia, and are the same as for all acute myopathies with rhabdomyolysis.

Mildly affected horses (heart rate < 60 bpm, normal rectal temperature and respiratory rate, no dehydration) may be treated with rest and phenylbutazone (2.2 mg/kg, orally or IV every 12 hours for 2 to 4 days). Horses should be given mild exercise with incremental increases in workload as soon as they no longer have signs of muscle pain. Access to water should be unrestricted.

Severely affected horses (heart rate > 60 bpm, rectal temperature > 39° C [102° F], 8% to 10% dehydrated, reluctant or unable to walk) should not be exercised, including walking back to the stable, unless it is unavoidable. Isotonic, polyionic **fluids**, such as lactated Ringer's solution, should be administered IV to severely affected horses to correct any hypovolemia and to ensure a mild diuresis to prevent myoglobinuric nephropathy. Less severely affected horses can be treated by administration of fluids by nasogastric intubation (4 to 6 L every 2 to 3 hours). Although it has been recommended that urine should be alkalinized by administration of mannitol and sodium bicarbonate (1.3% solution IV, or 50 to 100 g of sodium bicarbonate orally every 12 hours) to minimize the nephrotoxicity of myoglobin, this therapy is not effective in humans at risk of myoglobinuric nephrosis. Affected horses should not be given diuretics (e.g., furosemide) except if they are anuric or oliguric after correction of hypovolemia.

Phenylbutazone (2.2 to 4.4 mg/kg, IV or orally, every 12 to 24 hours), **flunixin meglumine** (1 mg/kg IV every 8 hours), or **ketoprofen** (2.2 mg/kg IV every 12 hours) should be given to provide **analgesia**. **Mild sedation** (acepromazine 0.02 to 0.04 mg/kg IM, or xylazine, 0.1 mg/kg IM, both with butorphanol, 0.01 to 0.02 mg/kg) might decrease muscle pain and anxiety. Tranquilizers with vasodilatory activity, such as acetylpromazine (acepromazine), should only be given to horses that are well hydrated. **Muscle relaxants**, such as methocarbamol, are often used but have no demonstrated efficacy.

Recumbent horses should be deeply bedded and repositioned by rolling every 2 to 4 hours. Severely affected horses should not be forced to stand.

CONTROL

Although the cause has not been identified, a number of preventive measures are used, including the following: ensuring consistency of exercise (i.e., every day); dietary interventions to provide a high-fat, low-soluble-carbohydrate diet, with reduction of the amount of soluble carbohydrate in the diet on days when the horse will not exercise; and administration of dantrolene sodium.

Despite lack of clear evidence for a role for **vitamin E or selenium** deficiency in recurrent exertional rhabdomyolysis, horses are often supplemented with 1 IU/kg vitamin E and 2.5 µg/kg selenium daily in the feed. Care should be taken not to induce selenium toxicosis.

Sodium bicarbonate (up to 0.5 to 1.0 g/kg BW daily in the ration) and other electrolytes are often added to the feed of affected horses, but their efficacy is not documented. **Phenytoin** is administered at a dose rate of 6 to 8 mg/kg, orally, every 12 hours, and the dose is adjusted depending on the degree of sedation produced (a reduced dose should be used if the horse becomes sedated) or lack of effect on serum CK or AST activity. Phenytoin can be administered to horses for months, although its efficacy has not been demonstrated. **Dimethylglycine, altrenogest, and progesterone** are all used on occasion in horses with recurrent rhabdomyolysis, but again without demonstrated efficacy.

The feeding of high-fat, low-soluble-carbohydrate diets is useful in the prevention of recurrent exertional rhabdomyolysis in Thoroughbred horses,[4] and dietary modifications that reduce feeding of grain (oats) are common in Standardbred horses in Sweden (and likely elsewhere).[4]

Administration of **dantrolene sodium** (1 to 3 mg/kg, PO q24 h) has been advocated for prevention or amelioration of recurrent exertional rhabdomyolysis, and the pharmacokinetics of dantrolene in horses have been determined.[11,12] Dantrolene reduces calcium efflux from the sarcoplasmic reticulum and is a muscle relaxant. Plasma concentrations are greatest when it is administered with feeding, and feed restriction for more than 4 hours before oral administration decreases gastrointestinal absorption of dantrolene.[11] There is only relatively weak laboratory or field trial evidence of the efficacy of dantrolene in prevention of the disease.[13]

POLYSACCHARIDE STORAGE MYOPATHY OF HORSES

Polysaccharide storage myopathy, a myopathy of principally Quarter horses and related breeds, but also occurring with high frequency in draft breeds, is characterized by excessive accumulations of amylase-resistant glycogen (evident as amylase-resistant polysaccharide on periodic acid–Schiff [PAS] staining) in muscle and signs of exertional rhabdomyolysis. One form of the disease is associated with a specific mutation in the GYS1 gene (polysaccharide storage myopathy 1 [PSSM1]) and another with an identical phenotype but without the same genetic abnormality (PSSM2).[1]

ETIOLOGY

PSSM1 is the result of a single missense G-to-A gain-of-function mutation in the skeletal muscle glycogen synthase (GYS1) gene that results in a histidine (H) substitution for arginine (R) in the enzyme.[1,2] The mutation is dominant, with both homozygotic (AA, both H alleles) and heterozygotic (GA, one H allele, one R allele) animals affected. Homozygotes for the H allele are more severely affected than are heterozygotes, as indicated by accumulation of amylase-resistant polysaccharide in muscle and elevated resting serum CK and AST activities.[3] The mutation is conserved in the haplotype of many affected horse breeds, has been present in horses for over 1200 years, and is widely distributed among breeds of horses, with the mutation identified in over 30 breeds.[2] The gene is well characterized in equids.[4]

The etiology of PSSM2 is not known, but it is not associated with the same mutation as PSSM1.

EPIDEMIOLOGY

A polysaccharide storage myopathy characterized by accumulation of polysaccharide in muscle was described in Quarter horses and other breeds and subsequently recognized as being either of amylase-resistant polysaccharide or amylase-sensitive polysaccharide. Approximately 48% of 831 muscle samples from horses with PSSM tested positive for the GYS1 mutation, with 16% of horses with amylase-sensitive polysaccharide accumulation having the H allele and 70% of horses with amylase-resistant having the allele. Of the 831 horses, 31 (3.7%) were homozygous for the H allele (gene AA), 379 (45.6%) were heterozygous (HR for enzyme, GA for gene), and 430 were homozygous normal (RR for enzyme, GG for gene). The presence of the mutated gene (heterozygous form) increases the risk of clinical exertional rhabdomyolysis by 7 times in Warmblood horses.[5]

The disease and mutation are recognized in many breeds, with the greatest frequency in Quarter horses and related breeds and draft breeds worldwide.[1,6-14] Allele frequencies are available for PSSM in horses in the United States (Percheron, 0.346; Belgian, 0.242; Paint, 0.041; Quarter horse, 0.034; Appaloosa, 0.030; Morgan, 0.005; Shire, 0.003; Thoroughbred, 0.000) and Europe (South German Coldblood, 0.117; Saxon-Thuringian Coldblood, 0.068; Shire, 0.000; Hanoverian, 0.000).[14] The GYS1 mutation was detected in 11 breeds, with a prevalence of genetic susceptibility to type 1 PSSM from 0.5% to 62.4%. The GYS1 mutation was not found in the sampled Thoroughbreds, Akhal-Tekes, Connemaras, Clydesdales, Norwegian Fjords, Welsh Ponies, Icelandics, Schleswig Coldbloods, or Hanoverians, but failure to detect the mutation does not guarantee its absence from the breed, although it does imply a low prevalence.[14]

PSSM, based on examination of muscle biopsy from a convenience sample of 164 Quarter horses, occurs in 6% to 12% of overtly healthy Quarter horses in the United States.[6] Allele frequencies for type 1 PSSM among Quarter horses in the United States range from 0.055 to 0.155, depending on the population sampled.[15]

The mutation, and disease, are common in Percheron and Belgian draft horses in Europe, and the disease is reported in Normandy Cob draft horses.[11,16] Of a nonrandom selection of continental European draught horses belonging to 13 breeds, 62% (250 of 403) tested were found to carry the mutant allele.[9] The highest percentages of GYS1-positive horses were found in the Belgian trekpaard (92%, 35 of 38 horses tested), Comtois (80%, 70 of 88), Netherlands trekpaard (74%, 17 of 23), Rheinisch-Deutsches kaltblut (68%, 30 of 44), and Breton (64%, 32 of 51).[9] There is genetic evidence of historical selection pressure in favor of the mutated genotype in Belgium draft horses, but not in American Quarter horses.[17]

The mutation has not been detected in purebred Thoroughbred, Standardbred, and Arabian horses.[1,18]

It appears that the GYS1 mutation arose in heavy (draft) breeds of horses in Europe over 1200 years ago, as indicated by its high frequency in European draft breeds, but not English draft breeds, and the lower prevalence of the mutation in lighter breeds.[9] Light breeds with closely kept stud books that have prevented ingress of genes over centuries, such as Thoroughbreds and Standardbreds, do not carry the mutant gene.

Animal risk factors for exertional rhabdomyolysis include breed (as discussed previously) but not sex or age.[6,19] Quarter horses that carry a mutation of the RYR1 (ryanodine) gene and the mutated GYS1 gene have more severe expression of the disease.[20]

Prolonged periods of rest or irregular exercise schedules are risk factors for development of exertional rhabdomyolysis associated with the disease.

PATHOGENESIS

Mutation of the GYS1 gene causes increased activity in muscle glycogen synthase activity without an increase in activity of glycogen branching enzyme.[2] There is subsequent accumulation of amylase (diastase)-resistant polysaccharide (polyglucosan)—proglycogen and macroglycogen with fewer branching points and more straight chains—in skeletal muscle.[2,21] The reason that accumulation of polysaccharide causes myopathy and exertional rhabdomyolysis is unclear. It does not appear to be related to availability of energy within the cell, although this is uncertain, and it could be related to physical damage caused by accumulation of polysaccharide in vacuoles within predominantly type 2A fibers of homozygous horses.[3]

CLINICAL FINDINGS

The clinical findings are variable and range from sporadic to episodic exertional rhabdomyolysis of varying severity. Notably, 6% to 12% of overtly healthy (asymptomatic) Quarter horses in the United States have histologic evidence of the disease.[6] The acute clinical syndrome does not vary importantly from that of other exertional rhabdomyolysis syndromes. Horses with PSSM1 do not have important cardiac abnormalities as part of their disease syndrome.[22]

Muscle biopsy reveals accumulation of amylase (diastase)-resistant polysaccharide (PAS-positive) inclusions in vacuoles in predominantly, but not exclusively, type 2A and type 2X fibers.[3] Examination of muscle biopsies from candidate horses should be done with consideration of the risk of false-positive findings, especially if the amylase-resistant nature of the polysaccharide is not determined. Horses with PSSM2 will have excess accumulation of amylase-resistant polysaccharide but will not have the mutation in the GYS1 gene. PSSM is most accurately diagnosed in muscle biopsy specimens on the basis of appearance of amylase-resistant, abnormal polysaccharide, not amylase-sensitive glycogen, regardless of fixation technique.[23]

CLINICAL PATHOLOGY

Most Quarter horses and related breeds, but not draft breeds, with the GYS1 mutation have elevations in serum CK and AST at rest.[3] Mildly affected or apparently nonaffected horses have moderate increases in serum CK, AST, and LDH activity after moderate exercise. Severely affected horses have large increases in CK and other muscle-derived enzymes. Serum CK and AST activities peak approximately 5 to 6 and 24 hours after exercise, respectively, and in the absence of further muscle damage, serum AST might not return to normal levels for 7 to 10 days.

NECROPSY FINDINGS

Gross lesions may vary depending on whether or not the horse died from severe rhabdomyolysis or was euthanized after being recumbent. Affected muscles may be pale pink or diffusely red-tinged, which can be mistaken for autolysis. Any of the large power muscle groups and the diaphragm can be affected. The kidneys may be swollen and dark red as a result of myoglobinuria. In chronic cases with repeated episodes, muscle atrophy may be marked, or the muscles may be of normal size but contain pale streaks where myofibers have been replaced by fat.

Microscopically, the presence of amylase-resistant, abnormal polysaccharide inclusions in the cytoplasm of type 2 myocytes is the most sensitive and specific diagnostic indicator for polysaccharide storage myopathy.[23] Other lesions, such as fiber atrophy, internal nuclei, and fatty infiltration, may be present. Muscles most often affected include the semimembranosus, semitendinosus, gluteal, longissimus, and pectoral muscles and the diaphragm.[24]

Samples for Postmortem Confirmation of Diagnosis

Samples of semimembranosus, semitendinosus, gluteal, and diaphragmatic muscles for H & E and PAS stains are used for confirmation of the diagnosis. Frozen sections of biopsies are better suited for studying myopathies because many histopathologic features of skeletal muscle are obscured by formalin fixation.[23]

DIAGNOSTIC CONFIRMATION

Biochemical confirmation of muscle damage is achieved by demonstration of increased serum CK or AST activity in horses with compatible clinical signs. In breeds with known or strongly suspected genetic basis for PSSM1, gene testing for the GYS1 mutation provides evidence of the PSSM1. Confirmation is achieved by examination of a muscle biopsy (see Diagnostic Algorithm in Fig. 15-1). If the muscle biopsy demonstrates the presence of amylase-resistant polysaccharide and the horse is negative for the AA or AG mutation in the GYS1 gene, then the horse has PSSM2.

DIFFERENTIAL DIAGNOSIS (See Table 15-2)

- Muscle cramping induced by ear (*Otobius megnini*)
- Laminitis
- Colic
- Pleuritis
- Aorto-iliac thrombosis
- Other myopathies

TREATMENT

The treatment chosen depends on the severity of the disease. The **general principles** are rest; correction of dehydration and electrolyte abnormalities; prevention of complications, including nephrosis and laminitis; and provision of analgesia, and are the same as for all acute myopathies with rhabdomyolysis (see "Myopathies of Horses").

CONTROL

The feeding of high-fat, low-soluble-carbohydrate diets is useful in the prevention of clinical signs in affected horses with either PSSM1 or PSSM2 and is reported to be useful in controlling the disease.[19] Horses should have a regular exercise program, preferably with frequent turn-out to pasture, and be fed a diet rich in long-chain fatty acids with low starch content (<10%) and high in fat (10% of digestible energy).[25-27]

EQUINE HYPERKALEMIC PERIODIC PARALYSIS

SYNOPSIS

Etiology Defect in sodium channel of skeletal muscle.

Epidemiology Disease of Quarter horses and crossbreds. Inherited as an autosomal-dominant trait with variable penetrance.

Clinical signs Episodes of muscle fasciculation, stridor, muscle weakness, and flaccid paralysis.

Clinical pathology Hyperkalemia during episodes. Gene probe to detect mutated gene.

Lesions None.

Treatment Palliative. Potassium-free intravenous fluids. Acetazolamide.

Control Selective breeding. Low-potassium diet.

ETIOLOGY

Hyperkalemic periodic paralysis (HYPP) is caused by a heritable defect in the sodium channel of skeletal muscle. The mutation, of which only one form has been identified, results in substitution of a cytosine for guanine, with consequent replacement of phenylalanine by leucine in a transmembrane protein regulating sodium flux across the cell membrane and T-tubule.[1] The disease is transmitted as an autosomal-codominant trait, with the result that homozygotes are more severely affected than heterozygotes, and phenotypic expression (disease severity) differs among heterozygotes.

EPIDEMIOLOGY

The disease is familial and affects Quarter horse and crossbred descendants of a single Quarter horse sire, Impressive. More than 50,000 registered Quarter horses are related to known carriers of the disease. Quarter horses with the disease are presumably selected because they outperform unaffected animals in the Halter classes in which they compete at horse shows, although recent rule changes have changed this practice. The disease occurs in breeds derived from or crossed with Quarter horses, including Appaloosas, American Paint horses, and crossbreds. Of 651 elite performance American Quarter horses, 200 control American Quarter horses, and 180 control American Paint horses (APHs), allele frequency for HYPP in all animals was 0.008, APHs had high prevalence of HYPP of 0.025, and Halter horses had significantly greater allele frequency for HYPP of 0.299,[2] consistent with the alleles associated with the desired phenotype. Approximately 14% of 51 Quarter horses in Mexico have the N/H genotype, with 2% having the H/H genotype. Allele frequencies were 0.157 N and 0.843 normal.[3]

The disease is inherited in an **autosomal-codominant** manner. Therefore 50% of the offspring of the breeding of a heterozygote and a normal animal will carry the trait, as will 75% of the offspring of the breeding of two heterozygotes. Of the breeding of two heterozygotes, 50% of progeny will be heterozygotes, 25% homozygotes for the mutated gene, and 25% homozygotes for the normal gene. Animals homozygous for the abnormal gene are uncommon, representing only 0.9% of animals tested for the disease. The low prevalence of the homozygote genotype is likely a reflection of severity of disease and the reduced likelihood that homozygotic animals will reach sexual maturity.

The risk of a **heterozygous** animal being affected with periodic paralysis is variable. Most heterozygous horses appear normal and never experience an attack, whereas others have severe episodes starting at a young age. **Homozygous** horses are much more likely to have severe manifestations of the disease at a young age.

PATHOGENESIS

The abnormality in the sodium channel coded for by the mutated gene predisposes the horse to episodes of complete depolarization of the muscle membrane and flaccid paralysis. The mutation in the sodium channel increases the probability that any one channel is open, with the result that the resting membrane potential in affected horses is higher (less negative and closer to the depolarization threshold) than that of normal horses. This results in frequent depolarizations of individual muscle fibers, causing muscle fasciculations. The weakness associated with severe episodes of the disease results from failure of sodium channels to close after depolarizations. Opening of potassium channels when the muscle is depolarized results in movement of potassium out of the muscle cell and the development of hyperkalemia.

CLINICAL SIGNS

The disease in **heterozygous** animals is characterized by periods of muscle fasciculation and tremor that progress to weakness, paralysis, and recumbency. Such episodes may last minutes to hours, and most resolve spontaneously. Horses often sweat, have prolapse of the third eyelid, and have contractions of facial and locomotor muscles during episodes. Episodes may be mistaken for colic. Inspiratory stertor commonly noted during episodes is probably attributable to laryngeal and pharyngeal dysfunction.

Episodes are more frequent and severe in **homozygous** animals, and signs of **laryngeal and pharyngeal dysfunction**, such as stridor and dysphagia, occur in almost all of these animals. Endoscopic examination of homozygotes reveals pharyngeal collapse, laryngopalatal dislocation, and laryngeal paralysis. The disease can manifest in foals as young as 7 days of age. The severity of signs in some homozygotes diminishes with age.

Electromyographic demonstration of myotonic discharges, prolonged insertional activity, and doublets and triplets is a sensitive and specific indicator of the disease.

Horses with HYPP have reduced exercise tolerance compared with normal horses. Homozygotic horses have laryngospasm, airway obstruction, hypoxia, hypercapnia, and ventricular depolarizations during intense exercise, which is not recommended for these horses.

CLINICAL PATHOLOGY

Hyperkalemia (>5.5 mEq/L) during or immediately after episodes is characteristic of the disease, although the existence of a normokalemic variant has been suggested.

Diagnostic confirmation has in the past been achieved by provocative testing by administering potassium chloride (88 to 166 mg/kg, orally) to suspect horses. However, the development of genotyping has rendered provocative testing obsolete and, for humane reasons and because of the risk of death, its use is not recommended. The **test of choice** for demonstrating the presence of the mutated gene is a specific **gene probe**. The probe can be applied to various tissues, but blood or hair, with attached root (a plucked hair), are preferred for diagnostic testing of live animals. This test classifies horses as normal, heterozygous, or homozygous but does not indicate the propensity of heterozygotes to exhibit the disease. Samples can be analyzed in the United States at the Veterinary Genetics Laboratory of the University of California (www.vgl.ucdavis.edu).

DIFFERENTIAL DIAGNOSIS

- Colic
- Laminitis
- Hypocalcemia
- Botulism
- Exertional rhabdomyolysis
- Upper airway obstruction

NECROPSY FINDINGS

There are no characteristic findings on necropsy examination.

TREATMENT

Acute Episodes

Most acute episodes resolve spontaneously or with only minor treatment. The aim in treating more severe or prolonged episodes is to **reduce the plasma potassium concentration** by intravenous infusion of isotonic potassium-free fluids such as sodium chloride, sodium bicarbonate, or dextrose.[4] Some authors recommend infusion of calcium gluconate, but others caution against its use. A practical approach is the slow IV administration of 0.25 to 0.5 mL of 23% calcium gluconate per 1 kg of body weight (125 to 250 mL for a 500-kg horse) diluted in isotonic sodium chloride or, preferably, 5% dextrose. Administration of $NaHCO_3$ at 1 mL/kg IV has been suggested.

Prevention of Episodes

Maintaining affected horses on a **low-potassium diet** reduces the frequency with which episodes occur. Alfalfa (lucerne); some oils, including soyabean; molasses; lite salt (a mixture of KCl and NaCl); and many sweet feeds are potassium rich and should be avoided. Grass hay (timothy) and straw and oats, corn, and barley are low in potassium. There are commercial feeds that have a guaranteed low concentration of potassium. Alternatively, diets can be formulated using feed of known potassium concentration, as determined by feed analysis. Care should be taken that diets are nutritious and contain appropriate concentrations and ratios of calcium and phosphorus.

Acetazolamide (2 to 4 mg/kg, every 12 hours) reduces the severity and frequency of episodes and is widely used to control the disease. The drug is poorly absorbed in horses, but the concentration required in plasma of horses to achieve a pharmacodynamic effect is lower than that of humans.

CONTROL

The disease is heritable, and carriers are readily identified; thus, a breeding program to eliminate the disease is feasible.

MALIGNANT HYPERTHERMIA IN HORSES

Malignant hyperthermia is a disease of Quarter horses and other breeds induced by exposure to halothane, succinylcholine, or similar depolarizing agents and various other stressors. It also occurs in pigs, dogs, and humans.[1] The disease in Quarter horses is caused by a mutation in the RyR1 gene, with subsequent dysfunction of calcium handling within the cell.[2] There is excessive release of calcium from the sarcoplasmic reticulum on exposure to halothane, with development of hyperthermia, hypercapnia, and lactic acidosis, and often death.[2] There is no apparent breed, age, or sex predilection for the sporadic disease. Breed is clearly a predilection for affected Quarter horses. The mutation in Quarter horses can be detected by analysis of the genome.[3]

The clinical signs are rapid onset of hyperthermia, sweating, muscle fasciculation, tachycardia, tachypnea, and muscle rigidity in anesthetised horses. There is acidosis, hypercapnea, and, in acute cases, increases in serum activity of CK. Elevations in CK might not be evident in horses that die peracutely. Treatment is supportive and includes prompt removal of the inciting agent (halothane), cooling, correction of acid : base and electrolyte abnormalities, and prevention of myoglobinuric nephrosis.

PORCINE STRESS SYNDROME (MALIGNANT HYPERTHERMIA)

SYNOPSIS

Etiology Inherited defect caused by an autosomal-recessive gene at a single locus with incomplete penetrance. Also known as the halothane-sensitivity gene, or porcine stress syndrome (PSS) mutation, which is a single-point mutation of nucleotide 1843 in the skeletal muscle gene for the calcium-release channel of the sarcoplasmic reticulum.

Epidemiology Worldwide in major breeds of swine: Landrace, Yorkshire, Duroc, Pietrain, and Poland China. Market-weight pigs and adult sows and boars. Prevalence of defective gene varies between breeds and countries. Syndromes precipitated by stress of transportation, high environmental temperatures and humidity, exhaustive exercise, and halothane anesthesia. Major economic importance because of deaths and poor-quality pork.

Signs

- Porcine stress syndrome: death during transportation
- Malignant hyperthermia: induced by halothane anesthesia; results in muscular rigidity and death
- Pale, soft, exudative pork: rapid rigor mortis after slaughter followed by excessive dripping of carcass and pale, watery pork; dark, firm, and dry pork is a variation
- Back-muscle necrosis: reluctance to move, acute swelling and pain over back; some may die; subacute form also possible

Clinical pathology Halothane test. Blood creatine kinase test. Blood typing. DNA-based test for PSS mutation gene.

Lesions Pale skeletal muscles in PSS deaths. Pale muscles in back-muscle necrosis.

Diagnostic confirmation—necropsy findings. Identification of homozygous animals with tests.

Differential diagnosis list

- Mulberry heart disease
- Acute septicemias attributable to salmonellosis, erysipelas, pasteurellosis, and anthrax
- Intestinal volvulus
- Heat exhaustion
- Suffocation during transportation.

Treatment None.

Control Genetic selection. Reduction of environmental and management stressors.

ETIOLOGY

Considerable attention from breeders has greatly reduced the occurrence of this condition in recent years.

Three closely related stress syndromes occur in pigs. Porcine stress syndrome (PSS) is characterized by acute death induced by stressors such as transport, high ambient temperature, exercise, and fighting, which results in progressive dyspnea, hyperthermia, disseminated vasoconstriction, and the rapid onset of rigor mortis. Pale, soft, and exudative pork (PSE) occurs postmortem in some pigs slaughtered by conventional methods. Malignant hyperthermia (MH) is a drug-induced stress syndrome characterized by muscle rigidity and hyperthermia occurring in susceptible pigs following the use of halothane or the muscle relaxant suxamethonium. Back-muscle necrosis of pigs is a special manifestation of PSS.

Malignant hyperthermia also occurs in humans. PSS is caused by an inherited defect as a result of an autosomal-recessive gene at a single locus with incomplete penetrance. It is also known as the halothane sensitivity gene, or PSS mutation, which is single-point mutation of nucleotide 1843 in the skeletal muscle gene for the calcium-release channel of the sarcoplasmic reticulum. The PSS defect renders muscle hypersensitive to stimulation by various stressors. In stress-susceptible pigs there is a rapid onset of anaerobic glycolysis and loss of control of skeletal muscle metabolism in response to stress and anoxia.

The gene is commonly known as the halothane-sensitivity gene (HAL gene) because pigs with the homozygous genotype can be identified with the halothane test, which results in malignant hyperthermia. The halothane gene is located within a group of blood-type genes on the same chromosome, allowing identification of affected pigs by blood typing. A single-point mutation in the porcine gene for the skeletal muscle ryanodine receptor channel is associated with malignant hyperthermia in five major breeds of heavily muscled swine. There is then massive muscle contraction and release of heat. Comparison of the sequences of the HAL genes of PSS and normal pigs revealed a single mutation at nucleotide 1843 in the cDNA derived from the HAL gene.

EPIDEMIOLOGY

Prevalence and Occurrence

This subject needs to be kept in perspective. It has recently been suggested that only 4% of inferior-quality meat is a result of genetics (halothane positive), with the remainder being caused by preslaughter and post-slaughter treatment.

PSS occurs worldwide, but there is considerable breed and area variation in its prevalence. In some European countries the prevalence is a major problem in pig production because of the inadvertent selection for this trait in genetic improvement programs. This underlies the problems of selection based purely on performance and production characteristics.

The prevalence of PSS in the swine population can be determined by the use of screening tests applied on the farm or when pigs enter swine performance test stations. The halothane test and the CK test are useful for this purpose. A DNA-based test with 99% accuracy is also available. In European breeds, the prevalence varies from 0% to 88%, with up to 100% in the Pietrain breed. The prevalence of halothane susceptibility is low in the Danish Landrace breed in Denmark. Based on the halothane test, 1.5% of young boars entering a Record of Performance Test Station in Canada were positive reactors. The reactors originated from 7.5% of 107 herds. The halothane succinylcholine test was a more sensitive test because 18% of the same pigs were identified as reactors.

Using a DNA-based test, in a survey of 10,245 breeding swine of various breeds from 129 farms in the United States, Canada, and England, approximately 1 of 5 pigs was a heterozygous carrier of the PSS mutation, and 1% were homozygous. The prevalence of the PSS mutation was 97% for 58 Pietrain, 35% for 1962 Landrace, 15% for 718 Duroc, 19% for 720 Large White, 14% for 496 Hampshire, 19% for 1727 Yorkshire, and 16% for 3446 crossbred swine. The PSS gene frequencies for these breeds were 0.72, 0.19, 0.08, 0.10, 0.07, 0.10, and 0.09, respectively. The PSS mutation has also been identified in Poland China and Berkshire breeds. These gene frequencies were 30% to 75% lower in Canadian swine than in U.S. swine, with the exception of Yorkshires, for which the gene frequency is threefold in Canadian swine.

Risk Factors

Animal Risk Factors

Susceptibility to the PSS is inherited, and the biochemical events leading to PSE, transport death, or malignant hyperthermia are triggered by several external influences or stressors in the living animal. PSS probably occurs in all breeds of pigs, but the incidence is highest in pigs selected for heavy muscling, and stress-susceptible pigs are leaner and more meaty. These include the Pietrain and Poland China breeds and also some European strains of Landrace, where a score for

muscling and growth rate, feed conversion, and back fat has been included in the selection index. A recent study has shown that there are considerable breed differences, in that halothane-stress-susceptible pigs and Hampshires suffer more severely from heat stress than Yorkshires, Danish Landrace, and Duroc boars.

There is a correlation between halothane susceptibility and carcass traits. Halothane status is the most important factor influencing pork quality, although preslaughter handling and stunning method also influence the carcass quality.

Halothane-positive animals usually score higher for visual conformation of the loin and ham than halothane-negative pigs. The progeny of reactor boars are also more susceptible than the progeny of nonreactors. Until recently it was thought that the major limitation of the halothane test was that it identified only those pigs that are stress-susceptible to the syndrome. It is now known that the halothane-sensitivity gene is expressed in heterozygous pigs, where it is likely to cause poor carcass quality.

Landrace pigs can be divided into those that are sensitive to halothane and develop PSE pork postmortem, those that are resistant to halothane but develop PSE pork, and those resistant to halothane and PSE pork (the normal pig). Muscle from pigs susceptible to malignant hyperthermia and PSE pork has significantly higher glucose-6-phosphate levels and lower phosphocreatine under thiopentone anesthesia than muscle from pigs susceptible to PSE and normal pigs. Altered muscle fiber type is not the primary basis of the disease complex.

Environmental and Management Risk Factors

The most important precipitating factors are transportation at high environmental temperatures and humidity, exhaustive exercise, and, under experimental conditions, the more specific reaction toward the anesthetic halothane. Response of pigs to transport is dependent on genotype, particularly at high temperatures such as 36° C (97 F). Experimentally, psychological mechanisms can precipitate the PSS. The effects of mixing, transportation, and duration of lairage can have profound effects on the carcass characteristics of susceptible pigs. Death during transportation and PSE are associated with fear, defensive or aggressive reactions in unfamiliar social environments, and conflict with other unfamiliar pigs or people. Other activities that may trigger malignant hyperthermia include restraint, mating, farrowing, fighting, and vigorous exercising.

Economic Importance

The economic losses associated with PSS are attributable to mortality from transport death and inferior meat quality as a result of PSE pork. As a result of the excessive rates of production of lactic acid and heat, sarcoplasmic proteins denature, thereby causing a deterioration of the water-binding capacity of muscle. The increased osmotic activity resulting from end products of hypermetabolism causes an influx of water from the extracellular space, resulting in hemoconcentration and increased intramyofiber water content. The muscle becomes pale, soft, and exudative, sour-smelling, and loose textured. The shrinkage resulting from water loss during storage, transport, and processing of the carcass is the major cause of wholesale losses at pork-packing plants. PSE carcasses yield less bacon, and the drip loss from fresh PSE meat is more than doubled compared with normal carcasses. Another cause of lost revenue with MH-susceptible swine is their decreased average daily weight gains, conception rates, litter sizes, and boar breeding performance.

PATHOGENESIS

The molecular basis for susceptibility to the PSS is a hypersensitive triggering mechanism of the calcium-release channel of skeletal muscle sarcoplasmic reticulum. The calcium channel, also known as the ryanodine receptor, plays a critical role in the initiation of muscle contraction. The PSS defect renders muscle hypersensitive to stimulation by various stressors. Stress-susceptible pigs cannot tolerate stress and lose control of skeletal muscle metabolism. The stress may be from external influences such as transportation, fear and excitement, or halothane anesthesia. There is excessive catecholamine release and the sudden onset of anaerobic glycolysis of skeletal muscle, excessive production of lactate, and excessive heat production, which, in conjunction with peripheral vasoconstriction, leads to hyperthermia. Following exertional or thermal stress, susceptible pigs undergo more extensive physiologic change than do resistant pigs. Halothane-sensitive pigs are more susceptible to becoming nonambulatory when subjected to multiple stressors and may be more prone to producing inferior pork products. The blood glucose concentrations are dependent on the MH genotype, with the homozygous-positive animals having the highest levels and the homozygous-negative animals having the lowest. The changes in carbohydrate metabolism at rest in MH-positive animals are caused by latent increases of intracellular Ca^{2+} concentrations. Under physical load conditions there is higher lipolysis, which may be the result of an indirect activation of the lipolytic system via catecholamine-induced cAMP turnover.

Depending on the nature, severity, and duration of the stress, the syndrome may manifest in different ways:

- The porcine stress syndrome causes rapid death following severe stress.
- The PSE pork and dark, firm, dry (DFD) pork are seen after slaughter, which might have been preceded by mild stressors during lairage.
- The malignant hyperthermia is drug-induced.

PSE pork is attributed to increased glycolysis after slaughter. In muscles that develop DFD pork, the muscle glycogen is already depleted before slaughter. When PSE develops in a muscle, pH drops to values lower than 5.8 at 45 minutes after death. In normal muscles, the pH decreases from approximately 7 in living muscles to 5.3 to 5.8 at 24 hours after death. The lower pH in PSE muscles, combined with a high carcass temperature within the first hour after death, causes the proteins in the muscles to denature. This contributes to the pale color of PSE meat and to its reduced water-holding capacity. Development of muscles with PSE characteristics seems to be initiated by a combination of lower muscle pH already at exsanguination and a faster pH decrease.

Malignant hyperthermia is the drug-induced and often fatal stress syndrome occurring in susceptible pigs within 3 minutes following the inhalation of a mixture of halothane and oxygen. Susceptible pigs develop limb rigidity and a hyperthermia, which are not easily reversed and may result in death. There is an increased rate of intracellular ATP hydrolysis leading to a progressive failure of ATP-dependent Ca^{2+} accumulation by the sarcoplasmic reticulum and/or the mitochondria, with a rise in myoplasmic concentration of Ca^{2+} and consequent contraction of muscle. The same molecular defect occurs in lymphocytes from affected susceptible pigs. There is no histomorphometric evidence of cardiac abnormalities in MH-susceptible pigs. The mitochondria from predominantly red muscle fibers have a greater calcium-binding capacity than those from predominantly white-muscle-fiber areas. There is extreme rigidity of skeletal muscles, hyperthermia, tachycardia, cardiac arrhythmia, an increase in oxygen consumption, lactate formation and high-energy phosphate hydrolysis in muscle, respiratory and metabolic acidosis, and a rise in the CK activity and concentrations of potassium, lactate, glucose, free fatty acids, and catecholamines in blood. There is a large release of glucose and potassium from the liver, which contributes to the hyperglycemia and hyperkalemia. There is a marked α-adrenergic stimulation, which is responsible for the heat production in MH-susceptible pigs. However, the β-adrenergic response in stress-sensitive and stress-resistant pigs is inconsistent. The lactic acidemia is severe because of the overproduction of lactate peripherally and failure of normal lactate uptake.

Malignant hyperthermia can also be induced using methoxyflurane, isoflurane and enflurane, and succinylcholine.

Exposing stress-susceptible pigs to halothane or exercise induces glycolysis, but the

mechanisms are different. There are no histochemical differences between muscles of susceptible and normal swine. There is some indication that halothane causes a transient but significant vasoconstrictive action, which could be a contributing factor in initiating the severe reactions in malignant hyperthermia. Electron microscopy of platelets from stress-susceptible pigs reveals a defect characterized by dilatation of the open canalicular system.

CLINICAL FINDINGS

Porcine Stress Syndrome (Transport Death)

Death during or following transport to market may be significant and is more prevalent when overcrowding occurs and during the hot summer period. If seen alive, affected pigs initially show a rapid tremor of the tail, general stiffness associated with increased muscular rigidity, and dyspnea to the extent of mouth-breathing. The body temperature is elevated, often beyond the limits of the clinical thermometer, and there are irregularly shaped areas of skin blanching and erythema. At this stage the affected pig is frequently attacked by other pigs within the group. The pig collapses and dies shortly afterward, and the total time course of the syndrome is generally of the order of 4 to 6 minutes.

Malignant Hyperthermia

Malignant hyperthermia is also a manifestation of the PSS. It may be induced in stress-susceptible pigs by stress and injectable (succinyl choline, acepromazine, ketamine) or inhalation anesthesia with potent volatile anesthetics such as halothane or isoflurane. It is characterized by the development during anesthesia of increased muscle metabolism with muscular rigidity, lactic acidosis, a marked increase in basal metabolic rate, increased oxygen consumption and carbon dioxide production, severe hyperthermia and tachycardia, tachyarrhythmia, and death. Death is a result of the peripheral circulatory changes that are produced by severe acidosis, vasoconstriction, hyperkalemia, reduced cardiac output, and hypotension. Once fully developed, the syndrome is irreversible. The syndrome poses a hazard in swine anesthesia, which can be averted by prior medication with dantrolene and has received considerable study as a model for an analogous syndrome in humans. It has also been used as a method for determining stress susceptibility for genetic selection programs.

Pale, Soft, and Exudative Pork

In stress-susceptible pigs, after slaughter, the inferior quality of the meat, with its pale, soft, exudative (PSE) characteristics, is obvious. This is caused by excessive postmortem glycolysis with lactic acid production and a rapid fall in muscle pH, with depigmentation and reduced water binding as a consequence. In affected muscle, rigor mortis occurs rapidly after slaughter but then decreases, so that affected carcasses have been "set" and postmortem drip is excessive. Affected pork has a pH of less than 6 and generally a temperature of 41° C (106° F) or greater 45 minutes after slaughter, compared with the normal pork with a pH above 6 and a temperature less than 40° C (104° F). This causes denaturation of muscle proteins, leading to affected meat that has inferior taste, cooking, and processing qualities and does not accept curing as readily. The occurrence of this syndrome is considerably influenced by the stress of transport and handling before and during slaughter, and this aspect of the syndrome is of major economic importance. Rapid chilling helps prevent PSE, but chill type has no effect.

Dark, Firm, and Dry Pork

Dark, firm, and dry (DFD) pork has darker color and higher ultimate pH than normal meat. In muscles that develop DFD, the muscle glycogen is already depleted before slaughter, which may be related to prolonged transport with fasting.

Back-Muscle Necrosis

Acute necrosis of the longissimus dorsi occurs in German Landrace pigs and other breeds. The acute syndrome lasts approximately 2 weeks and is characterized by swelling and pain over the back muscles, with arching or lateral flexion of the spine and reluctance to move. The swelling and pain then subside, but there is atrophy of the affected muscle and development of a prominent spinal ridge. Some regeneration may occur after several months. Acute cases may die. The syndrome occurs in young adults weighing from 75 to 100 kg. The mild form may be undetectable except for pigs lying down near the feed trough. In the severe form, affected pigs may assume the dog-sitting position with a hunched-up back.

CLINICAL PATHOLOGY

Several testing methods are available for predicting susceptibility.

Halothane Test

The halothane test is highly reliable for the identification of pigs that are homozygous for the single recessive gene responsible for susceptibility to PSS. However, the test is not 100% accurate because of the incomplete penetrance of the halothane sensitivity trait (not all homozygous MH-susceptible pigs react by developing limb rigidity). Penetrance of the halothane sensitivity trait is estimated to vary from 50% to 100% depending on the breed, herd, and investigators. The test detects the worst clinical outcomes, and it will not identify all the pigs that will develop PSE. There is now evidence that it will detect the heterozygote. Stress-susceptible pigs are sensitive to halothane at 8 weeks of age, and if the anesthetic challenge is removed immediately after obvious signs of limb rigidity develop and before the development of fulminant hyperthermia, the mortality from the procedure is negligible. Pigs that remain unreactive for a challenge period of 5 minutes are considered normal.

A halothane-sensitive muscle defect can be present in certain individuals that do not develop rigid malignant hyperthermic episodes on brief exposure to halothane. A longer halothane exposure combined with succinylcholine is required if these false negatives are to be identified. The halothane test has good predictive value for the occurrence of PSE. However, there may be breed variations, as mentioned previously.

A decrease in the amplitude of the phosphocreatine (PCr) signal in the in vivo 31 P nuclear magnetic resonance spectrum of skeletal pigs is an early and 100% predictive measurement for the detection of malignant hyperthermia in anesthetized piglets. Nuclear magnetic resonance techniques such as magnetic resonance imaging and magnetic resonance spectroscopy are sensitive diagnostic aids for detecting the onset of PSS in young animals and for following the metabolic changes in muscle tissue during the syndrome.

Halothane concentration markedly affects the outcome of halothane testing, and either higher halothane concentrations or longer exposure might be required to identify positive reactors in a heterogeneous population. The ionophore A23187, a lipophilic carboxylic antibiotic that binds and transports divalent cations across both natural and artificial membrane bilayers, allows clear differentiation between the muscles of normal and pathologic animals and may be a useful adjunct to the halothane test.

Blood Creatine Kinase Levels

The blood creatine kinase (CK) levels are higher in stress-susceptible pigs. Pigs are subjected to a standard exertion test, and blood samples are taken 8 to 24 hours later and analyzed for CK. The original research indicated a good correlation between CK levels and the halothane test. There is also an increase in CK levels in pigs as they are transported from the farm to the abattoir. However, not all pigs that develop PSE have increased serum levels of CK. Increased CK activity is highest in stress-susceptible pigs of a certain phenotype Phi-B, and their total plasma CK levels are higher than those of nonreactors. The initial test was modified so that blood could be collected as drops on a filter paper and sent to a laboratory for identification by a bioluminescent technique. A recent evaluation of a commercial CK screening test using the method of bioluminescence compared with the halothane challenge test on young boars entering a Record of Performance Test Station revealed that it was an inadequate indicator of susceptibility

to PSS or MH. In a different study the CK levels of piglets 8 to 10 weeks of age predicted halothane-induced stress syndrome with an accuracy of 87% to 91%.

Plasma pyruvate kinase activity has been compared with CK activity as an indicator of PSS. Both enzymes are increased significantly in homozygous halothane-reacting pigs compared with nonreacting pigs. Pyruvate kinase activity was less variable within groups than CK activity, which may allow more effective discrimination between the two different genotypes. However, age-related effects and the failure to identify heterozygotes may restrict the use of plasma pyruvate activity as a diagnostic test.

Blood Typing

Blood typing is also used as a method for the identification of susceptible pigs. On one of the chromosomes of the pig, a region with four known loci has been identified. These loci contain the genes responsible for variants of the enzymes 6-phosphogluconate dehydrogenase and phosphoferose isomerase (PHI). The H-blood group system is determined by one of the loci, and halothane sensitivity is also determined by genes at a locus in this region. This region is of special interest because a close connection has been found between this and important carcass traits such as the PSE condition. Thus blood grouping may be used to detect halothane-sensitive pigs and heterozygote carriers.

A DNA-based blood test can now be used to detect the HAL gene status. It can be adapted for rapid batch analysis of many samples simultaneously, is less invasive, and can be applied to as little as 50 µL of blood. The test is more than 99% accurate, is cost-effective, and can be used to determine the prevalence of the PSS mutation in various breeds of swine in various countries. A recent study showed that 23% of pigs classified as Hal-1843–free based on a DNA test responded abnormally to halothane anesthesia.

Pale, Soft, and Exudative Pork

Pale, soft, and exudative pork (PSE) is evaluated by a meat quality index that combines meat color, pH at 24 hours postmortem, and water-binding capacity. Susceptible lines can be identified by carcass inspection and the results applied to sibling or progeny selection. A recent approach is the measurement of mitochondrial calcium efflux. Mitochondria isolated from Mm longissimus dorsi muscle exhibit a rate of Ca^{2+} efflux twice that of normal pigs. Most of the tests readily predict the worst examples of the syndrome but are not sufficiently precise to be able to identify tendencies toward it, which restricts their value in breeding programs.

Erythrocyte Osmotic Fragility

Erythrocyte osmotic fragility may be correlated with malignant hyperthermia and is being examined as a possible aid in the determination of susceptibility.

Other Tests

Any reliable test that can identify stress-susceptible pigs without using halothane testing is attractive. Increased peroxidation of the erythrocytes may be an improved diagnostic test for PSS. Differences in the levels of cortisol, creatinine, aspartate aminotransferase, and lactate dehydrogenase are highly significant between halothane-sensitive and halothane-negative lines of pigs.

An allele-specific PCR (AS-PCR) technique has been developed. A PCR followed by reduction endonuclease assay has been developed and used on plucked hair as a source of genomic DNA. In a test with this method, 9 of 12 Pietrains tested were homozygous or heterozygous. A one-step procedure has been developed called mutagenically separated PCR (MS-PCR).

NECROPSY FINDINGS

In PSS, rigor mortis is present immediately following death, and carcass putrefaction occurs more rapidly than normal. The viscera are congested, and there is usually an increased quantity of pericardial fluid and pulmonary congestion and edema. The muscles—especially the gluteus medius, biceps femoris, and longissimus dorsi—are pale, wet, and soft. In back-muscle necrosis, these changes appear grossly to be confined to the epaxial musculature. Histologically, the lesions in skeletal muscle may be minimal and are easily obscured by autolysis. In some instances only interstitial edema is visible, whereas in animals that have survived repeated episodes there is obvious phagocytosis of degenerate myofibers, with ongoing regeneration and fibrosis. The most typical microscopic finding is hypercontraction of myofibers, characterized by division of the cell into irregularly sized segments by transverse and sometimes branching bands. Degenerate sarcoplasm of a floccular or sometimes hyaline character may be present. Degenerative changes may also be detected in myocardial cells.

Samples for Confirmation of Diagnosis

- Genetic analysis—50 g frozen muscle (DNA ANALYSIS) and hair for PCR tests
- Histology—formalin-fixed skeletal muscle (several sections, including longissimus dorsi), heart (LM)
- Biochemistry—it has been reported that pigs with PSS develop metabolic acidosis in association with respiratory acidosis, which is manifested as lower values of acid–base excess and HCO_3—with higher H^+ concentrations and P_{CO_2} compared with resistant pigs.

DIFFERENTIAL DIAGNOSIS

The acute nature of porcine stress syndrome (PSS) and its relation to stress serve to differentiate it from most other syndromes causing sudden death in market- and adult-sized pigs. The sudden death syndrome must be differentiated from:

- Mulberry heart disease
- Acute septicemias attributable to salmonellosis, erysipelas, pasteurellosis, and anthrax
- Other causes of sudden death, including intestinal volvulus, heat exhaustion, and suffocation during transportation
- Hypocalcemic tetany resulting from severe vitamin D deficiency, which can produce a similar clinical syndrome
- Porcine viral encephalomyelitis, which can also result in a similar clinical syndrome in post-weaned pigs; pathologic and biochemical examinations differentiate these from the PSS

TREATMENT

Early recognition enables successful treatment. Any drug administration should cease. Aggressive cooling using icepacks and alcohol baths should be instituted. The acute syndromes are usually not treated. Several drugs are available for the protection of pigs against drug-induced malignant hyperthermia. A combination of acepromazine and droperidol will delay the onset or prevent the occurrence of halothane-induced malignant hyperthermia. Dantrolene is also effective for treatment and prevention. The therapeutic dose is 1 to 3 mg/kg BW IV and 5 mg/kg orally as a preventative. Carazolol is effective for the prevention of transport death when given 3 to 8 hours before transportation and improves meat quality compared with untreated susceptible animals. Acute back necrosis has been treated successfully with isopyrin and phenylbutazone. Experimentally, the supplementation of the diets of stress-susceptible pigs with vitamin E and C will provide some protective effect on cell-membrane integrity.

CONTROL

The control of this syndrome depends on genetic selection and possible eradication of the PSS mutation and reduction of the severity of stress imposed on pigs.

Genetic Selection

The best strategy for control of this complex is not clear. Several factors must be considered. Swine homozygous for the PSS mutation are at very high risk for developing PSS and severe PSE to make them useful for market pigs. They are used primarily as a source of the PSS mutation for breeding programs and research purposes. Using swine that are heterozygous for the PSS mutation as market pigs may be advantageous. They benefit from the positive effects of the

mutation, have minimal risk of developing PSS, and may have acceptable prevalence and severity of PSE, if the environmental and management risk factors that precipitate PSE are minimized during marketing and slaughter. The mutation is not a prerequisite for leanness and muscularity, and it is possible for breeders to eradicate the gene from their breeding stock. The negative effects of the halothane gene on fresh pork quality are well known. However, such a policy may result in the loss of an easily accessible and cost-effective selection criterion for favorable carcass characteristics. The PSS mutation has been used successfully in most swine breeds for increasing leanness and muscling. With the development of the DNA-based test for the PSS mutation, the mutation can be selected for with high precision and accuracy, and its expression can be finely controlled in a breeding program.

The various testing methods described under "Clinical Pathology" are used to identify pigs with the halothane gene. The tests can be applied to breeding stock entering swine performance test stations or on a herd basis. A reliable diagnostic test such as a DNA-based blood test to identify the gene will provide the basis for elimination of the gene or its controlled inclusion in swine breeding programs.

Management of Stressors

Control through reduction of stress is not easily applied because frequently the syndrome is induced by routine minor procedures within the piggery. The incidence of transport deaths or the necessity for immediate slaughter salvage of severely stressed pigs on arrival at the abattoir and the occurrence of PSE meat characteristics are a significant economic problem in some countries. The necessity to climb an upper deck in the transport poses a significant stress, and the use of single-deck transports or mechanical lifts for multiple-deck transports, and the shipment of pigs in containers, has resulted in a decreased incidence. The provision of spacious, well-ventilated transport vehicles and spray-cooling of pigs on arrival at the holding pens is also beneficial. Pigs should not be slaughtered directly after arrival at the abattoir and should be rested for at least 1 to 2 hours if they have been stressed only by transportation. In cases of severe physical exertion, even more time should be allowed for recovery. Where possible transport distance should be kept to a minimum, and transport should be avoided on excessively hot days.

PIETRAIN CREEPER PIGS

A progressive muscular weakness is found in stress-susceptible Pietrain pigs. A similar condition might have been seen in Landrace. It was originally described in one to three herds in the United Kingdom. It is probably an autosomal-recessive gene and is a progressive familial myopathy. In each litter one-quarter to one-third of piglets may be affected. The syndrome commences with muscle tremor at 2 to 4 weeks of age, in the hindlimbs progressing to the forelimbs, followed by reluctance to stand, limbs being flexed, and standing on tip-toe, with walking on flexed carpal joints leading to complete recumbency by 12 weeks of age. At this stage the pigs move with a creeping gait with the limbs flexed. The pigs remain alert and feed and grow normally. There are no neuropathologic lesions, but there are myopathic changes, especially in the forelimbs. In these muscles there are very variable muscle cells with internal nuclei.

ASYMMETRIC HINDQUARTER SYNDROME OF PIGS

Asymmetric hindquarter syndrome of pigs was first reported in Germany and Belgium and was recognized in the United Kingdom in 1968. In these cases perineurial fibrosis was a feature, and it was thought that the condition resulted from either a neurogenic atrophy or a periarticular fibrosis extending to the peripheral nerves.

In this syndrome variable asymmetry of the hindquarters is evident during early growth of the animal and obvious by 80 kg live weight. An asymmetric distribution of subcutaneous fat is also noted, and possibly skin dimpling. The muscle most frequently affected is the semimembranosus, followed by the semitendinosus, biceps femoris, adductor femoris, and gracilis. The muscles show changes that can be described as myofibril degeneration, interstitial fibrosis, and dystrophic changes.

Several breeds, including Landrace, Large White, and Hampshire, have been found affected, but the problem is generally restricted to certain herds and to certain families within these herds, suggesting that a genetic liability exists for this condition. The mechanism of inheritance studied from test matings is not simple. Whatever the cause, there is a marked reduction in the number of muscle fibers. Both sexes may be involved, and the condition may involve either hindlimb.

Despite a marked reduction in muscle mass, there is no detectable abnormality in gait. The cause is unknown, although it appears to result from suboptimal muscle growth rather than degenerative loss. In the only cases recorded from outside Europe, a group of seven Australian pigs were examined in detail; in one of these pigs the affected semitendinosus weighed only 41% of the normal, unaffected one. Perineural fibrosis and myopathy have been observed in some cases.

PORCINE CONGENITAL SPLAYLEG (SPLAYLEG SYNDROME IN NEWBORN PIGS)

Porcine congenital splayleg (PCS) is also called spraddle leg, but more usually myofibrillar hypoplasia. This may be an erroneous term because this hypoplasia occurs in many normal pigs and may be a normal feature of postnatal muscle growth. This clinical condition of splayleg occurs in newborn piglets in most countries and is characterized by a temporary inability to stand with the hindlimbs.

ETIOLOGY

The etiology is unknown, but based on epidemiologic evidence, it is multifactorial. The current hypothesis is that the disease is caused by an interaction of genetic and nongenetic factors, a polygenic mode, or expression of many genes without dominance.

Splayleg is not characterized by general muscular atrophy in the affected hindlimbs.[1]

The studies of Czech workers have suggested that the patho-morphology of the condition resembles that of glucocorticoid-induced myopathy in humans and animals. Dexamethasone given to minisows from the first to the last days of pregnancy produced a disorder characterized by splayleg syndrome with retardation of both muscle growth and myofibrillogenesis in their newborn piglets. It has also been experimentally produced following the administration of pyrimethamine.

There may be pathways indicated in gene expression for the further investigation of congenital splayleg.[2] It may be that the combined differential expression of MAFbx (a major atrophy marker) and P311 (a novel protein down regulated in all PCS muscles) is of potential in the diagnosis of subclinical PCS.[3]

EPIDEMIOLOGY

The prevalence of the disease in the United Kingdom is 0% to 4%, and the morbidity in affected herds varies from 2% to 27%. The case-fatality rate is approximately 50% and is attributable to crushing, chilling, and starvation because affected piglets are not able to move around normally. The disease is more common in the Pietrain, Welsh, Landrace, and Large White breeds of swine; Landrace pigs may be especially susceptible. This suggests a genetic basis, but test-matings, with the exception of a few, have not been successful in reproducing the disease. On most farms the disease affects both male and female piglets. In a recent

retrospective analysis of the incidence of the disease in a swine herd over a period of 5 years, the overall frequency was 1.74 times greater in males than females, and the birth weight of splayleg piglets tended to be subnormal. The environmental factors that have been associated with some outbreaks include slippery floors, a dietary choline deficiency, and the ingestion of **Fusarium toxin** by pregnant sows. Choline deficiency is unlikely to be a factor, and no other factors have been substantiated as etiologic factors or epidemiologic determinants.

PATHOGENESIS

The pathogenesis of the disease is unclear. In affected pigs there is myofibrillar hypoplasia, but this is also a feature of many muscles in normal pigs. There are simply too few maturing type I fibrils in the muscles, particularly of the foreleg, lumbar epaxial group, and the hindlimb, to carry weight. The semitendinosus appears to be the most significantly affected muscle. However, because myofibrillar hypoplasia may also be present in normal unaffected littermates, it has been difficult to explain the pathogenesis of the muscular weakness. The use of morphometrics has enabled the detailed determination of the myofibrillar hypoplasia. In addition to myofibrillar hypoplasia, in splayleg pigs there is a higher content of sarcoplasmic RNA, reflected ultrastructurally by the presence of numerous ribosomes. The extramyofibrillar space was also filled with glycogen in splayleg pigs. In myofibrillar hypoplasia induced with glucocorticoids given to the pregnant sow, none of the pigs had splaylegs, but the extramyofibrillar space contained little glycogen. There were also many glycogen-filled phagosomes and residual bodies, indicating a difference in the metabolism of glycogen in the first 2 or 3 days after birth. In a study of natural cases there was hypoplasia, but there was an increased accumulation of glycogen, especially within the large extramyofibrillar spaces, in comparison with the normal pigs. These authors also found an anomalous distribution of glucose-6-phosphatase in splayleg-affected muscles, in that the activity was concentrated at the periphery of the extremely dilated cisternae of the sarcoplasmic reticulum. In the normal muscles this enzyme activity was normal. This distribution could account for the slower utilization of glycogen in affected muscles and therefore would account for the build-up. Quantitative image analysis of skeletal muscle revealed that the arrangement of the myofibrils within the fascicles of affected and unaffected pigs was different.

Some studies have found both quantitative (hypoplastic type) and qualitative (dystrophic type) insufficiencies in affected pigs that represent a temporary perinatal developmental disturbance. This could explain the muscular weakness and the recovery that occurs.

CLINICAL FINDINGS

There is a temporarily impaired functionality of the hindleg muscles immediately after birth. Essentially, the adductors are not as powerful as the abductors.

Larger litters may be more affected, possibly because these tend to be born earlier. The clinical signs are usually obvious in 2 to 3 hours after birth when the litter should be standing and walking around the creep area. Affected piglets are unable to stand, their hindlimbs are splayed sideways or forward, and the animals rest in sternal recumbency. Sometimes the forelimbs are also splayed. Most severely affected piglets are unable to move; less severely affected animals are able to move slightly. Many pigs have soiled hindlimbs and perineum as a result of being unable to stand. As a result, the piglets are likely to be crushed or have difficulty gaining access to their source of nourishment. Affected piglets are normal in other respects, have a normal appetite, and will suck the sow if placed near a teat. In the experimental induction there was hypoplasia but no clinical signs, which is further evidence for suggestions that the condition has a threshold for clinical signs and has strong maternal influences.

TREATMENT

Treatment can be successful. If the pigs are able to suck or if they are fed artificially for 2 to 4 days, recovery will occur within 1 week in about 50% of cases. The ambulatory capacity of affected pigs can be improved, and mortality reduced, by taping or loosely tying together the hindlimbs for a period of up to 1 week. The method of loose tying of the hindlimbs consists of a figure-of-eight bandage (2.5-cm-wide adhesive tape) being fixed around the metatarsal bones, leaving a space between the legs of up to 7 cm depending on the size of the piglet. The legs should be tied together within a few hours after the syndrome is obvious; a delay of several hours will decrease the prognosis. The provision of a nonslip floor surface such as a carpet or sack may also be helpful. Many farmers will tell you that repeated massaging of the limbs will also improve the survival rate.

CONTROL

Whether or not to cull the boar depends on the pedigree value of the animal, the incidence of the disease, and the probability that the boar is responsible. There is no evidence that the disease is monogenic. However, the incidence is highest in the Landrace breed, which suggests a hereditary predisposition. In deciding whether to use a suspected carrier animal, there is a need to distinguish between different situations. The consequences of disease are felt differently at the different levels of organization of the pig industry. A boar of high merit for performance traits may be more economical to retain as breeding stock even though some progeny are affected with the disease than a less superior boar whose progeny are unaffected. If stress of the pregnant sow is a factor, control of the disease may be dependent on the selection of stress-resistant boars and sows.

Concurrent disease should be controlled; producers report a higher percentage of splayleg piglets after a period of porcine respiratory and reproductive syndrome (PRRS) infection. There are also suggestions that induced early farrowing and zearalenone poisoning may also be complicating factors to prevent.

Inherited Diseases of Bones

Congenital skeletal abnormalities are relatively common in large animals and can be genetic, teratogenic, or nutritional in origin.[1-3] Exposure of developing fetuses to a wide variety of toxic compounds, maternal mineral deficiencies or imbalances, or exposure to one of a number of infectious agents at certain stages of gestation can create skeletal lesions indistinguishable from those caused by a genetic abnormality. In some cases, teratogenic or nutritional causes of skeletal abnormalities can appear very similar to genetic causes, and distinguishing among them can be challenging.[3] For example, chondrodysplasia associated with intrauterine zinc or manganese deficiency have similar clinical features and histologic lesions to mild forms of hereditary chondrodysplasia.[3] Therefore, historical data are essential in any attempt to distinguish genetic and acquired causes of skeletal lesions; as many animals as possible should be examined, and samples should be collected for future analysis, such as genetic testing.

ETIOLOGY

Over 350 defects in cartilage and bone development are identified in humans.[4] Although substantially fewer are identified in large animals, this large number in humans underscores the many potential diseases in animals. The situation in many production animal industries is compounded by the "founder effect" and widespread use of elite sires by means of artificial insemination that leads to the frequent emergence of recessive genetic defects, which cause important economic and animal welfare concerns.[2,5] Table 15-10, modified from Dittmer and Thompson,

Table 15-10 Inherited skeletal diseases of livestock with known mutations and proposed mechanisms.

Disease	Breed/mutation/OMIA no.	Proposed mechanism
Bulldog chondrodysplasia	Dexter cattle, other miniature cattle breeds Mutated gene, Aggrecan (*ACAN*), OMIA: 001271-9913	ACAN is the main proteoglycan expressed by chondrocytes during cartilage. formation in the primordial limb bud.
Angus dolichocephalic long-nosed dwarfism	Angus cattle Mutated gene; cGMP-dependent type II protein kinase (*PRKG2*); OMIA: 001485-9913	PRKG2 is required for growth-plate development because it regulates SOX9, a critical transcription factor involved in endochondral ossification and the control of growth-plate collagens type II and X.
Ellis van Creveld syndrome 2	Japanese Brown cattle, Gray Alpine cattle	Part of the primary cilia, thought to have a role in regulating sonic hedgehog, a key regulator of skeletal development.
Arachnomelia	Italian Brown, Simmental, German Fleckvieh, and Brown Swiss cattle Mutated gene; molybdenum cofactor synthesis step 1 (*MOCS1*), sulfite oxidase (*SUOX*); OMIA: 001541-9913, 000059-9913	Increased sulfite levels result in atypical bone development.
Osteopetrosis with gingival hamartomas	Belgian Blue cattle Mutated gene; chloride/proton exchanger, lysosomal anion transporter (*CLCN7*); OMIA: 001887-9913	CLCN7 and associated subunit osteopetrosis associated transmembrane protein (Ostm1) are on lysosome membranes and the ruffled border of osteoclasts. Mutations in CLCN7 and Ostm1 impair acidification of resorption lacunae.
Osteopetrosis	Red Angus cattle Mutated gene; anion exchange transporter (*SLC4A2*); OMIA: 000755-9913	The SLC4A2 transporter exchanges bicarbonate ions for chloride ions. As a result of proton secretion during acidification of resorption lacunae, mutations in this transporter result in accumulation of bicarbonate ions, leading to toxic osteoclast alkalinization.
Marfan syndrome	Japanese Black cattle Mutated gene; fibrillin 1 (*FBN1*); OMIA: 000628-9913	Fibrillin is a component of the extracellular microfibrils present in connective tissues. Fibrillins regulate TGF-b and BMP availability, and the decreased bone mineral density and decreased mechanical strength seen in Marfan syndrome are thought to be attributable to increased activation of TGF-b signaling.
Autosomal-recessive hypophosphatemic rickets, type I	Corriedale sheep Mutated gene; dentin matrix protein 1 (*DMP1*); OMIA: 001542-9940	Dentin matrix protein 1 (DMP1) is a noncollagenous bone protein involved in bone mineralization. In addition, decreased DMP1 results in increased FGF23 and subsequent phosphaturia.
Spider lamb syndrome	Suffolk sheep, Hampshire sheep Mutated gene; fibroblast growth factor receptor 3; OMIA: 001703-9940	Mutation removes FGFR3 inhibition of chondrocytes entering the hypertrophic chondrocyte phase, resulting in increased length of long bones.
Texel chondrodysplasia	Texel sheep Mutated gene; sodium-sulfate transporter (*SLC13A1*); OMIA: 001400-9940	In addition to changes in the cartilage matrix, undersulfation of cartilage proteoglycans leads to altered Indian hedgehog signaling, resulting in decreased chondrocyte proliferation.[2,5]
Schmid metaphyseal chondrodysplasia	Yorkshire pig Mutated gene; collagen, type X, alpha 1 chain (*COL10A1*); OMIA: 001718-9825	Type X collagen is expressed by hypertrophic chondrocytes, and this mutation prevents trimerization of the collagen X chains.
Vitamin D–dependent rickets type I	Hannover pig Mutated gene, 25-hydroxyvitamin D 1-α-hydroxylase (*CYP27B1*); OMIA: 000837-9825	CYP27B1 is required for the formation of active vitamin D (1,25-dihydroxyvitamin D). Decreased active vitamin D leads to hypocalcemia and hypophosphatemia, impaired cartilage and bone mineralization, and decreased chondrocyte apoptosis.

Modified from Dittmer and Thompson.[3]

provides a listing of currently recognized inherited skeletal diseases of livestock, the associated mutations, and mechanisms underlying the disease.[3]

PATHOGENESIS

Bone development and remodeling is a complex process involving timely expression and control of numerous genes and epigenetics factors, and there is increasing understanding of the role of these factors in creation of bone and cartilage.[4,6] The large number of genes involved in osteogenesis and cartilage formation and development, and the crucial and nonredundant role of many of these genes, means that a wide range of skeletal defects occur in humans and domestic animals. A variety of transcription and growth factors are identified as being involved in the pathogenesis of skeletal defects. This allows etiologic, rather than morphologic, classification of diseases and abnormalities. **Osteochondrodysplasia** (or skeletal dysplasia) includes generalized abnormalities in chondro-osseous tissues, whereas *dysostosis* refers to a localized malformation of an individual bone or group of bones.[2] Osteochondrodysplasias are now mostly classified according to the underlying defect, rather than the morphologic presentation.[7] Most of the skeleton develops through processes involving endochondral ossification, and abnormalities in cartilage formation or structure can have widespread effects on the skeleton. Defects in cartilage formation that result in skeletal abnormalities are called **chondrodysplasia**. **Achondroplasia**, referring to an absence of cartilage, should be reserved for diseases characterized by a lack of cartilage, rather than abnormalities in its composition or structure.[2]

CLINICAL FINDINGS

Animals with acquired defects often have substantial variation in clinical signs and lesions and can improve over time, whereas animals with disease caused by genetic defects usually have a consistent clinical presentation and pathology. Clinical signs of the various diseases are described under those headings.

Diagnosis

If a disease is determined to be of genetic origin, a number of approaches can be used to detect mutations, include sequencing candidate genes, single-nucleotide polymorphism array with genome-wide association studies, and exome or whole-genome sequencing.[3] Use of genome-wide, high-density single-nucleotide polymorphism (SNP) panels, or next-generation genomic analysis, combined with an understanding of livestock populations, allows for rapid positional identification of genes and mutations that cause inherited defects.[5] However, a thorough understanding of the history of the animal's disease, its clinical presentation, and its lesions is essential for establishing a reliable diagnosis.

Differential diagnoses for inherited skeletal diseases of animals are shown in Table 15-11 (modified from Dittmer and Thompson).[3]

TREATMENT AND CONTROL

There is no effective treatment for genetic diseases, and affected animals are usually euthanized. Control is based on an understanding of the mode of inheritance, identification of carrier animals (for diseases with recessive inheritance), and selective breeding or testing and removal of heterozygotes from the breeding pool.

INHERITED OSTEOGENESIS IMPERFECTA

The term *osteogenesis imperfecta* covers a heterogeneous group of connective tissue diseases caused by quantitative or qualitative defects in type I collagen.

The disease is recorded as being inherited in Holstein–Friesian cattle and New Zealand Romney sheep.

Cattle

It is transmitted as an autosomal-dominant trait. Calves are clinically abnormal at birth, with the main presenting signs being bright-pink teeth and slackness of the flexor tendons on all four feet so that the animals are unable to stand. The calves become progressively worse, to the point where they cannot walk. The full list of abnormalities in this syndrome includes smaller-than-normal body size at birth, a dome-shaped cranial vault, and fragility of bones, manifested by multiple fractures occurring during birth. The defect is one of connective tissue cells in which there is a faulty production of collagen and intercellular cement. Radiologic examination demonstrates growth-arrest lines and multiple fractures in the long bones and thin dentine and enamel layers on the teeth, which are pink because of the exposed condition of the enlarged pulp. The excessive mobility of the joints results from the small bulk of the ligaments and tendons.

A syndrome of simple bone fragility occurs in Charolais cattle and is called osteogenesis imperfecta.

Sheep

The disease in New Zealand Romney sheep[1] is similar to that in Holstein–Friesian cattle with additional lesions of thickness of the diaphyses and reduction in size of the medullary cavity, moderate brachygnathia inferior, subcutaneous edema, skin fragility, and a dark blue color of the sclera. It is inherited as an autosomal dominant trait, and was thought to have developed as a new mutation in the testicular cell line of the parent ram.

INHERITED DWARFISM

Most inherited food animal dwarfs are chondrodysplastic, and the disease occurs in cattle and sheep.

Sheep

Brazilian hair sheep of the Cabugi breed, which are typically shorter and more compact than other breeds, have a form of skeletal dysplasia characterized by lambs born with craniofacial abnormalities and dwarfism that die at 2 to 6 months of age.[1] Dwarf lambs are much smaller than normal, with short legs, a domed head with superior brachygnathism, sternal deformities, and exophthalmic eyes situated more laterally in the head than normal. There is disproportionate shortening of the appendicular bones. The disease is inherited as an incomplete dominant trait, with the shortened face, a feature of the Cabugi breed, representing the heterozygous state and the more severe, often lethal, dwarfism occurring in homozygotes.

A syndrome of **dwarfism, brachygnathia, cardiomegaly, and renal hypoplasia syndrome** occurs in Poll Merino/Merino sheep in Australia.[2] The disease is a lethal genetic disorder associated with homozygosity in genetic material located toward the distal end of chromosome OAR2, from 220,932,050 to 221,939,408, which includes approximately 25 genes.[3] Segregation analysis suggests the disorder is transmitted as an autosomal trait with a recessive mode of inheritance. Affected lambs are dwarfs with multiple defects in the skeleton, heart, liver, and kidneys.

Cattle

Snorter Dwarfs

Snorter dwarfs are no longer important because of successful efforts in eliminating carriers of the gene. These calves are short-legged with short, wide heads and protruding lower jaws. The mandibular teeth may protrude 2 to 4 cm beyond the dental pad, preventing effective grazing and necessitating hand-feeding if the animal is to survive. There is protrusion of the forehead and distortion of the maxillae, and obstruction of the respiratory passages results in stertorous respiration and dyspnea. The tip of the tongue usually protrudes from the mouth, and the eyes bulge. There is some variation between affected animals in their appearance at birth. In most cases the defects are as just described, but they become more exaggerated as the calf grows. In addition, abdominal enlargement and persistent bloat develop. The head is disproportionately large. The calves fail to grow normally and are about half the weight of normal calves of the same age.

The predominant form of the condition appears to be inherited as a simple recessive character, although the relationship of the "comprest" types to the total syndrome is more complex. Heterozygotes vary widely in conformation, but some of them show minor defects that may be attractive to cattle breeders who were seeking a chunkier, short-legged type of animal. For this reason, indiscriminate selection toward the heterozygote undoubtedly occurred, resulting in widespread dissemination of the character. Herefords and Aberdeen Angus are the breeds most commonly affected, but similar dwarfs occur also in Holstein and Shorthorn cattle, and typical dwarf animals have been produced by mating heterozygous Aberdeen Angus and Herefords. Besides the shortness of limbs, there is also a looseness of attachment of limbs and abnormal mobility of joints. The disorder of dolichocephalic long-nosed dwarfism in American Angus cattle is attributable to a nonsense mutation in exon 15 of cGMP-dependent type II protein kinase (PRKG2).[4]

Ellis van Creveld syndrome (bovine chondrodysplastic dwarfism) occurs Grey Alpine cattle, Japanese Brown cattle, and

Table 15-11 Differential diagnoses for inherited skeletal diseases of animals

Disease	Clinical signs and lesions
Abnormal head shape	
Genetic	Usually has recessive inheritance, so only small numbers of animals affected. Breeds: Angus, Dexter, Japanese Brown, Tyrolean Grey, and Holstein–Friesian cattle; Texel, Merino, and Cabugi sheep; Danish Landrace pigs. Clinical signs have a consistent presentation, typically with minimal variation. Normal liver zinc and manganese concentrations. Shortened long bones (mild to severe depending on the gene affected), epiphyses potentially mushroomed, domed head, + brachygnathia inferior. Decreased thickness of physes, particularly hypertrophic zone; histologic lesions present in severe forms but mild or nonexistent in other forms.
Chondroplasia—nutritional	Prevalence generally higher than expected for inherited forms of chondrodysplasia. History of drought or adverse weather events during pregnancy and exposure of pregnant animals to unusual supplementary feeding or toxic plants. Variation in severity of dwarfism and twisted limbs; animals with mild cases improve after birth. Shortened long bones, epiphyses can be mushroomed. Decreased thickness of physes, particularly hypertrophic zone; histologically, lesions may be mild or nonexistent. Low liver zinc or manganese concentrations; if deficiency occurred for a finite period during gestation, zinc or manganese concentrations can return to normal.
Plant toxins	*Veratrum californicum* toxicity in sheep: shortening metacarpal/metatarsal + other bones, fusion of metacarpal bones, arthrogryposis, hypermobility of hock joints. Wild lupins (*Lupinus* spp.): cattle; shortening and rotation of limb bones, flexion contracture, arthrogryposis.
Vitamin A intoxication	Pigs: shortening of long bones, abnormally shaped long bones and carpal/tarsal bones, osteoporosis. Calves: possibly associated with "'hyena disease"; premature closure of hindlimb growth plates, segmental narrowing of physes.
Vertebral abnormalities	
Brachyspina	Cattle; smaller-than-normal size, shortened vertebral column as a result of fusion of vertebrae, and long thin limbs. Irregular areas of ossification separated by cartilage, fusion of epiphyses, and diaphysis of adjacent vertebrae.
Complex vertebral malformation	Cattle; smaller-than-normal size, consistent arthrogryposis of forelimbs + hindlimbs, shortening of cervical and thoracic vertebral column, hemivertebrae, fused vertebrae, scoliosis. Cardiac abnormalities in ~50% of cases.
Shortened spine	*Veratrum californicum:* cattle; decreased coccygeal vertebrae, arthrogryposis. Parbendazole toxicosis: compression/fusion vertebrae, absence of various limb bones, curvature of long bones.
Scoliosis, kyphosis, torticollis	Wild lupins: see also craniofacial defects and shortened limbs. Conium maculatum: cattle, sheep, pigs; + arthrogryposis, carpal flexure, cleft palate *Nicotiana tabacum, N. glauca:* cattle/pigs; + arthrogryposis, brachygnathia. Locoweed (*Astragalus* spp., *Oxytropis* spp.): cattle/sheep; also brachygnathia. *Lathyru* spp., *Vicia* spp.: cattle/sheep; + arthrogryposis, rotation of forelimbs.
Manganese deficiency	Cattle; congenital spinal stenosis and premature closure of growth plates associated with Mn deficiency but not proven.
Limb abnormalities	
Syndactyly	Autosomal recessive with incomplete penetrance and variable expression in Holstein–Friesian, Angus, Chianina, Hereford, Simmental, German Red Pied, Indian Hariana, and Japanese native cattle. Right forelimb most commonly involved, but all limbs may be affected. *Veratrum californicum* toxicosis in cattle.
Angular limb deformity	*Trachymene* spp.: sheep; outward bowing, particularly of forelimbs. Locoweed (*Astragalus* spp., *Oxytropis* spp.): cattle/sheep; also limb contractures, osteoporosis.
Congenital hyperostosis	Severe edema: soft tissues of limbs (particularly antebrachium). Radiating trabeculae of new periosteal bone.
Tibial hemimelia	Bilateral tibial hemimelia, cryptorchidism, ventral abdominal hernia, + meningocele.
Abnormalities in multiple axial and appendicular bones	
Spider lamb syndrome	Excessively long limbs and neck leading to angular limb deformities, scoliosis/kyphosis, sternal deformities, Roman nose, degenerative joint disease. Multiple irregular islands of ossification in epiphyseal cartilage.
Schmallenberg virus, Akabane virus, bunyaviruses	Arthrogryposis (Schmallenberg, Akabane); torticollis, kyphosis, scoliosis, lordosis (Schmallenberg); brachygnathia inferior (Schmallenberg); and central nervous system abnormalities (Schmallenberg, Akabane, bluetongue virus).
Plant toxins	Wild lupins, *Conium maculatum, Nicotiana* spp.

Modified from Dittmer KE, Thompson KG. Approach to investigating congenital skeletal abnormalities in livestock. Veterinary pathology. 2015; 52:851.

Tyrolean Grey cattle, in which it is an autosomal-recessive defect with the phenotype of short limbs, joint abnormality, and ateliosis.[5,6] Long bones of affected animals have insufficient endochondral ossification with irregularly arranged chondrocyte, abnormal formation of cartilaginous matrix, and partial disappearance of the epiphyseal growth plates. The mutated gene is Ellis van Creveld syndrome 2 gene (EVC2),[5,6] also known as LIMBIN; OMIA: 000187-9913, causing a defect in the primary cilia, which is thought to have a role in regulating sonic hedgehog, a key regulator of skeletal development.

These disorders should not be mistaken for chondrodysplasia caused by nutritional deficiencies, which characteristically occur with a much higher incidence in affected herds after periods of drought or nutritional stress.[7-9]

Inherited Congenital Achondroplasia With Hydrocephalus

First recorded as **bulldog calves** in Dexter cattle, this inherited defect has since been observed in a variety of forms in other breeds, including Jerseys, Guernseys, Holsteins, and Japanese Brown cattle. Chondrodysplasia in the Holstein–Friesian breed sharing morphologic features with the Dexter bulldog calves have been reported from the United States, the Netherlands, Great Britain, and recently in Denmark. Dexter bulldog–type calves have occurred in French and Danish Holstein calves in a familial pattern related to the sire Igale Masc, and it is likely that the genetic disorder is present in the Holstein breed worldwide.

Characteristic features of lethal chondrodysplasia (Dexter bulldog) calves in Australian Dexter cattle include abortion, disproportionate dwarfism, a short vertebral column, marked micromelia, a relatively large head with retruded muzzle, cleft palate and protruding tongue, and a large abdominal hernia.[5] Histologic changes in limb bones are consistent with failure of endochondral ossification. Dexter chondrodysplasia is considered to be inherited in an incompletely dominant manner, with the homozygous form producing the congenital lethal condition. Based on analysis of the contribution of three obligate heterozygotes whose semen has been widely used in artificial insemination in Australia, it is estimated that the heterozygote frequency is 19% within the registered Australian Dexter herd.

Affected calves are often aborted, but some reach full term and cause fetal dystocia because of the extreme hydrocephalus. The forehead bulges over a foreshortened face with a depressed, short nose. The tongue protrudes, the palate is cleft or absent, the neck is short and thick, and the limbs are shortened. Accompanying defects are fetal anasarca and hydrops amnii in the dam.

The defect is primarily chondrodystrophy rather than achondroplasia; the nasal bones and maxillae do not grow. Hydrocephalus develops because of the deformed cranium. In most breeds the condition is inherited as a simple recessive character, but a dominant form has occurred in Jerseys. The heterozygous form in Dexters is easily recognized by the shortness of the limbs. The heterozygote in other breeds is normal in appearance.

Miscellaneous Dwarfs

Other types of dwarfs have been described and include **"comprest"** and **"compact"** cattle in Herefords and Shorthorns and various other forms of **proportional dwarfs**. For example, in Charolais, miniature calves have been recorded that are exact replicas of normal calves but weigh only 5 to 16 kg at birth and are born 2 or more weeks prematurely. Most are dead at birth or die soon after so that the condition is effectively lethal. Proportional dwarfs occur also in Simmentals.

Other forms of chondrodystrophy, including "bulldog calves" and a form that causes fatal nasal obstruction in the German Black Spotted breed of cattle, have also been recorded. In the latter there are multiple deformities of limb bones, and the condition appears to be inherited as a result of the influence of a single recessive gene.

CONGENITAL OSTEOPETROSIS

Osteopetrosis is a skeletal disorder of humans and animals characterized by the formation of overly dense bones. The disease is reported in Angus, Red Angus, Hereford, Simmental, and Holstein cattle.[1] The inherited defect is recorded in Aberdeen Angus calves, which are stillborn and undersized. The major manifestations are shortening of the mandible with protrusion of the tongue, impaction of the lower molars, a patent fontanelle, and the characteristic lesion of shortness of the long bones and absence of a marrow cavity in them. The absence of the marrow cavity, caused by defective remodeling of the bone, gives it a homogeneous shaft, leading to the colloquial name of "marble bone." Genetically affected calves are typically aborted late in gestation, display skull deformities, and exhibit a marked reduction of osteoclasts. The disease is caused by a deletion mutation within bovine SLC4A2,[1] encoding an anion exchanger protein, causing loss of SLC4A2 function that induces premature cell death and likely results in cytoplasmic alkalinization of osteoclasts, which, in turn, may disrupt acidification of resorption lacunae.

INHERITED PROBATOCEPHALY (SHEEPSHEAD)

This defect is inherited in Limousin cattle. The cranial bones are deformed so that the head resembles that of a sheep. The accompanying defects in the heart, buccal cavity, tongue, and abomasum increase the chances of an early death.

INHERITED ATLANTO-OCCIPITAL DEFORMITY

(See "Congenital Defects of the Nervous System.")

INHERITED AGNATHIA

Partial or complete absence of the mandibles with ventral displacement of the ears occurs in sheep and is categorized as a lethal recessive because the sheep are unable to graze properly.

INHERITED DISPLACED MOLAR TEETH

Inherited as a simple recessive character, the defect of displaced molar teeth usually results in the death of affected calves within the first week of life. The six premolars of the lower jaw are impacted or erupted in abnormal positions, often at grotesque angles. The mandible is shorter and narrower than normal. There is no abnormality of the incisors or upper jaw.

INHERITED JAW MALAPPOSITION

Defective apposition of upper and lower incisors, or lower incisors and dental pad, in ruminants may result in inefficient grazing and malnutrition. Abnormal protrusion of the mandible (mandibular **prognathism**) is of most importance in ruminants, and there is good evidence that abnormal length of the mandible is inherited. Among British breeds of **cattle** the defect is more common in beef than in dairy breeds. In Herefords and Angus the inheritance is thought to be conditioned by a single recessive gene.

Brachygnathia, underdevelopment of the mandible, has also been recorded in Dairy Shorthorn, Jersey, Holstein, Ayrshire, and Simmental cattle, with the defect so severe in some cases that the animals are unable to suck. In Angus cattle, brachygnathia can occur linked to a generalized degenerative joint disease, in which all joint surfaces are involved. Affected animals,

detected at a few days to 4 months of age, are not viable. Inheritance of the defect is probably conditioned by a recessive gene.

A less severe degree of **brachygnathia** has been recorded in Merino and Rambouillet **sheep**. The mode of inheritance is suggested to be by the interaction of several pairs of genes. Brachygnathia occurs in Poll Merinos in Australia as part of the lethal brachygnathia, cardiomegaly, and renal hypoplasia syndrome.[1] The disorder is also caused by intrauterine infection by the Schmallenburg virus.[2]

Mandibular prognathism occurs as a part of other, more general defects, including achondroplastic dwarfism and inherited displaced molar teeth. It is associated with mutations in the MATN1 gene in donkeys.[3]

Brachygnathia is also seen in **horses** but is not recognized as inherited. Maxillary prognathism is associated with two SNPs within a region on the distal end of chromosome ECA 13 in horses.[4]

INHERITED CRANIOSCHISIS (CRANIUM BIFIDUM)

The disease occurs in a number of pig breeds, but has been shown to be inherited only in Poland China pigs and their crossbreds. There is a deficit in the cranial bones, and meningoceles or encephaloceles may result. The pigs are not viable. Genetic experiments have shown the inheritance to be of a recessive character with varying penetrance.

Many single cases of cranial and spinal deformity in farm animals have been likened to the human Arnold–Chiari malformation, but a specific syndrome of protrusion of the medulla oblongata and the cerebellum through the foramen magnum into the spinal canal has not been identified in a hereditary context in these species. Cases of cranium bifidum are reported on lambs and calves, but the inherited basis, if any, is unclear.[1-3]

INHERITED CRANIOFACIAL DEFORMITY

The defect is incompatible with life. One form in Border Leicester lambs is characterized by a variable degree of nasomaxillary hypoplasia, often associated with incomplete cerebral development with less pronounced sulci and gyri than normal. It appears to be inherited in a simple autosomal-recessive mode. A similar lethal defect is recorded in Angus cattle (as brachygnathia superior) in association with generalized degenerative joint disease.

Cyclopia (cyclops anomaly) is commonly associated with ingestion of plants, such as *Veratrum californicum,* containing cyclopamine, which is an inhibitor of the sonic hedgehog pathway.[1-3] Cyclopia of other cause, or unknown cause, occurs sporadically.[4]

INHERITED ARACHNOMELIA (INHERITED CHONDRODYSPLASIA)

Cattle

Arachnomelia, a suspected inherited disease of Simmental, Brown Swiss, Italian Brown calves, Fleckvieh,[1] and other European breeds of cattle, is manifested by excessively long, thin distal extremities, which give the calves a spidery look—hence the term *arachnomelia*. The bones are fragile, and there is curvature of the spine, foreshortening of the mandible, and associated cardiac and vascular defects. In Swiss Braunvieh cattle it is combined with arthrogryposis. The mutation is a 2-bp deletion mutation c.1224_1225delCA in exon 11 of the molybdenum cofactor biosynthesis protein 1 (MOCS1) gene in Simmental and Fleckvieh cattle[1,2] and a 1-bp insertion c.363–364insG in the sulfite oxidase (SUOX) gene of Brown Swiss cattle.[3] It is inherited as a simple recessive trait.

Sheep

Spider Lamb Syndrome

A hereditary chondrodysplasia is recorded in Suffolk and Hampshire lambs in which the limbs are thin and disproportionately long and have abnormal positions of the bones near the joints, causing abnormalities of posture. The disease is caused by a nonsynonymous T > A transversion in the highly conserved tyrosine kinase II domain of a positional candidate gene, fibroblast growth factor receptor 3 (FGFR3).[4] The mutant FGFR3 allele has an additive effect on long-bone length, suggesting that the disease is not inherited as a strict monogenic, mendelian recessive trait but is determined primarily by the presence of the mutant FGFR3 allele and influenced by an animal's genetic background. In contrast to FGFR3 mutations causing dwarfism in humans, this single-base change results in a skeletal overgrowth. There is also less muscle than normal. In severe cases the deformities are obvious at birth and may be lethal. In less severe cases the deformities do not become apparent until the lambs are several weeks old. The defects are readily visible in x-rays before clinical signs develop, and affected lambs can be detected in this way. The diagnostic lesion is multiple irregular islands of ossification in the upper limb joints. Spinal deformities, especially kyphoscoliosis, and cranial deformities, including a roman nose, deviation of the nose poll axis, and shortening of the mandible, are observed in some lambs (Fig. 15-16).

Inheritance by an autosomal-recessive gene with complete penetrance and variable expressivity has been established as the cause in Suffolks. The defect is thought to be one of deficiency of an insulin-like growth factor (IGF) and IGF-binding proteins. Differentiation from arthrogryposis-hydranencephaly is important because of the superficial similarity of the two diseases.

Inherited Chondrodysplasia in Texel Sheep

A chondrodysplasia resulting in a dwarfing phenotype has occurred in a Texel sheep flock as a newly recognized recessively inherited genetic disease of the Texel breed. The disorder in this breed is attributable to a 1-bp deletion of T (g.25513delT) at the 107bp position of exon 3 in the SLC13A1 gene (solute carrier family 13 [sodium/sulfate symporters], member 1). The mutation g.25513delT shifts the open reading frame of SLC13A1 to introduce a stop codon and truncate C-terminal amino acids.[5] Heterozygotes appear clinically normal. Affected lambs appear normal at birth but show evidence of dwarfism, wide-based stance, and exercise intolerance as early as 1 week of age. Death usually occurs within 3 months, often after developing bilateral varus deformity of the forelimbs. Some severely affected lambs die with respiratory distress, probably as a result of tracheal collapse. Gross and microscopic lesions of variable severity were present in the tracheal, articular, epiphyseal, and physeal cartilage. In severe cases, articular cartilage in major joints was eroded from weight-bearing surfaces. The trachea was flaccid, was abnormally kinked, and had thickened cartilaginous rings and a narrow lumen. Affected sheep that survived to breeding age commonly developed severe degenerative joint disease. Histologically, chondrocytes were disorganized and surrounded by concentric rings of abnormal fibrillar material, and the matrix often contained focal to coalescing areas of chondrolysis. The disease has considerable potential as a suitable model for studying various forms of therapy for human chondrodysplasia.

COMPLEX VERTEBRAL MALFORMATION IN HOLSTEIN CALVES

A lethal congenital defect of the axial skeleton of purebred Holstein calves has been reported in Denmark, the United States, and the United Kingdom. It is caused by a mutation in the gene *SLC35A3* coding a uridine-diphosphate-*N*-acetylglucosamine transporter.[1] A single-base transversion of guanine to thymine has been located in the abnormal allele at position 559. It is present in both copies of the allele, and the mutation is lethal. It is a simple recessive genetic defect that requires that both the sire and the dam of an affected calf are carriers.

Most affected calves are born between day 250 and 285 of gestation. Approximately 80% of homozygous affected fetuses are aborted before gestation day 260. Birth weights are reduced. Most affected calves are stillborn, but affected calves occasionally are born alive. Euthanasia must be performed for humanitarian reasons.

In premature, stillborn, and neonatal affected calves, the defect is characterized by congenital growth retardation, malformed vertebrae, and tetramelic arthrogryposis. There is shortening of the cervical and thoracic parts of the vertebral column as a result of multiple hemivertebrae, fused and misshaped vertebrae, and scoliosis. Growth retardation and vertebral malformation are typical lesions. Malformation of the head, primarily in the form of dysplasia or palatoschisis, also occurs.

Symmetric flexures of the carpal and joints and the metacarpophalangeal joint in combination with a slight lateral rotation of the phalanges are also present. Similar low-grade arthrogryposis is present in the pelvic limbs. Heart defects were present in 50% of affected calves (interventricular septal defects, dextroposition of the aorta, and eccentric hypertrophy of the right ventricle).

Retrospective genotyping of affected calves according to the mutation in the *SLC35A3* gene determined that there were homozygous affected, heterozygote, and homozygous normal genotypes. The morphologic expression of the malformation is wide, but certain aspects such as growth retardation, vertebral malformation, and symmetric arthrogryposis are nearly constant findings. A presumptive diagnosis of the malformation can be made in most cases based on necropsy findings combined with pedigree analysis and genotyping. Breeding studies were carried out in Denmark using selected cows that were progeny of sires with a heterozygous genotype for the malformation and were pregnant after insemination with semen from another sire with heterozygous malformation genotype. The number of calves born with the malformation was less than expected, suggesting increased intrauterine mortality. Fertility traits in Holsteins are severely affected by the malformation phenotype of the fetus. If the fetus is homozygous for the malformation, 29% of the cows will abort before gestation day 100, increasing to 45% at day 150 and 77% at day 260. Rates of nonreturn to service, frequency of calvings after the first insemination, and interval from insemination to next calving were significantly reduced by a fetal malformation phenotype.

Pedigree analysis and DNA analyses of semen from sires used for insemination have found a widely branched familial occurrence of the malformation in the Holstein breed.

The mutation in the *SCL35A3* gene has been traced to the U.S. sire Penstate Ivanhoe Star, born in 1963, and his widely used son Carlin-M Invanhoe Bell, born in 1974. Descendants of this bull in China have a heterozygote carrier frequency of 9.54% and 16.7% in Poland.[2,3] The frequency of carriers in Girolando dairy cattle in Brazil is less than 2%.[4] The malformation mutation is not restricted to descendants of the American Holstein–Friesian bull Carlin-M Ivanhoe Bell. Through these sires and elite sires genetically related to them, the defect has been disseminated in the Holstein breed worldwide. PCR testing is available to detect heterozygotes.[2] Testing is available on registered or registerable Holstein animals only through the Holstein Association (Holstein USA), through one of the National Association of Animal Breeders' member AI organizations, or at the Van Haeringen Laboratorium, Wageningen, the Netherlands.

INHERITED REDUCED PHALANGES (AMPUTATES, ACROTERIASIS, ECTROMELIA)

The defect of inherited reduced phalanges has been recorded in cattle and appears to be inherited as a single recessive character.[1,2] The limbs are normal down to the metacarpal and metatarsal bones, which are shorter than usual, but the first two phalanges are missing, and the normal hooves and third phalanges are connected to the rest of the limb by soft tissues only. The calves are unable to stand but can crawl about on their knees and hocks.

Hereditary Hemimelia

The bilateral absence of the distal half of the limb (e.g., the patella) and shortening or absence of the tibia, often accompanied by hydrocephalus, meningoceles, ventral abdominal hernia, and cryptorchidism, comprise the syndrome known as tibial hemimelia. It is inherited in the Galloway breed of cattle. An autosomal-recessive mode of inheritance is assumed. A concerted program of eradicating the defect has been undertaken, based on test matings and examination for defects of 90-day fetuses obtained by terminating pregnancy with prostaglandin. Hemimelia and amelia also occur in sheep.[3]

Hereditary Peromelia of Mohair Goats

The syndrome of hereditary peromelia of mohair goats includes agenesis of the phalanges and parts of the metacarpus and metatarsus affecting one or more limbs; it follows an autosomal-recessive mode of inheritance.

Amputates

An even more serious defect, in which the mandible and all the bones below the humerus and stifle are vestigial or absent, has been reported in British, French, and German Friesians. It appears to be conditioned by the inheritance of a single recessive gene. Similar "amputates" have been shown not to be inherited. The disease occurs in Italian buffalo, in which it is associated with chromosomal instability.[4,5]

INHERITED CLAW DEFORMITY

Extra claws (**polydactylism**) and fusion of the claws (**syndactylism**) are known hereditary defects of cattle, the former in the Normandy breed and the latter in Holsteins, Angus, Hereford, and Chianina.[1,2] Polydactyly in pigs appears to be inherited, in some forms, as an autosomal-recessive trait with incomplete penetrance, although the genetic abnormality is unclear.[3]

Dactylomegaly (enlarged dewclaws), often associated with syndactyly or deviation of the adjacent major digit and creating a clubfooted appearance, may be inherited in Shorthorn cattle. In most cases they cause no more than inconvenience but an association of syndactyly with susceptibility to hyperthermia is recorded, and some of these animals die of hyperthermia when subjected to high environmental temperatures.

Adactyly is a recorded but less-well-defined defect in cattle and sheep in which the hooves are absent at birth.

There is good field evidence that **corkscrew claw** or **curled toe** is an inherited defect in cattle, especially in beef breeds, but also in Holstein–Friesians. It is almost always the lateral claw that is affected. In some breeds it is more common in the hindfeet; in others it is more common in the front feet. In the affected digit the third phalanx is much smaller than normal and is narrower and longer. The soft tissue and the horn are correspondingly deformed so that the horn grows much longer and narrower and tends to curl over the sole so that the cow walks on the wall of the hoof. The claw also curls over the front of the other digit of the limb. There are often cracks in the front of the claw, originating at the coronet and causing serious lameness. All affected animals suffer gait abnormalities as they get older and heavier. Much of this is attributable to distortion and wear of the articular surfaces in the companion claw, which has to carry much more weight than is usual. Marked changes in the affected digit are detectable by anteroposterior radiography.

INHERITED MULTIPLE EXOSTOSIS

Multiple exostosis affecting both cortical and medullary bone of the limbs and ribs has been described in Quarter horses and Thoroughbreds in the United States. The lesions are visible externally but cause little apparent inconvenience. It is inherited as a single autosomal-dominant gene. Restriction nuclease analysis is used to diagnose the disease.

INHERITED CONGENITAL HYPEROSTOSIS (THICK FORELIMBS OF PIGS)

This defect is thought to be caused by the inheritance of a simple recessive character. Affected piglets show obvious lesions at birth, and although many of them die or are destroyed immediately, a proportion of them may survive. The forelimbs are markedly enlarged below the elbows, and the skin is tense and may be discolored. There is difficulty in standing and moving about, and starvation and crushing contribute to the mortality rate. There is extensive edema of the subcutaneous tissues, thickening of the bones, and roughness of the periosteum. It is thought that the primary lesion is a separation of the periosteum from the bone.

INHERITED RICKETS

An inherited form of rickets occurs in purebred Corriedale sheep in New Zealand, with an incidence of up to 20 lambs out of 1600 over a 2-year period. Affected sheep have decreased growth rate, thoracic lordosis, and angular limb deformities, with low serum calcium and phosphate concentrations and normal 25 hydroxyvitamin D and 1,25 dihydroxyvitamin D_3 concentrations.[1-3] The disease is inherited as a simple autosomal-recessive disorder caused by a nonsense 250C/T mutation on exon 6 in the dentin matrix protein 1 gene (DMP1).[4] This mutation introduces a stop codon (R145X) and could truncate C-terminal amino acids. Affected sheep are "T T" genotypes, carriers are "C T," phenotypically normal related sheep are either "C T" or "C C," and unrelated normal sheep from other breeds are "C C." A simple diagnostic test can identify carriers with the defective "T" allele. Necropsy examination reveals segmental thickening of physes, growth-arrest lines, collapse of subchondral bone of the humeral head, thickened cortices, and enthesophytes around distal limb joints.[5] other features include hypertrophic chondrocytes at sites of

endochondral ossification; inappropriate and excessive osteoclastic resorption; microfractures; and wide, unmineralized osteoid seams lining trabeculae and filling secondary osteons.[5]

The disease of pigs is indistinguishable from rickets as a result of nutritional inadequacy.[6] The pigs are healthy at birth. Subsequently there is hypocalcemia, hyperphosphatemia, and increased serum alkaline phosphatase activity. The defect is a failure of active transport of calcium through the wall of the small intestine.

INHERITED TAILLESSNESS AND TAIL DEFORMITY

Complete absence of the tail or deformity of the appendage occur relatively commonly as a congenital defect. The disease "crooked-tail syndrome" in Belgian Blue cattle is attributable to a loss-of-function mutation of the bovine MRC2 gene that impairs production of Endo18 protein. Affected cattle have signs of impaired endochondral ossification and skeletal and muscular malformations. The mutation is also associated with muscular attributes in heterozygotes, including double muscling (as a result of a defect in the myostatin gene), that are desirable traits and result in 25% of Belgian Blue cattle being carriers for the condition.[1]

A syndrome of **vertebral and spinal dysplasia** occurs in Holstein cattle. There are tail malformations and neurologic dysfunction, with gait abnormalities of the hindlimbs. The deformities and neurologic dysfunctions vary from subtle or mild (limited to tail deformities) to paraparesis. The syndrome is inherited in a dominant mode with incomplete penetrance.[2]

CONGENITAL CHONDRODYSTROPHY OF UNKNOWN ORIGIN (CCUO, "ACORN" CALVES, CONGENITAL JOINT LAXITY AND DWARFISM, CONGENITAL SPINAL STENOSIS)

A noninherited condition has been described in the United States, Europe, Africa, Australia, and New Zealand that resembles inherited dwarfism.[1] The disease occurs in poor-range areas and is thought to be attributable to a maternal nutritional deficiency during the middle trimester of pregnancy.[2] The specific dietary factors involved have not been determined.

Cases are characterized by damage to physeal growth plates with subsequent failure of growth of long bones. Abnormal osseous development of the head causes superior brachygnathia. Shortening of the shafts of the long bones of the limbs is accompanied by rotated limbs and bending at the joints, and calves nurse and stand with difficulty. Deformities of the nasal turbinates and trachea are often present and frequently lead to breathing difficulties. Incoordination, arching of the back, and a tendency to bloat, which may cause death, also occur. The dentition is normal. Muscle spasticity, wry neck, circling, falling backward, and goose-stepping occur rarely. Serologic results for Akabane virus, Aino virus, bovine virus diarrhea virus, and Bluetongue are typically negative.[3]

Most of the calves are born alive; in badly affected herds, as many as 15% of calves may be affected. The original name for the condition (Acorn calves) was derived from the common occurrence of acorns in the diet of affected herds, although the acorns are not thought to have any etiologic significance. Currently, an unknown nutritional deficiency or deficiencies, possibly including manganese,[3] during the second trimester is thought to be the cause.

Inherited Diseases of Joints

INHERITED ARTHROGRYPOSIS (INHERITED MULTIPLE TENDON CONTRACTURE)

Inherited fixation of limb joints present at birth is recorded in many breeds of cattle, especially in Belgian Blue, Shorthorn, Charolais, Piedmont, and Swedish Dole. It is inherited as a single recessive mutation in the *PIGH* gene in Belgian Blue cattle.[1] The disease occurs in Swiss Large White pigs as part of the **arthrogryposis multiplex congenita** complex of clinical abnormalities that includes inferior brachygnathism and spinal curvature.[2]

There are many environmental causes of the disease, the most well recognized of which are Schmallenberg and Akabane virus infection of early pregnancy (discussed under that heading).[3]

Simple Arthrogryposis

The limbs of affected calves are fixed in flexion or extension and cause dystocia as a result of abnormal positioning and lack of flexibility. There is no involvement of joint surfaces, and the joints can be freed by cutting the surrounding tendons or muscles. There is atrophy of limb muscles, and those calves that are born alive are unable to stand and usually die or are destroyed within a few days.

Arthrogryposis With Dental Dysplasia

Arthrogryposis with dental dysplasia in cattle appears to be inherited in a dominant manner. The teeth are soft, fleshy, and easy to bend. There is no defect of bones or joints other than marked softness and the presence of excess cartilage at the epiphyses. There is abnormal ossification of the cartilage. The calves are of normal size, do not cause dystocia, and, although they are unable to stand because of the excessive flexibility of the limbs, they can suck. Hypostatic pneumonia usually develops and causes death of the calf.

Arthrogryposis With Palatoschisis

Arthrogryposis with palatoschisis (SAP) is inherited as a simple recessive trait with low penetrance in pure French Charolais in France and high penetrance in 7/8 Charolais cattle in Canada, where the gene frequency is high in purebred and crossbred Charolais. Among crossbred Charolais cattle the homozygous condition is almost always markedly expressed and lethal, but a high percentage of purebred homozygous cattle show slight to no visible effect of the gene and survive. Because of the low rate of prevalence in France, attempted eradication does not appear to be economical.

In this syndrome all limbs are usually affected but the front limbs more than the hindlimbs, and the more distal joints are more rigidly fixed than proximal ones. The muscles of affected limbs are atrophic and pale in color. Histologic changes in the spinal cord suggest that the muscle atrophy is neurogenic. In affected calves the gestation period may be longer than normal by an average of 2 weeks.

Arthrogryposis With Multiple Defects

In Simmentals a combined set of defects includes arthrogryposis, often with the limbs in a wraparound position around the body, underdevelopment of the mandible, curvature of the spine, and defects of the heart and main vessels.

Arthrogryposis in Species Other Than Cattle

Inherited arthrogryposis has also been recorded in Merino and Corriedale **sheep** and in Norwegian Landrace **pigs,** in which it is thought to be inherited as a simple recessive trait. The Corriedale defect is associated with other lesions, including brachygnathia inferior, hydranencephaly, and thoracic scoliosis. Inherited arthrogryposis in pedigree Suffolk lambs has been described.[1] Breeding studies using superovulation and embryo transfer were used to increase the numbers

of offspring from females that were carrying the gene or genes responsible for the defect, which is inherited as an autosomal-recessive trait.

Ovine heritable arthrogryposis multiplex congenita is a congenital syndrome in lambs characterized by curvature, hunching, and twisting of the thoracic spine, with associated abnormalities of the ribs and sternum, distal arthrogryposis of the carpal and tarsal joints, and cleft hard and soft palate or palatoschisis (a median fissure of the palate) and is an autosomal-recessive inherited disease.[4] Affected lambs are born full term but die shortly after birth. Affected lambs have slightly reduced body weight (as a result of low muscle mass) compared with normal newborn lambs of the same flock. The syndrome is similar to **bovine heritable arthrogryposis multiplex congenita** in Angus cattle and **porcine heritable arthrogryposis multiplex congenita**.[2]

An inherited arthrogryposis also occurs in Norwegian Fjord **horses**. The arthrogryposis affects the hindlimbs, and there are accompanying defects of polydactyly, palatoschisis, and brachygnathia in some. Most foals are unable to stand, and the defect must be considered to be a lethal one.

INHERITED MULTIPLE ANKYLOSES

Multiple ankylosis affecting all limb joints has been recorded as an inherited congenital defect of Holstein calves. The abdomen of the dam shows marked enlargement at month 6 to 7 of pregnancy, and this may occasion some respiratory distress. Excessive fetal fluids are present, and insertion of the hand per rectum is impeded by the distended uterus. Abortion during the last month of pregnancy is a common occurrence. Affected fetuses have a very short neck, ankylosed intervertebral joints, and varying degrees of ankylosis of all limb joints. The limbs are fixed in flexion, and there is some curvature of the spine. Fetal dystocia always occurs, and embryotomy or cesarean section is necessary to deliver the calf.

Ankylosis of limb joints combined with **cleft palate** occurs occasionally in Charolais cattle and is suspected of being inherited. **Ankylosis of the coffin joint**, developing at several weeks of age, has been reported in Simmental calves. The etiology of the condition is not clear.

INHERITED PATELLAR SUBLUXATION

Unilateral or bilateral subluxation occurs as an inherited defect in *Bos indicus* cattle and in water buffalo (*Bubalus bubalis*). Shetland ponies also have a predisposition, and a monogenic autosomal-recessive transmission is suspected. There is periodic lameness, with the affected limb held in rigid extension; the patella is displaced medially.[1]

REFERENCE

1. Busschers E. *Equine Vet Educ*. 2009;21:464.

INHERITED HYPERMOBILITY (LAXITY) OF JOINTS

Inherited hypermobility of joints is recorded only in Jersey cattle. It has assumed great importance because of the great popularity of a sire that carried the gene. There is abnormal flexure and extension of all joints but especially the hock, stifle, hip, knee, elbow, and shoulder joints. The muscles are much atrophied, and the joints look very enlarged as a result. It is impossible for the calves to stand, but they are bright, alert, and eat well. The limbs are so flexible that they can be bent into extraordinary positions and almost tied in knots. A drawer sign, a displacement of the articular surfaces laterally, produced by manual pressure, can be elicited easily and with a displacement of up to 2 cm. There are no detectable lesions in the nervous or musculoskeletal systems. Although the disease is known to be inherited as a simple autosomal-recessive trait, it has also been seen in circumstances that preclude inheritance being the cause.

INHERITED HIP DYSPLASIA

An inherited defective development of the acetabulum occurs in Dole horses. There is no clinical evidence of the disease at birth, but osteoarthritis of the joint and disruption of the round ligament develop subsequently. Hip dysplasia occurs in Belgian Blue cattle.[1]

16 Diseases of the Skin, Eye, Conjunctiva, and External Ear

Introduction

The major functions of the skin are:

- To maintain a normal body temperature
- To maintain a normal fluid and electrolyte balance within the animal
- To create a mechanical barrier to protect the body from noxious agents and organisms
- To act as a sensory organ perceiving those features of the environment that are important to the subject's survival

In general, these functions are not greatly impeded by most diseases of the skin of large animals, with the exceptions of failure of the sweating mechanism, which does seriously interfere with body temperature regulation, and severe burns or other skin trauma, which may cause fatal fluid and electrolyte loss.

The major effects of skin diseases in large animals are esthetic and economic but can also present a considerable animal welfare concern. Discomfort and scratching interfere with normal rest and feeding, and when the lips are affected, there may be interference with prehension. The unsightly appearance of the animal distresses the owner. There is loss of the economic coat, and the sales value and acceptability of animals for transport and appearance in exhibitions is greatly reduced.

Primary/Secondary Lesions

Diseases of the skin may be primary or secondary in origin. In primary skin disease the lesions are restricted initially to the skin, although they may subsequently spread from the skin to involve other organs. Conversely, cutaneous lesions may be secondary to disease originating in other organs. Differentiation between primary and secondary skin diseases should be attempted by seeking evidence that organs other than the skin are affected. If there is no such evidence produced during a thorough clinical examination of the patient, it is reasonable to assume that the disease is primary. Even if involvement of other organs is diagnosed, it is still necessary to determine whether the involvement constitutes the primary state or whether it has developed secondarily to the skin disease. This decision can be based on the chronology of the signs, elicited by careful history taking, and a detailed knowledge of the individual diseases likely to be encountered.

Taking an accurate anamnesis and doing a complete clinical examination must precede the careful examination of the skin itself, using the proper technique of examination. The veterinarian may need to employ advanced diagnostic procedures such as histopathological examination of a biopsy specimen to define the type of lesion present.

The purpose of this chapter is to describe the basic skin lesions so that the differential diagnosis, up to the point of defining the type and nature of the lesion, the pathoanatomical diagnosis, can be accomplished. A definitive etiologic diagnosis requires further examination and is included in the discussion of the specific diseases.

Clinical Signs and Special Examination

A general clinical examination is followed by a special examination of the skin and must include inspection and, in most cases, palpation. Additional information can be obtained by taking swabs for bacteriologic examinations, scrapings for examination for dermatophytes and metazoan parasites, and biopsy for histopathological examination.

Biopsy material should include abnormal, marginal, and normal skin. Artifacts are common in biopsy specimens, including nonrepresentative sampling, crushing the specimen by forceps or hemostat, and inadequate fixation.

A Wood's lamp finds a special use in the examination of the skin for dermatophytes.

Descriptions of lesions should include size, depth to which they penetrate topographic distribution on the body, and size of the area affected. Abnormalities of sebaceous and sweat secretion, changes in the hair or wool coat, and alterations in color and temperature of the skin should be noted, as should the presence or absence of pain or pruritus.

Lesions

An accurate definition of the lesions, summarized in Table 16-1, is an essential part of a dermatologic patient's clinical record. The table makes a primary differentiation into discrete and diffuse lesions, and these categories need to be further categorized in terms

Table 16-1 Terms used to identify skin lesions

Name of lesion	Nature of lesion	Relation to skin surface	Skin surface
Scales	Dry, flaky exfoliations	On surface only, no penetration of skin	Unbroken
Excoriations	Traumatic abrasions and scratches	Penetration below surface	Variable skin surface damage—depends on severity
Fissures	Deep cracks	Penetrate into subcutis	Disrupted
Dry gangrene	Dry, horny, black, avascular, shield-like	Above skin, usually all layers affected	Removed
Early, moist gangrene	Blue-black, cold, oozing serum	In plane of skin or below	Complete depth of subcutis
Keratosis	Overgrowth of dry, horny, keratinized epithelium	Above skin	Undamaged stratum corneum is retained
Acanthosis	Like keratosis but moist, soft	Above skin	Prickle cell layer swollen; is really part of skin
Hyperkeratosis	Excessive overgrowth of keratinized, epithelium-like scab	Above skin	Skin surface unbroken
Parakeratosis	Adherent to skin	Above skin	Cells of stratum corneum nucleated and retained; really part of skin
Eczema	Erythematous, itching dermatitis	Superficial layer of epidermis affected	Weeping, scabby disruption of surface
Hypermelanosis	Increased deposits of melanin (e.g., melanosis, meloderma)	In epidermis or dermis	Unbroken
Hypomelanosis	Decreased deposits of melanin	In epidermis or dermis	Unbroken
Discrete lesions			
Vesicle, bleb, bulla, blister	Fluid (serum or lymph)-filled blister 1–2 cm diameter	Above skin surface, superficial	Unbroken but will slough
Pustule	Pus-filled blister, 1–5 mm	Above, superficial	Will rupture
Wheal	Edematous, erythematous, swellings, transitory	Above, all layers affected	Undamaged
Papules (pimples)	Elevated, inflamed, necrotic center, up to 1 cm diameter	Above surface, all layers affected	Points and ruptures
Nodules, nodes	Elevated, solid, up to 1 cm diameter Acute or chronic inflammation. No necrotic center	Above surface, all layers	Surface unbroken
Plaque	Larger nodule, up to 3–4 cm diameter	All layers affected; raised above surface	Surface unbroken
Acne	Used synonymously with *pimple* but strict meaning is infection of sebaceous gland	Above surface of skin; all layers affected	May point and rupture
Comedo	Plugged (sebum, keratin) hair follicle	Raised above skin	May rupture
Impetigo	Flaccid vesicle, then pustule, then scab, up to 1 cm diameter	Raised above skin; very superficial	Upper layers destroyed
Scab (or crust)	Crust of coagulated, blood, pus, and skin debris	Raised above skin	Disrupted, depth varying with original lesion
Macule (patch)	Small area of color change; patch is larger	Within superficial layers	Unbroken

of size (e.g., they may be limited diffuse lesions or extensive localized ones).

Abnormal Coloration

The parameter of abnormal coloration includes jaundice, pallor, and erythema. In animals these conditions are rarely visible in light-colored skins. Red–purple discoloration of the skin of septicemic, white pigs may be dramatic, but no diagnostic significance can be attached to its degree. Early erythema is a common finding where more definite skin lesions are to develop, as in early photosensitization. The blue coloration of early gangrene (e.g., of the udder and teat skin in the early stages of peracute bovine mastitis associated with *Staphylococcus aureus*) is characterized by coldness and loss of elasticity.

Hypopigmentation of the skin may be general, as in albino, pseudoalbino, and lethal white animals. Local patches of hypopigmentation are characteristic of vitiligo and leukoderma.

Pruritus

- **Pruritus or itching** is the sensation that gives rise to scratching.
- **Hyperesthesia** is increased sensitivity to normal stimuli.
- **Paresthesia** is perverted sensation, a subjective sensation, and not diagnosed in animals.

All sensations that give rise to rubbing or scratching are therefore included with pruritus, more properly defined as scratching. Pruritus can arise from peripheral or central stimulation. When it is peripheral in origin, it is a primary cutaneous sensation, similar to heat, cold, pain, and touch; it differs from pain because it is purely epidermal, whereas pain can still be felt in areas of skin denuded of epidermis. Thus itching does not occur in the center of deep ulcerations or in very superficial lesions, such as those of ringworm, where only the hair fibers and keratinized epithelium are involved. Itching can be elicited over the entire skin surface but is most severe at the mucocutaneous

junctions. Common causes include the following.

Cattle
- Sarcoptic and chorioptic mange
- Lice infestation
- Nervous acetonemia
- Aujeszky's disease

Sheep
- Lice, mange, ked, blow-fly, and itch-mite infestations
- Scrapie

Horses
- Chorioptic mange on the legs
- Queensland (sweet) itch along the dorsum of the body
- Lice infestation
- Perianal pruritus from *Oxyuris equi* infestation

Pigs
- Sarcoptic and chorioptic mange
- Lice infestation

All Species
- Early stages of photosensitive dermatitis
- Urticarial wheals in an allergic reaction
- **"Licking syndromes,"** such as those that occur in cattle on copper-deficient diets, are accompanied by pica and the licking of others as well as themselves. They are examples of depraved appetites developed in response to nutritional deficiency and are not a response to pruritus.
- **Itching of central origin** derives mainly from the scratch center below the acoustic nucleus in the medulla. It may have a structural basis, as in scrapie and pseudorabies, or it may be functional in origin, as in the nervous form of acetonemia. The only lesions observed are those of a traumatic dermatitis with removal of the superficial layers to a variable depth, breakage or removal of the hairs, and a distribution of lesions in places where the animal can bite or rub easily.

Secretion Abnormalities of Skin Glands

The activity of the **sweat glands** is controlled by the sympathetic nervous system and is for the most part a reflection of body temperature. Excitement and pain may cause sweating as a result of cerebral cortical activity. A generalized form of hyperhidrosis, apparently inherited, has been recorded in Shorthorn calves. Local areas of increased or decreased sweating may arise from peripheral nerve lesions or obstruction of sweat gland ducts. A generalized anhidrosis is recorded in horses and occasionally in cattle.

Excess secretion of sebum by **sebaceous glands** causes oiliness of the skin or seborrhea, but its pathogenesis is poorly understood.

Abnormalities of Wool and Hair Fibers

Deficiency of hair or wool in comparison to the normal pilosity of the skin area is **alopecia** or **hypotrichosis**.

Hirsutism, abnormal hairiness, manifested by a long, shaggy, and usually curly coat, is most common in aged ponies with adenomas of the pars intermedia of the pituitary gland.

The character of the fiber may also vary with variations in the internal environment. For example, in copper deficiency the crimp of fine wool fibers is lost, and the wool becomes straight and "steely." Alternation in coat color, achromotrichia, may be generalized or segmental along the fiber.

Principles of Treatment of Diseases of the Skin

PRIMARY TREATMENT

For a specific treatment, accurate diagnosis of the condition and the identification of underlying cause must precede the selection of any topical or systemic treatment. Hair coat and debris on and around the affected area must be removed to enable topical applications to come into direct contact with the affected skin. In bacterial diseases susceptibility tests on cultures of the organism are advisable. Bacterial resistance to antimicrobials used in veterinary dermatologic practice is a concern. The uncritical use of antimicrobials either locally or systemically should be avoided to contain the development of bacterial resistance to microbials. Specific skin diseases caused by bacteria, fungi, and metazoan parasites are reasonably amenable to treatment with the appropriate specific remedy. Identification of the fungal or parasitic organism presumably causing the disease allows for selection of a pharmacologic substance and route of administration with documented efficacy against the agent in question and can prevent frustrating treatment failures.

Removal of the causative agent in allergic diseases and photosensitization may be impossible, and symptomatic treatment may be the only practicable solution. Symptomatic treatment may also be indicated for welfare reasons in cases where the underlying cause of the disorder could not (yet) be identified. The veterinarian must be aware that in these cases antiinflammatory treatment, although indicated, may complicate further diagnostic workup. In some instances the primary disease may be confounded by the presence of a secondary agent, which can lead to confusion in diagnosis.

SUPPORTIVE TREATMENT

Supportive treatment may include prevention of secondary infection by the use of bacteriostatic ointments or dressings and the prevention of further damage from scratching.

- Effective treatment of pruritus depends on the reduction of central perception of itch sensations by the use of ataractic, sedative, or narcotic drugs administered systemically or on successful restraint of the mediator between the lesion and the sensory end organ. In the absence of accurate knowledge of the pathogenesis of pain, it is usual to resort to local anesthetic agents, which are short-lived in their activity, and corticosteroids, which are longer-acting and effective, provided that vascular engorgement is part of the pruritus-stimulating mechanism.
- When large areas of skin are involved, it is important to prevent the absorption of toxic products by continuous irrigation or the application of absorptive dressings. Losses of fluid and electrolytes should be compensated by oral or parenteral administration of fluids containing the necessary electrolytes.
- Ensure an adequate dietary intake of protein, particularly sulfur-containing amino acids, to facilitate the repair of skin tissues.
- Boredom contributes significantly to an animal's response to itch stimuli, and close confinement of affected animals is best avoided.

Diseases of the Epidermis and Dermis

PITYRIASIS

Primary pityriasis is characterized by excessive bran-like scales on the skin and is caused

by overproduction of keratinized epithelial cells. The etiology is uncertain. The diagnosis is based on clinical presentation and can be supported by further diagnostic testing ruling out other differential diagnoses. Proposed causative or predisposing factors are as follows:

- Hypovitaminosis A
- Nutritional deficiency of B vitamins, especially of riboflavin and nicotinic acid, in pigs, or linolenic acid, and probably other essential unsaturated fatty acids
- Poisoning by iodine

Secondary pityriasis is characterized by excessive desquamation of epithelial cells and usually associated with the following:

- Scratching in flea, louse, and mange infestations
- Keratolytic infection (e.g., with ringworm fungus)

Pityriasis scales are accumulations of keratinized epithelial cells, sometimes softened and made greasy by the exudation of serum or sebum. Overproduction, when it occurs, begins around the orifices of the hair follicles and spreads to the surrounding stratum corneum.

Primary pityriasis scales are superficial, accumulate where the coat is long, and are usually associated with a dry, lusterless coat. Itching or other skin lesions are not features. Secondary pityriasis is usually accompanied by the lesions of the primary disease.

Pityriasis rosea or pustular psoriaform dermatitis is a skin condition of piglets that is clinically and histopathologically distinct from human pityriasis rosea (see also **"Pityriasis rosea"**).

Pityriasis is identified by the absence of parasites and fungi in skin scrapings.

DIFFERENTIAL DIAGNOSIS

- Hyperkeratosis (see following discussion)
- Parakeratosis (see following discussion)
- Swine erysipelas (for pityriasis rosea in pigs)
- Porcine dermatitis and nephropathy syndrome (for pityriasis rosea in pigs)
- Ringworm (for pityriasis rosea in pigs)

TREATMENT

Primary treatment requires correction of the primary cause.

Supportive treatment commences with a thorough washing, followed by alternating applications of a bland emollient ointment and an alcoholic lotion. Salicylic acid is frequently incorporated into a lotion or ointment with a lanolin base.

HYPERKERATOSIS

Epithelial cells accumulate on the skin as a result of excessive keratinization of epithelial cells and intercellular bridges, interference with normal cell division in the granular layer of the epidermis, and hypertrophy of the stratum corneum.

Local hyperkeratosis may be caused by the following:

- Mechanical stress on pressure points (e.g., elbows, hocks, or brisket) when animals lie habitually on hard surfaces
- Mechanical and/or chemical stress (e.g., **teat-end keratosis** of dairy cows that can be caused by improper milking machine settings, overmilking, improper use of teat sanitizers or cold weather)
- Parasitism (e.g., hyperkeratotic form of sarcoptes mange of pigs and small ruminants)

Generalized hyperkeratosis may be caused by the following:

- Poisoning with highly chlorinated naphthalene compounds
- Chronic arsenic poisoning
- Inherited congenital ichthyosis
- Inherited dyserythropoiesis–dyskeratosis
- Infection with *Scopulariopsis brevicaulis*, a fungus, was recently associated with generalized hyperkeratosis in a calf and a goat kid.[1,2]

The skin is dry, scaly, thicker than normal, usually corrugated, hairless, and fissured in a gridlike pattern. Secondary infection of deep fissures may occur if the area is continually wet. However, the lesion is usually dry, and the plugs of hyperkeratotic material can be removed, leaving the underlying skin intact.

Confirmation of the diagnosis is by the demonstration of the characteristically thickened stratum corneum in a biopsy section, which also serves to differentiate the condition from parakeratosis (see also "Parakeratosis") and inherited ichthyosis (see also "Congenital and Inherited Skin Defects").

Primary treatment depends on correction of the cause. Supportive treatment is by the application of a keratolytic agent (e.g., salicylic acid ointment).

PARAKERATOSIS

Parakeratosis, a skin condition characterized by incomplete keratinization of epithelial cells, can have various causes:

- Caused by nonspecific chronic inflammation of cellular epidermis
- Associated with dietary deficiency of zinc
- Part of an inherited disease (described later in the chapter)

The initial lesion comprises edema of the prickle cell layer, dilatation of the intercellular lymphatics, and leukocyte infiltration. Imperfect keratinization of epithelial cells at the granular layer of the epidermis follows, and the horn cells produced are sticky and soft, retain their nuclei, and stick together to form large masses, which stay fixed to the underlying tissues or are shed as thick scales.

The lesions may be extensive and diffuse but are often confined to the flexor aspects of joints (referred to historically in horses as **mallenders** and **sallenders**). Initially the skin is reddened, followed by thickening and gray discoloration. Large, soft scales accumulate, are often held in place by hairs, and usually crack and fissure; their removal leaves a raw, red surface. Hyperkeratosis scales are thin and dry and accompany an intact, normal skin.

Parakeratosis in pigs is most commonly seen in swine 2 to 4 months of age and responds to dietary supplementation of zinc. Zinc deficiency in affected animals can be absolute or relative. The latter can be caused by excessive dietary calcium or phytic acid content or by a deficiency in essential fatty acids, which all interfere with the intestinal absorption of zinc.

The diagnosis is made based on the clinical presentation and can be confirmed by the identification of imperfect keratinization in a histopathological examination of a biopsy or a skin section at necropsy.

DIFFERENTIAL DIAGNOSIS

- Hyperkeratosis
- Pachyderma
- Ringworm
- Sarcoptic mange
- Greasy pig disease (*Staphylococcus hyicus* infection)
- Inherited ichthyosis
- Inherited parakeratosis of calves
- Inherited dermatosis vegetans in pigs
- Inherited epidermal dysplasia

TREATMENT

Primary treatment requires correction of any nutritional deficiency (specifically, correcting zinc and preventing excessive dietary calcium content).

Supportive treatment includes removal of the crusts by the use of keratolytic agent (e.g., salicylic acid ointment) or by vigorous scrubbing with soapy water, followed by application of an astringent (e.g., white lotion paste), which must be applied frequently and for some time after the lesions have disappeared.

PACHYDERMA

Pachyderma, including scleroderma, is thickening of the skin affecting all layers, often including subcutaneous tissue, and usually localized but often extensive, as in lymphangitis and greasy heel in horses. There are no specific causes, with most cases being a result of a nonspecific chronic or recurrent inflammation.

In affected areas the hair coat is thin or absent, and the skin is thicker and tougher than usual. It appears tight and, because of its thickness and reduced volume of subcutaneous tissue, cannot be picked into folds or moved easily over underlying tissue. The skin surface is unbroken, and there are no lesions and no crusts or scabs as in parakeratosis and hyperkeratosis.

Confirmation of the diagnosis depends on histopathological examination of a biopsy. The cells in all layers are usually normal, but the individual layers are increased in thickness. There is hypertrophy of the prickle cell layer of the epidermis and enlargement of the interpapillary processes.

DIFFERENTIAL DIAGNOSIS

Parakeratosis
Cutaneous neoplasia
Papillomatosis

TREATMENT

Primary treatment requires removal of the causal irritation, but in well-established cases little improvement can be anticipated, and surgical removal may be a practical solution when the area is small. In early cases local or systemic corticosteroids may effect a recovery.

IMPETIGO

Impetigo is a superficial eruption of thin-walled, small vesicles, surrounded by a zone of erythema, that develop into pustules, then rupture to form scabs.

In humans, impetigo is specifically a streptococcal infection, but lesions are often invaded secondarily by *staphylococci*. In animals the main organism found is usually a staphylococcus. The causative organism appears to gain entry through minor abrasions, with spread resulting from rupture of lesions causing contamination of surrounding skin and the development of secondary lesions. Spread from animal to animal occurs readily.

Two specific examples of impetigo in large animals are as follows:

- **Udder impetigo** (udder acne) of cows
- **Contagious impetigo,** also known as **exudative epidermitis** (see also "Udder Impetigo") or "**greasy pig disease,**" caused by *Staphylococcus hyicus* (see also "Exudative Epidermitis/Greasy Pig Disease")

Confirmation of the diagnosis is by isolation of *staphylococci* from vesicular fluid.

DIFFERENTIAL DIAGNOSIS

Cowpox/buffalopox, in which the lesions occur almost exclusively on the teats and pass through the characteristic stages of pox
Pseudocowpox, in which lesions are characteristic and also restricted in occurrence to the teats
Pityriasis rosea (for greasy pig disease)
Sarcoptic mange (for greasy pig disease)
Ringworm

TREATMENT

Primary treatment with antibiotic topically is usually all that is required because individual lesions heal so rapidly (see also under "Greasy Pig Disease").

Supportive treatment is aimed at preventing the occurrence of secondary lesions and spread of the disease to other animals. Twice-daily bathing with an efficient germicidal skin wash is usually adequate.

URTICARIA

Urticaria (hives) is a skin condition characterized by development of topical dermal edema becoming apparent as cutaneous wheals. Horses are the most commonly affected species. In acute cases hives appear suddenly and regress within hours. Longer-lasting or even chronic cases are characterized by the continuous recurrence of new wheals on the skin for days or even months. Urticaria can occur as localized allergic reaction only affecting parts of the skin or as part of a more severe systemic allergic reaction.

ETIOLOGY

Although urticaria in many cases is of allergic origin, nonallergic causes such as physical stress on the skin (e.g., through squeezing [pressure urticaria or dermatographism] or exposure to low ambient temperature [cold urticaria]) can result in the development of urticaria.

In horses chronic urticaria is most commonly associated with feed allergies. Specifically, in some of the chronic and recurrent cases a causative allergen cannot be found and the underlying etiology remains obscure. In humans the presence of serum immunoglobulin G (IgG) autoantibodies targeting immunoglobulin E (IgE) or the IgE receptor has been documented in a subset of patients with chronic urticaria of unknown etiology. An autoimmune basis for chronic urticaria has therefore been proposed.[1,2]

Primary urticaria can be caused by the following:

- Insect stings
- Contact with stinging plants
- Ingestion of unusual food, with the allergen, usually a protein
- Occasionally an unusual feed item (e.g., garlic to a horse)
- Administration of a particular drug (e.g., penicillin, streptomycin, possibly guaifenesin or other anesthetic agent)
- Allergic reaction in cattle following vaccination for foot-and-mouth disease
- Death of warble fly larvae in tissue
- Milk allergy when Jersey cows are dried off
- Transfusion reaction
- Cutaneous vasculitis (purpurea hemorrhagica)
- Local skin trauma (dermatographism)
- Temperature induced (heat, cold, sunlight)
- Infection—parasitic, bacterial, fungal, viral

Secondary urticaria occurs as part of a syndrome, such as the following:

- Respiratory tract infections in horses, including strangles and the upper respiratory tract viral infections
- Erysipelas in pigs

PATHOGENESIS

Degranulation of mast cells liberating chemical mediators of inflammation that result in the subsequent development of dermal edema is the presumed cause for the development of urticaria. A primary dilatation of capillaries causes cutaneous erythema. Exudation from the damaged capillary walls causes local edema in the dermis, and a wheal develops. Only the dermis, and sometimes the epidermis, is involved. In extreme cases the wheals may expand to become seromas, when they may ulcerate and discharge. The lesions of urticaria usually resolve in 12 to 24 hours, but in recurrent urticaria an affected horse may have persistent and chronic eruption of lesions over a period of days or months.

CLINICAL FINDINGS

Wheals, mostly circular, well-delineated, steep-sided, easily visible elevations in the skin, appear very rapidly and often in large numbers, commencing usually on the neck but being most numerous on the body. They vary from 0.5 to 5 cm in diameter, with a flat top, and are tense to the touch. There is often no itching, except with plant or insect stings, and no discontinuity of the epithelial surface, exudation, or weeping. Pallor of the skin in wheals can be observed only in unpigmented skin. Other allergic phenomena, including diarrhea and slight fever, may accompany the eruption. The onset of the lesions is acute to peracute, with the wheals developing within minutes to hours after exposure to the triggering agent. When associated with severe adverse systemic responses, including apnea, respiratory arrest, atrial fibrillation, cardiac arrest, or sudden death, the case qualifies as one of anaphylaxis.

Subsidence of the wheals within 24 to 48 hours is usual, but they may persist for 3 to 4 days because of the appearance of fresh lesions. In some very sensitive horses,

dermatographism, the production of a continuous wheal following the pattern of a blunt-pointed instrument drawn across the skin, can be demonstrated about 30 minutes later.

Urticaria lasting 8 weeks or longer is classified as chronic or recurrent urticaria, which may require testing for atopic disease using intradermal skin testing and serum testing for antigen-specific IgE.

Adverse reactions in dairy cattle following annual vaccination for foot-and-mouth disease are characterized by wheals (3 to 20 mm in diameter) covering most of the body, followed by exudative and necrotic dermatitis. The affected areas become hairless, and the wheals exude serum and become scabbed over. Edema of the legs is common, and vesicles occur on the teats. The lesions appear 8 to 12 weeks postvaccination and may persist for 3 to 5 weeks. Loss of body weight and lymphadenopathy also occur. Pruritus, depression, and a drop in milk yield are common. Adverse effects of parenteral administration of penicillin streptomycin in the form of a type I hypersensitivity reaction that was associated with rapid development of urticaria have been reported.[3]

CLINICAL PATHOLOGY

The diagnosis in most cases is based on the clinical presentation, possibly in combination with a history of local or systemic exposure to a potential allergen. Biopsies show that tissue histamine levels are increased, and there is a local accumulation of eosinophils. Blood histamine levels and eosinophil counts may also show transient elevation.

Opinions over the usefulness of intradermal skin tests in horses are strongly divided. Although intradermal testing may be of use in some cases, results are often difficult to interpret, and the panel of available allergens may not be the most appropriate for horses.[4] Intradermal tests in horses without atopy and horses with atopic dermatitis or recurrent urticaria using environmental allergens indicate a greater number of positive reactions for intradermal tests in horses with atopic dermatitis or recurrent urticaria compared with horses without atopy. This provides evidence of type I IgE-mediated hypersensitivity for these diseases.

DIFFERENTIAL DIAGNOSIS

Urticaria is manifested by a sudden appearance of a crop of cutaneous weals, sometimes accompanied by restlessness, mostly in horses, occasionally in cattle. Identification of the etiology is also helpful in diagnosis but is often difficult, depending on a carefully taken history and examination of the environment.

The **differential diagnosis list** is limited to angioedema, but in urticaria the lesions can be palpated in the skin itself. Angioedema involves the subcutaneous tissue rather than the skin, and the lesions are much larger and more diffuse. The two conditions may appear in the same animal at the same time.

TREATMENT

Primary Treatment

Spontaneous recovery is common in acute cases with incidental exposure to an allergen. In chronic or recurrent cases identification and removal of the allergen must be a priority. A change of diet and environment, especially exposure to the presumably causal insects or plants, is standard practice.

Supportive Treatment

Corticosteroids, antihistamines, or epinephrine by parenteral injection provides the best and most rational treatment, especially in the relief of the pruritus. One treatment is usually sufficient, but lesions may recur. The local application of cooling astringent lotions such as calamine or white lotion or a dilute solution of sodium bicarbonate is favored. In large animal practice parenteral injections of calcium salts are used, with apparently good results.

Long-term medical management of persistent/chronic urticaria involves the administration of corticosteroids and/or antihistamines. Oral administration or prednisone or prednisolone at the lowest possible dose on alternate days is the method of choice. The antihistamine of choice is oral hydroxyzine hydrochloride, initially at 1 to 2 mg/kg administered twice daily or three times daily, followed by gradual reduction to a minimum maintenance dose required to keep the horse free of lesions.

TREATMENT

Acute anaphylaxis with urticaria in horses:
- Epinephrine: 3 to 5 mL/450 kg of a 1:1000 solution IM or SC (can be combined with steroids) (R-1)

Acute urticaria in horses:
- Dexamethasone soluble 0.01 to 0.1 mg/kg IV or IM q24 h for 3 to 7 days (R-1)

Chronic or recurrent urticaria:
- Prednisolone 0.25 to 1.0 mg/kg IV or PO q24 h. Reduce to 0.2 to 0.5 mg/kg q48 h (R-1)
- Dexamethasone 0.01 to 0.02 mg/kg PO q48-72 h (R-1). Further reduce dose until the lowest dose keeping the animal free of signs is determined.
- Hydroxyzine hydrochloride 0.5 to 1.0 mg/kg IM or PO q8 h (R-2)
- Diphenhydramine hydrochloride 0.7 to 1 mg/kg q12 h (R-2)
- Chlorpheniramine 0.25 to 0.5 mg/kg q12 h (R-2)

DERMATITIS AND DERMATOSIS

SYNOPSIS

Etiology Any disease of skin, including those characterized by inflammation. All pathogens, infectious, chemical, physical, allergic, autoimmune.

Epidemiology Sporadic or outbreak; acute or chronic course; cosmetic to lethal; of most importance because of constraints on movement, sale, or exhibition; may affect animal welfare.

Clinical signs Primarily localized to skin, including lesions varying from parakeratosis and pachyderma to weeping, through necrosis, vesicles, and edema. Secondarily signs of shock, toxemia, anaphylaxis.

Clinical pathology Positive findings in the area of skin swabs or scrapings.

Necropsy lesions Inflammatory, degenerative, or vascular lesions in skin biopsy.

Diagnostic confirmation Positive finding in skin biopsy.

Treatment Primary treatment is removal of the (presumed) causative agent; supportive treatment includes treatment for pruritus, secondary infection, shock, toxemia, or fluid and electrolyte loss.

ETIOLOGY

Some of the identifiable occurrences of dermatitis in food animals and horses are as follows.

All Species

- Mycotic dermatitis as a result of *Dermatophilus congolensis*, in horses, cattle, and sheep
- *S. aureus*, a common finding in cases in all species, either as a sole pathogen or combined with other agents
- Ringworm
- Photosensitive dermatitis
- Chemical irritation (contact dermatitis) topically
- Arsenic—systemic poisoning
- Mange mite infestation—sarcoptic, psoroptic, chorioptic, demodectic mange

- Trombidiiform mite infestation (tyroglyphosis)
- Biting flies, especially *Culicoides* spp.; observed most commonly in horses, but also in other species
- *Stephanofilaria* spp. dermatitis
- *Strongyloides (Pelodera)* spp. dermatitis
- Besnoitiosis (*Besnoitia* spp.)

Cattle

- Udder impetigo (udder acne)—*Staphylococcus* spp.
- Udder cleft dermatitis of cattle
- Dermatitis interdigitalis (see following discussion)
- Ulcerative mammillitis—udder and teats only
- Cutaneous botryomycosis of the udder caused by a combination of trauma and infection by *Pseudomonas aeruginosa*
- Cowpox/buffalopox
- Flexural seborrhea
- Lumpy skin disease of cattle—painful nodules (2 to 5 cm) develop over the entire body, caused by pox virus, serotype *lumpy skin disease virus* (LSDV)
- Foot-and-mouth disease—vesicles around natural orifices; vesicular stomatitis with lesions on teats and coronet
- Bovine virus diarrhea, bovine malignant catarrh, bluetongue—erosive lesions around natural orifices, eyes, coronets
- Potato dermatitis in cattle, horses, and swine associated with prolonged feeding of potato distillery wastes; erythematous skin disease of distal limbs suspected to be of allergic origin
- Dermatitis as a result of the ingestion of *Vicia villosa* and *Vicia dasycarpa*
- Bovine exfoliative dermatitis

Sheep and Goats

- Strawberry footrot—proliferative pustular dermatosis linked to spirochete-like organisms and *Dermatophilus* and *Rhizobium*
- Dermatophilosis (lumpy wool disease, rain scald)—*Dermatophilus congolensis*
- Fleece rot—constant wetting and associated with *Pseudomonas aeruginosa*
- Staphylococcal dermatitis—exudative dermatitis around eyes, ears, and base of horns in sheep; vesicles possibly present on teats and udder in goats
- Sheeppox
- Contagious ecthyma—*Parapoxvirus* (*Orf*)
- Ulcerative dermatosis—caused by similar but antigenically distinct virus to Orf
- Rinderpest, peste de petits ruminants, bluetongue—as for cattle
- Foot-and-mouth disease and vesicular stomatitis
- Itch-mite (*Psorergates ovis*) infestation
- Blow-fly infestation (cutaneous myiasis)
- Elaeophoriasis (*Elaeophora* spp. infestation)
- Caprine idiopathic dermatitis
- Postdipping necrotic dermatitis (see following discussion).

Horses

- Staphylococcal pyoderma caused by *S. aureus*/*Staphylococcus intermedius*
- *Staphylococcus hyicus* in a syndrome reminiscent of greasy heel
- Dermatophytes, including ringworm, follicular dermatitis, hyphomycosis (pythiosis), tinea versicolor dermatitis
- Summer eczema (also Queensland or sweet itch)—sensitivity to *Culicoides* spp. sandflies
- Dermatophilosis/rain scald—*D. congolensis*
- *Actinomyces viscosum* causing skin pustules and nodules
- Horsepox
- Canadian horsepox
- Viral papular dermatitis (see following discussion)
- Vesicular stomatitis—vesicles around natural orifices
- Vesicular dermatitis around nasal area, eyes, and ears in horses stabled on shavings of a tree of the *Quassia* spp.
- Spongiotic vesicular dermatitis of unknown etiology
- Sporotrichosis
- Atopic dermatitis (IgE-mediated hypersensitivity)
- Chronic eosinophilic dermatitis (see following discussion)
- Pemphigus, lupus erythematosus, erythema multiforme, eosinophilic dermatitis and stomatitis (described separately in following discussion)
- Molluscum contagiosum (see following discussion)
- Linear hyperkeratosis (see following discussion)
- Nodular necrobiosis
- Equine aural plaque (see following discussion)
- Uasin Gishu disease
- Cutaneous habronemiasis
- Equine tropical lichen (see following discussion)
- Midline ventral dermatitis as a result of infestation with *Hydrotaea irritans* (horn fly and buffalo fly)
- Trombidiiform mites, e.g., *Pyemotes tritici* and *Acarus (Tyroglyphus) farinae*
- Ulcerative dermatitis, thrombocytopenia and neutropenia in neonatal foals (see Alloimmune hemolytic anemia of the newborn (neonatal isoerythrolysis, isoimmune hemolytic anemia of the newborn).

Pigs

- Ulcerative granuloma—*Borrelia suilla*
- Contagious epidermitis—*Staphylococcus hyicus* ("greasy pig disease")
- Pig pox
- Swine vesicular disease, vesicular exanthema of swine, foot-and-mouth disease—vesicles around natural orifices
- Contact with fresh parsnip tops, celery
- Sunburn
- Porcine necrotic ear syndrome (see following discussion)
- Nonspecific nutritional dermatitis—experimental nutritional deficiency of nicotinic acid, riboflavin, pantothenic acid, biotin
- Pityriasis rosea
- Idiopathic chronic recurrent dermatoses

Special Local Dermatitides

Special local dermatitides include dermatitis of the teats and udder, the bovine muzzle and coronet, and flexural seborrhea, and are dealt with under their respective headings.

PATHOGENESIS

Dermatitis is an inflammation of the deeper layers of the skin involving the blood vessels and lymphatics. The purely cellular layers of the epidermis are involved only secondarily. The noxious agent causes cellular damage, often to the point of necrosis, and, depending on the type of agent responsible, the resulting dermatitis varies in its manifestations. It may be acute or chronic, suppurative, weeping, seborrheic, ulcerative, or gangrenous. In all cases there is increased thickness and increased temperature of the part. Pain or pruritus is present, and erythema is evident in unpigmented skin. Histologically there is vasodilatation and infiltration with leukocytes and cellular necrosis. These changes are much less marked in chronic dermatitis.

CLINICAL FINDINGS

Affected skin areas first show erythema and increased warmth. The subsequent stages vary according to the type and severity of the causative agent. There may be development of discrete vesicular lesions or diffuse weeping. Edema of the skin and subcutaneous tissues may occur in severe cases. The next stage may be the healing stage of scab formation; if the injury is more severe, there may be necrosis or even gangrene of the affected skin area. Spread of infection to subcutaneous tissues may result in a diffuse cellulitis or phlegmonous lesion. A distinctive suppurative lesion is usually classified as pyoderma. Deep lesions that cause damage to dermal collagen may cause focal scarring and idiopathic fibrosing dermatitis (see following discussion).

A systemic reaction is likely to occur when the affected skin area is extensive. Shock, with peripheral circulatory failure, may be present in the early stages. Toxemia as a result of absorption of tissue breakdown products, or septicemia as a result of invasion

via unprotected tissues, may occur in the later stages.

Individual dermatitides are as follows:

- **Interdigital dermatitis** is a low-grade exudative inflammation of the interdigital skin of cattle housed indoors and standing continuously in slurry. This condition has been linked to *Dichelobacter nodosus.*
- **Ovine postdipping necrotic dermatitis** is associated with *P. aeruginosa* and related to dipping in solutions containing no bacteriostatic agent. Necrotic lesions (1 to 3 cm in diameter), with cellulitis down to the underlying muscle, occur only along the backline and may be related to trauma during dipping. It may be accompanied by an outbreak of fatal otitis media with *P. aeruginosa* present in the lesion.
- **Ovine atopic dermatitis**: Only the wool-less parts of the skin are affected by symmetric erythema, alopecia, lichenification, and excoriation. Only occasional sheep in the flock are affected, and these are affected each summer, with remission during the winter months.
- **Caprine idiopathic dermatitis**: Alopecic, exudative dermatitis of all ages and both sexes of pygmy goats is characterized by hair loss and scaling and crusting around the eyes, lips and chin, ears, poll, perineum, and ventral abdomen. Histologically the lesions have a psoriasis-like form.
- **Chronic equine eosinophilic dermatitis** is characterized by marked acanthosis and hyperkeratosis, and eosinophilic granulomas in the pancreas, salivary glands, and other epithelial organs. The systemic involvement is accompanied by severe weight loss. The disease is chronic, and the cause unknown.
- **Spongiotic vesicular dermatitis** has been described in horses. Lesions are characterized by a multifocal, exudative, oozing dermatitis characterized histologically by epidermal spongiotic vesicles and perivascular eosinophilic, neutrophilic, and mixed mononuclear inflammation. Some horses are pruritic.
- **Equine nodular necrobiosis (eosinophilic granuloma)**: Firm, small (up to 1 cm in diameter) nodules, usually a number of them, occur on the sides of the trunk and neck. A hypersensitivity reaction to insect bites has been proposed as the underlying cause. The lesions consist largely of an accumulation of eosinophils.
- **Molluscum contagiosum** is a chronic, progressive dermatitis characterized by raised, hairless lesions 0.5 to 2 cm in diameter, covered by soft keratin, that bleed profusely when the horse is groomed. The lesions are on the face, shoulders, trunk, lateral aspects of limbs, fetlocks, and pasterns. Histologic examination identifies the disease because of the presence of characteristic inclusions in cells. These are thought to be poxvirus virions, but the virus cannot be cultivated from the lesions. There is no specific treatment
- **Systemic lupus erythematosus** (SLE) is an extensive dermatitis, manifested as a scaly, crusty dermatitis of the face, neck, and trunk, with loss of hair over the lesions, edema of the limbs, and mild to moderate lymph node enlargement. Multiple ulcers 11 cm in diameter are present on the oral mucosa, especially the mucocutaneous junctions of the lips and nares, and on the tongue. There is a severe systemic reaction, including a marked loss of body weight, a temperature up to 39.5° C (103.1 F), heart rate of 80/min, respiratory rate up to 60/min, painful swollen joints containing sterile serous fluid, stiff gait, reluctance to move, and persistent lateral recumbency. SLE is an immune-mediated disease with a characteristic histopathology including a necrotizing lymphocytic dermatitis and focal accumulations of lymphocytes in the liver, membranous glomerulonephritis, and synoviocyte hyperplasia. An antinuclear antibody test is diagnostic. No treatment is effective, and the disease runs a chronic progressive course marked by remissions and exacerbations.
- **Discoid lupus erythematosus** is an uncommon, benign variant of the systemic disease, with cutaneous lesions similar to those in the major disease but with no involvement of other tissues.
- **Erythema multiforme** is a self-limiting skin disease of horses and cattle characterized by macular, papular, urticarial, or bullous skin lesions but without any abnormality of the epidermis or loss of hair, and with no apparent itching or pain. The lesions occur symmetrically on most parts of the body, persist for long periods, and increase in size up to 5 cm to form annular or crescent-shaped wheals. Spontaneous disappearance of the lesions after about 3 months is usual. Symptomatic treatment may be effective but is not usually necessary.
- **Equine aural plaque**: Multiple white plaques, resembling papilloma and about 1 cm in diameter, develop on the inner surface of the ear pinna of horses. This condition has been associated with the papillomavirus that is thought to be transmitted by biting insects.
- **Equine tropical lichen** is an intensely irritating, papular eruption in the skin on the side of the neck, under the mane, on the shoulders, and at the tailhead, occurring in summer and recurring annually. The disease closely resembles the cutaneous sensitivity to *Culicoides* spp. but responds dramatically to treatment with ivermectin. Microfilariae, thought to be *Onchocerca* spp., can be found in histologic sections.
- **Linear hyperkeratosis** is most common in horses, especially Quarter horses. One case has been recorded in cattle. Lesions appear spontaneously in horses 1 to 5 years old and persist, usually for life. They appear first as isolated scaly lumps, which then coalesce to form a ridge, usually vertical, 3 to 4 cm wide and up to 70 cm long, of hyperkeratotic, hairless skin. There may be one or more lesions, commonly on the sides of the neck and chest. Symptomatic treatment appears to have no effect on the lesions.
- **Idiopathic fibrosing dermatitis**: As the end stage of several severe dermatoses, this causes damage to dermal collagen. Manifested by multiple fibrous plaques in the skin caused by sclerosis of the skin or subcutis, it resembles human morphea and the skin granulomas of animals.
- **Porcine dermatitis–nephropathy syndrome**, an idiopathic low-morbidity but highly fatal disease of feeder pigs, is characterized by papular vascular dermatopathy, systemic necrotizing vasculitis, and exudative and proliferative glomerulonephritis. Skin lesions are full-depth necrosis appearing as multiple flat red–blue papules up to 2 cm in diameter (which may coalesce to form large plaques) on any part of the body. Some pigs die of glomerulonephritis without skin lesions having been apparent. Many cases that show only skin lesions recover spontaneously in several weeks. The disease may disappear if the commercial grain ration used is ground more coarsely.
- **Porcine necrotic ear syndrome** is an extensive necrosis of the edges of the ears. The cause is unknown, but the possibility that a combination of *S. hyicus* infection and trauma by biting by pen mates is the cause seems high.
- **Porcine idiopathic chronic, recurrent dermatitis** has been recorded in sows in specific farrowing houses. Boars and piglets were not affected, and lesions disappeared as soon as the sows left the houses. Annular macules 11 cm in diameter and patches of erythema 11 cm in diameter occur only on white skin. There are no systemic signs.
- **Equine staphylococcal pyoderma** is a serious disease because the lesions are intractable to treatment and are so painful to touch that the horse is hard to handle, and the presence of the lesions under the harness, where they

commonly are, prevents the horse from working kindly. Harness horses are at a particular disadvantage. Individual lesions are raised nodules, 3 to 5 mm in diameter, covered by a small, easily removed scab. When these lift, they take a tuft of hair with them, and a small crater is left. A little pus exudes, and only a red serous fluid can be expressed. Individual lesions last a long time, at least several weeks, and fresh crops occur, causing the disease to spread slowly on the animal.

Pemphigus

Pemphigus is an autoimmune disease of the skin occurring in mature horses, usually 5 years of age or older, as well as in foals. Vesicles and pustules are usually very difficult to find because they progress rapidly to crusts, exfoliation, alopecia, and scaling.[1] There are a number of manifestations, of which pemphigus foliaceus is the most common. Pemphigus vulgaris and bullous pemphigoid, in contrast, are rare. Pemphigus is a chronic autoimmune disease often accompanied by severe weight loss.

Pemphigus foliaceus is not only the predominant form of pemphigus but also the most common autoimmune disease of the horse. The classic, but rarely seen, primary lesion is a vesicle or pustule. Usually, the earliest lesions visible are crusted papules best seen in lightly or nonhaired skin adjacent to mucocutaneous junctions—the nostrils, eyelids, or lips. Lesions rapidly coalesce to form multifocal or diffuse areas of crusting. Pemphigus foliaceus occurs as a generalized scabby, weeping dermatitis, but it may be localized as circumscribed, circular lesions in the mouth and vulva and on the skin at mucocutaneous junctions. The lesions are subepidermal bullae, from which the top layer can be pulled away, and are sore to the touch. In some cases the lesions are around the coronary bands on all limbs. Edema, urticaria, pruritus, and pain of the extremities, especially the hindlimbs, and the ventral abdominal region may result in pronounced lameness.

The differential diagnoses include all skin diseases caused by scaling and crusting. These include dermatophytosis, dermatophilosis, staphylococcal dermatitis and folliculitis, systemic granulomatous disease, and primary or idiopathic abnormalities of keratinization.

The diagnosis is based on history, clinical presentation, skin cytology, and histopathology. Immunohistochemical staining and direct immunofluorescence examination, consisting of a fluorescein–antihorse IgG applied to the lesion, can confirm the diagnosis. Corticosteroid or gold (aurothioglucose) therapy has been reported to result in improvement, but an inexorable deterioration is usual. Pemphigus foliaceus is recorded in goats as a widespread disease characterized by the presence of scales, sometimes in heavy crusts, and involvement of the coronets.

CLINICAL PATHOLOGY

Examination of skin scrapings or swabs for parasitic, bacterial, or other agents is essential. Culture and sensitivity tests for bacteria are advisable to enable the best treatment to be selected. Skin biopsy may be of value in confirming the diagnosis and determining the causal agent. In allergic or parasitic states there is usually an accumulation of eosinophils in the inflamed area. In mycotic dermatitis organisms are usually detectable in the deep skin layers, although they may not be cultivable from superficial specimens.

DIAGNOSIS

The clinical features of dermatitis are apparent. The characteristic features of the etiologic types of dermatitis are described under each specific disease. **Diagnostic confirmation** is by histopathological demonstration in a biopsy specimen.

DIFFERENTIAL DIAGNOSIS

Hyperhidrosis and **anhidrosis** are dysfunctions of sweating and have no cutaneous lesion.

Cutaneous neoplasm is differentiable on histopathological examination.

Epitheliogenesis imperfecta is a congenital absence of all layers of skin.

Vascular nevus is a congenital lesion commonly referred to as a "birthmark."

TREATMENT

Primary treatment must be to remove the noxious physical or chemical agent from the environment or to supplement the diet to repair a nutritional deficiency. The choice of a suitable treatment for infectious skin disease will depend on the accurate identification of the etiologic agent.

Supportive treatment includes both local and systemic therapy. Local applications may need to be astringent, either as powders or lotions in the weeping stage or as greasy salves in the scabby stage. The inclusion of corticosteroids or antihistamine preparation is recommended in allergic states, and it is desirable to prescribe sedative or anesthetic agents when pain or pruritus is severe.

If shock is present, parenteral fluids should be administered. If the lesions are extensive or secondary bacterial invasion is likely to occur, parenterally administered antibiotics or antifungal agents may be preferred to topical applications. To facilitate skin repair, a high-protein diet or the administration of protein hydrolysates or amino acid combinations may find a place in the treatment of valuable animals. Nonspecific remedies such as gold-containing remedies (e.g., aurothioglucose) are commonly used in autoimmune diseases such as pemphigus.

The use of vaccines as prophylaxis in viral and bacterial dermatitides must not be neglected. Autogenous vaccines may be most satisfactory in bacterial infections. An autogenous vaccine is particularly recommended in the treatment of staphylococcal dermatitis in horses and bovine udder impetigo, in which long and repeated courses of treatment with penicillin produce only temporary remission. An autogenous vaccine produces a cure in many cases.

PHOTOSENSITIZATION

SYNOPSIS

Etiology Caused by the accumulation of photosensitizing substances (PSs) in the skin, resulting in the local irritation of unprotected, unpigmented skin after exposure to sunlight. Four types of photosensitization are differentiated based on the underlying etiology.
- Type I, or primary, caused by intake of primary PS.
- Type II, as a result of inherited defects of porphyrin metabolism.
- Type III, or hepatogenous, as a result of liver damage and ensuing faulty excretion of phylloerythrin.
- Type IV, or idiopathic, as a result of undetermined etiology.

Epidemiology Exposure to PSs and sunlight of specific wavelength. Similar incidence of sporadic cases and outbreaks. Always life-threatening condition unless exposure to sunlight can be avoided.

Clinical signs Primary cases have cutaneous signs only (erythema, edema, necrosis, gangrene of light-colored skin or mucosae exposed to sunlight). Secondary cases have also signs of hepatic dysfunction (jaundice, prostration, short course, death) or porphyrin metabolism.

Clinical pathology Nil for evidence of photosensitivity. In secondary cases there is evidence of the primary disease.

Necropsy lesions Only skin lesions in primary cases. Secondary cases show liver lesions or evidence of porphyrin accumulation.

Differential diagnosis Clinical evidence of restriction of damage to white, wool-less skin on body dorsum and lateral aspects of limbs, teats, corneas, and tongue and lips.

Treatment Primary: remove from exposure to sunlight and PS. Supportive: treat for infection, shock, toxemia.

ETIOLOGY AND EPIDEMIOLOGY

Photosensitization is caused by exposure of tissue containing certain photoactive

substances to light of specific wavelength. Substances with the potential to accumulate in skin and get activated by solar irradiation are termed **photosensitizing substances (PSs)**. Skin containing an excess of PSs that is exposed to sunlight while unprotected by hair, wool, or pigmentation is most affected. PSs release unstable high-energy molecules when exposed to a wavelength of light above 320 nm that reacts with substrate molecules in the skin. The result is the formation of free radicals causing cell damage in outer cells and becoming clinically apparent as inflammation, edema, ulceration, and even necrosis of the skin.

Photosensitization differs from sunburn in that it requires the presence of a photosensitizing agent, it is triggered by exposure to a wavelength of light between 320 and 400 nm (in contrast to sunburn, which in most cases is the result of exposure to light with lower wavelength), its onset is rapid (in contrast to the more delayed onset with sunburn), and skin lesions are considerably more severe than with sunburn.

Based on the origin of the photosensitizing agent, photosensitization has been classified into four classes, as follows:

- **Type I,** primary photosensitization caused by PSs of exogenous origin (no underlying primary pathology of the organism)
- **Type II,** photosensitization caused by aberrant pigment metabolism
- **Type III,** hepatogenous photosensitization caused by disturbed liver function
- **Type IV,** idiopathic photosensitization that is of undetermined etiology

Another form of photosensitization that is of little importance in livestock is the **photoallergic photosensitization** related to an immunologic response involving T-cell-mediated delayed hypersensitivity.

Type I, Primary Photosensitization

Exogenous PSs can enter the organism through oral ingestion (e.g., PSs contained in feed), parenteral administration (e.g., certain drugs), or direct absorption through skin. In livestock oral ingestion is the most common route of exposure, with PSs being either contained in the diet or, less commonly, an orally administered drug. Photosensitization as a result of the ingestion of exogenous photodynamic agents usually occurs when the plant is in the lush green stage and is growing rapidly. Livestock are affected within 4 to 5 days of going to pasture, and new cases cease soon after the animals are removed. In most cases the plant responsible must be eaten in large amounts and will therefore usually be found to be a dominant inhabitant of the pasture. All species of animals are affected by photodynamic agents, although susceptibility may vary between species and between animals of the same species. PSs that occur naturally in plants include the following:

- Dianthrone derivatives—hypericin in *Hypericum perforatum* (St. John's wort) and other *Hypericum* spp. and fagopyrin in seeds and dried plants of *Fagopyrum esculentum* (buckwheat)
- Furocoumarins in *Cymopterus* spp. (wild carrot), *Ammi majus*, and *Thamnosma texana*
- Perloline from perennial ryegrass (*Lolium perenne*)
- Cocoa shells in feedlot rations causing photosensitization in feedlot calves
- Gluten metabolites in dairy cattle concentrates being fed to horses
- *Erodium moschatum*, an exotic weed in South Africa, causing photosensitization in sheep
- Unidentified photodynamic agents in *Medicago denticulata* (burr trefoil) and the aphids that infest it, and in *Brassica* spp., *Erodium* spp., and *Trifolium* spp.

Drug-related photosensitization has been reported after oral treatment with phenothiazine, an antiparasitic drug, and anecdotally after treatment of cows with corticosteroids to induce parturition (photosensitive dermatitis of the teats, escutcheon, and udder).

Type II, Photosensitization as a Result of Aberrant Pigment Metabolism

The PSs associated with type II photosensitization are porphyrins that may accumulate in an organism with disturbed heme synthesis. The only known examples in domestic animals are the two rare inherited conditions of **congenital porphyria erythropoietica** (pink tooth) and **congenital protoporphyria erythropoietica** described in Limousin cattle.

Type III, Hepatogenous Photosensitization

Hepatogenous photosensitization is the most common form of the disorder in livestock. The PS is invariably **phylloerythrin**, a normal end product of chlorophyll metabolism excreted in the bile. When biliary secretion is obstructed by hepatitis or biliary duct obstruction, phylloerythrin accumulates in the body and may reach levels in the skin that make it sensitive to light. Although hepatogenous photosensitization is more common in animals grazing green pasture, it can occur in animals fed entirely on hay or other stored feeds and in animals exposed to hepatotoxic chemicals (e.g., carbon tetrachloride). There appears to be sufficient chlorophyll, or breakdown products of it, in stored feed to produce critical tissue levels of phylloerythrin in affected animals. The following list includes those substances or plants that are common causes of hepatogenous photosensitization. The individual plants are discussed in more detail in the section on poisonous plants.

Plants Containing Hepatotoxins

- *Pithomyces chartarum* fungus on perennial ryegrass, causing **facial eczema of sheep**
- *Periconia* spp. fungus on Bermuda grass
- Cyanobacteria associated with blue-green algae (water bloom) on drinking water in ponds, dams, and dugouts—*Microcystis flosaquae*
- Lupins—*Lupinus angustifolius* plus the accompanying fungus, *Phomopsis leptostromiformis*
- Signal grass (*Brachiaria decumbens* and *Brachiaria brizantha*), a common component of established pastures in Brazil
- Alligator weed (*Alternanthera philoxeroides*), a South American aquatic plant causing photosensitization in dairy cattle in Australia and New Zealand
- Weeds, including lantana (*Lantana camara*), *Lippia rehmanni*, sacahuiste (*Nolina texana*), coal oil bush (*Tetradymia* spp.), alecrim (*Holocalyx glaziovii*), ngaio (*Myoporum laetum*), *Crotalaria retusa*, ragwort (*Senecio jacobea*), *Sphenosciadium* spp.

Plants Containing Steroidal Saponins

The following plants containing steroidal saponins cause crystal-related cholangiohepatopathy:

- *Agave lecheguilla*, *Narthecium ossifragum*, *Panicum* spp. (panic and millet grasses), and *Tribulus terrestris* (caltrop, geeldikkop), plants that are grazed particularly by sheep
- *Narthecium ossifragum* (bog asphodel)—Sheep (lambs) grazing on pastures containing *N. ossifragum* on the west coast of Norway and in Scotland, northern England, Ireland, and the Faroe Islands have been affected by alveld, a hepatogenous photosensitivity disease. The disease is known as alveld (literally, "elf fire") in Norway; plochteach, saut, or yellowses in the British Isles; and ormajuka ("worm disease") in the Faroe Islands. Pastures containing *N. ossifragum* in these countries are commonly used for grazing sheep. Photosensitization of sheep grazing this plant usually occurs in 2- to 6-month-old lambs and is rarely seen in adult sheep. It produces similar clinical signs to those resulting from facial eczema, a disease most commonly seen in New Zealand and associated with the fungal toxin sporidesmin.

Congenitally Defective Hepatic Function

Inherited congenital photosensitivity in Corriedale and Southdown lambs is an inherited defect in the excretion of bile pigment.

Type IV, Photosensitization of Uncertain Etiology

In the following diseases it has not been possible to ascertain whether the photosensitization is primary or as a result of hepatic insufficiency:

- Feeding on rape or canola (*Brassica rapa*), kale, lucerne or alfalfa (*Medicago sativa*), burr medic or burr trefoil (*Medicago denticulata*), *Medicago minima*, *Trifolium hybridum* (alsike or Swedish clover), and *Erodium cicutarium* and *Erodium moschatum* (lamb's tongue, plantain)
- Cattle feeding on water-damaged or moldy alfalfa hay or alfalfa silage; extensive outbreaks usually with no signs suggestive of hepatic disease
- Cattle, sheep, and horses grazing lush pasture; many clinical cases occur sporadically
- Corticosteroids used systemically to terminate parturition in cows
- Phenanthridium used in the treatment of trypanosomiases

PATHOGENESIS

Penetration of light rays to sensitized tissues causes local cell death and tissue edema. Irritation is intense because of the edema of the lower skin level, and loss of skin by necrosis or gangrene and sloughing is common in the terminal stages. Nervous signs may occur and are caused either by the photodynamic agent, as in buckwheat poisoning, or by liver dysfunction.

Hepatogenous photosensitization involves production of a toxin, by a higher plant, fungus, or cyanobacterium (algae), that causes liver damage or dysfunction, resulting in the retention of the photosensitizing agent phylloerythrin.

CLINICAL FINDINGS

General Signs

Skin lesions are limited to lightly or unpigmented skin directly exposed to light; pigmented parts of the integument remain unaffected. Early signs include erythema and swelling of the muzzle, nasal and ocular discharge, and photophobia. Local edema is often severe and may cause drooping of the ears; closure of the eyelids and nostrils, causing dyspnea; and dysphagia as a result of swelling of the lips. As the disease progresses, fissuring followed by sloughing of the thick skin is observed. Keratitis may be present and become severe enough to cause blindness. Behavioral changes are a result of intense irritation and include restlessness and scratching and rubbing of affected skin parts. When the teats are affected, the cow may kick at them and walk into ponds to immerse the teats in water, sometimes rocking backward and forward as if to cool the affected parts. In nursing ewes there may be resentment toward the lambs sucking, and heavy lamb mortalities as a result of starvation may result. General depression, anorexia, and even recumbency may occur but are related to liver injury and disturbed liver function.

Skin Lesions

Skin lesions are initially erythema, followed by edema and subsequent weeping with matting and then shedding of clumps of hair, and finally gangrene. The lesions have a characteristic distribution, restricted to the unpigmented areas of the skin and to those parts that are exposed to solar rays. They are most pronounced on the dorsum of the body, diminishing in degree down the sides, and are absent from the ventral surface. The demarcation between lesions and normal skin is very clear-cut, particularly in animals with broken-colored coats.

Predilection sites for lesions are the ears; conjunctiva, causing opacity of the lateral aspect of the cornea; eyelids; muzzle; face; lateral aspects of the teats; and, to a lesser extent, the vulva and perineum. In solid black cattle dermatitis will be seen at the lips of the vulva, on the edges of the eyelids, and on the cornea. Linear erosions often occur on the tip and sides of the tongue in animals with unpigmented oral mucosa. In severe cases the exudation and matting of the hair and local edema cause closure of the eyelids and nostrils. In the late stages necrosis or dry gangrene of affected areas leads to sloughing of large areas of skin.

Systemic Signs

Systemic signs include shock in the early stages, as a result of extensive tissue damage. There is an increase in the pulse rate, with ataxia and weakness. Subsequently a considerable elevation of temperature (41° to 42° C, 106° to 107° F) may occur.

Nervous Signs

Nervous signs, including ataxia, posterior paralysis and blindness, and depression or excitement, are often observed. A peculiar sensitivity to water is sometimes seen in sheep with facial eczema: when driven through water, they may lie down in it and have a convulsion.

CLINICAL PATHOLOGY

In most cases a presumptive diagnosis can be made based on clinical presentation in combination with the history of the patient (recently pastured, access to certain plants, etc.). There are no specific diagnostic tests to confirm photosensitization.

Hepatogenous photosensitization can be diagnosed by analysis of plasma phylloerythrin concentration using a spectroscopic method. Plasma or serum fluorescence can be used to measure the elevation of phylloerythrin above normal levels before hepatogenous photosensitization. The levels of phylloerythrin in plasma of lambs grazing *N. ossifragum* are increased from a normal of less than 0.05 µg/mL to more than 0.3 µg/mL when clinical signs of photosensitization are observed. Levels in skin are also increased.

In lambs in which facial eczema was experimentally induced by dosing with the mycotoxin sporidesmin, the plasma concentrations of phylloerythrin were increased from a normal of less than 0.1 µmol/L to 0.3 µmol/L when clinical signs were evident. The concentration of phylloerythrin in the skin began increasing 2 to 3 days later than that in the blood.

Determining the presence of liver damage or disturbed liver function is indicated. Icterus is highly suggestive of hepatogenous hypersensitization but should be confirmed by measuring the serum activity of specific liver enzymes and the serum bilirubin concentration.

NECROPSY FINDINGS

In primary photosensitization, lesions are restricted to white-haired or pale-skinned areas of skin or mucosa that have been exposed to sunlight, and they vary from necrosis to gangrene. Lesions characteristic of hepatic injury or metabolic defects of porphyrin metabolism are described elsewhere.

Diffuse hepatocellular hydropic degeneration and hyperplasia of the smooth endoplasmic reticulum associated with marked multifocal cholangitis in the portal triads with bile duct proliferation are characteristic of the hepatic lesions of sheep grazing *Brachiaria decumbens*. Foam cells are present in the liver and mesenteric and hepatic lymph nodes of cattle grazing *Brachiaria* spp. Hepatocellular degeneration is the primary event in alveld photosensitization in sheep. High concentrations of conjugated episapogenins are present in both the liver and bile in alveld-affected lambs.

DIFFERENTIAL DIAGNOSIS

The diagnosis of photosensitivity depends almost entirely on the distribution of the lesions. It can be readily confused with other dermatitides if this restriction to unpigmented and hairless parts is not kept in mind.

Mycotic dermatitis is often mistaken for photosensitization because of its tendency to commence along the back line and over the rump, but it occurs on colored and white parts alike.

Frequent wetting, as in periods of heavy rainfall, along the back in horses or cattle with a dense hair coat.

Bighead of rams associated with *Clostridium novyi* infection may also be confused with photosensitization, but the local swelling is an acute inflammatory edema, and many clostridia are present in the lesion.

Keratitis sometimes seen in photosensitization can been confused with those of pinkeye, but that disease is not accompanied by extensive dermatitis.

Continued

Sunburn is a very rare differential that has been reported in white swine, closely shorn sheep, and white-faced horses only.

Treatment

Primary treatment includes immediate removal from direct sunlight, prevention of ingestion of further toxic material, and the administration of laxatives to eliminate toxic materials already eaten. In areas where the disease is enzootic the use of dark-skinned breeds may make it possible to utilize pastures that would otherwise be too dangerous.

Local treatment is governed by the stage of the lesions. Nonsteroidal antiinflammatory drugs (NSAIDs), corticosteroids, or antihistamines can be administered parenterally and adequate doses maintained. To avoid septicemia, the prophylactic administration of antibiotics may be worthwhile in some instances.

Diseases of the Hair, Wool, Follicles, and Skin Glands

ALOPECIA AND HYPOTRICHOSIS

ETIOLOGY

Alopecia and hypotrichosis are defined as lack of hair in any quantity on a normally haired body surface.[1] In contrast to alopecia, which describes hair loss of a skin surface with previously normal hair growth, hypotrichosis refers to a condition where there was no hair growth or abnormally low hair growth in the first place. Some texts define alopecia simply as hair loss and subdivide alopecia into a congenital and an acquired form, the former also being referred to as hypotrichosis. Acquired alopecias are further subdivided into cicatrical and noncicatricial alopecia.

Both may be caused by the following conditions.

Failure of Follicles to Develop

- Congenital hypotrichosis
- Hypotrichosis in piglets without dental dysplasia

Loss of Follicles

- Cicatricial alopecia as a result of scarring after deep skin wounds that destroy follicles—Cicatricial alopecia occurs following permanent destruction of the hair follicles, and regrowth of hair will not occur. Examples include physical, chemical, or thermal injury; severe furunculosis; neoplasia; and certain infections, such as cutaneous onchocerciasis.

Failure of the Follicle to Produce a Fiber

Congenital

- Inherited symmetric alopecia
- Congenital hypotrichosis/hypotrichosis and anodontia defect (alopecia of variable degree associated with incomplete dentation, mainly occurring in male calves)
- Hypotrichosis in Polled Hereford calves
- Lethal hypotrichosis in Holstein–Friesian calves (generalized alopecia, with sparse hair on muzzle, eyelids, and ears—affected calves die within hours of life)
- Viable hypotrichosis in different cattle breeds (Guernsey, Jersey, Holstein–Friesian: generalized alopecia with sparse hair growth on legs, tail, eyelids, and ear pinnae)
- Hair-coat-color-linked follicle dysplasia
- Inherited dyserythropoiesis and dyskeratosis
- In baldy calves combined with adenohypophyseal hypoplasia
- Congenital hypothyroidism (goiter) as a result of iodine deficiency in the dam

Acquired

- Neurogenic alopecia as a result of peripheral nerve damage
- Infection in the follicle
- Epidermolysis bullosa in calves[2]
- Alopecia areata of horses and, less commonly, cows characterized by one or more round lesions of nonpruritic, nonscarring alopecia over the face, neck, shoulders, and brisket[3]
- Bovine besnoitiosis[4]

Loss of Preformed Fibers

- Dermatomycoses—ringworm
- Mycotic dermatitis in all species as a result of *D. congolensis*
- Metabolic alopecia subsequent to a period of malnutrition or severe illness (e.g., calves having suffered severe diarrhea or calves with incomplete function of the reticular groove reflex [rumen drinker calves])[5]
- Alopecia of calves fed milk replacer containing fats of nonanimal origin (whale, palm, or soya oil); fibers grown during the period of nutritional or metabolic stress have a zone of weakness and are easily broken
- Traumatic alopecia as a result of excessive scratching or rubbing associated with louse, tick, or itch-mite infestations; rubbing against narrow doors, feed troughs, or tethers in confined housing; rubbing against harness in working animals
- Poisoning by thallium, selenium, arsenic, mercury, or the tree *Leucaena leucocephala*
- Idiopathic hair loss from the tail-switch of well-fed beef bulls
- Sterile eosinophilic folliculitis of cattle
- Wool slip
- In many primary skin diseases (e.g., parakeratosis, hyperkeratosis, dermatitis, cutaneous neoplasia, sarcoid, pythiosis), hair loss at the site of local lesions

PATHOGENESIS

In inherited hair defects the underlying cause can be disturbed hair follicle formation resulting in a reduced hair follicle quantity or disturbed functionality of hair follicles that are present in adequate numbers. Noncicatricial alopecia is caused by reversible trauma to previously functional hair follicles by inflammation or mechanical trauma, which results in disturbed or interrupted synthesis in the hair bulb and ensuing shedding or fracture of hairs. Cicatricial alopecia is characterized by an irreversible destruction of hair follicles most commonly caused by physical, chemical, or thermal injury or severe inflammation.

Chemical depilation produced by cytotoxic agents, such as cyclophosphamide, occurs as a result of induced cytoplasmic degeneration in some of the germinative cells of the bulb of the wool follicle. The alteration in cell function is temporary, so that regrowth of the fiber should follow.

The pathogenesis of alopecia areata, primarily occurring in horses but also in cattle, has been associated with damage to growing hair mediated by T lymphocytes presumably specific for antigens of the hair matrix (autoimmune disease).[3] A genetic predisposition for alopecia areata has been discussed for humans.

CLINICAL FINDINGS

When alopecia is a result of breakage of the fiber, the stumps of old fibers or developing new ones may be seen. When fibers fail to grow, the skin is shiny and in most cases is thinner than normal. In cases of congenital follicular aplasia, the ordinary covering hairs are absent, but the coarser tactile hairs around the eyes, lips, and extremities are often present. Absence of the hair coat makes the animal more susceptible to the effects of sudden changes of environmental temperature. There may be manifestations of a primary disease and evidence of scratching or rubbing.

Alopecia areata in horses primarily affects the mane, head, and tail, whereas in cattle extensive alopecia affecting large parts of the body has been reported.[3,6] Cases reported in the literature are primarily from animals showing first signs at adult age.[3,6] In cattle a predisposition of black-haired breeds (Black

Angus, Aberdeen Angus, Eringer) has been proposed.[3]

Congenital hypotrichosis results in alopecia that is apparent at birth or develops within the neonatal period.

CLINICAL PATHOLOGY

If the cause of the alopecia is not apparent after the examination of skin scrapings or swabs, a skin biopsy will reveal the status of the follicular epithelium. Alopecia areata is characterized by bulbar and peribulbar lymphocyte infiltration, primary targeting anagen hair follicles.[3] In early stages several biopsies may be required to identify this pattern of infiltration. More advanced stages show dysplastic follicles with mild to moderate concentric fibrosis surrounding rudiments of hair bulbs.[5]

DIFFERENTIAL DIAGNOSIS

Diagnostic confirmation of alopecia is by visual recognition, the diagnostic problem being to determine the primary cause of the hair or fiber loss.

TREATMENT

Primary treatment consists of removing the causes of trauma or other damage to fibers. In cases of faulty follicle or fiber development treatment is not usually attempted.

ACHROMOTRICHIA

Achromotrichia is a deficient pigmentation in hair or wool fiber, which may manifest as follows:

- Bands of depigmentation in an otherwise black wool fleece are the result of a transitory deficiency of copper in the diet.
- Cattle on diets containing excess molybdenum and deficient copper show a peculiar speckling of the coat caused by an absence of pigment in a proportion of hair fibers. The speckling is often most marked around the eyes, giving the animal the appearance of wearing spectacles.
- General loss of density of pigmentation in all coat colors (e.g., Hereford cattle shade off from their normal deep red to a washed-out orange)

LEUKODERMA AND LEUKOTRICHIA

Several skin diseases of the horse are characterized by an acquired loss of melanin pigment in the epidermis or hair. Melanocytes in the epidermis and those in the hair bulbs are frequently affected independently. Leukotrichia occurs when the melanocytes in the hair bulbs lose their normal amount of melanin pigment. When the melanocytes in the epidermis are affected and the skin loses normal pigmentation, the abnormality is leukoderma. Whereas leukotrichia can be observed as a single entity, leukoderma is most commonly associated with leukotrichia.

ETIOLOGY

The etiology and pathogenesis of leukoderma are unknown, but trauma, inflammation, autoimmune reactions against melanocytes, local injections with epinephrine-containing local anesthetics, and defects of the autonomous nervous system have been discussed. Specific forms of leukoderma have been linked to hereditary gene defects (see following discussion).

PATHOPHYSIOLOGY

The unknown underlying cause appears to result in acquired loss of functional melanocytes.

CLINICAL FINDINGS

The forms of leukotrichia/leukoderma have been reported in horses:

- **Reticulated leukotrichia**: Alopecia and ensuing leukotrichia in a characteristic cross-hatched or reticulated pattern. Yearlings and occasionally older animals are affected, and Quarters horses appear to be predisposed.
- **Spotted leukotrichia**: Multiple, sharply demarcated area of leukotrichia of 1 to 3 cm in diameter.
- **Juvenile Arabian leukoderma**: Most common form of leukoderma in horses, reported in young Arabian and occasionally in Quarter horses. One- to 2-year-old animals develop leukoderma on eyelids, periocular skin, muzzle, nares, genitalia, anus perineum, and inguinal region.
- **Hyperesthetic leukotrichia**: Condition of unknown etiology that is characterized by the development of single or multiple very painful crusts on the dorsal midline from withers to tail. Crusts disappear and pain resolves after 2 to 3 months, while leukotrichia persists.
- **Albinism and lethal white foal syndrome:** Albinism refers to a congenital lack of melatonin pigment in skin, hair, and other normally pigmented tissues. Albinism can occur as partial or complete albinism, the latter being inherited as autosomal-dominant trait that is only viable in the heterozygous state. The homozygous state results in a nonviable embryo that is resorbed in early gestation. A different form of lethal white foal syndrome results in homozygous expression of the associated trait and affects a subset of American Paint horses with the so-called frame overo color pattern.

CLINICAL PATHOLOGY

A reduced number of melanocytes within epidermis and follicular epithelium in combination with complete loss of melanin pigment from the epidermis are typical findings.

TREATMENT

No specific treatment is currently available

VITILIGO

Vitiligo is a presumably acquired autoimmune disorder characterized by patchy depigmentation of the skin described in horses, cattle, and other species.

ETIOLOGY

Although the etiology of vitiligo is still unknown, evidence corroborating the hypothesis that vitiligo is an acquired autoimmune disease associated with the production of antimelanocyte antibodies has accumulated over the last decades.[1] Other etiologies discussed in the literature are an increased susceptibility of melanocytes to certain melatonin precursor molecules or local nerve injuries. A genetic etiology is suspected in Arabian horses and Holstein–Friesian cattle.

PATHOPHYSIOLOGY

The underlying cause results in a complete, although sometimes reversible, loss of functional melanocytes in a small area of the dermis.

CLINICAL FINDINGS

Vitiligo has been reported in different breeds, without apparent gender predisposition. Although the condition can develop at any age, it most commonly is observed in young animals. Typical presentation is a patchy depigmentation of the skin of the muzzle, eyelids, and occasionally anus and other body regions. The degree of depigmentation can vary over time, and the condition may even completely resolve, making the

interpretation of anecdotal treatment successes difficult. The defect is esthetic only.

CLINICAL PATHOLOGY

Histopathological examination reveals a complete absence of melanocytes from affected areas. Increased numbers of Langerhans cells and epidermal vacuolization have been reported in some cases.[1]

TREATMENT

No specific treatment with confirmed efficacy is currently available. Anecdotal reports of improvement after supplementation of vitamins and minerals (vitamin A and copper) are available.[1] Because of the possible genetic predisposition, the use of affected animals for breeding has been discouraged.

SEBORRHEA

ETIOLOGY

The etiology of seborrhea is still not understood. Historically seborrhea was considered to be the result of excessive secretion of sebum onto the skin surface. More recently seborrhea was classified as disease of abnormal cornification and keratinization of the skin rather than of excessive sebum production because there is little evidence for abnormal function of the sebaceous glands. In large animals it is always secondary to dermatitis or other skin irritations that result in excessive crusting, scaling, or oiliness, such as the following:

- Exudative epidermitis of pigs associated with *S. hyicus*
- Greasy heel of horses, including infection with *S. hyicus*
- Greasy heel of cattle
- Flexural seborrhea of cattle
- Besnoitiosis of cattle associated with *Besnoitia besnoiti*

CLINICAL FINDINGS

In primary seborrhea there are no lesions, only excessive greasiness of the skin. The sebum may be spread over the body surface like a film of oil or be dried into crusts, which can be removed easily. Sebaceous glands may be hypertrophied.

Flexural Seborrhea

Flexural seborrhea is most common in young periparturient dairy cows. Severe inflammation and a profuse outpouring of sebum appear in the groin between the udder and the medial surface of the thigh or in the median fissure between the two halves of the udder. Extensive skin necrosis follows, causing a pronounced odor of decay, which may be the first sign observed by the owner (see also under "Udder Cleft Dermatitis"). Irritation may cause lameness, and the cow may attempt to lick the part. Shedding of the oily, malodorous skin leaves a raw surface beneath; healing follows in 3 to 4 weeks.

Greasy Heel of Cows

Cows grazing constantly irrigated, wet pastures or in very muddy conditions in tropical areas may develop local swelling, with deep fissuring of the skin and an outpouring of vile-smelling exudate on the back of the pastern of all four feet but most severely in the hindlimbs. Affected animals are badly lame, and their milk yield declines sharply. Moving the cows to dry land and treating systemically with a broad-spectrum antibiotic effects a rapid recovery.

Greasy Heel of Horses (Scratches)

Greasy heel occurs mostly on the hind pasterns of horses that stand continuously in wet, unsanitary stables. Some cases do occur in well-managed stables. It has been suggested that secondary infections associated with either *S. aureus* and *D. congolensis* may be causative factors. Dermatophytosis, chorioptic mange, and photosensitization are also possible causative factors.

Lameness and soreness to touch are a result of excoriations called scratches on the back of the pastern that extend down to the coronary band. The skin is thick and greasy; if neglected, the condition spreads around to the front and up the back of the leg. This involvement can be severe enough to interfere with normal movement of the limb.

CLINICAL PATHOLOGY

The diagnosis is based on the clinical presentation and on ruling out other skin conditions resulting in abnormal cornification and keratinization. The primary cause of the seborrhea may be diagnosed by a suitable examination for the presence of parasitic or bacterial pathogens. Histopathology may be supportive to rule out other causes.

DIFFERENTIAL DIAGNOSIS

The lesion is characteristic, and diagnostic confirmation is by histopathological examination of a biopsy specimen; the principal difficulty is to determine the primary cause. All the types listed may be mistaken for:

Injury, commonly wire cuts or rope burn

Flexural seborrhea for injury, usually a result of straddling a gate or wire fence

Greasy heel of horses for chorioptic mange

TREATMENT

With secondary seborrhea the primary objective of treatment must be to resolve the underlying cause. Topical and symptomatic treatment of the affected skin is indicated for relief and to assist in control of the disease. Seborrheic shampoos and lotions can either be keratolytic or keratoplastic. Keratolytic products may initially worsen the scale production by chemically debriding the stratum corneum but will eventually result in reduced scale formation. Particularly during the initial phase, frequent washing of the affected skin to remove debrided cells is important. Keratoplastic ointments slow the mitotic rate of the epidermis, thereby reducing scale formation. Emollients are useful after washing the skin to rehydrate, lubricate, and soften the skin. In severe cases associated with pyoderma or even skin necrosis, the use of local and systemic broad-spectrum antibiotics may be indicated.

FOLLICULITIS

ETIOLOGY

Etiology includes inflammation and possibly infection of hair follicles that can be caused by suppurative organisms (often *staphylococci*), secondary to follicular trauma, obstruction of sebaceous gland ducts, or more rarely as result of an autoimmune reaction. Identifiable forms of folliculitis as individual diseases include the following:

- Staphylococcal dermatitis of horses
- Contagious acne of horses
- Benign facial folliculitis of sucking lambs
- Staphylococcal folliculitis of goats
- Bovine sterile eosinophilic folliculitis

PATHOGENESIS

Depending on the underlying etiology, inflammatory cells infiltrate the walls and lumen of hair follicles. With more extensive inflammation, neutrophils may also infiltrate perifollicular tissue, resulting in formation of larger abscesses (**furunculosis**). Increased pressure and tissue lysis will result in a rupture of the hair follicle with an ensuing granulomatous dermal reaction.

CLINICAL FINDINGS

Folliculitis may present with skin lesions in almost any location of the skin. Early stages present as papules or pustules with hairs emerging through the lesions. Involvement of the hair follicle allows one to differentiate this condition from impetigo, where the hair follicle is not involved.[1] Later focal crusting and alopecia and pruritus may develop. Pustule rupture leads to contamination of the surrounding skin and development of further lesions, such as ulcerations and draining tracts. Severe cases can be associated with pain, pyrexia, and feed-intake depression. Chronic folliculitis can affect skin pigmentation and cause permanent destruction of hair follicles, which results in cicatricial alopecia.

In **bovine sterile eosinophilic folliculitis**, the multiple lesions are crusted, alopecic,

3- to 5-cm-diameter nodules on all parts of the body except the limbs. They are composed largely of eosinophilic cells and are negative on culture.

Staphylococcal folliculitis in goats can be generalized, with pustules developing in the periocular and periauricular area, ventral abdomen, medial thighs, and distal limbs.[1] Involvement of the udder skin can occasionally occur.

Benign folliculitis of suckling lambs can develop from the first week of life and consists of small pustules and crusts on the lips, nostrils, ventral tail, and perineum. The condition resolves spontaneously over several weeks.

CLINICAL PATHOLOGY

Swabs should be taken for bacteriologic and parasitologic examination. Histopathological findings include microabscesses associated with hair follicles, along with abscessation and necrosis of the epidermis, dermis, and subcutaneous tissue. Cellular infiltration with mononuclear cells and granulocytes is another common finding.

DIFFERENTIAL DIAGNOSIS

Diagnostic confirmation is by demonstration of infection of hair follicles in a biopsy specimen.

Udder impetigo of cattle; lesions do not involve hair follicles in the first place.

Dermatophytosis

Dermatophilosis

Besnoitiosis of cattle

Viral infections caused by BHV (types 1, 2, and 4), BVD, bovine *parapox virus,* cowpox, buffalopox, bluetongue virus, vesicular stomatitis, foot-and-mouth disease

Exudative epidermitis of pigs (greasy pig disease) as a result of *S. hyicus*, with extensive seborrheic dermatitis

Ulcerative dermatitis of face in adult sheep

Ecthyma (orf)

Facial eczema of sheep; caused by hepatogenous photosensitization

Leg dermatitis down to coronet of sheep

Chronic pectoral and ventral midline abscesses in horses as a result of *Corynebacterium pseudotuberculosis;* not a skin lesion but it resembles furunculosis.

TREATMENT

Primary treatment consists of identifying and eliminating possible primary causes. Topical treatment commences with clipping and cleaning the skin by washing followed by a disinfectant rinse, for instance, with chlorhexidine-based products. Affected areas should be treated with antibacterial ointments or lotions. If the lesions are extensive, the parenteral administration of antibiotics is recommended. The course of treatment should last 1 week; in chronic cases this may need to be at least 1 month; a broad-spectrum preparation is recommended.

For **supportive treatment**, infected animals should be isolated and grooming tools and blankets disinfected.

Diseases of the Subcutis

SUBCUTANEOUS EDEMA (ANASARCA)

ETIOLOGY

Extensive accumulation of edema fluid in the subcutaneous tissue is part of general edema and is caused by the same diseases, as follows.

Increased Hydrostatic Pressure

- Congestive heart failure
- Vascular compression by a mass (e.g., anterior mediastinal lymphosarcoma, large hematoma)
- Vascular obstruction of blood vessels or lymphatic vessels (e.g., thrombophlebitis or thrombosis)

Hypoproteinemic (Hypooncotic) Edema

- Reduced albumin production in the liver associated with chronic inflammation or liver insufficiency (e.g., fascioliasis or liver cirrhosis)
- Nephrotic syndrome with protein loss into urine (e.g., renal amyloidosis in cattle)
- Protein-losing enteropathy (e.g., intestinal nematodiasis or paratuberculosis in cattle)

Increased Blood Vessel Permeability

- Inflammation (e.g., **dourine** of horses or equine infectious anemia, bacterial infections by *Clostridium* spp. or *Anthrax*)
- Allergic reaction (e.g., purpura hemorrhagica of horses, insect stings)

Fetal Anasarca

- Some pigs with congenital goiter also have myxedema, especially of the neck.
- Sporadic cases resulting from unknown causes are sometimes associated with deformities (e.g., in Awassi sheep).
- Congenital absence of lymph nodes and some lymph channels causes edema to be present at birth.

DIFFERENTIAL DIAGNOSIS

Diagnostic confirmation is by clinical detection of serous fluid in a subcutaneous site.

In male ruminants, **extravasation of urine** as a result of urethral obstruction and rupture.

Subcutaneous hemorrhage, hematoma or seroma, which is not necessarily dependent, nor bilaterally symmetric.

Ventral hernia, usually unilateral and does not pit on pressure.

Cellulitis, usually asymmetric, hot, often painful, does not pit on pressure and can be sampled by needle puncture.

PATHOGENESIS

Alteration in the balance between the hydrostatic pressure of intravascular fluids, the blood and lymph, and the osmotic pressure of those fluids or changes in the integrity of the filtering mechanism of the capillary endothelium (leaky vessels) leads to a positive advantage by the hydrostatic pressure of the system and causes a flow of fluid out of the vessels into the tissues.

CLINICAL FINDINGS

There is visible swelling, either local or diffuse. The skin is puffy and pits on pressure; there is no pain unless inflammation is also present. In large animals the edema is usually confined to the ventral aspects of the head, neck, and trunk and is seldom seen on the limbs.

CLINICAL PATHOLOGY

Anasarca is a clinical diagnosis, but many estimates (e.g., arterial blood pressure, serum and urine protein levels) provide contributory evidence. Normal total protein concentrations in serum or plasma allow one to rule out hypooncotic edema. Differentiation between obstructive and inflammatory edema can be made by cytologic and bacteriologic examination of the fluid.

TREATMENT

Primary treatment requires correction of the primary causal abnormality. Supportive treatment will also depend on the underlying cause but can consist of transfusing plasma or whole blood in cases of hypooncotic edema, or antiinflammatory or diuretic therapy in cases of inflammatory or allergic edema.

ANGIOEDEMA (ANGIONEUROTIC EDEMA)

ETIOLOGY

Transient, localized subcutaneous edema as a result of an allergic reaction and caused by endogenous and exogenous allergens provokes either local or diffuse lesions. Angioedema occurs most frequently in cattle and horses on pasture, especially during the period when the pasture is in flower. This suggests that the allergen is a plant protein. Fish meal may also provoke an attack.

Recurrence in individual animals is common. Angioedema can also occur as adverse reaction to parenteral administration of certain antibiotics, vaccines, blood, plasma, or other IV fluids.

PATHOGENESIS

The precise type of hypersensitivity reaction has not yet been determined, but most cases appear to be associated with a type I or type III hypersensitivity reaction. After an initial erythema, local vascular dilatation is followed by leakage of plasma through damaged vessels.

CLINICAL FINDINGS

Local lesions most commonly affect the head, with diffuse edema of the muzzle, eyelids, conjunctiva, and cheeks. Occasionally only the conjunctiva is affected, so that the eyelids are puffy, the nictitating membrane is swollen and protruding, and lacrimation is profuse. Affected parts are not painful to touch, but shaking the head and rubbing against objects suggest irritation. Salivation and nasal discharge may be accompanying signs.

Perineal involvement includes vulvar swelling, often asymmetric, and the perianal skin, and sometimes the skin of the udder, is swollen and edematous. When the **udder** is affected, the teats and base of the udder are edematous and cows may paddle with the hind limbs, suggesting irritation in the teats. Edema of the lower limbs, usually from the knees or hocks down to the coronets, is a rare sign.

Systemic signs are absent, except in those rare cases where angioedema is part of a wider allergic response, when bloat, diarrhea, and dyspnea may occur, often with sufficient severity to require urgent treatment.

CLINICAL PATHOLOGY

The blood eosinophil count is often within the normal range, but may be elevated from a normal level of 4% to 5% up to 12% to 15%.

DIFFERENTIAL DIAGNOSIS

Diagnostic confirmation is found with sudden onset and disappearance of edema at the typical sites.

Subcutaneous edema as a result of vascular pressure occurs mostly in dependent parts and is not irritating.

In horses, and rarely in cattle, angioedema may be simulated by **purpura hemorrhagica**, but hemorrhages are usually visible in the mucosae in purpura.

TREATMENT

Primary treatment to remove the specific cause is usually impossible, but affected animals should be removed from the suspected source of allergens. Cattle running at pasture should be confined and fed on dry feed for at least a week.

Supportive treatment to relieve the vascular lesion is always administered even though spontaneous recovery is the rule. In acute cases with suspected anaphylaxis, epinephrine should be administered parenterally. For subacute cases, corticosteroids or other antiinflammatories are preferred over antihistamines or epinephrine; usually only one injection is required.

TREATMENT

Acute anaphylaxis with angioedema:
- Epinephrine: 3 to 5 mL/ 450 kg of a 1:1000 solution IM or SC (can be combined with steroids) (R-1)

Acute angioedema in horses:
- Dexamethasone soluble 0.01 to 0.1 mg/kg IV or IM q24 h for 3 to 7 days (R-1)
- Hydroxyzine hydrochloride 0.5 to 1.0 mg/kg IM or PO q8 h (R-2)
- Diphenhydramine hydrochloride 0.7 to 1 mg/kg q12 h (R-2)
- Chlorpheniramine 0.25 to 0.5 mg/kg q12 h (R-2)

SUBCUTANEOUS EMPHYSEMA

ETIOLOGY

Emphysema, free gas in the subcutaneous tissue, occurs when air or gas accumulates in the subcutaneous tissue as a result of the following:

- Air entering through a cutaneous wound made surgically or accidentally, particularly in the axilla or inguinal region
- Extension from pulmonary emphysema
- Air entering tissues through a discontinuity in the respiratory tract lining (e.g., in fracture of nasal bones; trauma to pharyngeal, laryngeal, and tracheal mucosa caused by external or internal trauma, as in lung puncture by a fractured rib; trauma to the trachea during an attempt to pass a nasoesophageal tube; following a tracheal wash procedure to assist in the diagnosis of respiratory disease where the trachea does not seal quickly to air movement after removal of the trocar)
- Extension from vaginal lacerations in cattle, particularly in cattle with vaginal prolapse and following dystocia, or cattle with puerperal metritis and gas accumulation in the uterus
- Gases migrating from abdominal surgery because the abdominal cavity is usually at a negative pressure relative to atmospheric pressure
- Gas gangrene infection

PATHOGENESIS

Air moves very quickly in a dorsal manner through fascial planes, especially when there is local muscular movement. For example, when a lung is punctured, or in cases of severe interstitial pulmonary edema, air escapes under the visceral pleura and passes to the hilus of the lung, and hence to beneath the parietal pleura, between the muscles, and into the subcutis, particularly between the dorsal aspects of the scapulae.

CLINICAL FINDINGS

Visible subcutaneous swellings are soft, painless, fluctuating, and grossly crepitant to the touch, but there is no external skin lesion. In gas gangrene, discoloration, coldness, and oozing of serum may be evident. Affected areas of skin are moderately painful to touch. Emphysema may be sufficiently severe and widespread to cause stiffness of the gait and interference with feeding and respiration. The source of the subcutaneous emphysema is usually directly ventral to the most severely affected area, which is usually along the back.

CLINICAL PATHOLOGY

Clinical pathology is not necessary except in cases of gas gangrene, when a bacteriologic examination of fluid from the swelling should be carried out to identify the organism present.

DIFFERENTIAL DIAGNOSIS

Diagnostic confirmation is based on the observation of crepitus and the extreme mobility of the swelling; these distinguish emphysema from other superficial swellings.

Anasarca, dependent and pits on pressure (see previous discussion).

Hematoma, seroma at injury sites, confirmed by needle puncture (see following discussion).

Cellulitis is accompanied by toxemia, confirmed by needle puncture.

TREATMENT

Primary treatment is to address the source of the air, but this may be impossible to locate or to close. **Supportive treatment** is only necessary in the extremely rare case where emphysema is extensive and incapacitating, in which case multiple skin incisions may be necessary. Gas gangrene requires immediate and drastic treatment with antibiotics.

LYMPHANGITIS

Lymphangitis is characterized by inflammation and enlargement of the lymph vessels and is usually associated with lymphadenitis.

ETIOLOGY

Lymphangitis in most cases is a result of local skin infection with subsequent spread to the lymphatic system. Common causes are as follows.

Cattle
- Bovine farcy caused by *Mycobacterium farcinogenes* and *Mycobacterium senegalense*
- Cutaneous tuberculosis associated with atypical mycobacteria, rarely *Mycobacterium bovis*

Horse
- Epizootic lymphangitis (equine histoplasmosis) as a result of *Histoplasma capsulatum var. farciminosum*
- Ulcerative lymphangitis as a result of *Corynebacterium pseudotuberculosis*
- Glanders (farcy) caused by *Burkolderia mallei*
- Sporotrichosis
- Sporadic lymphangitis
- Strangles in cases where bizarre location sites occur
- In foals, ulcerative lymphangitis associated with *Streptococcus zooepidemicus*

PATHOGENESIS
Spread of infection along the lymphatic vessels causes chronic inflammation and thickening of the vessel walls. Abscesses often develop, with discharge to the skin surface through sinuses.

CLINICAL FINDINGS
An indolent ulcer usually exists at the original site of infection. The lymph vessels leaving this ulcer are enlarged, thickened, and tortuous and often have secondary ulcers or sinuses along their course. Local edema may result from lymphatic obstruction. In chronic cases much fibrous tissue may be laid down in the subcutis, and chronic thickening of the skin may follow. The medial surface of the hindlimb is the most frequent site, particularly in horses.

CLINICAL PATHOLOGY
Bacteriologic examination of discharge for the presence of the specific bacteria or fungi is common practice.

TREATMENT
Primary treatment requires vigorous, early surgical excision or specific antibiotic therapy.

Supportive treatment is directed toward removal of fluid and inflammatory exudate and relief of pain.

PANNICULITIS
Panniculitis is diffuse inflammation of subcutaneous fat that has been associated with a number of causes, such as trauma, infection, postinjection site inflammation, insect bite, neoplasia, drug eruption, and dietary factors (excessive intake of polyunsaturated fatty acids or vitamin E deficiency). Deep-seated, firm, and painful nodules or plaques that can reach a diameter of 15 cm or more, often in large numbers, anywhere over the body but especially on the neck and sides, most commonly occur in young horses and rarely in cattle. The lesions may fluctuate greatly in size and number, or even disappear spontaneously. In a few cases there is transient fever, reduced feed intake, and weight loss. Lameness may be evident in horses with extensive lesions.

Diagnosis is by histologic examination of a biopsy specimen. At necropsy examination there are no other lesions. The lesions reduce in size and number after the administration of dexamethasone but recur when treatment stops.

HEMATOMA
Hematoma refers to extravasation of whole blood into the subcutaneous tissues.

ETIOLOGY
Accumulation of blood in the subcutaneous tissues beyond the limit of that normally caused by trauma may be a result of defects in the coagulation mechanism or a result of increased permeability of the vessel wall.

Common causes include the following:
- Traumatic rupture of large blood vessel
- Dicoumarol poisoning from moldy sweet clover hay
- Purpura hemorrhagica in horses
- Bracken poisoning in cattle; other granulocytopenic diseases manifested principally by petechiation, with lesions observed only in mucosae
- Systemic disease associated with disseminated intravascular coagulopathy (DIC)
- Hemangiosarcoma in subcutaneous sites
- Neonatal bovine pancytopenia
- Inherited hemophilia

PATHOGENESIS
Leakage of blood from the vascular system can cause local swellings, which interfere with normal bodily functions but are rarely sufficiently extensive to cause signs of anemia.

CLINICAL FINDINGS
Subcutaneous swellings resulting from hemorrhage are diffuse and soft, with no visible effect on the skin surface. There may be no evidence of trauma. Specific locations of subcutaneous hemorrhages in horses include the frontal aspect of the chest—as a result of fracture of the first rib in collisions at full gallop, and often fatal through internal hemorrhage—and perivaginal at foaling, causing massive swelling of the perineum and medial aspect of the thigh.

CLINICAL PATHOLOGY
Visual examination of a needle aspirate confirms the existence of subcutaneous hemorrhage. Diagnosis of the primary cause is greatly assisted by platelet counts and prothrombin, clotting, and bleeding times.

TREATMENT
Primary Treatment
Primary treatment targets removal or correction of the cause.

Supportive Treatment
The hematoma should not be opened until clotting is completed, except in the case of a massive hemorrhage that is interfering with respiration, defecation, or urination. If blood loss is severe, blood transfusions may be required. Parenteral injection of coagulants can be justified if the hemorrhages are recent and severe.

DIFFERENTIAL DIAGNOSIS

Hematomas as a result of coagulopathies are usually associated with hemorrhages into other tissues, both manifestations being a result of defects in clotting or capillary wall continuity. Single hematomas (e.g., from trauma) must be differentiated from abscesses, seromas, and neoplasias.

Diagnostic confirmation is by needle puncture of the swelling, avoiding excessive blood loss (that would decrease pressure on the leaking vessel) and contamination of a possibly sterile fluid pocket.

NECROSIS AND GANGRENE
Necrosis is tissue death; gangrene is sloughing of dead tissue. When either change occurs in the skin, it involves the dermis, epidermis, and subcutaneous tissue.

Different types of gangrene are recognized:
- **Dry gangrene** is primarily caused by arterial occlusion resulting in tissue ischemia. Affected tissue appears dry and shrunken, with dark discoloration and a clear demarcation line from healthy tissue. There is no bacterial infection or putrefaction because bacteria fail to survive in the desiccated tissue.
- **Wet gangrene** is most common after sudden blockage of venous blood flow resulting in ischemia while the affected tissue is saturated with stagnant blood. Tissue trauma (e.g., from mechanical trauma or burns) and ischemia result in release of tissue water and give the affected area a moist and swollen appearance. Because the moist and protein-rich tissue facilitates bacterial growth, infection with saprogenic microorganisms is common. This infection results in the putrid and rotten aspect and odor of the tissue and may cause septicemia.
- **Gas gangrene** is caused by *C. perfringens* (see also "Malignant Edema").

ETIOLOGY

Severe **damage to the skin** in the following categories causes gangrene:

- Severe or continued trauma (e.g., pressure sores, saddle and harness galls, carpal or tarsal necrosis in recumbent animals)
- Strong caustic chemicals (e.g., creosote)
- Severe cold or heat, with bushfires and stable fires being the worst offenders. Frostbite is an unusual occurrence in animals unless the patient has a circulatory deficit (e.g., in the neonate, in severe shock or toxemia).
- Beta-irradiation
- **Infections**, especially:
  - Erysipelas and salmonellosis in pigs
  - Clostridial infections in cattle, affecting subcutis and muscle
  - Staphylococcal mastitis in cattle; pasteurella mastitis in sheep
  - Bovine ulcerative mammillitis of the udder and teats
- **Local vascular obstruction**—obstruction by thrombi or arterial spasm causes skin gangrene but includes deeper structures, also from poisoning by:
  - *Claviceps purpurea*
  - *Festuca arundinacea* (probably as a result of an accompanying fungus)
  - *Aspergillus terreus*
  - Mushrooms
- Intradermal injection of local anesthetics containing epinephrine have been associated with dry gangrene of injected skin in cattle.

Similar cutaneous and deeper-structure involvement occurs in systemic infections in which bacterial emboli block local vessels (e.g., in salmonellosis in calves, and after tail vaccination of calves with *Mycoplasma mycoides*).

Other Causes

- Final stages of photosensitive dermatitis and flexural seborrhea
- Screw-worm infestation

PATHOGENESIS

The basic cause of gangrene is interference with local blood supply by external pressure; by severe swelling of the skin, as in photosensitization; or by arteriolar spasm or damage to vessels by bacterial toxins.

CLINICAL FINDINGS

With **dry gangrene** the lesion is dry from the beginning, and the area is cold and sunken, with red–brown discoloration and without offensive odor, resembling mummified tissue. Bacterial infection is commonly not present. Sloughing of dry tissue may take a long time, and the underlying surface usually consists of granulation tissue.

With **wet gangrene** the initial lesion is moist and oozing, and the affected area is swollen, raised, discolored, and cold. Separation occurs at the margin, and the affected skin may slough before it dries; the underlying surface is raw and weeping. Because wet gangrene is in most cases accompanied by infection with saprophytic pathogens, affected tissue often has a putrid and rotten aspect and odor. Systemic disease may result from absorption of toxic products from tissue breakdown and bacteria, resulting in septicemia.

The presentation of **gas gangrene** is discussed under "Malignant Edema."

DIFFERENTIAL DIAGNOSIS

Confirmation of the diagnosis is by visual recognition.

Gangrenous mastitis in cows or ewes.

Photosensitive dermatitis.

Claviceps purpurea poisoning.

TREATMENT

Primary treatment requires removal of the etiologic insult.

Supportive treatment comprising the application of astringent and antibacterial ointments may be required in cases of wet gangrene to facilitate separation of the gangrenous tissue and to prevent bacterial infection. Aggressive tissue debridement of necrotic tissue and in severe cases amputation of affected body parts may be required. Systemic antibiotics do not reach gangrenous tissue but are indicated whenever septicemia is suspected.

SUBCUTANEOUS ABSCESS

Most subcutaneous abscesses are matters of purely local and esthetic concern, but if they are sufficiently extensive and present with active **localized infection**, they may cause mild toxemia. Their origins include the following.

Trauma

Most subcutaneous abscesses are the result of traumatic skin penetration with resulting infection. For example, **facial subcutaneous abscesses** are common in cattle eating roughage containing foxtail grass (*Hordeum jubatum*). Several animals in a herd may be affected at one time. The awns of these plants migrate into the cheek mucosa, causing subcutaneous abscesses containing *Trueperella* (formerly *Arcanobacterium*) *pyogenes* and *Actinobacillus* spp. The abscesses contain purulent material, are well encapsulated, and must be surgically drained and treated as an open wound. Medical therapy with parenteral antimicrobials and iodine is ineffective.

Hematogenous

Rarely the infection reaches the site via the bloodstream (e.g., chronic pectoral abscesses of horses, infections in foals with *R. equi*, infections in all species with *Corynebacterium pseudotuberculosis*, infections in lambs with *Histophilus somni* or *Pseudomonas pseudomallei*).

Extension

Abscesses may originate by **extension** from lesions of furunculosis, pyoderma, or impetigo or by **contiguous spread** by contact from an internal organ (e.g., from traumatic reticuloperitonitis).

CUTANEOUS CYSTS

Cysts contained by an epithelial wall enclosing amorphous contents or living tissue may be congenital, inherited defects or acquired as a result of inappropriate healing of accidental wounds. They are smooth, painless, about 1.5 to 2.5 cm in diameter, round, and usually fluctuating, although inspissated contents may make them feel quite hard. The skin and hair coat over them are usually normal, although some may leak mucoid contents onto the skin. Epidermoid cysts are lined with skin; dermoid cysts usually contain differentiated tissue such as sebaceous glands and hair follicles; dentigerous cysts contain teeth or parts of them. Acquired cysts include apocrine, sebaceous, and keratin varieties.

Developmental cysts, which are present from birth, are usually located at specific anatomic sites, and include the following:

- **Branchial cysts** in the neck, formed from an incompletely closed branchial cleft
- **False nostril cysts** in horses
- **Wattle cysts** in goats

Cysts may occur anywhere on the body, but most commonly they are found near the dorsal midline. In horses a common site is the base of the ear.

Other diseases that cause cutaneous nodules in horses include collagenolytic granuloma, mastocytosis, amyloidosis, lymphoma, sarcoidosis, and infestation with *Hypoderma* spp.

Surgical excision for cosmetic reasons is common practice.

GRANULOMATOUS LESIONS OF THE SKIN

Granulomatous lesions are chronic inflammatory nodules, plaques, and ulcers; they are cold, hard, and progress slowly, often accompanied by lymphangitis and lymphadenitis. In many cases there is no cutaneous discontinuity or alopecia. Some of the common causes in animals are as follows.

Cattle

- Bovine farcy caused by *M. farcinogenes* and *M. senegalense*
- Actinobacillosis (botryomycosis) caused by *Actinobacillus lignieresi*

- Infestation with *Onchocerca* spp.
- Infestation with larvae of *Hypoderma* spp.
- Infection with *Mucor* spp. fungi in thick-walled nodules in the skin on the posteroventral aspect of the udder
- Lechiguana associated with the sequential infection with *Dermatobia hominis* and *Mannheimia granulomatosis*. The condition has been reported in Brazilian cattle, which develop very large granulomata consisting of fibrous tissue that develop in subcutaneous sites in any part of the body.[1]

Sheep

- Strawberry footrot—*D. congolensis*
- Ecthyma
- Ulcerative lesions of lower jaw and dewlap associated with *A. lignieresi*

Horses

- Tumorous calcinosis, which causes hard, painless, spherical granulomata, up to 12 cm in diameter, near joints and tendon sheaths, especially the stifle joint
- Cutaneous amyloidosis
- Collagenolytic granuloma (nodular necrobiosis)—the most common nodular skin disease of the horse. The etiology is unknown. There are multiple firm nodules located in the dermis, ranging in size from 0.5 to 5 cm in diameter. The overlying skin surface and hair are usually normal. Biopsy reveals collagenolysis. Treatment consists of surgical removal and possibly the administration of corticosteroids.
- Botryomycosis, or bacterial pseudomycosis, results from bacterial infection at many sites, often accompanied by a foreign body. Lesions on the limbs, brisket, ventral abdomen, and scrotum vary in size from nodules to enormous fungating growths composed of firm inflammatory tissue riddled by necrotic tracts, leading to discharging sinuses, often containing small yellow-white granules or "grains." Surgical excision is the only practicable solution.
- Equine eosinophilic granuloma—nonalopecic, painless, nonpruritic, firm nodules, 2 to 10 cm in diameter and covered by normal skin, develop on the neck, withers, and back of horses, especially in the summer. The cause is unknown, and palliative treatment, surgical excision, or corticosteroid administration is usually provided.
- Systemic granulomatous disease (equine sarcoidosis)—a rare disease of horses characterized by skin lesions and widespread involvement of the lungs, lymph nodes, liver, gastrointestinal tract, spleen, kidney, bones, and central nervous system
- *Burkolderia mallei*—cutaneous farcy or glanders
- *Actinomadura* spp. and *Nocardia brasiliensis*—painless mycetomas
- *Histoplasma farciminosum*—epizootic lymphangitis
- *Corynebacterium pseudotuberculosis*—ulcerative lymphangitis
- *Habronema megastoma* and *Hyphomyces destruens* as causes of swamp cancer, bursattee, Florida horse leech, and blackgrain mycetoma
- Infestation with *Onchocerca* spp.
- Chronic urticaria

Pigs

- *Actinomyces* spp. and *B. suilla* cause lesions on the udder.

Non-Infectious Diseases of the Skin

INSECT BITE HYPERSENSITIVITY IN HORSES (EQUINE SEASONAL ALLERGIC DERMATITIS)

Insect bite hypersensitivity (IBH) is an intensely pruritic dermatitis of horses caused by hypersensitivity to insect bites, especially *Culicoides* spp. and, less frequently, *Simulium* spp.

ETIOLOGY

The disease is caused by type I (immediate) hypersensitivity to salivary antigens introduced into the skin by the bites of sandflies and other insects. There may be a lesser role for type IV (cell-mediated) hypersensitivity in the disease. *Culicoides brevitarsus* is the cause in Australia, *Culicoides pulicaris* in the United Kingdom and Europe, and *Culicoides obsoletus* in Canada. *Stomoxys calcitrans*, the stable fly, and *Simulium* spp. cause the disease. The distribution of the skin lesions and seasonal nature of the disease are related to the feeding habits of the inciting insect. For instance, *C. pulicaris* has a predilection for landing at the mane and tail, and this is where the lesion is most commonly seen.

EPIDEMIOLOGY

The prevalence of the disease varies depending on environmental factors, and possibly characteristics of the local horse population. Up to 60% of horses are reported to be affected in areas of Queensland, Australia; 22% in Israel; and 18% of Icelandic horses in Norway. The prevalence in Switzerland is very low in regions above 1000 m and 1.6% in lower areas. The prevalence of the disease in Dutch Shetland Ponies (>7000) assessed over 3 years was 8.8%.[1]

The disease is quite common worldwide in areas where **hot and humid summer weather** favors the causative insects: Sweden, the United Kingdom, Japan, Israel, Hong Kong, North America, Australia, the Philippines, India, and France. Most cases occur during **summer,** and lesions disappear during cooler weather. Lesions disappear when the horses have been stabled in insect-proof barns for several weeks or are moved outside the geographic range of the inciting insect.

The disease is characteristically sporadic and affects only a few of a group of horses. However, because the predilection to the disease is inherited, there may be multiple cases among related animals on a farm. The prevalence of the disease increases with age; 3.4% of Icelandic horses 1 to 7 years of age compared with 32% of horses older than 14 years were affected.

The disease has a demonstrated genetic basis in some breeds, including heritability of 0.08 (standard error [SE] = 0.02) on the observed binary scale and 0.24 (SE = 0.06) on the underlying continuous scale in Dutch Shetland ponies.[1] Variants in the major histocompatibility complex (MHC) class II region are associated with disease susceptibility, with the same allele (COR112:274) associated with the disease in Icelandic ponies and Exmor ponies. In addition, homozygosity across the entire MHC class II region is associated with a higher risk of developing the disease ($p = 0.0013$).[2] Genes not encoding MHC and associated with IBH in Old Kaldruby horses include interferon gamma (IFNG), transforming growth factor beta 1 (TGEB1), Janus kinase 2 (JAK2), thymic stromal lymphopoietin (TSLP), and involucrin (IVL).[3] Expression of genes associated with allergy and immunity in the skin of affected horses indicates a role for these pathways in the disease.

PATHOGENESIS

Reaginic antibodies (IgE) produced in response to exposure to proteins in insect saliva bind to mast cells in the skin; when exposed to the antigen, they are associated with degranulation of the mast cell. Horses with IBH have IgE antibodies that react with constituents of the salivary gland of *Culicoides* spp., whereas horses that do not have the disease have IgG, but not IgE, antibodies against *Culicoides* spp. salivary gland antigens. Horses that have not been exposed to *Culicoides* spp. do not have either antibody to the insect salivary gland antigen. IgE antibodies against *Culicoides* spp. are present on a seasonal basis in horses that do not have evidence of the disease, indicating that the presence of these antibodies, although necessary for development of the diseases, is not sufficient and that other factors are involved.[4]

The antigen in saliva of *Culicoides* sp. and *Simulium* spp. has identical IgE epitopes, demonstrating that the disease in some horses is caused by IgE-mediated cross-reactivity to homologous allergens in the

saliva of both species.[5] A specific antigen in midge (*Culicoides sonorensis*) saliva associated with IgE reaginic antibodies and causing both in vivo and in vitro activity mimicking IBH is a 66 kDa protein referred to as Cul s 1.[6]

Degranulating mast cells and intradermal or subcutaneous lymphocytes release various vasoactive substances and cytokines that cause inflammation and accumulation of eosinophils in the skin of affected areas and eosinophilia. The distribution of the lesions on patients reflects the insects' preferred feeding sites. Ponies with seasonal allergic dermatitis have greater numbers of circulating CD5+ and CD4+ T lymphocytes than do normal animals. Increased numbers of CD3+ T lymphocytes, most of which are CD4+, and eosinophils are present in the skin of affected ponies after injection of *Culicoides* antigen. Furthermore, in eotaxin and monocyte chemoattractant protein (MCP) 1, but not MCP-2 or MCP-4, mRNA expression is upregulated in skin biopsies of sweet itch lesions, demonstrating a mechanism for accumulation of eosinophils and T-2 lymphocytes in the lesions.

CLINICAL FINDINGS

Lesions are usually confined to the base of the tail, rump, along the back, withers, crest, poll, ears, and, less commonly, ventral midline. In severe cases the lesions may extend down the sides of the body and neck and onto the face and legs.

Pruritus is intense, especially at night, and the horse scratches against any fixed object for hours at a time. In the early stages, slight, discrete papules, with the hair standing erect, are observed. Constant scratching may cause self-mutilation, severe inflammatory lesions, and loss of hair. Scaliness and loss of hair on the ears and tail base may be the only lesions in mildly affected horses.

CLINICAL PATHOLOGY

Affected animals have **eosinophilia** and thrombocytosis.

Diagnosis is facilitated by skin biopsy, fungal culture, parasitologic examination of skin scrapings, and intradermal sensitivity testing. **Skin biopsy** of early lesions, before trauma masks the true picture, reveals edema, capillary engorgement, and eosinophilic and mononuclear perivascular infiltration. Fungal culture and parasitologic examination of **skin scrapings** are useful only in that they rule out dermatophytosis, onchocerciasis, and strongyloidosis. **Intradermal skin testing** demonstrates immediate and delayed sensitivity reactions to extracts of *Culicoides* spp. and *Stomoxys* spp. Recommended concentrations of insect antigen in the testing solution are 60 to 250 PNU per mL,[7] or 1:1000 w/v concentration of *Culicoides* spp. extracts relevant to the locality, providing useful support for a clinical diagnosis of equine insect hypersensitivity.[8]

Testing of serum for specific IgE antibodies holds potential for enhancing diagnostic strategies, but because of the detection of IgE antibodies against *Culicoides* spp. and *Simulium* spp. antigens in healthy horses,[4] the poor concordance between results of skin hypersensitivity testing and serum IgE concentration,[9] and the poor performance of serologic testing with enzyme-linked immunosorbent assay (ELISA) that uses the high-affinity IgE receptor (Fc epsilon R1 alpha),[10] serologic testing is currently not recommended.

DIFFERENTIAL DIAGNOSIS

Infection with larvae of *Onchocerca* spp., *Strongyloides* spp., or *Dermatophilus congolensis* can produce similar lesions. Alopecia of the tailhead may be caused by *Oxyuris equi*.

TREATMENT

The principles of treatment are removal of the inciting cause and suppression of the hypersensitivity reaction.

Removal of the inciting cause is achieved by preventing horses from being exposed to the inciting insects. This can be achieved by relocating the horse to a geographic region where the insects do not occur, stabling of the horse in an insect-proof stable during the periods of the day (early evening) when the insects are most active, or applying agents that kill the insects or otherwise prevent them from alighting on and biting the horse.

Suppression of the immediate hypersensitivity reaction or its sequelae can be achieved by administration of corticosteroids (prednisolone, 1 mg/kg orally every 24 hours initially, then reducing to as low of a maintenance dose as possible).

Hyposensitization (allergen-specific immunotherapy) has received attention for its potential efficacy in desensitizing affected horses. Two controlled clinical trials did not demonstrate a beneficial effect (although the placebo effect on the owners was impressive) in a representative sample of horses. These trials were blinded and used objective measures of efficacy.[11] A retrospective study using owner-reported responses (reduction in antipruritic therapy) found a response in 57% of horses.[12] There is insufficient high-quality evidence to support use of allergen-specific immunotherapy as routine treatment for IBH.

CONTROL

Reduce Exposure to Biting Midges

Horses should be housed in insect-proof buildings or, at a minimum, buildings that limit exposure of horses to midges by closure of doors and covering of windows with gauze. Impregnation of gauze with an insecticide further reduces biting rates. Stables should be situated in areas that have minimal midge populations, such as on hilltops or well-drained sites. Midge numbers on individual farms should be reduced by habitat alteration, so that areas of damp, organically enriched soils are eliminated.[13] Widespread use of insecticides is unlikely to be environmentally acceptable.

The feeding pattern of midges is such that housing of horses during the crepuscular periods and at night will significantly reduce biting rates and likelihood of infection. Horses kept at pasture should have insect repellents applied regularly and especially to provide protection during periods of high insect-biting activity. Diethyltoluamide, or DEET (*N,N*-diethyl-*meta*-toluamide), is the only commercially available repellent with documented activity against *Culicoides* spp. Application of deltamethrin (10 mL of 1% solution) to the skin of horses did not reduce the frequency of midge feeding in an experimental trial in the United Kingdom.[14] Installation of alphacypermethrin-impregnated mesh in jet stalls reduced the attach rate of *Culicoides* spp. by 6- to 14-fold and markedly reduced the number of *Culicoides* spp. insects collected from horses housed in the stalls compared with sentinel horses, suggesting that this might be a useful means of reducing exposure of housed horses to midges.[15]

SEASONAL ALLERGIC DERMATITIS OF SHEEP

A disease similar to seasonal dermatitis (insect bite hypersensitivity) of horses (see "Equine Seasonal Allergic Dermatitis," in this chapter) occurs in sheep in the United Kingdom, Brazil, Israel, and likely elsewhere.[1-3] The disease is also reported in goats in Brazil and suspected in New World camelids (alpacas) in New York State.[4,5] Up to one-third of a sheep flock can be affected, with the disease remitting and affected sheep appearing to fully or almost fully recover during the dry season in Brazil, or during winter in higher latitudes.[1] Because of the seasonal appearance of the disease during periods

Fig. 16-1 Lesions of seasonal allergic dermatitis in a Hampshire Down sheep. (Reproduced with permission from Correa TG et al. *Vet Parasitol* 2007; 145:181.[6])

when midges are present or most active, a cutaneous sensitivity to *Culicoides* spp., especially *C. obsoletus* in the United Kingdom or *Culicoides insignis* in Brazil, is suspected.[6] Cutaneous sensitivity to ground-up *Culicoides* spp. is present in affected sheep, and observed bites by *C. insignis* in sheep in Brazil caused pruritus.[6] Allergic dermatitis occurs in sheep infested with fleas (*Ctenocephalides* spp.), although rarely are sheep infested by fleas.[7] Similar skin lesions can occur in sheep infested with lice (*Bovicola ovis*) or scabies (*Psoroptes ovis*).[8] The equivalent disease in horses has a genetic basis, and this should be considered in sheep.[2,9]

The lesions are similar to those in horses and are located principally on the teats, udder, and ventral midline, but also on the tips of the ears, around the eyes, and on the nose and the lips (Fig. 16-1). Initially there is erythema and small red papules followed by development of alopecia and crust formation. The skin of the affected sheep is whitish and irregularly thickened, with alopecia, crusts, and intense pruritus. Histologically the lesions represent the changes characteristic of immediate (type I) hypersensitivity, evident as perivascular eosinophilic dermatitis.[6] Histologic lesions of the epidermis are hyperkeratosis, acanthosis, hypergranulosis, and moderate spongiosis with infiltration of the dermis by eosinophils, macrophages, and plasma cells. There are no diagnostic changes in the differential blood count. Treatment, if provided, should include topical or systemic administration of antihistamines or corticosteroids, although both might be restricted for use in food animals, and there is no formal evidence of efficacy. Affected animals recover when they are not exposed to midges.[1] Control is based on preventing or minimizing exposure to midges.

A very similar disease occurs in cattle in Japan. It is thought to be a result of an allergy to the bite of an external parasite.

ANHIDROSIS (NONSWEATING SYNDROME, PUFF DISEASE, DRY COAT)

Anhidrosis refers to the reduced or absent capacity to produce sweat. It affects horses and cattle. Reduced ability to sweat affects horses in hot and humid climates. Affected horses are unable to maintain their body temperature within safe limits, especially during or after exercise, and suffer heat stress and a reduction in athletic performance. The only effective treatment is to move the horses to a cooler environment.

ETIOLOGY

The etiology of anhidrosis is unknown, but it involves a reduction in the sensitivity of the sweat gland to β-2 adrenergic stimulation, the normal stimulus for sweating in the horse. Hypothyroidism does not contribute to anhidrosis, although anhidrotic horses have an exaggerated thyroid-stimulating-hormone response to administration of thyroid-releasing hormone.[1] The etiologic or pathogenic importance of this observation is unclear.

EPIDEMIOLOGY

The disease occurs in horses, and rarely in cattle, in countries with hot, humid climates, including tropical and semitropical regions.

The overall prevalence in horses is approximately 2% to 6% in Florida, with the highest prevalence in southern Florida (4.3%) and lowest in northern Florida (0.08%).[2] The prevalence of affected farms is 11%. There is no reported sex or color predilection. Thoroughbred horses and Warmblood horses in Florida are 4.4 (95% confidence interval [CI] 1.2 to 15.5) times and 13.9 (2.5 to 77.5) times as likely to have the disease as are Quarter horses.[2] None of 190 Arabian horses were affected.[2] Horses with a family history of the disease are approximately 6 times more likely to be affected.[2]

Both native and imported horses are affected, although horses born in the western and midwestern United States are at 2.5 times the risk of developing the disease as are native-born horses.[2] Among native horses, the age of onset of the condition ranges from 1 year to 10 years. Foals, especially of draft breeds, can be affected. Horses imported to endemic areas usually do not develop the disease within 1 year. The incidence and severity of the disease are highest in the hotter season, with most affected horses first exhibiting signs of the disease in the summer.[2]

The disease is rarely fatal unless severely affected horses are exercised in the heat, in which case death from heat stroke can occur. The major importance of the disease is the inability of affected horses to exercise and compete in athletic events.

PATHOGENESIS

Sweat is produced in horses by apocrine sweat glands that have a single type of secretory cell. The sweat glands are epitrichial (associated with a hair follicle) and have a density of about 800 per square centimeter, with a greater volume density of sweat glands in the summer compared with winter, in skin of healthy Thoroughbreds.[3] Evaporation of sweating is responsible for elimination of approximately 70% of the heat load of exercising horses (with a further ~20% attributable to evaporation from the respiratory tract).[4] Evaporation is essential for heat transfer because the latent energy of evaporation of 1 mL of water is 2.2 kJ (2260 kJ/kg of water). High heat transfer from the horse to the environment is possible because of the **high sweating rate** of strenuously exercising horses of up to 3300 g per meter square of skin surface area per hour or 10 to 12 liters per horse per hour.[4] The sweat of horses during exercise is alkaline (pH 8.0 to 8.9), is slightly hyperosmolar compared with plasma (290 to 340 mm Osmol), and has sodium concentrations that approximate those of plasma, potassium concentrations approximately 10 times those of plasma, and chloride concentrations double those of plasma.

The sweat glands are well innervated, and sweating is controlled by a combination of hormonal (β-2 adrenergic) and neural factors.[4] The apocrine sweat glands respond in vitro to both purinergic stimuli, including adenosine triphosphate (ATP), adenosine diphosphate (ADP), and uridine triphosphate (UTP), and application of isoprenaline, a β-agonist.[5,6] Both β-adrenoreceptor and purinergic receptors are present on the basolateral aspects of the sweat glands, but not the apical aspect.[6] Responses to isoprenaline or purinergic stimulants by sweat glands of anhidrotic horses are much reduced compared with those of sweat glands from unaffected horses.[6] The defect in sweating of anhidrotic horses is a consequence of failure of the gland to respond to either of the agonists for sweat production. This breakdown of cellular secretory function is thought to be the prime cause of lack of sweating, as opposed to earlier suggestions of obstruction of the sweat gland duct.[6]

Sweat production increases with increasing concentrations of epinephrine in blood up to a peak value, after which sweating rates decline. Anhidrotic horses have lower initial and peak rates of sweat production and lower overall sweat production than do normal horses during intravenous (IV) infusion of epinephrine.[7] Suggested, but unproved, mechanisms for decreased sweat production by anhidrotic horses includes diminished glandular sensitivity to epinephrine, failure

of secretory function, blocking of sweat gland ducts, fatigue of the gland, and gland atrophy.

Sweating is the predominant means by which horses dissipate heat. Reduction in the capacity to produce sweat results in an inability to effectively control body temperature during exercise and when temperature and humidity are high. The elevation in body temperature results in tachypnea in an attempt to dissipate heat through the respiratory tract. Hyperthermia impairs performance and, if severe, can result in heat shock, a systemic inflammatory response syndrome, and death.

CLINICAL FINDINGS

The most apparent clinical sign is lack of sweating in response to an appropriate stimulus, such as exercise. In severely affected horses, sweating is limited to the perineum, brisket, and areas under the mane and saddle. Less severely affected horses have a diminished sweat response and do not lather during exercise. The skin becomes dry and scurfy and loses its elasticity, and there may be alopecia, especially of the face.

Affected animals become extremely tachypneic when heat stressed, leading to the colloquial term for the disease, "dry puffer."[1] Affected horses have abnormally high respiratory rates after exercise that persist for at least 30 minutes after 30 minutes of lunging exercise. Affected horses have a respiratory rate twice that of healthy horses after exercise (60 bpm vs. 120 bpm).[1] The animal's appetite declines, and it loses weight. Athletic performance is severely compromised. Affected horses have higher body temperatures during exercise than unaffected horses, and this difference can persist for at least 30 minutes.[1]

Diagnostic confirmation is achieved by demonstrating reduced sweating in response to intradermal injection of epinephrine or the β-2 adrenergic agonists terbutaline and salbutamol. A crude test involves the intradermal injection of 0.1 mL of a 1:1000 dilution of epinephrine. If the horse sweats, then it is not considered to be completely anhidrotic. A semiquantitative test using epinephrine, terbutaline, or salbutamol may be useful in identifying partially anhidrotic horses. Normal horses sweat when 0.1 mL of 1:1,000,000 epinephrine is injected, whereas partially anhidrotic horses sweat only with higher concentrations (1:10,000 or 1:1000). Injections are usually made using small-gauge needles (25 g) into the skin over the lateral aspects of the neck. Terbutaline (0.1 mg/mL) injected intradermally induces sweating in approximately 4 minutes (+/– 1.7 min) in healthy horses and 10.5 minutes (+/– 7 min) in anhidrotic horses.[1]

A further refinement is the **quantitative intradermal terbutaline** sweat test in which 0.1 mL of solutions of terbutaline of 0.001, 0.01, 0.1, 1, 10, 100, and 1000 mg/mL are injected into the skin of the horse.[8] Preweighed absorbent pads are then taped over each site, removed after 30 minutes, and weighed. The amount of sweat produced is quantified as the change in weight of the pad. This technique, although not described in anhidrotic horses, provides a means of quantifying the sweat test.

The **prognosis** is poor for athletic function for affected animals that remain in hot and humid environments, but the condition may resolve if the horse is moved to a cool climate.

CLINICAL PATHOLOGY

Plasma epinephrine concentrations are reported to be higher in affected horses than in unaffected horses, but this has not been a consistent finding among studies.

NECROPSY FINDINGS

There are no characteristic gross lesions at necropsy. Histologic examination of the skin of affected horses reveals abnormalities in sweat gland morphology, including flattening of cells, loss of luminal microvilli, and a reduction in the number of secretory vesicles.[7] These findings are thought to be a consequence, rather than a cause, of the disease.

TREATMENT AND CONTROL

There is **no specific treatment** that restores the horse's ability to sweat, other than movement to a cooler climate. Affected horses for which translocation to a cooler environment is not feasible benefit from housing in air-conditioned stables so that exposure to high ambient temperatures is minimized. Exercise of affected horses during the coolest periods of the day is sensible. Affected horses are frequently administered **electrolyte supplements**, but these are without demonstrated benefit. However, as with all working horses, an adequate intake of sodium, potassium, and chloride should be ensured.

Administration of **thyroid hormone supplements** is not warranted and might be dangerous because they cause an increase the metabolic rate, and therefore heat production, of affected horses. **Vitamin E** administration has no demonstrated efficacy.

Removal of affected animals to cooler climates is often necessary, although air-conditioning of stables and maintenance of horses in higher country where they can be returned after a day's racing may enable susceptible horses to be kept locally.

WETNESS (MACERATION)

Frequent exposure to wetting, sufficient to keep the skin permanently wet for long periods, results in maceration with loss of dermal integrity and predisposes to fleece rot in sheep and mycotic or bacterial dermatitis in all species. In horses it leads to a superficial dermatitis along the dorsum, especially over the croup, and is known as scald. Frequent immersion of the lower limbs of cattle on irrigated pasture causes dermatitis on the backs of the pasterns, leading to mycotic dermatitis. Digital dermatitis of cattle can be induced by prolonged wetness of the skin, resulting in maceration, and inoculation with *Treponema* spp.[1] Wetting also predisposes to hypothermia in the young.

Standing in cold water for a period of more than 3 days causes the immersed parts to become edematous and congested and slough their skin in the form of a cuff around the limb. Recovery is slow and incomplete.

COCKLE

Cockle is a superficial nodular dermatitis of sheep recorded only in New Zealand that results in nodules in the skin that are of economic importance to the leather industry. The presence of cockle downgrades the value of the pelt, which is rendered unsuitable for suede and clothing.

Cockle is not usually diagnosed clinically, but examination by close inspection of the skin over the upper shoulder region after close shearing has high specificity for detection. The lesions are the result of an immune response in some sheep to infestation with the biting louse *B. ovis*. The occurrence of cockle and its severity are positively correlated with the severity of the louse infestation, and sheep that develop lesions have *B. ovis*–specific homocytotropic antibody. Serum histamine concentrations are significantly higher in louse-infested lambs than louse-naïve lambs.

Lesions commence on the neck and shoulders and may extend over the entire pelt. Widely distributed lesions, termed scatter cockle, are attributed to infestation with *B. ovis*, and this is the most common cause, but rib cockle may be a hypersensitivity to infestation with the sheep ked *Melophagus ovinus*. Pelt lesions in the dorsal midline region are usually a result of infection with *D. congolensis*.

CONTROL

Control rests with the control of *B. ovis*. For cockle control, sheep should be treated off-shears with pour-on or spray-on insecticide and, as soon as practical after shearing, treated by saturation dipping. Saturation dipping is required to significantly reduce louse populations. Prelambing dipping is also recommended to reduce the risk of lambs acquiring louse infestations.

WOOL SLIP, WOOL LOSS

Wool slip is a condition in which housed ewes, shorn in winter, lose part of their fleece and develop bald patches over a large area of the rear half of the back. This commonly starts at the base of the tail and progresses to the rump and back and less commonly the neck. There is no systemic disease; the skin is normal. Histologic examination of skin biopsies shows that in affected sheep the wool follicles are in the active anogen stage rather than the inactive telogen phase of unaffected cohort sheep, and the wool regrows immediately following loss. The loss of wool starts 2 to 3 weeks after shearing. All breeds are equally susceptible, and there is no effect of age or whether the sheep are carrying single or twin lambs; up to 40% of a flock may be affected. The wool loss occurs because of a premature and synchronized shedding of wool fibers and not because of a pathologic process that damages the wool fiber. Wool shedding can be induced experimentally by prolonged treatments with corticosteroids, and the current explanation for the wool shedding that occurs with the wool-slip syndrome is that blood corticosteroid levels rise after the stress of shearing and are maintained for a long period because of the trauma of being housed and shorn and kept in the cold. Blood zinc concentrations in sheep affected with wool slip are within the normal range, and there is no epidermal change as occurs in zinc deficiency.

The prevention of the condition is aimed at reducing the severity and length of the stress period by shearing the sheep at the time of entry to winter housing and ensuring a good nutritional plane in the postshearing period. This hypothesis as to cause may not be correct because the syndrome has also been seen in the summer in Wiltshire shorn sheep that had little history of stress in the period immediately preceding the wool slip.

Wool slip should not be confused with the normal shedding of wool that occurs in breeds such as the Wiltshire or Shetland in the spring period. Loss of wool along the backline also occurs in older longwool sheep and may be exacerbated by lambs playing or sleeping on the ewe.

Impairment of wool growth and a thinning of fiber diameter can occur during the course of any severe disease, such as bluetongue, pregnancy toxemia, or footrot, temporarily affecting the growth of the fleece. This results in a segment of the wool fiber that has decreased tensile strength, and the condition has the name *tender wool*. Following recovery from the inciting disease the wool growth is normal, but there is a line of wool with poor tensile strength in the staple. This can be observed in the intact fleece as a line of decreased fiber diameter, often with a change in crimp character and discoloration as a result of entrapment of dust. The wool may break if the staple on either side of this break is sharply snapped between the fingers. The fleece may subsequently be shed in part or in whole at the level of the defect, a condition known as wool break. Tender wool downgrades the value of a fleece and has economic significance in wool-producing sheep.

Zinc deficiency can reduce keratinization, reduce wool growth, and occasionally result in fleece loss in sheep. Wool loss associated with pruritus occurs in association with external parasite infestations and with scrapie and pseudorabies in ruminants.

Pelodera dermatitis, characterized by thickening of the skin and complete wool loss in affected skin areas, has been recorded in winter-housed sheep where there was poor bedding management. The condition affected the majority of the ewes at risk. The parasite *Pelodera (Rhabditis) strongyloides* is a free-living nematode commonly present in decaying organic material but can invade hair follicles to produce an inflammatory response. Histologic examination of the skin showed the presence of the parasite in wool follicles and infiltration of eosinophils and mast cells in connective tissue. Affected skin areas were those that had contact with the bedding when the sheep were lying down, and large numbers of the nematode were found in the bedding. Clinical signs regressed with the more frequent provision of new bedding and disinfection of the stable.

WOOL EATING

Wool eating can occur as a result pica associated with micronutrient deficiency. A condition called *shimao zheng*, occurring in a region of the Gansu province of China, has wool eating as its primary manifestation. The disease has a seasonal occurrence, with the peak incidence in January through April. Both goats and sheep are affected, but the incidence and severity are much higher in goats, where 90% may show signs. Affected animals bite the wool or hair off their own or other animals' bodies, particularly in the hip, belly, and shoulder areas. Histology on biopsies shows heavily keratinized epithelial cells, a decreased number of hair follicles, and aggregated foci of lymphocytes in the dermis. Controlled trials have shown that the condition can be corrected by supplementation with sulfur, copper, and iron. Wool eating is also recorded in Israel, possibly associated with trace-element copper and zinc deficiency, and in housed superfine Merino sheep in Australia fed grain-based supplements, where it is corrected by the provision of roughage in the form of hay. Wool and hair loss in individual sheep and cattle in association with excessive licking have been recorded and are postulated as psychogenic dermatoses.

IDIOPATHIC NASAL/PERIORAL HYPERKERATOTIC DERMATOSIS OF CAMELIDS (MOUTH MUNGE)

Idiopathic nasal/perioral hyperkeratotic dermatosis is a common skin condition of llamas and has anecdotally been reported in alpacas. The ailment is characterized by a thickening of the stratum corneum of the epidermis resulting in hyperkeratotic plaques and crusts in the perinasal and perioral region. Similar skin lesions may occur on the perineum, ventral abdomen, medial hind- and forelegs, axillae, and inguinal region, in which case the condition is more globally referred to as idiopathic hyperkeratosis.[1] The etiology of this condition is poorly understood but has been categorized as zinc-responsive dermatosis because cases responsive to high oral doses of zinc have been reported.

CLINICAL FINDINGS

Individual animals of either sex between 6 and 24 months of age are commonly affected. Animals present with thick papular crusts and plaques covering the periocular and perioral area, occasionally obstructing the nostrils. Secondary dermatitis that waxes and wanes is common, but pruritus is usually mild or absent.[2]

CLINICAL PATHOLOGY

The diagnosis is based on clinical presentation and by ruling out other differentials. Histologic examination of skin biopsies shows epidermal and follicular orthokeratotic hyperkeratosis that can be associated with dermal infiltration with lymphocytes, macrophages, and occasionally eosinophiles.[1] The degree of infiltration is dependent on the extent of secondary inflammation.[3] The treatment outcome of diagnostic therapy consisting of oral zinc supplementation will

contribute to confirming or refuting the diagnosis.[3]

The usefulness of measuring the serum zinc concentration in affected animals is doubtful because the condition could not be linked to subnormal plasma zinc concentrations in affected animals.[4]

DIFFERENTIAL DIAGNOSIS

- Chorioptic mange
- Dermatophilosis
- Dermatophytosis
- Viral contagious pustular dermatitis
- Bacterial dermatitis

TREATMENT

Supplementing the diet with zinc, either by offering zinc-enriched feed or by supplementing organic or anorganic zinc, for a minimum of 2 months has been suggested. Current recommendations are to supplement either zinc sulfate (2 g/d and animal) or zinc methionine (4 g/d and animal) for a period of 2 to 3 months before reassessing the patient to determine the treatment effect.

Treatments targeting at resolving secondary dermatitis consist of local and/or systemic administration of antibiotics. The topical use of a 7% iodine tincture to control secondary dermatitis and of chlorhexidine-based shampoos to loosen hyperkeratic crusts has been recommended. The use of topical or systemic glucocorticoids has been proposed in cases not responsive to antibiotic therapy.

TREATMENT

Oral treatment:
- Zinc sulfate (2 g/d and animal q24 PO for 2 to 3 months) (Q2)
- Zinc methionine (4 g/d and animal q24 PO for 2 to 3 months) (Q2)

Topical treatment:
- Chlorhexidine-based shampoo (3%, once to twice a week locally) (Q1)
- Topical treatment for secondary dermatitis:
- Iodine tincture (7%, once to twice a week locally) (Q2)
- Topical antibiotic skin ointments (based on culture and sensitivity testing to control secondary dermatitis) (Q2)
- Topical skin ointments containing glucocorticoids in cases unresponsive to antibiotics (Q2)

Systemic treatment:
- Systemic antibiotics (based on culture and sensitivity testing to control secondary dermatitis) (Q2)
- Systemic glucocorticoids in cases unresponsive to oral zinc supplementation and antibiotic therapy (Cave: pregnant animals) (Q2)

Bacterial Diseases of the Skin

METHICILLIN-RESISTANT *STAPHYLOCOCCUS AUREUS*

Staphylococcal skin disease in animals[1] is not uncommon and includes udder dermatitis in cattle; secondary infections to chorioptic mange or orf in goats (may also be *S. chromogenes* and occasionally *S. hyicus*); dermatitis of the head in sheep; and in pigs, usually *S. hyicus* but also possibly *S. sciuri*, *S. rostri*, *S. pasteuri*, *S. hominis*, *S. warneri*, *S. hemolyticus*, *S. epidermidis* (may be methicillin resistant), and *S. chromogenes*.[2]

INTRODUCTION

Methicillin (formerly meticillin in the United Kingdom) was introduced into human medicine in the 1950s to treat penicillinase-resistant *S. aureus* (SA).

Methicillin-resistant *S. aureus* (MRSA) strains have an altered protein-penicillin binding protein (PBP2a) that has a low affinity for all beta-lactam antibiotics (i.e., penicillins and cephalosporins). The protein is encoded by the *mecA* gene.

The MRSA strains may also have or not have a penicillinase enzyme (a beta-lactamase). *Spa*-typing is a method of typing *S. aureus* based on repeats located on several housekeeping genes.

Multilocus sequence typing (MLST) is a method of typing based on the sequence of several housekeeping genes. Similar sequence types may be grouped together in clonal complexes (CCs).

This protein is encoded by the gene *mecA*, which resides on a mobile genetic element called a staphylococcal chromosomal cassette (SCC*mec*). The detection of this gene is the best detection for MRSA.[3]

Methicillin is no longer used in human medicine, but oxacillin, nafcillin, and cloxacillin, which are very similar, are still used, although the resistance to these is usually lower than it is to methicillin.

The serious problem is that MRSA organisms are also often resistant to other antimicrobials, in particular aminoglycosides, macrolides, tetracyclines, and fluoroquinolones.[4]

Human Public Health

MRSA organisms cause infections, can be carried both persistently or intermittently, can colonize, and can also cause contamination. The infection can be mild or severe and sometimes fatal. There is a wide range of human prevalence in many countries. In some countries, a certain lineage may be most common.

Over the years, the types found in humans will change as new clones arise and they introduce new toxins.[5] The type CC398 is the most common animal type isolated from humans and is associated with increased mortality and morbidity. It also carries endotoxin genes but has only once been associated with food poisoning.

These bacteria have been an important cause of nosocomial infections for over 40 years.[6]

Type CC398 is a poor persistent colonizer of humans.[7] It is also less transmissible than non-ST398 in humans and in Dutch animals.[8]

Very rarely are these large animal-associated MRSA organisms responsible for serious infections in humans, although they have been found in deep-seated infections in skin and soft tissue and in pneumonia and septicemia. However, in most cases these infections with hospital-acquired MRSA (HA-MRSA) are inapparent, except when there is stress, such as in surgical situations or in immunocompromised patients.

A new strain has arisen in the Netherlands with no link to existing established Dutch risk factors for acquisition. In one study, a quarter of the 5545 MRSA isolates were from defined risk groups; 26% were CC398, and 74% were non-CC398.[9] Increases in CC398 have occurred in patients with or without contact with livestock and have led to an increase in carriers and infections.[10] Over the period from 2002 to 2008, there was a 925% increase in the number of cases in the laboratory database. Most cases involved CC398, with *spa* type *t*567 particularly overrepresented in sepsis and post-trauma osteomyelitis. CC398 was also more likely to be multiresistant than other types of MRSA. Simply put, the increase in CC398 has led to more carriers and infections.

MRSA accounts for approximately 20% of all bloodstream infections in U.S. hospitals and approximately 65% of the *S. aureus* infections in intensive care units, and it killed approximately 18,000 Americans in 2005.

Veterinarians

The carriage of MRSA by veterinarians in Australia attending a conference in 2009 has been investigated.[11] Industry and government veterinarians had the lowest levels of MRSA carriage at 0.9% prevalence. Those with horses as a major workload had 11.8% prevalence, and those on horse work only had 21.4% prevalence. Veterinarians with a dog and cat practice had 4.9% prevalence. The conclusion was that MRSA was an occupational hazard for those working in clinical practice in Australia.

A study of veterinarians showed that MRSA and livestock-associated MRSA (LA-MRSA) infection levels were 9.5% and 7.5%,

respectively, in Belgium and Denmark (all Danish MRSA are LA-MRSA). A strong association was found with live pigs.[12] At the 2008 meeting of the American College of Veterinary Surgeons, a survey sampled 341 people; 17% of the veterinarians and 18% of the technicians were positive for MRSA. Contact with small ruminants in the previous 30 days, living with a person with MRSA diagnosed in the previous year, and working where there is a person specifically in charge of an infection control program were associated with colonization.[13]

Veterinary students conducting diagnostic investigations were also sampled.[14] Thirty students visited 40 pork farms and found MRSA on 30% of the farms; 22% of the students picked up the infection following exposure, but all were clear within 24 hours of the visit.

Pig Farmers

Thirty-five persons were screened for MRSA and sent on holiday; 27 of the farmers (77%) carried MRSA at least transiently. For 59% of the farmers, the infection was not cleared after the holiday away from pigs.[15]

Butchers

Colonization of butchers with LA-MRSA has been documented in markets in Hong Kong;[16] 300 pork butchers were sampled, and 17 were positive. Although five strains were health-care associated, the high incidence of *t*899 (CC9) suggests that cross-contamination from pork products occurs quite frequently.

Animal MRSA

Animal MRSA strains are found in farm animals, and it is likely that people in contact with these animals and their families, such as veterinarians, farmers, farm workers, and abattoir workers, may acquire these organisms. In the European Union, there are many animal MRSA types, but the most common type in farm animals is CC398. It is found commonly in pigs, veal calves, and broiler chickens. This type does not appear to be a risk to abattoir workers. There is also no evidence, as yet, that this strain can cause infection or generate carriers in humans when found in food. Where workers work full time, the incidence of MRSA is higher, and less if part time.

In general, the presence of multiple virulence profiles within a MRSA genotype in an animal species suggests possible reverse zoonosis and the potential for new MRSA clones by gaining or losing additional genes.[16]

If the *staphylococci* are resistant, then treatment with antibiotics to which the *staphylococci* are resistant can increase the proportion of infected pigs and increase the numbers of bacteria present. Generally, MRSA organisms are poor responders to treatment, and infected patients have a high death rate.

For years, the problem was restricted to hospitals (HA-MRSA). These strains were the main group for over 40 years, and they are resistant to many antibiotics. Since then, the incidence of HA-MRSA has decreased and now only accounts for about 20% of all infections, particularly those occurring in intensive care units.

Community-associated MRSA (CA-MRSA) developed in the 1960s, and strains were found outside of hospitals. In particular, these strains were isolated from cats, dogs, and horses and consisted of *S. intermedius* and *S. pseudointermedius*. It is now estimated that CA-MRSA may account for about 13,000 infections annually that require hospitalization, with a resultant 1400 deaths.

In 2003, large-animal-associated MRSA (LA-MRSA) strains were discovered. These were largely CC398, as determined by MLST. In different countries various types are found. For example, in Germany CC5, CC9, and CC97 are often found. In a German study of 14,036 MRSA samples, there were 578 *spa* types.[17] Where there are large numbers of these, such as in pigs, the possibility of colonization and infection rises.[18] LA-MRSA strains share some virulence factors with human strains, but they also have distinct virulence factors.[19] Exchange of these genes encoding virulence factors may extend the host range and thereby threaten public health.

ETIOLOGY

Three types of MRSA are currently recognized, as described in the previous sections: HA-MRSA, CA-MRSA, and LA-MRSA. Originally, the HA-MRSA strains were most common, then the CA-MRSA strains became problematic as the incidence of HA-MRSA decreased, and currently LA-MRSA strains are receiving increased attention.[20]

The CC398 (ST 398) type is 12 times more likely to be carried by pig farmers than nonfarmers, and cattle farmers are more than 20 times more likely to be carriers. LA-MRSA strains, which do not spread rapidly in the human population, emerged in the 1960s following poor response to treatment. It is now thought that half of the swine herds in Iowa carry LA-MRSA CC398. Pig farmers in Switzerland were found to be carriers of CC398.[21]

LA-MRSA strains were first described in a pig in 2003 and in other species in 2005 and 2007,[22,23] and since then cases have occurred in several countries.[24-28] LA-MRSA strains are an important source of infection in humans. It is thought that people spending a lot of time with pigs are at a higher risk of testing positive.[29] LA-MRSA strains were first noticed as spreading to humans in 2008 after cases reached hospitals in the Netherlands[30] and Denmark. Pig exposure has been cited as an important factor in LA-MRSA colonization in humans.[31,32] There is apparent transmission between pigs, pig farmers, and their families.[33] Pig farmers are 760 times more likely to be colonized by LA-MRSA than the general population.[22] LA-MRSA strains are not typable by pulsed field gel electrophoresis (PFGE) because of the presence of a novel DNA methylation enzyme. For this reason, *spa* types have been isolated from pigs and their human contacts; however, the majority are classified as sequence type (ST) 398 by MLST, suggesting that ST398 strains are adept at colonizing pigs and can be transmitted between pigs and their human contacts.

MRSA infections spreading from dogs and horses to humans are not usually important causes of infection; they tend to be sporadic and involve human skin infection.

In one study, 4 out of 13 workers at a teaching and research farm had MRSA, but a variety of animals (dairy cattle, beef cattle, sheep, horses, pigs, and goats) did not.[34] A unique sequence was found in pigs in Europe, and it was found that the new MRSA clone ST398 belonged mainly to random *spa* types *t*034, *t*011, and *t*108. ST398 is considered the main reservoir of LA-MRSA infection, and it is the main type that subclinically affects pigs. The transmission of ST398 to humans is dependent on the intensity of the animal contact,[35] but spread to the local community is not very frequent.[36]

CC398 is the predominant clone in animals.[37] Genes confirming metal resistance are commonly found in CC398, and only a few non-CC398 types carry these genes. This suggests that the use of metal-containing compounds in pig production may aid in the selection for LA-CC398.

EPIDEMIOLOGY

Distribution

MRSA can be found in nearly any location. It has been found in Korea[38] in a variety of forms in pigs (ST398, ST541, and HA-ST72). It has been found in Italy in a slaughterhouse study, suggesting a high risk from pork products. It was found in Sweden in cattle.[39] In the United States, United Kingdom, and Denmark, it has been found in pigs and pig workers.[40] At the equine hospital in Turkey,[41] 48% of the horses, 92.3% of the clinical staff, and 71.4% of the environmental samples were positive for MRSA. In France, three MRSA strains belonging to *t*034 *spa* were identified.[42] *S. aureus* was identified in 59/60 necropsies where *staphylococci* were implicated, and the organism was associated with 1.7% of the total equine deaths. The other case was associated with *S. pseudointermedius.*

In a study of veterinary hospital environments, MRSA was found in 12% of the environments. In the small-animal hospital, it was 16%; equine hospital, 4%; and large-animal hospital, 0%. The strain was usually type *spa* 100, which is commonly found in the United States.[43] MRSA was found in fattening pigs in Germany (152/290), all of

which were ST398 cases. In Belgium, pigs were found to be already colonized in the farrowing house.[44] Various strains were found in Japan, including ST398 and ST9, but also ST5, ST97, and ST705.[45] In Belgium, 94% of the open farms and 56% of the closed farms were found to be infected,[46] and management and age-related trends were found to be important. There is a low level of MRSA incidence in Switzerland.[21] In Ireland, MRSA has been found in horses and dogs, but not cats,[47] and in three distinct clones (CC5, CC8, and CC22).[47]

Colonization

Colonization commences at birth, and piglets born to positive sows rapidly become infected; thus, by weaning, all the offspring are positive.

Subclinical nasal infection is common in pigs.[25,48] In other studies, the prevalence was found to increase rapidly after weaning but then fall during the finishing period,[44] and the strains were found to circulate from the nursery unit to the finishing unit. Where there is a doubling of veal calf, cattle, and pig populations in a municipality, there appears to be an increase of MRSA over the other types of *S. aureus* in the population.[18]

Pigs in slaughterhouses were found to be colonized by MRSA in different EU countries.[24,29,40,49]

Transmission

Air inlets and outlets have been found to be contaminated, contributing to MRSA transmission. Regular airborne transmission of LA-MRSA and deposition, strongly influenced by wind direction and season, up to 300 m was found in MRSA-positive pig farms.[50,51] LA-MRSA is regularly found downwind of pig and poultry barns (73% and 44%, respectively) but at low concentrations, suggesting that colonization is unlikely.

In a study in Denmark, MRSA was found in the dust and in five different age groups of pigs.[52,53] Inside pig and poultry barns, the levels were much higher. MRSA has also been found in the exhaust air from piggeries. In one study, 85% of all barns had MRSA in the air, and boot swabs and feces were also positive.[51]

In one study, nine fomites were investigated, and all transmitted MRSA to pig skin, except soap.[54] The nonporous fomites were able to transmit to the pig skin many weeks after contamination. In one study it was found that use of mobile phones by healthy workers in the health-care industry raised the possibility of transferring infection to workers, patients, and people outside the hospital.[55]

MRSA can be considered a contaminant of the environment[51] and has been detected on field surfaces.[56] There is a highly significant positive association between nasal carriage of MRSA in animals and the ability to isolate MRSA from dry surfaces.[57]

Pig workers have a significant risk of transmission.[58] Transmission to humans is associated with contact time, which is why workers are more likely to be carriers than the other members of the family. People who visit farms regularly to buy eggs or milk, or even for private farm visits, are more likely to be colonized.

Shower units on conventional swine farms have been shown to be infected.[59] MRSA can be isolated at postmortem examinations.[60] In a recent study, it was found that pharyngeal tissues had a high level of MRSA and thus may be more important in transmission than was previously thought because nose-to-nose contact with infected pharyngeal tissues is possible.[61]

In an experimentally induced infection with two sequence types (ST398 and ST9) and four commonly found *spa* types (*t*011, *t*08, *t*034, and *t*899), it was found to be difficult to produce carriage after nasal/gastrointestinal infection of piglets. Vaginal inoculation of the sow resulted in persistent carriage of *t*011-ST398 and *t*899-ST9 in all newborn piglets.[62] A low-dose inoculation was shown to be capable of horizontal transmission between pigs.[63] The major risk of transmission of ST398 is probably through trading of piglets.[64]

In a U.S. study in Ohio, 3% of the pigs were found to be positive for MRSA before slaughter, 11% in the lairage, and 2% in the carcasses, along with 4% of the retail pork.[65] The most common type was ST5, followed by ST398.

RISK FACTORS

Management is an important factor, although direct transmission is probably the most important. Animal carriers and human carriers present a hazard.

Risk factors also include herd size. The larger the herd, the more likely it is that MRSA is present.

Low incidence at birth is common, which slowly increases and stays positive for weeks, and then the prevalence slowly declines. In one study, 33% of sows were infected before farrowing, but the level had risen to 77% before weaning. Transmission rates were higher in preweaning pigs than in postweaning pigs[66] and spread rapidly in weaned piglets.[67]

There are usually up to three *spa* types per herd. The sow herd determines the production-chain levels of infection. The level of infection in piglets depends on the sow's colonization.

In all systems, the prevalence decreases with age.[68,69] If a pig herd is positive, people can be positive. If the pigs are positive, then farm dust certainly will be. Environmental contamination is therefore a risk. In one study, MRSA was found in dust, boots, socks, feces, air, and the shower units.[59]

In dairy herds the use of antibiotics is a risk factor, as are dairy hygiene and the age of the cow population. In pigs, LA-MRSA may persist without the use of antibiotics.[70]

If there are no positive pigs, then usually there are no positive people.[71] Farm visits are associated with the acquisition of MRSA, but most of these cases are only temporary.[27] At the 2006 International Pig Veterinary Society (IPVS) conference, 276 pig vets from a large number of countries were sampled, and 12.5% tested positive for MRSA.

On Swiss pig farms, it was shown that SA (including MRSA), endotoxin, and fungi levels were higher in the winter, so there may be a seasonal effect.[72] The incidence of MRSA is higher in zinc-treated and antibiotic-treated pigs.[73]

Pigs

It is generally acknowledged that the pig is the main reservoir for MRSA in large animals. *S. hyicus* is usually present in pigs but differs from *S. aureus* in that it does not have the *mecA* gene. Other species in pigs may include *S. chromogenes*, *S. epidermidis*, *S. sciuri*, *S. warneri*, *and S. xylosus*. A new species (*S. rostri*) has been found in the nasal cavity of pigs in Switzerland.[74]

There is known transfer between pigs and humans,[23,33,75,76] but it rarely spreads to the community.[77] Under some circumstances, MRSA strains can also produce enterotoxin. MRSA strains have been implicated in swollen ears, umbilical abscesses, vegetative endocarditis, subcutaneous abscesses, foot lesions, arthritis, osteomyelitis, mastitis, metritis, and enteritis.

There is a low incidence of MRSA in the United States compared with Europe. MRSA has been found in pigs in France, the Netherlands, Denmark, and Singapore.[24,40,78] In one study of Irish pigs, no cases of MRSA were found, and only two workers tested positive.[79] In finishing units in Italy, 11 different *spa* types were found, and this report identified ST9 for the first time in Europe and ST1 and ST97 for the first time in pigs.[80] In Spain, slaughter pigs are commonly affected with CC398 and CC97.[81] Free-range pigs in Spain are also infected (CC398 and *t*1011).[82] In Belgium, 94% of pigs on open farms were infected, compared with 56% of pigs on closed farms.[67] Thus far, in pigs in Europe, ST398 does not seem to be highly resistant to most antibiotics, with the exception of tetracyclines and perhaps macrolides.

The existence of lineages in species has been shown; for example, cattle often have CC133 and CC151, CC5 is common in poultry, and CC8 is common in horses. In pigs, the most common clonal complex is CC398,[83] which is different from the HA-MRSA and CA-MRSA in strains in humans,[48,84] but CC30, CC9, and CC49 have all been found. There are differences in colonization patterns of the different MRSA types in pigs.[85] CC9 is most common in Asia; ST8 has been found on a Norwegian pig

farm, and the low occurrence suggests that this strain may be less able to colonize and persist on pig holdings.[86] There is considerable heterogeneity of the resistance genes in the complex, so CC398 may acquire multiple antimicrobial antiresistance genes.[87] It easily acquires genetic material, and therefore strains with increased resistance will develop.

ST398 seems to prefer pigs but has no host specificity.[88] The same authors suggested that ST398 has an apparent lack of virulence genes in a unique genetic background. It does not, for example, usually produce Panton-Valentin E leukocidin.

In a study in the Netherlands, it was found that the MRSA strains were usually resistant to at least three but sometimes five out of six antibacterials.[89]

There may be a link with cephalosporin usage in pigs.[90]

In Switzerland, there is a low level of MRSA in pigs, although transfer to humans may happen frequently. This low level is a result of the very low level of antibiotic use for pigs in Switzerland.[21] MRSA ST49 was found in Switzerland, and it has been suggested that it has been selected in the Swiss pig husbandry because a nearly threefold increase was noted over a 3-year period.[91]

MRSA is commonly present in pigs in Denmark as a reservoir, but not in other species.[92] In pigs, it has been shown that 74% of the CC398 strains from Denmark had a reduced susceptibility to zinc chloride,[93] which is important as a reflection of the use of zinc oxide to prevent *Escherichia coli* scours.

In a study of slaughterhouse pigs in Switzerland, it was found that 89% of farms screened[54] were positive for SA. Although no MRSA strains were found, there was widespread antimicrobial resistance, particularly to penicillin (62.5%) and tetracycline (33.3%). The *S. aureus* isolates belonged to Ridon *spa* types *t*034, *t*208, and *t*899.[94]

In a large study of herds in the Netherlands (202 pig farms), MRSA was present in 67% of the breeding herds and 71% of the finishing herds. MRSA was found in 40% of small herds and 80% of the larger herds.

A study in pigs and people in Canada in 2008 showed that 45% of the farms were affected, but only 24.9% of the pigs[29] and 20% of the farmers. The most common type was the same as that found in Europe, CC398 of *spa* type 539 (Ridon *t*034). The same strains were found in the pigs and personnel on the five farms where human colonization was present.

A pig can be colonized with several strains at any one time.

Cattle

MRSA has been associated with mastitis in cattle.[95,96] In a Belgian study, the presence of *mecA* was investigated in 118 MRSA strains from 118 different farms with *S. aureus* mastitis, and MRSA was found in 11 samples; all were CC398 (*t*011 or *t*567).[97] Non *S. aureus* MRSA strains have also been studied in veal calves, dairy cows, and beef cattle, and most of the organisms were *S. sciuri*, *S. lentus*, *S. fleurette*, and occasionally *S. epidermidis*.[98] In a long-term study of MRSA ST1, *t*127 mastitis in a dairy cow was reported.[99]

The first isolations from bulk-tank milk in the United Kingdom were described in 2012,[100] and in these strains a *mecC* homologue was described. In a subsequent study of UK cattle veterinarians, only 8/307 delegates were positive for MRSA, and none had the *mecC* homologue.[101,102]

MRSA has been found in milk from the udder in Switzerland and at high levels in milk in Africa. It was found to be present at quite high levels in Iran (28%), but at low levels in India and Japan. It can invariably be found on the skin of the udder and the inside of the thigh. Generally, in Europe, the United States, and Canada, the level of MRSA in cattle is quite low. In a study of U.S. bulk-tank milk samples, only 4% had MRSA (6/150).[103]

The most common MRSA strain is generally CC398, but there may be more than one strain of different types on the same farm, which suggests that subtypes may have been imported onto the farms or that a strain of CC398 has undergone diversification.[104]

In one study, 88% of dairy farms had MRSA (90/102), 458/2151 (28%) of the cattle were positive, 32% of the farmers were positive, and only 8% of the family members were positive; the prevalence in the humans decreased in the vacation periods.

A novel *mecA* homologue has been found in humans and cattle in Denmark. In a study in Denmark, a new *mecC* gene was discovered. In a study of 411 cows, it was found that 3.9% had MRSA, and all were positive for *mecA*, negative for *mecC*, and negative for Panton–Valentine-leukocidin (PVL).[105] The MRSA-positive level was much lower than in Dutch pigs and veal calves.

In a study of 36 German dairy herds, CC398 strains were found in all 36; no PVL genes were detected, but a hemolysin gene was found.[106] In another German study, it was found that where dairy cattle were kept in an area with a large number of pigs, the MRSA level was approximately 2%; where there were no pigs, the level was less than 1%.[107]

In the Netherlands, in a study during 2008 to 2009, over 50,000 milk samples were examined from 14 different dairy herds, and only 14 MRSA strains were found. All were CC398 and the usual *spa* types (*t*011, *t*108, and *t*889) commonly found in pigs. Not all of the strains possessed PVL genes, and all were resistant to two or more antibiotics.

In the United Kingdom, a study of *S. aureus* in milk samples showed that 31/940 were resistant to cefoxitin and/or oxacillin, and 3/24 tested positive for the novel *mecA* variant. This variant is 70% homologous to the *mecA* gene, and it is located on a newly recognized SCC *mecA* element designated SCC *mecXI*. Most isolates were MLST 1245, CC130, and *spa* type *t*843.[100]

A study showed the correlation between MRSA in humans and the percentage of positive cows in a herd; 36% of human nasal swabs and 61% of bovine nasal swabs were positive. In addition, 44% of bulk milk tests were also positive.

A new type showing resistance to cefoxitin and/or oxacillin has been detected in bulk milk and mastitis cases in England and Wales and also in humans from England and Denmark. The isolates are negative for the *mecA* gene and in latex agglutination tests for PBP2, encoded by *mecA* in standard tests. This new variant *mecA* gene was found in 13/940 samples examined. Most of these isolates were MLST 1245, CC130, and *spa* type *t*843.

In a study of beef cattle in the United States, MRSA was not isolated from 491 nasal swabs and 488 fecal samples.[108]

Veal Calves

In a study in veal calf farms, it was found that 38% of farmers had MRSA, and 16% of family members also had MRSA. Carriage was related to contact, and a family member was more likely to be positive when the farmer was positive. Only a small percentage consisted of persistent carriers, and only 7.5% were not CC398.[109]

In a study of rose and white veal calves, it was found that rose veal calves had less MRSA than white veal calves, and the conclusion was that care had to be gene taken in the use of antibiotics.[110] Conversely, it has been suggested that MRSA increased in calves with the length of the production cycle but was not related to antibiotic use.[109]

A high carriage rate of LA-MRSA was found in Belgian veal calves compared with other farm types, and they were significantly more resistant to antibiotics than the pig strains. Most were CC398 in the multispecies survey, but MRSA CC130 and CC599 carrying the *mecC* gene were detected in the beef and dairy cattle.[111]

Sheep and Goats

S. aureus is widely carried in sheep and goats and shows considerable diversity.[112,113] It has been isolated from goats with mastitis.[114] In a study of 179 sheep, 41% were positive; in a small sample of goats, 11/17 were positive. Twelve ST types were found and 26 *spa* types. Most commonly these were ST133. Only three MRSA strains were found in all of the positive strains, and two were ST130 and 1 ST398.[115]

Small Animals

MRSA was first recognized in dogs and cats in the United States. In pets, the MRSA strains can include a number of species, including *S. epidermidis*, *S.*

pseudoepidermidis, *S. hemolyticus*, *S. hominis*, *S. capitis*, *S. cohnii*, and *S. warneri*.[116,117] It usually passes from humans to pets and then back again. Usually, the strains in pets are the same as those found in the local hospitals.

A strain harboring the *mecA* gene has been isolated from humans, dogs, cats, and a guinea pig in Germany.[118]

In a study in the United States of dogs, cats, horses, pigs, and other species, 24 isolates were resolved into four PFGE clones (USA100, USA300, USA500, and USA800) and into sequence types (ST5, ST8, ST105, ST830, and ST956; or two clonal complexes, CC5 and CC8).[119]

A study of companion animals in the London area found that 26/1692 samples were positive for MRSA. Animals presented for treatment were more likely to be positive than healthy animals. MRSA carriage was rare, and it is likely that companion animals were contaminated vectors rather than true reservoirs.[120,121] A case-control study in the United Kingdom showed that significant risk factors for MRSA were the number of antimicrobial courses, the number of days admitted to veterinary clinics, and the presence of surgical implants. A risk study in the United States and Canada in dogs showed that both MRSA and methicillin-sensitive *S. aureus* (MSSA) were common on the ears of pets and that the risk factors were antibiotic treatments (beta-lactams and fluoroquinolones) and intravenous catheterization. MRSA did not transmit readily from apparently healthy dog to healthy dog in a study carried out in a rescue center.[122]

Horses

Humans who work with horses are sometimes affected by MRSA. MRSA can cause serious skin disease and soft tissue infections in horses. It is most easily cultured from the nostril, with carriage from 55 to 771 days.[123] The most vulnerable horse appears to be the long-term hospitalized horse.[124] Exposure to veterinary care may predispose both healthy horses and horse handlers to MRSA.[125]

MRSA was first recognized in horses in 1996 and since then has become a problem in horse clinics in Europe and North America. Originally, the strain was CC8 (*t*8 and *t*254), but this strain has been replaced by CC398, and recent evidence suggests that human strains may appear in horses. The horse is likely a low-level contributor to LA-MRSA in Belgium, where CA-MRSA is at a low level.[126]

MRSA was recognized in horses in the United States in 2005. In one study in the United States, it was not found on a pleasure horse farm but was found on a racehorse farm, where 61% of nasal samples and 71% of environmental samples tested positive.[127]

In the United States, the most common strain is CC500, whereas in Europe it is CC398, which is highly prevalent in horses and veterinary personnel at equine clinics.

In the Netherlands, there were no cases of MRSA in 2002, but by 2008 MRSA was found to be present in 375 of the SA samples. The CC398 strain currently predominates (*t*1011, *t*2123, and *t*064).

During an outbreak in a teaching hospital, some of the personnel tested positive, in addition to 57% of the environmental samples, including samples from the students' and staff members' rooms. In another study, 81 swabs from 42 horses on four farms were examined, and 11 species of *staphylococci* were found; 17/42 were untypable.[128]

MRSA was reported in Sweden in 2012, where 8/10 horses were infected in a veterinary hospital and two other infected horses were found close by. In another hospital study, 12/84 horses and 16/139 staff at a veterinary teaching hospital had MRSA. ST5 was the culprit. The risk was greater in the veterinarians and in the full-time rather than the part-time staff.[129]

The first strain of MRSA isolated in horses in the United Kingdom was ST398 from two horses and reported in 2009.[130]

A survey of horses admitted to the Berne University Clinic showed that 2.2% of the horses had MRSA.[131]

It has been found in Lusitano horses at the Lisbon teaching hospital.[132]

In a large study of 209 racehorses, 13 veterinarians, and 14 environmental surfaces, it was found that 48.3% of the equines, 92.3% of the vets, and 71% of the environmental samples were positive for a variety of staphylococcal species.[41]

In another study of nasal swabs from horses, 42 strains of MRSA were found,[133] again from a variety of staphylococcal species (*S. sciuri*, *S. xylosus*, *S. lentus*, *S. aureus*, and *S. capitis*). All the species contained the *mecA* gene.

Other Species

Poultry

People working with broilers have higher levels of MRSA than the general population (5.5% compared with < 0.1%) in the Netherlands. However, the level is lower than in those working with pigs and veal calves.[134] In another Dutch study of broiler flocks, slaughterhouses, and personnel, it was found that the risk was greater when dealing with live animals. Over 36% of the flocks were positive and 6% of the broilers. During the production day the level of MRSA infection increased from 8% to 35%. Most strains were ST398, but there were also large numbers of ST9.

In a study of mixed pig and poultry farms,[135] MRSA was most frequently isolated from the cloaca, nose, pharynx, and skin under the wings. There was a low prevalence in the broilers (0% to 28%) on the farm, but 82% to 92% of the pigs had MRSA. The broilers may be less sensitive to the ST398 strain than pigs. The farmer may have been part of the cause of the spread of the MRSA from the pigs to the poultry on the same mixed farm.

Turkeys

A study showed that 18/120 turkey farms had MRSA, as did 22/59 people on the farms. Those with frequent access were most likely to test positive.[136]

Donkeys

In a study of donkeys in Sicily, 40/46 donkeys were found to be positive for *staphylococci*. Of the 80 isolates examined, 52/80 were *S. aureus*. Nine genera were found; most of these were MSSA, and only 14 were MRSA. The *mecA* gene was found in 6/52 SA cases.

Donkeys could be a reservoir for the CC133 lineage.

Wild Boar

So far no important MRSA cases have been found in wild boar.[137]

Backyard Pigs

A study in the United States of backyard pigs suggested that there were no major differences from domestic commercial pigs,[138] and that in all probability there was no greater risk for human infection from these pigs.

In a study of farms in Connecticut (considered noncommercial) and their pig handlers (263 pigs and 9 humans on 35 farms), it was found that 51% of farms, 30% of pigs, and 22% of the handlers were positive for MRSA. The swine had HA-MRSA, CA-MRSA, and LA-MRSA, but the humans only had HA -strains of MRSA. The PVL gene was found in 7/8 of MRSA isolates, and this was the first time this gene had been found in pigs in the United States.[139]

Camels

MRSA has been described in an alpaca, which was infected with a human epidemic clone.[140]

Fish

MRSA have been isolated from Tilapia. In one study, 559 isolates of *staphylococci* were obtained; 198 (35%) were *S. aureus*, and 98 (50%) of these were MRSA.[141]

Zoo Animals

There are few reports of MRSA in zoo animals (skin in an elephant, rumen in a Moufflon, digit of a rhinoceros).[142]

Other Sources

Holding Areas

The abattoir holding area may act as a reservoir for MRSA, but this area does not appear to disseminate MRSA into the processing lines.[143]

Working in a lairage area or in a dehairing area was the major risk factor for MRSA carriage in pig slaughterhouse workers. The overall prevalence is low and decreases along the slaughterhouse line.[144]

The high prevalence of nasal carriage in slaughterhouse workers is largely associated with working with pigs.[144,145]

State Fairs

A study at two state fairs in the United States showed that only 25/157 pigs (15.9%) were positive for *S. aureus*, and only two MRSA cases were found.[146]

Food

There is no doubt that MRSA acquired on the farm can be transferred through to processing, but there is no significant evidence of cross-contamination between carcasses.[147]

In a German study the contamination rate was highest in nasal swabs at stunning (64.7%) and was low in carcasses (6%), meat at processing (4.2%), and final products (2.8%). MRSA can be identified at all points in the food chain.[148,149]

Food may be contaminated by MRSA, but there is no evidence that this leads to increased carriage rates in humans, either in food handlers or the public. It has been found in meat,[150,151] and its incidence in meat was not uncommon.[152] MRSA can enter the slaughterhouse on or in animals and therefore does occur in raw meat emanating from the abattoir. ST398 has been found in up to 11.9% of retail meat samples in several studies in different parts of the world.[153]

In a study of retail meat samples (raw pork, chicken, beef, and turkey) from stores in Iowa, there was an overall presence of 16% positivity for MRSA, but only two isolates from pork were positive, although one had the PVL gene. The study suggested that MRSA rates in retail meat supplies, especially pork, were low.[154]

In Denmark, imported broiler meat had the highest levels of MRSA (18%), followed by imported pork (7.5%) and Danish pork (4.6%). In the same study, CC398 was found in Danish beef (1.4%). In addition to ST398, CC30 was also found for the first time.[155]

The transfer of MRSA from retail pork products to food-contact surfaces and the potential for consumer exposure has been described.[156] Pork loins, bacon, and fresh pork sausage were inoculated with mixed MRSA, vacuum packed, and stored for 2 weeks at 5 degrees C (41 F); the products were then placed on knives, cutting boards, and a human skin model for 5 minutes. Transfer to the cutting board occurred in 39% to 49%, to the knives in 17% to 42%, and to the human skin model in 26% to 36%. The transfer ranged from 2.2% to 5.2% across all products and contact surfaces.

PATHOGENESIS

S. aureus can produce many virulence factors, including protein A, technoic acid, coagulase, staphylokinase, deoxyribonuclease (DNase), lipase, hyaluronic acid, leucocidin, enterotoxins, and exfoliative toxins.

PATHOLOGY

MRSA has been detected in less than 1% of all pig postmortems. It is found both as a primary pathogen and as mixed infections, mainly in suckling and weaned pigs. Joints are more often affected than tissues. MRSA organisms live in clusters between the cilia or as singletons on the cilia in the respiratory tract. There are no morphologic changes when pig tracheal explants are experimentally infected. In an experimental infection,[157] there was colonization of lymph nodes (ileocecocolic).

DIAGNOSIS

MRSA organisms can be identified by phenotypic methods or genotyping. Samples are taken directly from lesions, biopsies, or blood culture onto selective and nonselective media. Contamination can be detected by swabbing noses (individuals), sampling dust (in herds and flocks), and food sampling. Increased sensitivity is obtained when using selective liquid enrichment media. *Spa* typing is available for lineage studies.[158]

Diagnosis of MRSA is based on culture, colony morphology, MLST on the protein A gene sequencing (*spa* typing), coagulase testing, antimicrobial sensitivity testing, and confirmation with Ceftiofur resistance and polymerase chain reaction (PCR) for the *mecA* gene.

CONTROL

Control should focus on the careful use of antimicrobials and consistent application of hygiene measures to reduce the spread of infection.[159] The reduction of access and exposure to pigs is most important. This means that movement restrictions and farm-level hygiene measures are the only possibilities.

There should be methods for harmonizing the sampling, detecting, and quantifying of MRSA in humans and animals and for detecting MRSA as a contaminant in food and the environment. Professionals connected with animals should also be tested on entry to the hospital. Transfer from animals to humans is difficult to control. Hand washing before and after contact is essential, as is avoiding direct contact with nasal secretions, saliva, and wounds. MRSA organisms can be killed with photodynamics.[160]

There is a clear difference between colonization and infection with MRSA.[161] Disinfection programs may temporarily reduce MRSA strains for the sow and piglets, but they do not result in a complete removal.[162] These programs are more effective in farrowing units than in finishing units.[163] Control programs in abattoirs should involve reduction in carcass contamination.[164]

DERMATOPHILOSIS (MYCOTIC DERMATITIS CUTANEOUS STREPTOTRICHOSIS, SENKOBO DISEASE OF CATTLE, LUMPY WOOL OF SHEEP)

The disease is commonly called mycotic dermatitis in sheep and cutaneous streptotrichosis in cattle, although other local names exist including Senkobo skin disease in central Africa, Kirchi in Nigeria, and Saria in Malawi. Dermatophilosis is a name common to the disease in all species.

SYNOPSIS

Etiology *Dermatophilus congolensis*

Epidemiology Organism present in minor carriage lesions on face and feet. Serious disease occurs when body skin is broken by shearing or insect bites, or macerated by prolonged wetting, coupled with management practices that promote transmission. The disease has significant importance in cattle in tropical areas, whereas in high-rainfall temperate climates it occurs mainly in sheep and horses. In tropical areas ticks promote severe infection in cattle by suppression of immune function.

Clinical findings Sheep: hard crusts distributed over backline palpable in fleece. Cattle and horses: nonpruritic crusting dermatitis, initially with paintbrush tufts of hair. In cattle in tropical areas, extensive skin lesions.

Clinical pathology Branching filaments containing cocci in pairs.

Diagnostic confirmation Clinical. Organisms in scrapings or biopsy sections, culture, polymerase chain reaction (PCR).

Treatment Antibiotics. Topical antibacterial in horses.

Control Avoidance of skin trauma and of management practices that promote transmission. Use of topical bactericides to prevent infection of shear cuts, and of skin in risk periods. Acaricides in cattle.

ETIOLOGY

D. congolensis is the infective agent but requires damage to the skin from other causes to establish infection. The organism is dimorphic and grows as branched filamentous mycelia containing dormant zoospores that are transformed by moisture to the infective stage of motile isolated cocci. There is considerable genetic diversity between isolates. Isolates from the same geographic region are not necessarily closely genetically related, although genotypic variation between isolates is correlated with the host species.

EPIDEMIOLOGY

Occurrence

Geographic Occurrence

The disease occurs in all areas of the world but can be epizootic in tropical and subtropical areas of the world, where it can result in considerable economic loss. Surveys of large numbers of cattle in Africa report prevalence rates approaching 15%, with a 100% infection rate in some herds at the time of peak seasonal prevalence. In temperate climates the disease is usually sporadic but can still be

of considerable economic importance where predisposing factors pertain. For example, an incidence ranging from 10% to 66% was recorded in nine dairy herds, where shower cooling was the predisposing factor to disease.

High prevalence in sheep flocks occurs in the high- and medium-rainfall areas of Australia. Significant clinical disease has been reported as far north as Canada, the northern United States, and Scotland, and as far south as New Zealand.

Host Occurrence

Disease occurs in cattle, sheep, goats, horses, and donkeys, and occasionally in deer, pigs, camels, and wildlife species. Animals of all ages are susceptible, including sucklings a few weeks old.

Source of Infection

The major source of infection for outbreaks of clinical disease exists with minor active lesions on the face and feet in otherwise healthy carrier animals, and with infection in scabs still carried in the hair and wool from healed lesions.

D. congolensis is not highly invasive and does not normally breach the barriers of healthy skin. These barriers include the stratum corneum, the superficial wax layer produced by the sebaceous glands, and, on the body of sheep, the physical barrier of the wool. On the feet and face, these barriers are easily and commonly broken by abrasive terrain or thorny and spiny forage and feedstuffs.

Dermatophilus may infect these lesions and may be transmitted mechanically by feeding flies to result in minor infection on the face and feet. This subclinical carriage form of the disease is common in most herds and flocks, and the minor lesions are most evident at the junction of the haired and nonhaired areas of the nares and of the claws and dewclaws. Minor lesions may also be present in the haired areas of the face and feet and on the scrotum and, in lambs, on the skin along the dorsal midline of the back. They are of no clinical significance to the animal except that they provide a source of more serious infection when other areas of the skin surface are predisposed to infection.

Transmission

Transmission occurs from the carriage lesions by contact from the face of one animal to the fleece or skin of another, and from the feet to the skin during mounting. Infection can be transmitted mechanically by flies and ticks and mediate infection by contaminated dips.

Environmental and Management Risk Factors

Sheep

Prolonged wetting of the fleece is the major risk factor and leads to emulsification of the wax barrier and maceration of the skin surface with disruption of the stratum corneum. A prolonged and heavy rain is sufficient to do this, especially if followed by warm and humid weather that retards drying of the fleece. Increased environmental humidity and temperature, as distinct from wetting of the skin, does not appear to promote the development of lesions. Moisture releases infective zoospores from carriage lesions, and these may be carried mechanically by flies that are attracted to the wet wool. The motile zoospores are aided in their movement to the skin surface by the moisture of the fleece and their positive chemotactic response to carbon dioxide at the skin surface.

A protracted wetting period of the fleece can also occur following dipping, jetting, or spraying of sheep for external parasites when these procedures are conducted at periods greater than 1 to 2 months after shearing; the incidence of mycotic dermatitis in sheep has been shown to increase with the time period between shearing and dipping. The infection onto the fleece comes primarily from the lesions on the face and feet and is promoted by tightly yarding sheep following these procedures.

Shearing cuts also destroy the barriers of the skin, and cuts may become infected mechanically by flies, physically by tight yarding after shearing, and by mediate infection in **dips** when sheep are dipped immediately following shearing. The resultant lesions do not spread over the body but provide a significant source of infection for other sheep in the flock when management or climatic circumstances lead to a high degree of flock skin susceptibility. Skin infection can also occur following infection with contagious ecthyma.

Cattle

Temperate Zones

Outbreaks in herds and severe disease in individuals are uncommon but can occur associated with high rainfall, with attack rates of 50%. There is a particular tendency for lesions to occur on the rump and back in females and males, probably as a result of the introduction of infection through minor skin abrasions caused by mounting. Lesions down the flanks of cattle may also result from abrasions and direct infection from the dewclaws during mounting. Other penetrating lesions caused by eartags or biting flies can also result in minor lesions.

The use of periodic showers or continual misting to cool cattle during hot periods is a risk factor for infection in dairy herds. Intercurrent disease and stress are also risk factors, and in infected dairy herds a higher incidence has been observed during the first weeks of parturition in first-calf heifers that also had endometritis or mastitis.

Tropical Zones

Climate is the most important risk factor and in tropical and subtropical regions; the disease has its highest incidence and severity during the humid, high-rainfall season. Animals in which the disease regresses are usually reinfected repeatedly in successive wet seasons. As in sheep, the disease in cattle requires disruption of natural skin barriers. However, prolonged wetting of the skin of cattle does not appear to be a major predisposing factor by itself, and the seasonal occurrence is associated with a concomitant increase in tick and insect infestation.[1] For example, a study in Ethiopia found that although prevalence was higher in cattle in the wet season, in both seasons, infestation with *Ambylomma variegatum* significantly affected the occurrence of disease, with infested cattle having a risk 7 times higher.

Tick infestation, particularly with *A. variegatum*, *Hyalomma asticum*, and *Boophilus microplus*, is strongly associated with the occurrence of extensive lesions of dermatophilosis, which can be minimized by the use of acaricides.

The lesions of dermatophilosis on the body do not occur at the predilection sites for ticks, and it is thought that the importance of tick infestation relates to a tick-produced immune suppression in the host rather than mechanical or biological transmission.

Lesions do occur at predilection sites for biting insects, mainly *Stomoxys* spp., *Lyperosia* spp., *Glossinia* spp., *Calliphoria* spp., and mosquitoes. In Africa the disease is often combined with demodicosis to produce Senkobo disease, a more severe and often fatal combination.

Trauma to the skin produced by thorny bushes and the ox-pecker bird (*Buphagus africanus africanus*) can also initiate lesions.

Horses

Biting flies (*Stomoxys calcitrans*) are thought to act as mechanical vectors of the infection, and the housefly (*Musca domestica*) can carry infection. Skin damage from trauma or from ectoparasites can predispose for disease, as does wetting from rainfall or from **frequent washing**.

HOST RISK FACTORS

There are breed differences in susceptibility in cattle and sheep. In Africa, the N'dama and Muturu cattle breeds and native sheep are resistant, whereas Zebu, White Fulani, Renitleo,[2] and European breeds are susceptible. Within-breed differences in susceptibility are also apparent, and genetic markers have been identified in Zebu cattle and Merino sheep. Susceptibility in cattle can be influenced by genetic selection. For example, selection against susceptibility to dermatophilosis, based on a BoLA-*DRB3/DQB* class II haplotype, reduced the prevalence of disease in

Brahman cattle in Martinique from 76% to 2% over 5 years.

In the Merino, sheep of the strong- or medium-wool strains are more susceptible. Open-fleeced sheep and sheep with a low-wax and high-suint content in their fleece are more prone to infection.

PATHOGEN RISK FACTORS

D. congolensis does not live well off the body and in the normal environment, and it is susceptible to the external influences of pH and moisture fluctuations. In the laboratory it can survive for 4 years in otherwise sterile broth culture and for at least 13 years in dry scab material kept at room temperature.

EXPERIMENTAL DISEASE

Local lesions, but not with spread to extensive disease, can be readily reproduced in sheep and cattle by removal of the skin wax followed by local challenge. Genetic differences modulate the severity of the lesion that occurs.

ECONOMIC IMPORTANCE

Sheep

Damage to the fleece causes severe losses, up to 30% loss of value of wool and 40% loss of skin value, and may be so extensive in lambs that spring lambing has to be abandoned. Other losses in sheep are caused by interference with shearing and a very great increase in susceptibility to blow-fly infestation.

Cattle

In Africa the disease in cattle causes great losses and many deaths, and the it ranks as one of the four major bacteriologic diseases with equivalent importance to contagious bovine pleuropneumonia and brucellosis. Goats in the same area also suffer a high incidence. Losses are from direct animal loss, decreased work ability of affected oxen, reproductive failure from vulval infection or infection on the limbs of males preventing mounting, death from starvation of calves of dams with udder infection, loss of animal meat and milk production, and downgrading of hides. In temperate climates deaths are uncommon, but cows that fail to respond to treatment and have to be culled are not infrequent. In a study in nine herds in Israel, death or culling rates from this disease ranged from 2% to 17%, and there was an average 23% fall in milk production in affected cattle. Reproductive inefficiency is a common accompaniment in severe cases.

Zoonotic Implications

Human infection is reported, such as on the hand of a veterinarian working with infected sheep, but contagion from livestock is rare in spite of ample opportunity.

PATHOGENESIS

The natural skin and wool waxes act as effective barriers to infection. Minor trauma, or maceration by prolonged wetting, allows establishment of infection and multiplication of the organism in the epidermis. The formation of the typical pyramid-shaped crusts is caused by repeated cycles of invasion into the epidermis by hyphae, bacterial multiplication in the epidermis, rapid infiltration of neutrophils, and regeneration of the epidermis. The organism in the scab is the source for the repeated and expanding invasion, which occurs until immunity develops and the lesion heals. The scab then separates from the healed lesion but is still held loosely in place by hair or wool fibers. In sheep, the extensive maceration of skin that can occur with prolonged fleece wetting can result in extensive skin lesions under the fleece. In cattle, tick infestation suppresses immune function and promotes the spread of the lesion. Secondary bacterial invasion may occur and gives rise to extensive suppuration and severe toxemia.

CLINICAL FINDINGS

Sheep

Lesions are commonly not visible in sheep because they are obscured by the fleece, but the crusts can be palpated as hard masses at the surface of the skin (**lumpy wool disease**) and typically are distributed irregularly over the dorsal midline, with "ribs" spreading laterally and ventrally. The crusts are roughly circular, thick, up to 3cm, often distinctly **pyramidal** with a concave base, and often pigmented, and the underlying skin is moist and reddened. The muzzle, face, and ears, and the scrotum of rams, may also be involved. The health of the animal is unaffected unless the lesions are widespread.

Heavy mortalities can occur in very young **lambs,** where there can be extensive lesions over the body. Many develop cutaneous blow-fly myiasis, and in occasional cases a secondary pneumonia resulting from the organism may cause the death of the animal.

Cattle

The early lesion is a pustule, and the hair over the infected site is erect and matted in tufts (paintbrush lesions) with greasy exudate forming crumbly crusts that are hard to remove. These develop into scabs that are greasy and fissures at flexion points, and finally to scabs that are hard, horny, and confluent. The scabs vary in color from cream to brown, are 2 to 5 cm in diameter, and are often in such close apposition that they give the appearance of a mosaic. In the early stages the crusts are very tenacious, and attempts to lift them cause pain. Beneath the crusts there is granulation tissue and some pus. In the later stages, the dermatitis heals and the crusts separate from the skin and are held in place by penetrating hairs, but they are easily removed.

Lesions occur on the neck, body, and back of the udder and may extend over the sides and down the legs and the ventral surface of the body. Commonly they commence along the back from the withers to the rump and extend halfway down the ribcage. In some animals the only site affected is the flexor aspect of the limb joints, the inguinal area, or between the forelimbs.

In young calves, infection commences on the muzzle, probably from contact with the infected udder or because of scalding by milk in bucket-fed calves, and may spread over the head and neck.

Horses

Lesions in horses are similar to those in cattle. The hairs are matted together over the lesion, and an exudative dermatitis produces a firm mat of hairs and debris just above the skin surface. If this hair is plucked, the entire structure may lift off, leaving a characteristic ovoid, slightly bleeding skin area. No pruritus or irritation is apparent, although the sores are tender to the touch.

Infection can appear on the head, beginning at the muzzle and spreading up the face to the eyes, and if sufficiently extensive may be accompanied by lacrimation and a profuse, mucopurulent nasal discharge. In some horses the lesions are confined to the lower limbs, with a few on the belly. In very bad environmental conditions the lesions may be widespread and cover virtually the whole of the back and sides. The lesions on lower limbs are most common behind the pastern, around the coronet, and on the anterior aspect of the hind cannon bones. If the underlying skin cracks, the horse can become very lame. This variable distribution of lesions may depend on the inciting skin trauma.

Goats

Lesions appear first on the lips and muzzle and then spread, possibly by biting, to the feet and scrotum. They may extend to all parts of the body, especially the dorsal midline and inside the thighs. In some cases lesions commence on the external ear. Heavy crust formations may block the ear canal and the external nares.

CLINICAL PATHOLOGY

The causative organism may be isolated from scrapings or a biopsy section and is much easier to isolate from an acute case than a chronic one. Polymyxin B sulfate can be used to suppress contaminants. Typical branching organisms with double rows of zoospores can be seen in a stained impression smear made directly from the ventral surface of a thick scab pressed firmly onto a slide. The organism can also be demonstrated by fluorescent antibody. ELISA and counterimmunoelectrophoresis have been used to detect serologic evidence of infection, and a real-time PCR test for rapid detection of *D. congolensis* has been developed in Spain.[3]

NECROPSY FINDINGS

In animals that die, there is extensive dermatitis, sometimes a secondary pneumonia, and often evidence of intercurrent disease.

Samples for Confirmation of Diagnosis

- **Bacteriology**—affected skin and draining lymph node (CYTO FUNGAL CULT)
- **Histology**—formalin-fixed samples of these tissues (LM)

DIFFERENTIAL DIAGNOSIS

Ringworm

Staphylococcal dermatitis/folliculitis

Scabies

Pediculosis

Fleece rot—sheep

Other causes of dermatitis are listed in Tables 16.3 and 16.4.

TREATMENT

Sheep

Bactericidal dips are used but have limited efficacy because topical treatments do not penetrate the scab to the active lesion; they are more appropriate for control.

Antibiotic treatment at high dose for a single treatment is effective in reducing the proportion of active lesions in an affected flock. Antibiotics that are effective include procaine penicillin combined with streptomycin at a dose of 70,000 units/kg and 70 mg/kg, respectively; erythromycin at 10 mg/kg; long-acting tetracycline at 20 mg/kg; and combination of lincomycin and spectinomycin at a dose of 5 mg/kg and 10 mg/kg, respectively; all treatments are given intramuscularly. Treatments appear effective in wet weather. The usual strategy is to treat 8 weeks before shearing so that there is time for the lesions to heal and shearing to occur without interference from active lesions. Sheep may be dipped in a bactericidal dip after shearing, as detailed under "Control." An alternate approach is to cull affected sheep.

Cattle

With the disease that occurs in temperate areas, tetracycline (5 mg/kg body weight [BW]) repeated weekly as required is recommended, and long-acting tetracycline (20 mg/kg BW) in one injection is reported to give excellent results in cattle. Parenteral procaine penicillin G (22,000 IU/kg IM) daily for 3 days is also reported as efficacious.

With the disease that occurs in tropical areas and associated with tick infestation, there is no completely satisfactory treatment in herds with extensive involvement or those being constantly reinfected or exposed to predisposing causes. In general terms, better results are obtained during dry weather and in dry climates. In tropical Africa, treatments that are reasonably effective elsewhere are of little or no value.

Parenteral treatment with antibiotics, as described previously, can be used and should be used in conjunction with acaricides when ticks are present.

Horses

Topical therapy is most commonly used in horses, coupled with removal from whatever is causing prolonged wetness of the skin. Although horses generally respond well, in bad weather even they can be recalcitrant to treatment. Scabs can be removed by grooming under sedation and the lesions treated topically daily with povidone–iodine or chlorhexidine until the lesions heal. Benzoyl peroxide has keratolytic, antibacterial, and follicular flushing properties and is reported to be effective in therapy when applied topically at a concentration of 2.5%.

Severe cases can be treated daily for 3 days with procaine penicillin G at 20,000 units/kg intramuscularly alone or in combination with streptomycin at 10 mg/kg IM.

CONTROL

The principal approach, where possible, is the avoidance of predisposing factors. The disease usually disappears in dry weather. Isolation of infected animals and avoidance of contact by clean animals with infected materials such as grooming tools is desirable. Affected sheep should be shorn and/or dipped last.

Close yarding of sheep or factors that promote face-to-skin contact immediately after shearing or after dipping should be avoided. Insecticidal dips should contain a bactericide. Where dipping immediately after shearing is a risk factor, the severity of infection can be reduced by delaying dipping, for example, from the 1st to the 10th day after shearing, or by dipping in zinc sulfate immediately following shearing with later dipping in an insecticide. Alternatively, pour-on insecticides can be used.

Bactericidal dips will give some protection to sheep. Spraying or dipping of sheep in a 0.5% to 1.0% solution of zinc sulfate immediately after shearing is used to prevent infection of shear cuts. Spraying or dipping sheep in a 1% solution of alum (potassium aluminum sulfate) provides protection against infection for up to 70 days, with alum rendering the organism nonmotile, and can be used to provide protection during the rainy season in woolled sheep. Alum strips from the dip, and the dip requires frequent replenishment, with the amount depending on wool length. An alternate treatment is to dust alum along the back of the sheep.

With cattle in tropical areas, **tick control** (see Tick Infestations in this chapter) is most important in control of dermatophilosis. Attempts at prophylaxis by vaccination in both sheep and cattle have been unsuccessful; immunity appears to be isolate-specific.

SKIN TUBERCULOSIS

Chronic indurative lesions of the skin in cattle, occurring usually on the lower limbs, are called "skin tuberculosis" because they frequently sensitize affected animals to tuberculin.

ETIOLOGY

Acid-fast organisms can often be found in the lesions in small numbers. They have not been identified and are probably not true pathogens. Iatrogenic lesions may be caused by aluminum adsorbed vaccines that produce subcutaneous granulomas, which are colonized by acid-fast bacteria.

EPIDEMIOLOGY

The disease occurs in most countries of the world, particularly where animals are housed and incur minor abrasions and pressure sores. The frequent occurrence of lesions on the lower extremities suggests **cutaneous abrasions** as the probable portal of entry of the causative organism.

The lesions cause little inconvenience but are unsightly, and affected animals may give a suspicious or positive reaction to the tuberculin test when they are in fact free of tuberculosis. This becomes important when herds and areas are undergoing eradication and attention is focused on any condition that complicates the tuberculin test.

PATHOGENESIS

Tuberculoid granulomas occur at the site of infection, with spread along local lymphatic vessels but without involvement of lymph nodes.

CLINICAL FINDINGS

Small lumps 1 to 2 cm in diameter appear under the skin. The **lower limbs** are the most common site, particularly the forelimbs, and spread to the thighs and forearms, and even to the shoulder and abdomen, may occur. The lesions may be single or multiple and often occur in **chains** connected by thin cords of tissue. The nodules are attached to the skin; they may rupture and discharge thick cream-to-yellow pus. Ulcers do not

persist. Individual lesions may disappear, but complete recovery to the point of disappearance of all lesions is unlikely if the lesions are large and multiple.

CLINICAL PATHOLOGY

Affected animals may react to the tuberculin test. Bacteriologic examination of smears of pus may reveal the presence of acid-fast bacteria.

NECROPSY FINDINGS

The lesions comprise much fibrous tissue, usually containing foci of pasty or inspissated pus, and are sometimes calcified.

DIFFERENTIAL DIAGNOSIS

In herds with tuberculosis, reactors that have lesions of skin tuberculosis are disposed of in the usual way. In herds free of tuberculosis, a positive reaction to the tuberculin test in animals with skin tuberculosis is usually taken to be nonspecific; the affected animal is retained, provided it is negative on retest.

Bovine farcy (see also "Bovine Farcy")

Ulcerative lymphangitis (see also "Ulcerative Lymphangitis").

TREATMENT AND CONTROL

Treatment and control measures are not usually instituted, although surgical removal may be undertaken for cosmetic reasons.

MYCOBACTERIUM ULCERANS INFECTION (BURULI OR BAIRNSDALE ULCER)

Mycobacterium ulcerans causes progressive ulcers in the skin of humans, dogs, cats, alpacas, horses and wildlife.[1–5] Pigs can be infected experimentally.[6] The disease in humans occurs in at least 30 countries,[5] often as geographic clusters associated with water bodies. Wildlife, such as the common brushtailed possum (*Trichosurus vulpecula*) and ring-tailed possum (*Pseudocheirus peregrinus*) in southeastern Australia, are proposed as important components of the disease infection cycle, with *M. ulcerans* detected in the feces of 41% of possums in areas in which the disease is endemic and less than 1% in nonendemic areas.[5] Clusters of the disease in people are spatially associated with the presence of possums.[7] A relationship between wildlife and domestic animal disease has not been investigated or reported. The organism can be detected in a number of species of mosquitoes, although the importance of these species in spread of the infection and causation of disease is unclear.[7]

Infection by the organism causes extensive and progressive necrosis of the skin and underlying soft tissue, usually of the limbs or extremities. The disease is reported in the thigh of one horse and the withers and fetlock of another,[1] and the distal limb and face, respectively, of two alpacas.[4] Infection causes both ulcerating and nonulcerating granulomatous lesions in dogs and cats.[2] One of two horses affected died as a result of the disease, as did both alpacas.[1,4]

Diagnosis is by the demonstration of the organisms by Ziehl–Neilson staining of biopsies of lesions with confirmation by culture or, more conveniently and presumably with greater sensitivity, by PCR detection of *M. ulcerans* genome.[1,2,4]

Treatment is by surgical excision of the lesion. Therapy with antimycobacterial drugs such as rifampin, clarithromycin, or fluoroquinolones can be considered but is limited because of drug-induced toxicoses, including diarrhea, difficulty in long-term administration, and expense.

There are no accepted control measures. The disease has zoonotic potential, and affected animals and samples should be handled accordingly.

FLEECE ROT IN SHEEP

SYNOPSIS

Etiology Dermatitis associated with growth of chromogenic *Pseudomonas aeruginosa* following prolonged wetting of the skin of sheep.

Epidemiology Occurs with high incidence in sheep with susceptible fleece characters in wet seasons. Major risk factor for body flystrike.

Clinical findings Dermatitis with fleece coloration over the backline.

Diagnostic confirmation Clinical.

Control Selection of sheep with resistant fleece characters.

ETIOLOGY

Fleece rot develops as an exudative dermatitis following wetting of the fleece by rain. The growth of toxigenic strains of *Pseudomonas aeruginosa* is thought to be the major cause of the dermatitis, and the fleece coloration that usually accompanies it, but other *Pseudomonas* spp., including *P. maltophilia*, have been incriminated in the genesis of the condition. The enzyme phospholipase C in *P. aeruginosa* is a virulence determinant for this disease.

EPIDEMIOLOGY

Occurrence

The disease is common in most parts of Australia and occurs in South Africa and also in areas of New Zealand. Its occurrence is associated with wet years, and in these circumstances the incidence in affected flocks varies from 40% to 100%.[1,2]

Environmental and Host Risk Factors

Fleece rot occurs in sheep only in wet seasons and when the fleece is predisposed to wetting by its physical characters.

Prolonged rainfall, sufficient to wet sheep to the skin for a week, is required for this condition to occur. Young sheep (those < 10 months) are more susceptible than old, and heritable differences in fleece characters affect the susceptibility of individual sheep. These characters are probably related to the ease with which the skin can be wetted.

Fleece Characteristics

The degree of "grip" and body skin wrinkling are unimportant as factors affecting susceptibility, but fleece weight, fiber diameter and variability, staple density, and neck wrinkle are positively correlated with susceptibility. These characteristics produce visible differences between fleeces. Resistant sheep have closely packed elliptical wool staples with blocky tips and even crimp. Susceptible fleeces have thin staples of unevenly crimped wool and with a fringe-tipped appearance as a result of the protrusion of thicker wool fibers above the top of the staple. This fringed appearance is visible along the back and sides. Susceptible flocks are characterized by fleeces with longer, heavier, thicker staples with lower crimp frequency and higher fiber diameter and variability.

Fleeces with a high wax content are less susceptible, probably because of the waterproofing effect of the wax. This view is supported by the observation that disruption of the sebaceous layer on the skin increases its susceptibility to wetting.

Greasy fleece color has been found to be a good predictor of susceptibility to fleece rot in some studies but not others. Wool with a high suint content is highly susceptible.

Experimental Production

The disease can be reproduced experimentally by inoculating *P. aeruginosa* epicutaneously and wetting the fleece.

Economic Importance

Fleece rot causes considerable financial loss because of the depreciation in the value of the damaged fleeces and the increased need for chemical applications to treat or prevent body flystrike, for which it is a major risk factor.

PATHOGENESIS

With prolonged wetting, conditions of high humidity in the fleece microenvironment and the availability of rich nutrients from serous exudates and indigenous suint allow the proliferation of opportunistic skin and fleece bacteria, including *P. aeruginosa*, and

result in dermatitis. The predominant bacterium is usually *P. aeruginosa*, which inhibits the growth of other bacteria, and its pyocyanin produces a green color. Its rapid growth is accompanied by the production of the dermonecrotic toxin phospholipase C, which exacerbates the dermatitis and initiates the inflammatory cascade that draws neutrophils and lymphocytes into the skin.

In the experimental disease there is outpouring of serous exudate and infiltration of leukocytes into dermis, but *P. aeruginosa* is localized as aggregates at the leading front of the seropurulent exudate and never penetrates the dermis.

Other discolorations may occur depending on the predominance of a particular chromogenic bacterium, many of which belong to *Pseudomonas* spp. *P. maltophilia* can result in yellow–brown coloration, and *P. indigofera* results in blue coloration.

The odor produced by the bacteria and the serum protein on the skin surface is very attractive to blow flies, and most body strikes are a result of preexisting fleece-rot lesions. To add a further complication, *P. aeruginosa* also proliferates in the presence of organophosphorous insecticides and facilitates its biodegradation.

Sequencing of 16SrRNA genes to identify bacteria present before and after the onset of disease in an experimental flock at Trangie in Australia identified several new bacteria associated with fleece rot, and the bacterial populations differed between susceptible and resistant sheep.[3] It was concluded that although *P. aeruginosa* may be associated with severe fleece-rot lesions, there may be other bacteria associated with susceptibility or resistance to this condition. Subsequently, investigation of single-nucleotide polymorphisms between susceptible and resistant sheep identified 155 genes that were differentially expressed.[4] Fibulin (FBLN1) and fatty acid binding protein 4 (FAB4) were identified as key factors in resistance to fleece rot. If validated in larger populations, these could enable marker-assisted selection to increase the resistance of Merino sheep to fleece rot.[4]

CLINICAL FINDINGS

Lesions occur most commonly over the withers and along the back. In active cases, the wool over the affected part is always saturated, and the tip is more open than over unaffected areas. The wool is leached and dingy and in severe cases can be plucked easily. The skin is inflamed, and serous exudate produces bands of matted and colored fibers across the staple. The coloration of the fibers is commonly green, but may be yellow, yellow–brown, or red–brown and occurs in fibers at skin level or extending the full length of the staple.

The general health of the sheep is unaffected in typical fleece rot, but severe ulcerative dermatitis with mortality associated with *P. aeruginosa* can occur. For example, chronic ulcerative and necrotic dermatitis associated with *P. aeruginosa*, occurring on the tail, udder, and legs of sheep and accompanied by green coloration of the surrounding fleece, was recorded following excessive rain in the Mediterranean climate zone of Israel.

CLINICAL PATHOLOGY AND NECROPSY FINDINGS

Autopsy examinations are not carried out, and laboratory examination of the living animal is not usually necessary.

There are differences in the inflammatory response and in peripheral blood lymphocyte subsets between fleece-rot-resistant and susceptible sheep, with several different mechanisms likely to occur in resistant sheep.[2]

DIAGNOSIS

Fleece rot resembles mycotic dermatitis in body distribution and predisposing factors, but the typical scab is not present in fleece rot.

CONTROL

Treatment is unlikely to be of value, but some degree of control may be effected by selection of fleece-rot-resistant sheep for use in susceptible localities. In these same localities, shearing before the wet season should facilitate drying of the fleece and lessen susceptibility, although the variable and unpredictable timing of rainfall means that no shearing time will reliably prevent fleece rot. The heritability of resistance to fleece rot has been estimated to be between 0.35 and 0.4; thus, selective breeding programs have been advocated, with genetically selected lines showing increased resistance in high-risk environments.[2]

Considerable effort was invested into the investigation of vaccines against fleece rot in the 1980s and 1990s.[2] These reduced the severity of fleece rot in pen experiments, often by up to 60%, but when the infecting serotype of *P. aeruginosa* differed from the vaccine strain there was little cross protection.

BOLO DISEASE

This disease of the fleece of predominantly merino and Döhne merino sheep appears confined to the Eastern Cape province of South Africa and gets its name from the region where it was first described. An unclassified *Corynebacterium* spp. closely resembling *Corynebacterium pseudodiphtheriticum* and *Corynebacterium urealyticum* can be isolated from the skin of affected sheep. This organism is rarely isolated from the skin of sheep with normal fleeces. The disease can be experimentally reproduced by the topical application of the organism onto the intact skin of newly shorn sheep and sheep in 5-month wool, and the organism persists in the produced lesions for at least 169 days.

Bolo disease is a disease of medium- and medium–strong-wool Merino sheep having dense fleeces with a high yolk content. It occurs in sheep on natural grazing. There is no sex predilection, but older and poor-conditioned sheep are more severely affected. It can occur in semiarid climates, and there is no apparent seasonal or climatic influence or influence of external parasites. The attack rate in a flock can be as high as 90%, and the disease has considerable economic impact because as the wool is of inferior quality and low economic value.

Lesions occur most commonly on the sides of neck and the shoulders and are more easily seen in unshorn sheep as well-defined, dark gray to black patches and bands that vary in number and in size (20 mm to 30 cm in diameter) and are sunk below the surface of the tips of the surrounding staple. The underlying skin is red–purple in color, is tender to the touch, and breaks easily. There is a yellow sticky exudate on the surface of the skin and in between the wool fibers, resulting in a spiky staple. On freshly shorn sheep, the affected areas are chalky white.

Histologically there is acanthosis, superficial and follicular hyperkeratosis and hyperpigmentation, and sebaceous gland hypertrophy.

Treatment regimens are not defined, but high-dose parenteral penicillin as used in mycotic dermatitis might be effective.

Bolo disease can be differentiated from fleece rot and mycotic dermatitis by its clinical presentation and the epidemiologic circumstances in which it occurs.

STRAWBERRY FOOTROT OF SHEEP (PROLIFERATIVE DERMATITIS)

Strawberry footrot of sheep is a proliferative dermatitis of the lower limbs of sheep.

ETIOLOGY

The causative agent is thought to be *D. congolensis* (*Dermatophilus pedis*).[1]

EPIDEMIOLOGY

The disease is recorded in the United Kingdom and occurs extensively in some

parts of Scotland and in Australia. It is not fatal, but severely affected animals do not make normal weight gains. Up to 100% of animals in affected flocks may show the clinical disease.

All ages and breeds appear susceptible, but under natural conditions lambs are more commonly affected. Most outbreaks occur during the summer months, and lesions tend to disappear in cold weather. Although the disease is recorded naturally only in sheep, it can be transmitted experimentally to man, goats, guinea pigs, and rabbits. Complete immunity does not develop after an attack, although sheep recently recovered from contagious ecthyma may show a transient resistance.

The natural method of transmission is unknown, but the frequency of occurrence of lesions at the knee and coronet suggests infection from the ground through cutaneous injuries. Dried crusts containing the causative agent are infective for long periods, and ground contamination by infected animals, or infection from carrier animals, is the probable source of infection.

PATHOGENESIS

Histologically, the lesions are those of a superficial epidermitis similar to that of contagious ecthyma.

CLINICAL FINDINGS

Most cases appear 2 to 4 weeks after sheep have been moved onto affected, pasture but incubation periods of 3 to 4 months have been observed. Small heaped-up scabs appear on the leg from the coronet to the knee or hock. These enlarge to 3 to 5 cm in diameter and become thick and wart-like. The hair is lost, and the lesions may coalesce. Removal of the scabs reveals a bleeding, fleshy mass resembling a fresh strawberry, surrounded by a shallow ulcer. In later stages the **ulcer** is deep and pus is present. There is no pruritus or lameness unless lesions occur in the interdigital space. Most lesions heal in 5 to 6 weeks, but chronic cases may persist for 6 months.

CLINICAL PATHOGENESIS

Swabs and scrapings should be examined for the causative organism.

DIFFERENTIAL DIAGNOSIS

Lesions of strawberry footrot closely resemble those of contagious ecthyma but are restricted in their distribution to the lower limbs, whereas lesions of contagious ecthyma occur mostly on the face and less often on the legs. On careful examination, often both leg and face lesions are present. The absence of a systemic reaction and the proliferative character of the lesions differentiate it from sheeppox.

TREATMENT

There is little information on treatment. Antibiotics as used in dermatophilosis should be effective. In an unusual outbreak of lameness affecting 40% of a flock, with lesions resembling strawberry footrot but from which no organisms were isolated, the response to topical antibiotic and preparations was poor, although lesions did become less painful after bathing affected areas in a solution of lincomycin/spectinomycin.[2] Systemic treatment with tilmicosin and long-acting amoxicillin did assist healing.[2]

CONTROL

In the light of present knowledge, isolation of infected sheep and the resting of infected fields are the only measures that can be recommended.

REFERENCES

1. Radostits O, et al. Strawberry footrot. In: *Veterinary Medicine: A Textbook of the Disease of Cattle, Horses, Sheep, Goats and Pigs.* 10th ed. London: W.B. Saunders; 2007:1051.

CONTAGIOUS ACNE OF HORSES (CANADIAN HORSEPOX, CONTAGIOUS PUSTULAR DERMATITIS)

Contagious acne of horses is characterized by the development of pustules, particularly where the skin comes in contact with the harness.

ETIOLOGY

Corynebacterium pseudotuberculosis is the specific cause of this disease.

EPIDEMIOLOGY

The disease is spread from animal to animal by means of contaminated grooming utensils or harnesses. An existing seborrhea or folliculitis as a result of blockage of sebaceous gland ducts by pressure from the harness probably predisposes to infection. Inefficient grooming may also be a contributing cause.

Contagious acne is of limited occurrence and causes temporary inconvenience when affected horses are unable to work.

PATHOGENESIS

Infection of the hair follicle leads to local suppuration and the formation of pustules, which rupture and contaminate surrounding skin areas. Occasional lesions penetrate deeply and develop into indolent ulcers.

CLINICAL FINDINGS

The skin lesions usually develop in groups in areas that come into contact with the harness. The lesions take the form of papules that develop into pustules varying in diameter from 1 to 2.5 cm. There is no pruritus, but the lesions may be painful to touch. Rupture of the pustules leads to crust formation over an accumulation of greenish-tinged pus. Healing of lesions occurs in about 1 week, but the disease may persist for 4 or more weeks if successive crops of lesions develop.

CLINICAL PATHOLOGY

Swabs of the lesions can be taken to determine the presence of *C. pseudotuberculosis.*

DIFFERENTIAL DIAGNOSIS

Ringworm
Staphylococcal pyoderma
Nodular necrobiosis
Diagnostic confirmation
Isolation of *C. pseudotuberculosis* from lesions

TREATMENT

Affected animals should be rested until all lesions are healed. Frequent washing with a mild skin disinfectant solution followed by the application of antibacterial ointments to the lesions should facilitate healing and prevent the development of further lesions. Parenteral administration of antibiotics may be advisable in severe cases.

CONTROL

Infected horses should be rigidly isolated, and all grooming equipment, harnesses, and blankets must be disinfected. Grooming tools must be disinfected before each use. Vaccination is not likely to be effective because of the poor antigenicity of the organism.

EXUDATIVE EPIDERMITIS (GREASY PIG DISEASE)

ETIOLOGY

The condition of exudative dermatitis (marmite disease) is similar to staphylococcal scalded skin syndrome in humans associated with *S. aureus*. It is a skin condition of pigs of all ages. One human case of *S. hyicus* septicemia has been recorded.

S. hyicus is the cause of exudative epidermitis (EE) in suckling and weaned piglets. It also causes several other diseases sporadically in different animal species, bacteriuria in pigs, polyarthritis in pigs, abortion in pigs, flank biting and necrotic ear lesions, and pneumonia. It is a normal inhabitant of the skin of adults. Virulence is associated with toxins.[1,2]

In other species it has been associated with skin infections in horses, donkeys, and cattle; subclinical mastitis in cows; and osteomyelitis in heifers.

A second species, *Staphylococcus chromogenes*, is part of the normal skin flora of pigs, cattle, and poultry. It had been considered nonpathogenic until EE was associated with it in 2005. These strains produced exfoliative

toxin type B (ExLB), which was identified by PCR. A third species, *Staphylococcus sciuri*, has also caused EE.[3]

SYNOPSIS

Etiology *Staphylococcus hyicus* of at least six serotypes and many phage types.

Epidemiology Affects suckling and weanling piglets under 6 weeks of age; peak incidence under 1 week of age. Morbidity 20% to 100%; case fatality 50% to 75%. Organism carried by sow. Introduced by carriers.

Signs Marked cutaneous erythema and pain, dehydration, extensive greasy exudate; peracute cases die; less severe cases may survive. May cause ear necrosis syndrome.

Clinical pathology Bacterial culture of skin.

Necropsy findings Exudative epidermitis; degenerative changes in kidney.

Diagnostic confirmation Culture of organism.

Differential diagnosis See Table 16-2.

Treatment Penicillin parenterally.

Control Sanitation and hygiene of pens. In outbreaks, isolate affected piglets and sows.

EPIDEMIOLOGY

Occurrence

The disease occurs in all pig-producing countries. Most cases of exudative epidermitis occur in suckling and weaned piglets under 6 weeks of age, with a peak incidence in piglets under 1 week. Occasionally groups of pigs up to 3 months of age may be affected. Within litters the incidence is high; often all piglets are affected. The morbidity will vary from 20% to 100% and the case fatality rate from 50% to 75%. The organism has been isolated from the joint fluid of lame pigs affected with arthritis.[3] In 28% and 26% of studies of cases of exudative epidermitis, no cases of toxigenic *S. hyicus* could be detected. In a recent study of 314 cases in Denmark, it was shown that 20% had exfoliatum toxin A, 33% had B, 18% had C, and 22% had D in 60% of cases of EE investigated.

Method of Transmission

The source of the organism is unknown, but the gilt or sow is probably an inapparent carrier. It can be isolated from the skin of healthy in-contact piglets and healthy sows. It can be frequently isolated from the vagina of prepubertal gilts, and the majority of the litters from the same gilts may be colonized by the organism within 24 hours after farrowing. The maternal strains of *S. hyicus* persisted on the skin of the offspring piglets for the first 3 weeks of the piglets' lives—the critical period for outbreaks of exudative epidermitis. The organism has also been isolated from the atmosphere of buildings housing affected pigs. Bacteriophage typing of *S. hyicus* subspp. hyicus isolated from pigs with or without exudative epidermitis revealed two or more phage patterns in the isolates from each pig with the disease and a single-phage pattern in isolates from healthy pigs. It may also spread by aerosol.

Risk Factors

Animal Risk Factors

Field evidence suggests that environmental stress of various kinds, including agalactia in the sow and intercurrent infection, predisposes to the disease. Lesions commonly develop first over the head, apparently in association with bite wounds, which occur when the needle teeth have not been cut or have been cut badly. Other factors include fighting following mixing of litters, excessive humidity over 70%, and following sarcoptic mange. The presence of the disease in a swine herd can account for a 35% reduction in the margin of output over feed and veterinary costs over a 2-month period. It may also occur as a result of floor injuries.

Pathogen Risk Factors

Strains of *S. hyicus* can be divided into virulent and avirulent strains with regard to ability to produce exudative epidermitis in experimental piglets; both types of strain can be isolated simultaneously from diseased piglets. It has been shown that different types of *S. hyicus* expressing different types of toxin may be present in the same diseased pig.

S. hyicus produces an exfoliative toxin that can be used to reproduce the disease. There are several toxins, including ExLA, ExLB, ExLC, ExLD, SHETa, and SHETb.[4] Toxigenic *S. hyicus* is isolated more freely from diseases than healthy pigs.[5] Strains of the organism isolated from a large number of Danish pig herds indicated different electrophoretic motility and plasma-mediated antibiotic resistance patterns. The antibiotic and plasmid profiles of strains isolated from pig herds may be a reflection of the use of antibiotics in those herds. Different types of toxin are produced.

Recently the genes encoding for the exfoliative toxins SHETb, ExLA, ExLB, ExLC, and ExLD have been identified and sequenced.

The condition has been seen more frequently in cases of PRRS and PCV-2 infections. It is very resistant to drying and can persist in the environment.

The organism has been found as a frequent inhabitant of the skin of cattle and has been isolated from cattle with skin lesions. Naturally occurring lesions of dermatitis of the lower limbs of horses and similar lesions over the neck and back of donkeys have been recorded. Experimentally, the organism can cause lesions in horses similar to those of exudative epidermitis. A concurrent infection with *D. congolensis* has also been reported.

PATHOGENESIS

S. hyicus has cytotoxic activity for porcine keratinocyte cells in culture, particularly the cells of the stratum granulosum. At least six toxins have been found. There is also a virulence factor that helps resist phagocytosis by binding IgG.[6] The organism also produces a coagulase, streptokinase lipase, and has a fibronectin-like substance that aids attachment to skin cells.

The exfoliative toxins are actually epidermolysins that are active against desmoglein-1, which is a desmosomal cadherin-like molecule involved in cell-to-cell adhesion. The ExLs can cause blister formation in the porcine skin by digesting porcine desmoglein-1 in a similar way to exfoliative toxins of *S. aureus*.

The earliest lesion is a subcorneal pustular dermatitis involving the interfollicular epidermis. Exfoliation follows with sebaceous exudation and formation of a crust. In the well-developed case there is a thick surface crust composed of orthokeratotic and parakeratotic hyperkeratosis and neutrophilic microabscesses with numerous colonies of gram-positive cocci.

Although the principal lesion is an inflammatory–exudative reaction in the corium and upper layers of the epidermis, the disease is probably a systemic rather than a local one. Experimental infection of gnotobiotic pigs leads to dermatitis of the snout and ears, then the medial aspect of the thighs, the abdominal wall, and the coronets. The lesions can be produced experimentally by using crude extracellular products and a partially purified exfoliative toxin.

CLINICAL FINDINGS

The morbidity varies from 10% to 100% and the mortality from 5% to 90%, with an average of 25%. It is usually self-limiting, and as immunity rises, it may well disappear.

In the peracute form, which occurs most commonly in piglets only a few days of age, there is a sudden onset of marked cutaneous erythema, with severe pain on palpation, evidenced by squealing. Anorexia, severe dehydration, and weakness are present, and death occurs in 24 to 48 hours. The entire skin coat appears wrinkled and reddened and is covered with a greasy, gray–brown exudate that accumulates in thick clumps around the eyes, behind the ears, and over the abdominal wall. In the less acute form, seen in older pigs 3 to 10 weeks of age, the greasy exudate becomes thickened and brown and peels off in scabs, leaving a deep-pink-colored to normal skin surface. There is no irritation or pruritus. In the subacute form, the exudate dries into brown scales that are most prominent on the face, around the eyes, and behind the ears. In a small percentage of pigs, the chronic form occurs and the course is much

Table 16-2 Differential diagnosis of diseases of swine with skin lesions

Disease	Epidemiology	Clinical and laboratory findings	Response to treatment
Swinepox	Mainly suckling piglets. High morbidity but low mortality except in very young piglets. Usually associated with swine louse infestation.	Papules, vesicles, and circular red-brown scabs on ventral belly wall and over the sides and back. Pox characteristics.	None required except for insect and louse control. Spontaneous recovery in 3 weeks.
Skin necrosis	Suckling piglets. High morbidity with abrasive flooring.	Abrasion and necrosis starting shortly after birth and reaching maximum severity at about 1 week. Anterior aspect of carpus more common site but also fetlock, hock, elbow, and coronet. Bilateral. Necrosis and erosion of anterior two or three pairs of teats.	Usually none required. Recovery in 3–5 weeks. Protect area with tape if severe, plus topical antiseptics. Teat necrosis will render animal unsuitable for selection and breeding. Correction of flooring.
Exudative epidermitis (greasy pig disease)	Entire litters of sucklings pigs, most severe under 1 week of age, occurs up to 10 weeks, high case fatality in younger pigs.	Marked cutaneous erythema with seborrhea, severe dehydration, and death in piglets under 10 days. Older piglets covered with greasy exudate and recover. *S. hyicus* on culture.	Piglets under 10 days of age die in spite of therapy. Older pigs may survive with penicillin treatment topically and parenterally.
Dermatosis vegetans	Inherited and congenital, high morbidity. High case fatality by 8 weeks.	Erythema and edema of coronets, uneven brittle hooves, dry brown crusts on belly wall, giant-cell pneumonia. Club foot.	None indicated. Genetic control.
Pityriasis rosea	One or more piglets in litter after weaning. High morbidity, nil mortality.	Lesions begin as small, red, flat plaques that enlarge from 1–2 cm diameter with a prominent ring of erythematous skin covered in center by thin, dry, brown, loose scales. Lesions usually coalesce, forming a mosaic pattern, especially on belly. Scraping negative. No growth depression.	None required. Emollient to soothe the lesion. Recovery occurs in 4–8 weeks.
Parakeratosis (zinc deficiency)	Weaners and feeder pigs on diet low in zinc and high in calcium. Herd problem, high morbidity, no mortality.	Erythematous areas on ventral abdomen and symmetrically over back and legs develop into thick crusts and fissures. No pruritus. Skin scrapings negative. Growth rate depression.	Add zinc to diet 100 ppm. Adjust calcium. Recovery in 2–6 weeks.
Ringworm	Feeder and mature pigs. Usually several pigs within pen or shed. High morbidity with *M. nanum* in sows.	Centrifugally progressing ring of inflammation surrounding an area with scabs, crusts, and brown or black exudate. May reach large size. Bristles usually intact. No pruritus. Positive skin scrapings and hair. No ground depression.	Fungicides. In growers, spontaneous recovery in 8–10 weeks if well nourished. *M. nanum* in sows is persistent and responds poorly.
Facial dermatitis	Suckling piglets. High incidence in litters associated with fighting. Low mortality.	Lesions on cheeks—usually bilateral abrasions which become infected. Scabs hard and brown and difficult to remove. Overlie a raw shallow bleeding ulcer. Occasional extension to other areas.	Usually none indicated. Topical antibacterials. Clip teeth at birth.
Ulcerative granuloma	Young pigs but all ages. Sporadic Infection following abrasion. Poor hygiene.	Large swollen tumorous mass with several discharging sinuses. Central slough and ulcer.	Fair, depending on site. Surgical removal and/or sulfadimidine and streptomycin.
Sarcoptic mange	All ages of pigs. Herd problem. Reservoir of infection in sows. High morbidity. Nil mortality.	Intense pruritus. Mites on scraping. Erythematous spots with scale and minor brown exudation. Especially evident in thin skin areas. Secondary trauma to skin and bristles from rubbing. If severe, intense erythema. Chronic infections, thickening and wrinkling of skin. Depression or weight gain.	Good response to vigorous therapy with ascaricides. Treat on herd basis.
Allergic dermatoses to *Tyroglyphus* spp. (harvest mites)	Weaner and feeder pigs few weeks after eating dry ground feed from autonomic feeders.	Pinpoint erythematous spots and fragile scales. Intense pruritus. Skin scraping positive for mites.	Spontaneous recovery common. Insecticide effective.
Erysipelas	Feeder and adult pigs, occasionally weaners. Variable morbidity. Low mortality if treated early.	Small red spots developing to characteristic rhomboidal lesion, raised and red in color. Lesions may become joined and lose their characteristic shape. Progress to necrosis and desquamation. Fever and other signs of septicemia.	Penicillin.

longer; there is thickening with wrinkling of the skin and thick scabs that crack along flexion lines, forming deep fissures. Most peracute cases die, whereas piglets with the less severe forms will survive if treated. Some pigs are affected with ulcerative glossitis and stomatitis.

In older pigs lesions may be very limited. Sometimes just the ears are affected. Abortion in a sow has been attributed to the organism. In some cases pigs are dehydrated and emaciated. Surface lymph nodes may be enlarged or edematous. The condition is much more common when there are the immunosuppressive disorders (Porcine reproductive and respiratory syndrome virus, Porcine circovirus 2, Swine Influenza Virus).

CLINICAL PATHOLOGY

Bacterial examination of skin swabs may reveal the presence of S. hyicus. A phage typing system can be used to determine the presence of virulent strains and to distinguish them from less virulent strains.

NECROPSY FINDINGS

Necropsy of these dehydrated, unthrifty piglets often reveals a white precipitate in the renal papillae and pelvis. Occasionally this cellular debris causes ureteral blockage. Some piglets also have a mild ulcerative glossitis and stomatitis. Microscopically, there is separation of the cells of the epidermis in the upper stratum spinosum, exfoliation of the skin, erythema, and serous exudation. The crusting dermatitis features a superficial folliculitis and a hyperkeratotic perivascular dermatitis with intracorneal pustules and prominent bacterial colonies. Degenerative changes are visible in the renal tubular epithelium.

DIAGNOSIS

Diagnosis is usually made on the basis of clinical signs and lesions.

Samples for confirmation of diagnosis include the following:

- Bacteriology—samples of acute skin lesions for culture are best if the skin underneath the crusts is sampled or the local lymph nodes. The organism forms 3- to 4-mm white, nonhemolytic colonies on blood agar. It is catalase- and mannitol-negative but hyaluronidase-positive. Selective media can be used (potassium thiocyanate),
- Histology—formalin-fixed skin (multiple sites), kidney (LM)
- A PCR is available but requires a pure culture and large numbers of organisms to be successful. An ELISA has been developed for the toxins.[7]

DIFFERENTIAL DIAGNOSIS

Exudative epidermitis may resemble several skin diseases of pigs of all age groups (Table 16-2). However, in exudative epidermitis there is no pruritus or fever. In mange there is pruritus, and the lesions can be scraped. Ringworm can be cultured or skin scrapings made for microscopy. Pityriasis rosea is erythematous and self-limiting. Zinc deficiency in 2- to 4-month-old pigs is particularly found in Landrace, and the lesions are dry. Swinepox is usually local and rarely fatal. Careful gross examination of the lesions, particularly their distribution, the state of the hair shaft, the character of the exudate, and the presence or absence of pruritus, must be considered, along with skin scrapings and biopsies.

TREATMENT

In severely affected animals, injection is best followed by water and feed medication. Experimentally infected piglets respond favorably to a topical application of cloxacillin 10,000 IU/g of lanolin base and 1% hydrocortisone combined with parenteral cloxacillin. Treatment must be administered as soon as the lesions are visible. Procaine penicillin G at a dose of 20,000 IU/kg BW intramuscularly daily for 3 days is also recommended. The antimicrobial sensitivities determined in one field investigation revealed that all isolates were sensitive to novobiocin, neomycin, and cloxacillin. Novobiocin may be the antimicrobial of choice because *staphylococci* are universally sensitive to this antibiotic. However, there is no available information on the efficacy of antimicrobials for naturally occurring cases of exudative epidermitis. A study has suggested that lincomycin, amoxicillin, and cetaloxin (off-label use) seem to work well in the United Kingdom. Erythromycin, sulfathiazole, and trimethoprim may be the most useful drugs, whereas penicillin and tetracyclines may not be very useful. Resistance to penicillin, erythromycin, streptomycin, sulphonamides, and tetracycline is fairly common. There is, however, no correlation between genes and resistance patterns.[2] Naturally occurring cases in piglets under 10 days of age respond poorly, whereas older pigs recover with a skin wash using a suitable disinfectant soap. The most successful treatment is antibiotics and skin washing for a period of at least 5 to 7 days. It is also essential to make sure that there is sufficient dietary provision of zinc, biotin, fat, selenium, and vitamin E in the diet. Because there is dehydration, electrolyte therapy may help.

CONTROL

Improved hygiene, lower humidity, and dimmed lighting all help, as will control of concurrent infectious disease. Teeth clipping also reduces skin damage. Soft bedding also reduces skin damage (e.g., chopped straw is better than straw).

The infected accommodation should be cleaned, disinfected, and left vacant before another farrowing sow is placed in the pen. Strict isolation of the affected piglets and their dam is necessary to prevent spread throughout the herd. Dead piglets should be removed promptly from the premises, and in-contact sows should be washed with a suitable disinfectant soap. Maternal antibodies will protect piglets in the first few weeks of life. Prophylactic medication in feed or water has also helped.

Autogenous vaccines have been used, with varying degrees of success. It is important to use a strain that produces the exfoliative toxin, so the recent development of PCRs that identify the genes for toxin development will ensure that the right isolate is used for the autogenous vaccine. It will also facilitate the development of a commercial vaccine.

A novel approach to the control is bacterial interference. Experimentally, the precolonization of the skin of gnotobiotic piglets with an avirulent strain of *S. hyicus* will prevent the experimental reproduction of the disease with the virulent strain of the organism.

ULCERATIVE DERMATITIS (GRANULOMATOUS DERMATITIS) OF PIGS

Ulcerative granuloma is an infectious disease of pigs originally associated with the spirochete *Borrelia suilla* (formerly *B. suis*) and more recently *T. pedis*.[1] In some cases it has become more common where there is PCV2 infection. It is characterized by the development of chronic ulcers of the skin and subcutaneous tissues. It can be confused with necrotic ear syndrome and, more importantly, with swine vesicular disease when there are granulating lesions at the coronary groove.

For sows, it occurs most commonly under conditions of poor hygiene. Lesions occur on the central abdomen of sows and on the mammary glands. The lesions expand, often to 20 to 30 cm in diameter, on the belly of the sow. They are usually single or in small numbers. In adult animals there is considerable inconvenience if the lesions are permitted to develop. Necrotic ulcers on the udders of sows may continue to develop and extend deeper into areas with fistulae, and sloughing may result.

The faces of sucking piglets are affected, suggesting infection of cutaneous or mucosal

abrasions as the portal of entry. In some instances, these outbreaks have followed episodes of severe fighting. Initially the lesions are small, hard, fibrous swellings that ulcerate in 2 to 3 weeks to form a persistent ulcer with raised edges and a center of excessive granulation tissue covered with sticky, gray pus. All you may see is a grayish, crusty, weeping lesion that may spread. There is often coinfection with *S. hyicus* or beta-hemolytic streptococci, and the lesions may be contaminated by *Trueperella* (*Arcanobacterium*) *pyogenes*. The lesions commence about the lips and erode the cheeks, and sometimes the jawbone, and often cause shedding of the teeth.

In young pigs, usually at 5 to 7 weeks of age, the whole litter may be affected. Here the lower margin of both ears close to the junction with the neck, with extensive tissue destruction and sloughing, is affected. The major diagnostic problem is that the initial spirochetal lesions may be secondarily infected with environmental organisms such as *Fusobacterium* spp. or *T. pyogenes*, and the underlying spirochetes may be missed unless smears are viewed. The pathology usually involves edema, erythema, necrosis, ulceration, and purulent lesions. In young pigs there may be heavy losses as a result of severe damage to the face.

Differential diagnosis may include abscesses, foreign bodies, granulomas, and pressure necrosis. In growing pigs, the lesions need to be differentiated from necrotic lesions resulting from snout rubbing and ear biting, and those resulting from excessive self-trauma with mange infestation. It may be mistaken for lesions of *Actinomycosis* and *Nocardia* in sows, and swabs should be taken from the ulcers for bacteriologic examination. A fresh smear of the exudates usually shows the spirochetes, and if necessary they can be stained by silver stains or viewed in histologic sections. A course of potassium iodide given orally (1 g/35 kg up to 3 g) or a 5-day period of injections of penicillin are the methods of treatment. Topical tetracycline spray has been used effectively with early lesions followed by tetracycline injection in the deeper-seated and more chronic cases. Dusting with sulphanilamide, arsenic trioxide, or tartar emetic has also been recommended. Removal of large granulomas surgically has also been tried. Fly repellents should be used to prevent flystrike.

The injection of 0.2 mL of a 5% solution of sodium arsenite into the substance of the lesion is reported to give good results. Improvement in hygiene, particularly at the times of routine treatments, and disinfection of skin wounds should reduce the incidence in affected piggeries.

Viral Diseases of the Skin

PAPILLOMAVIRUS INFECTION (PAPILLOMATOSIS, WARTS)

SYNOPSIS

Etiology Papillomaviruses (PVs), including bovine papillomaviruses 1 through 13, equine papillomaviruses 1 through 7, and various other host-specific papillomaviruses.

Epidemiology Occur in all countries in all species but most common in young cattle and horses. Transmission is by direct contact and fomites. Risk factors for PV-associated diseases include ingestion of bracken fern (enzootic hematuria, alimentary squamous-cell carcinoma in cattle) and increasing age (penile squamous-cell carcinoma in equids).

Clinical findings Solid outgrowths of epidermis, may be sessile or pedunculated. Most common type in cattle occurs on head and neck and has cauliflower-like appearance, but lesion site and appearance vary with papilloma type. Alimentary (squamous epithelium) warts and squamous-cell carcinoma in cattle. Enzootic hematuria (bladder carcinoma) in cattle. In the horse, lesions are on the face and lips. Penile and prepucial papillomatosis and squamous-cell carcinoma in horses. Aural plaques in horses. Sarcoids in horses.

Clinical pathology None specific.

Lesions Papilloma or fibropapilloma.

Diagnostic confirmation Histology and DNA identification by polymerase chain reaction (PCR) in biopsy or tissue scraping.

Treatment Removal by surgery or cryosurgery. Vaccination with autogenous vaccine. Application of imiquimod 5% cream to aural plaques.

Papillomaviruses appear to infect all groups of amniotes, having been isolated from 54 species, including mammals, birds, and reptiles.[1] Study of this group of viruses is historically important in the context of demonstration of the possibility of a viral etiology for some neoplastic diseases.[2] Diseases associated with infection by papillomaviruses range from nonneoplastic lesions on epithelial surfaces (skin, urogenital tract, gastrointestinal tract) through to neoplasms, including in humans (human papillomavirus and cervical cancer).[3] Cutaneous warts in cattle, horses, sheep, and goats are benign tumors induced by host-specific papillomaviruses. These infect epithelial cells, causing hyperproliferative lesions that are benign and self-limiting and that, in most cases, spontaneously regress. The virus is also associated with neoplastic diseases, including bladder cancer in cattle ingesting bracken fern, carcinoma of the upper alimentary tract of cattle (usually associated with ingestion of bracken fern), and squamous-cell carcinoma of the penis and prepuce in horses. Papillomaviruses are usually quite host specific, with the exception of some bovine papillomaviruses, and require close contact for spread of infection.

ETIOLOGY

Papillomaviruses (PVs) are members of the Papillomaviridae family, which have a characteristic circular double-stranded DNA genome of around eight kilobase pairs (kbp) that usually contains at least six relatively conserved open reading frames (ORFs) in an early (E1, E2, E6, E7) and a late (L1, L2) region.[4] Papillomaviruses are characterized genetically by the L1 ORF.[4] To date, at least 112 nonhuman papillomaviruses have been identified, and there is the anticipation that more will be detected.[1] It appears that each species carries a suite of papillomaviruses—for example, 13 bovine papillomavirus (BPV) types have been identified in cattle (BPV-1 through BVP-13), 15 canine papillomavirus (CPV) types in dogs (CPV-1 through CPV-15), and 7 equine caballus papillomavirus (EcPV) types in horses (EcPV-1 through EcPV-7). The feline sarcoid-associated virus has been proposed as BPV-14; it can infect cattle but has not been demonstrated in horses.[5]

Unusually, horses are also infected by BPV-1 and/or BPV-2, and possibly BPV-13,[6] which are associated with development of sarcoids (see "Sarcoids" for further discussion).[7] Papillomaviruses have been isolated from camels, goats, deer, sheep, and pigs, usually from papillomas or similar epithelial lesions.[1] BPV-1 and BPV-2 are associated with papillomas in yaks and sarcoids in zebra, giraffes, and sable antelope.[8–10] New papillomaviruses continue to be identified.[11]

Cattle types show some site predilection or site specificity, as exemplified by the following partial listing:

- **BPV-1**—frond fibropapillomas of teat and skin and penile fibropapilloma
- **BPV-1 and BPV-2**—fibropapilloma of the skin of the anteroventral part of the body, including the forehead, neck, and back;[12] the common cutaneous wart
- **BPV-2**—cauliflower-like fibropapillomas of the anogenital and ventral abdominal skin
- **BPV-2**—associated with bladder cancer in cattle in association with the ingestion of bracken fern (*Pteridium* spp.) (see "Enzootic Hematuria)[13]
- **BPV-3**—cutaneous papilloma
- **BPV-4**—papilloma of the esophagus, esophageal groove, forestomaches, and small intestine; capable of becoming malignant, particularly in animals fed bracken fern; has site specificity to the upper alimentary tract

- **BPV-5,** and to a lesser extent BPV-1 and BVP-2, in fibropapilloma/papilloma of the mouth, esophagus, rumen, and reticulum of cattle and water buffalo[14]
- **BPV-5**—rice grain fibropapilloma on the udder; has also been demonstrated in cutaneous skin warts
- **BPV-6**—frond epithelial papillomas of the bovine udder and teats
- **BPV-7, BPV-9, and BPV-10**—lesions of the teats and udder[15,16]
- **BPV-10**—lingual papilloma[17]
- **BPV-12**—associated with papillomas[18]

Although a single BPV type is detected in an individual papilloma, a single animal can have papillomas at different sites associated with different BPV types.

Other papilloma of cattle that have regional distribution and may have separate antigenic identity are as follows:

- Oral papillomas, mostly in adult cattle and apparently reaching a high incidence, up to 16% in some areas; these are probably BPV-4
- Papilloma of the larynx in steers
- Papillomavirus has been observed in squamous-cell carcinoma of bovine eyes, although its etiologic role is unclear.

Other skin lesions in which papillomavirus plays an etiologic role are:

- Equine sarcoid, which is associated with BPV-1 and BPV-2, and possibly BPV-13 (see "Sarcoid," in this chapter)
- Squamous-cell carcinoma of sheep (likely OaPV-3, although this can be isolated from the skin of healthy sheep)[19]
- Epithelial tumors in goats (although the causal relationship is not clear)[20]
- Cauliflower-like tumor of the external nares in a chamois[21]

Equids

Papillomas, aural plaques, and squamous-cell carcinoma in horses are associated with infection by one of the seven equine papillomaviruses.[1] Cutaneous papilloma, including of the penis, and aural or genital plaques are associated with infection by EcPV-1 through EcPV-6.[1] EcPV-7 was isolated from a penile mass that was not histologically classified.[4] Penile papillomas are associated with infection by EcPV-2.[22] EcPV-2 DNA was detected in abnormal tissue in 15 of 16 cases of penile squamous-cell carcinoma, 8 of 8 cases of penile intraepithelial neoplasia, 4 of 4 cases of penile papilloma, and 1 of 2 lymph nodes containing metastatic tumor cells. EcPV-2 DNA was detected in 4 of 39 of penile swabs of healthy horses and in 0 of 20 vulvovaginal swabs.[23] Coinfection by more than one EcPV appears to be common.[4] Infection by equine papillomavirus EcPV-2, as demonstrated by detection of EcPV-2 DNA in lesions,[24] is associated with squamous-cell carcinoma of the genitalia of horses,[25] being transcriptionally active in tumor but not semen or swabs of healthy horses,[26] and detected in 91 of 103 tissue samples of horses with penile or preputial carcinoma and in 1 of 12 samples from horses free of the disease.[27] There is no evidence to date that EcPV-3 is associated with carcinoma of the penis or prepuce. Papillomavirus DNA is not detected in periocular squamous-cell carcinoma of horses.[28]

Sarcoids in equids are discussed under that topic.

Pigs

Papillomavirus specific to pigs has been isolated from skin of healthy pigs, but has not been associated with disease.[29]

EPIDEMIOLOGY

Occurrence

Papillomatosis has an international occurrence in all animal species, and sarcoids and urogenital tumors occur in almost all populations of horses. There are few studies of the seroprevalence of papillomaviruses in healthy animals. Five of 50 horses without evidence of skin disease or urogenital tumors in Switzerland had EcPV-2-specific DNA amplified but not EcPV-2-specific antibodies detected, 14 of 50 horses had antibodies against EcPV2 but no DNA detected, and both antibodies and viral DNA were detected in 4 of 50 horses. Neither specific antibodies nor viral DNA were found in 27 of 50 horses (54%).[30]

BPV-1 or BPV-2 infection is common in horses and cattle, being detectable by PCR and/or reverse transcription PCR (RT-PCR) in 14 of 70 blood samples (20%) and in 11 of 31 semen samples (35%) from healthy horses,[31] and in 8/12 blood samples of healthy cattle and in 8/9 samples from cattle with papillomatosis. Six of 8 papilloma-free cattle that were positive for BPV also had evidence of expression of BPV in blood.[32]

Papillomaviruses were detected in 28/45 of samples of horses with aural plaques, of which 4/45 were solely EcPV-3 and 17/45 were solely EcPV-4, with 7/45 being coinfected. Viral DNA was not detected in 17/45 of samples. Neither EcPV-3 nor EcPV-4 was detected in samples from 10 horses that did not have aural skin lesions.[33] Similar results demonstrating presence of papillomavirus antigen or EcPV DNA in papillomas, aural plaques, and sarcoids supports the etiologic associated between the virus and these diseases.[34]

Origin of Infection and Transmission

The method of spread is by **direct contact** with infected animals, with infection gaining entry through **cutaneous abrasions**. Viruses can also persist on inanimate objects in livestock buildings and infect animals rubbing against them. BPV-1 DNA is present in flies (*Musca domestica*, *Fannia carnicularis*, and *Stomoxys calcitrans*) trapped in stables of donkeys with sarcoids, suggesting the possibility that flies, and especially biting flies (*S. calcitrans*), are potential vectors.[35] The presence of BPV-1 and BPV-2 in blood of both horses and cattle raises the possibility of spread by biting flies independent of them feeding on actual lesions.

The means of transmission of the virus causing penile and preputial papillomas and squamous-cell carcinoma is unclear. Venereal transmission is possible, but lesions occur in animals that are not and have not been sexually active (e.g., geldings).

Crops of warts sometimes occur around eartags, at branding sites, or along scratches made by barbed wire, and they can be spread by tattooing implements, by dehorning shears, and by procedures such as tuberculin testing.

An extensive outbreak of perianal warts is recorded in beef heifers, the infection having been spread by rectal examination for pregnancy. A high prevalence of papillomas on the larynx of feedlot steers is ascribed to implantation of the virus in contact ulcers, which are also entry sites for *Fusobacterium nodosus* (a cause of calf diphtheria), so that the two diseases may occur in the one animal. An outbreak of periorbital papillomatosis in cattle is recorded in association with a heavy periorbital infestation with *Haematopinus quadripertusus*.

Animal Risk Factors

All species may be affected by papillomas or fibropapilloma, but it is most commonly reported in cattle and horses. With cattle, usually several animals in an age group are affected. Alimentary papillomas occur in up to 20% of cattle ingesting bracken fern, but in less than 4% of other cattle.[3]

Outbreaks have been recorded in sheep and goats, but the disease is uncommon in sheep. It is also uncommon in pigs, usually affecting the genitalia.

Papillomavirus infection is widespread in nondomestic species, including birds and reptiles, and is associated with disease in many of these species (see previous discussion).[1]

Age

Cutaneous papillomas of the head and neck occur predominantly in young animals, the lack of susceptibility of adults to natural infection being ascribed to immunity acquired by apparent or inapparent infection when young. The occurrence of cutaneous warts and their severity can be influenced by factors that induce immunosuppression, and latent infection has converted to clinical disease with the administration of immunosuppressive agents. Congenital infection is recorded in the foal and calf, but it is rare.

Alimentary papillomas in cattle, teat papillomas in cattle, and papillomas on the mammary glands of goats occur, or persist, at all production ages.

Squamous-cell carcinoma of the penis or prepuce occurs mostly in older horses (mean

age 20 y) and without apparent breed predilection.[36]

Experimental Production

The supernatant from a suspension of wart tissue, injected intradermally (ID) or applied to skin scarifications, is an effective means of experimental production of the disease. Lesions are restricted to the site of inoculation. Cutaneous and oral papillomas have been transmitted in cattle, and cutaneous papillomas have been transmitted in sheep and horses. The incubation period after experimental inoculation in cattle is 3 to 8 weeks but is usually somewhat longer after natural exposure.

Economic Importance

Cutaneous warts are quite common in young cattle, especially when they are housed, but ordinarily they cause little harm and regress spontaneously. In purebred animals they may interfere with sales and shows because of their unsightly appearance. Animals with extensive lesions may lose condition, and secondary bacterial invasion of traumatized warts can occur. Warts on the teats of dairy cows often cause interference with milking. In horses, the lesions are usually small and cause little inconvenience, but they are esthetically unattractive.

Urogenital lesions in equids, predominantly penile and preputial papillomas, can progress to squamous-cell carcinoma, which carries a poor prognosis unless treated early in the disease.[36]

PATHOGENESIS

The virus infects the basal keratinocytes, replicating its genome in the differentiating spinous and granular layers and causing the excessive growth that is characteristic of wart formation.[2] Expression of the late structural proteins of the virus is limited to the differentiated cells of the squamous layer where the new virus particles are encapsulated and shed into the environment as the cells die. The tumor contains epithelial and connective tissues and can be a papilloma or a fibropapilloma, depending on the relative proportions of epithelial and connective tissue present; papillomas contain little connective tissue, and fibropapillomas are mostly fibrous tissue, with very little epithelial tissue. Papillomas are the result of basal-cell hyperplasia without viral antigen production. Fibropapillomas are uncommon in horses but are the common lesion in cattle, sheep, and wild ruminants. Latent infection in the skin and lymphocytes has been demonstrated in cattle.

CLINICAL FINDINGS

Warts are solid outgrowths of epidermis that are sessile or pedunculated. Other papillomavirus-associated diseases include penile or prepucial lesions in horses, alimentary lesions in ruminants, enzootic hematuria in cattle ingesting bracken fern, and squamous-cell carcinoma of the urogenital or alimentary tracts.

Cattle

In cattle, warts occur on almost any part of the body, but when numerous animals in a group are affected it is common to find them all affected in the same part of the body. The most common papillomas occur in the skin of cattle under 2 years of age, most commonly on the head (Fig. 16-2), especially around the eyes, and on the neck and shoulders (Fig. 16-3), but they may spread to other parts of the body. They vary in size from 1 cm upward, and a dry, horny, cauliflower-like appearance is characteristic. In most animals they regress spontaneously, but the warts may persist for 5 to 6 months, and in some cases for as long as 36 months, with serious loss of body condition.

Warts on the **teats** manifest with different forms depending on the papillomavirus type and may show an increasing frequency with age. The **frond forms** have filiform projections on them and appear to have been drawn out into an elongated shape of about 1 cm in length by milking machine action. If sharp traction is used, they can often be pulled out by the roots.

The second form is the flat, round type, which is usually multiple, always sessile, and up to 2 cm in diameter. The third form has an elongated structure appearing like a **rice grain**. Teat warts may regress during the dry period and recur with the next lactation.

Perianal warts are esthetically unattractive, but they do not appear to reduce activity or productivity. **Genital warts** on the vulva and penis make mating impracticable because the lesions are of large size, are friable, and bleed easily. They commonly become infected and flyblown. They occur on the shaft or on the glans of the penis in young bulls, may be single or multiple, are pedunculated, and frequently regress spontaneously.

Alimentary tract papillomas can occur anywhere from the mouth to the rumen. They often appear as lines of warts, suggesting a predisposing effect of trauma as a result of ingestion of roughage. Papillomas occur on the lateral and dorsal aspects of the tongue, soft palate, oropharynx, esophagus, esophageal groove, and rumen. Papillomas occurring in the esophageal groove and in the reticulum are a cause of chronic ruminal tympany. Papillomas also can progress to squamous-cell carcinoma in cattle, with an inevitable fatal outcome.[3]

Less common manifestations of papillomatosis in cattle include lesions in the **urinary bladder**, which cause no clinical signs but may predispose to enzootic hematuria. BPV-4 papillomas in the upper alimentary tract of cattle being fed bracken fern are the focus for transformation to squamous-cell carcinomas. Cattle fed bracken fern are immunosuppressed, which promotes the persistence and spread of the papillomavirus, and mutagens in bracken fern cause neoplastic transformation of papilloma cells.

Fig. 16-2 **Warts on the face of a yearling Belgian Blue bull.**

Fig. 16-3 **A, Warts (papillomas) on the neck and shoulders of a Holstein–Friesian heifer. B, Extensive warts (papillomas) on the face, neck, and shoulder of a yearling Hereford bull.**

Goats

Papillomas most commonly occur on the face and ears but may occur on the skin generally, especially on unpigmented skin. Most completely regress, others regress and recur, and occasional lesions progress to carcinomas. Papillomas that occur on the teats are persistent and may spread through the herd.

Horses

Warts are confined to the lower face, the muzzle, nose, and lips, and are usually sessile and quite small, rarely exceeding 1 cm in diameter. Papillomas also occur on the penis and prepuce of both geldings and stallions,[36] and much less commonly on the vulva. All ages can be affected. Spontaneous recovery of papillomas on the head is usual, but the warts may persist for 5 to 6 months.

Aural plaques in horses are well-delineated lesions that affect the concave aspect of the pinna with a flat surface of whitish keratinous crust covering a shiny and erythematous skin surface. Lesions are single or multiple and coalescing and, in some cases, can cover almost the entire surface of one or both pinnae (Fig. 16-4).[37] The lesions are usually not pruritic, but some horses with aural plaques resist bridling or handling of the ears. A common concern is cosmetic in show horses.

Squamous-cell carcinoma of the penis and prepuce is usually evident as ulcerations or mass lesions and can be complicated

Fig. 16-4 **Coalescing plaques covered with a keratinous crust occupying most of the concave aspect of the horse's left ear, as viewed from the front.** (Reproduced from Torres SMF et al. *Vet Dermatol* 2010; 21:503.)

by secondary bacterial infection.[36] Approximately 40% of affected horses have purulent or blood-stained preputial discharge. Preputial edema or the inability to prolapse the penis occurs in approximately 10% of horses.[36] Lesions are most commonly (~80%) located on the glans of the penis and can have papillomas neighboring the neoplastic tumor. Metastasis to inguinal lymph nodes is common as the disease progresses and is more likely in horses with poorly differentiated tumor.[27] Intrathoracic (lung) metastases are rare. Survival is related to the degree of differentiation of the tumor (log rank $P < 0.001$), with a greater proportion of horses with less differentiated tumors dying of the disease (papilloma, 8.3%; G1, 26.1%; G2, 26.3%; G3, 63.3%; where G1 = well differentiated, G2 = moderately differentiated, and G3 = poorly differentiated) (Fig. 16-5).[27]

CLINICAL PATHOLOGY

There are no specific changes in the hemogram or blood chemistry of affected cattle. As noted previously, papillomavirus can be detected in blood and semen of healthy and affected animals, varying with the species of animal and papillomavirus.

Biopsy of a lesion can be used to differentiate papillomas from squamous-cell carcinoma. Biopsy of classic "warts" is unnecessary. However, it may be advisable when large growths are found on horses to determine whether the lesion is a verrucose form of sarcoid. Microscopically, true papillomas consist of a hyperplastic epidermis with scant dermal tissue, whereas in fibropapillomas the dermal component tends to predominate. The need to identify the specific virus in a crop of warts creates a requirement for serologic and histologic examinations.

Detection of viral DNA is achieved by RT-PCR or PCR, and serologic tests are available to determine exposure to some papillomaviruses.[16,18,27,38-40] As with all PCR assays, care must be taken to ensure that the appropriate primers are used.[40]

DIFFERENTIAL DIAGNOSIS

Clinically, there is little difficulty in making a diagnosis of dermal papillomatosis, with the possible exception of atypical papillomas of cattle, probably associated with an unidentified type of the papillomavirus. These lesions are characterized by an absence of dermal fibroplasia and are true papillomas rather than fibropapillomas. All ages of animals can be affected, and the lesions persist for long periods. They are characteristically discrete, low, flat, and circular, and they often coalesce to form large masses. They do not protrude like regular warts, and the external fronds are much finer and more delicate.

Horses:

Sarcoid
Melanoma

TREATMENT

Warts can be removed by surgery or cryosurgery. Crushing of a proportion of small warts, or the surgical removal of a few warts, has been advocated as a method of hastening regression, but the tendency for spontaneous recovery makes assessment of the results of these treatments very difficult. Partial resection of a wart(s) in a horse does not always promote resolution of the residue. Surgical removal can be followed by vaccination with an autogenous vaccine, although the efficacy of this approach is unclear. There is anecdotal concern that surgical intervention, and even vaccination, in the early stages of wart development may increase the size of residual warts and prolong the course of the disease.

Aural plaques in horses can be treated by application of imiquimod, an immunomodulator, and antiviral agents, as 5% cream applied three times a week, every other week, for 6 weeks to 8 months. Crusts were removed before each application of the cream and required sedation in most horses. Complete resolution of lesions was noted in all horses at the cessation of treatment, and the long-term resolution rate was 88%.[37] Imiquimod is used for treatment of penile papillomas and squamous-cell carcinoma in humans, but its use in horses for this purpose is not reported. Imiquimod is used for treatment of sarcoids in horses.[41]

Vaccination

For cattle, autogenous vaccines prepared from wart tissues of the affected animal are effective in many cases. Commercially available vaccines are available for cattle but may be less efficacious; an autogenous vaccine prepared for a specific problem has the advantage of including the local virus types. The vaccine is prepared from homogenized wart tissue that is filtered and inactivated with formalin. Because of the different BPV types, care is required in the selection of the tissues. In general terms they can be selected based on tumor type, location, and histologic composition. The alternative is to use many types of tissue in the vaccine. Animal-to-animal variation in regression following vaccination of a group of calves with a vaccine prepared from a single calf in the group has been attributed to more than one BPV type producing disease in the group. The stage of development is also important, and the virus is present in much greater concentration in the epithelial tissue of older warts than young ones. The vaccine can be administered subcutaneously, but better results are claimed for ID injection. Dosing regimens vary, but 2 to 4 injections 1 to 2 weeks apart are commonly recommended. Recovery in 3 to 6 weeks is recorded in 80% to 85% of cases where the warts are on the body surface or penis of cattle, but in only 33% when the warts are on the teats. The response of low, flat, sessile warts to vaccination is poor. Development of DNA vaccines for prophylaxis or therapy (which will likely use different genes) is active but experimental at this time.[42]

Other treatments no longer commonly used include the injection into the wart of

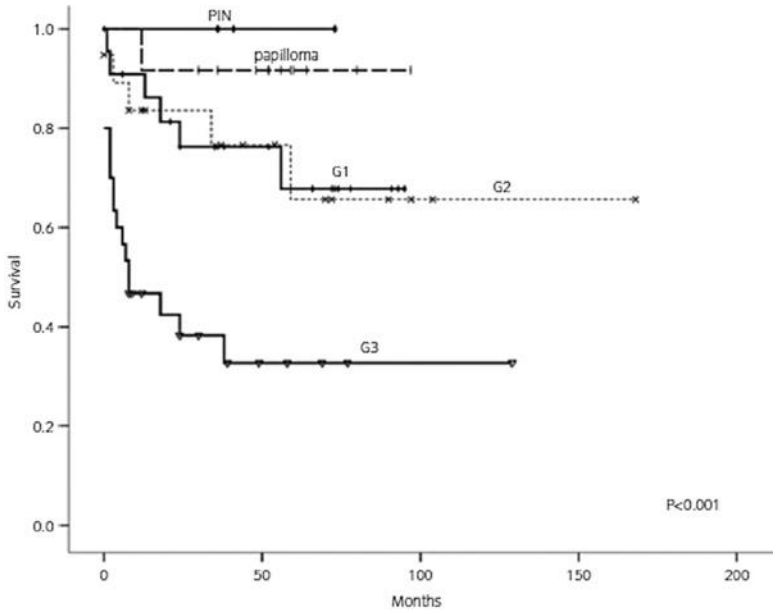

Fig. 16-5 Survival of horses with penile or preputial papilloma, or squamous-cell carcinoma (G1, well differentiated; G2, moderately differentiated; and G3, poorly differentiated. PIN, penile intraepithelial neoplasia). (Reproduced from van den Top JGB et al. *Equine Vet J* 2015; 47:188.)

proprietary preparations containing antimony and bismuth or the intralesional injection of bacille Calmette–Guérin (BCG).

CONTROL

Specific control procedures are usually not instituted or warranted because of the unpredictable nature of the disease and its minor economic importance.

Vaccination has been shown experimentally to be an effective prevention method and gives complete protection in cattle against stiff experimental challenge. The vaccine must contain all serotypes of the papillomavirus because they are very type-specific.

Avoidance of close contact between infected and uninfected animals should be encouraged, and the use of communal equipment between affected and unaffected animals should be avoided.

SARCOID

SYNOPSIS

Etiology Locally aggressive benign fibroblastic tumors of the skin associated with bovine papillomavirus (BVP) types 1 and 2 (BVP-1 and BVP-2).

Epidemiology Common tumor of equids, including horses, donkeys, mules, and zebras. Breed differences in prevalence. Transmission by close contact and infection of wounds.

Clinical findings Single or multiple lesions in the skin of limbs, lips, eyelids, eye, penile sheath, and base of the ears. Can present as warty growth or have the appearance of granulation tissue or as nodules beneath the skin. Spontaneous regression is rare.

Diagnostic confirmation Histopathology.

Treatment No single treatment modality has an advantage. Surgical excision, cryosurgery, immunotherapy, radiation, and local chemicals (intralesional cisplatin, acyclovir) are used.

Control None recognized.

ETIOLOGY

The cause of sarcoid in horses, mules, and donkeys is associated with infection by bovine papillomavirus (BPV) types 1 or 2, and possibly BPV-13.[1-6] Infection of young horses with BPV-1 virions induces nodular skin lesions 11 to 32 days after inoculation.[7] DNA of both types can be demonstrated in sarcoid tumors by PCR, as can the major transforming gene of BPV, E5, although papillomavirus has not been isolated from these tumors, nor have papillomavirus particles been demonstrated.[8] Variants of BPV-1 associated with sarcoids in horses have greater activity in equine cells than in bovine cells, indicating some adaptation or predilection of this variant for equine tissues.[9] The causative virus (BPV-1 or BPV-2) appears to vary geographically, with ~80% of cases in western Canada associated with BPV-2, as opposed to reports from other countries in which BPV-1 predominates.[10]

Genomic studies reveal that BPV-1 associated with sarcoids in horses likely diverged on multiple occasions from that in cattle at least 50,000 years before the present, and possibly much earlier, and well before domestication of either horses or cattle.[11]

It is speculated that this is a nonproductive infection in which viral DNA exists episomally, and a "hit-and-run" mechanism for pathogenesis has been proposed, in which infection by the virus, which resolves, induces changes that then lead to neoplastic transformation of tissue.[6]

However, given the demonstration of genetic susceptibility to sarcoid,[12] the cause is almost certainly multifactorial, with virus infection being an inciting event in susceptible animals. There does not appear to be a role for mutation in the tumor suppressor gene, *p53*, in the development of sarcoid in horses.

EPIDEMIOLOGY

Occurrence and Prevalence

Horses, donkeys, mules and zebras are affected, as are giraffes and sable antelope.[13-16] Skin lesions histologically similar to those in equids also occur in felids.[17] Equine sarcoid is the **commonest neoplasm** in horses, representing about 20% of all equine tumors diagnosed at necropsy, ~46% of all neoplastic skin lesions in horses at two sites in North America, and lesions in 21 of 68 horses examined in a first-opinion practice in the United Kingsom.[18,19] Sarcoids were the histologic diagnosis in 42% of skin samples submitted to veterinary diagnostic laboratories in Canada.[10]

Sarcoid tumors occur in 0.7% to ~11% of 3-year-old Swiss warmbloods[20] and 0.4% of Freiberger horses in Switzerland. Sarcoids made up 53% of all tumors located on the head and body.[18] Sarcoids occurred as solitary tumors in more than 99% of horses.[18]

Methods of Transmission

Transmission can be by infection of wounds, and castration is thought to be a risk factor, with flies as possible vectors. Close contact may facilitate transmission. BPV DNA has been detected in flies (*M. autumnalis*, *M. domestica*) and biting stable flies (*S. calcitrans*) associated with horses and donkeys with sarcoids.[21]

Experimental Reproduction

The disease has been transmitted with sarcoid tissue and cell free supernatant from minced sarcoid tumors. The disease has also been reproduced with bovine papillomavirus, although the experimentally produced tumors subsequently regressed, which seldom occurs with natural sarcoid.[6]

Animal Risk Factors

Horses with sarcoids had a mean age of 7 years (95% CI, 7.9 to 8.5 years). Horses with fibroblastic sarcoids are younger (median age of 5 years, range 0.6 to 25 years) than those with nodular (median 7, range 1.0 to 23), occult (median 7, range 1.1 to 21), verrucose (median 6, range 0.5 to 19), or mixed (median 6, range 0.5 to 31) sarcoids.[10] This wide age range highlights that sarcoids occur in young horses in addition to more aged animals. Risk of sarcoids was not associated with age or breed in two studies,[10,18] but other studies report that Appaloosa, Arabian, and Quarter horses are at greater risk than are Standardbreds or Thoroughbreds. Donkeys were overrepresented in one study,[10] and prevalence of disease was greater in populations of inbred zebra populations than in outbred populations (53% vs. 2%).[13]

There is a **genetically based susceptibility** to the disease, and the predisposition of horses to sarcoid is associated with the type of **major histocompatibility complex,** although this association is not universally accepted.[12] There are quantitative trait loci on equine chromosome (ECA) 20, 23, and 25 associated with genes that regulate virus replication and host immune responses.[22] Approximately 40% of the susceptibility to the disease in Swedish Halfbred horses is attributable to an autosomal-dominant equine leukocyte antigen (ELA)-linked gene. However, Swiss Warmbloods are no more likely to have the disease if their parent is diagnosed with sarcoids than if the sire is free of the disease.[20]

Environmental Risk Factors

Lesions commonly occur on traumatized areas.

PATHOGENESIS

The virus infects fibroblasts, and the infection is nonproductive. Viral DNA can be detected in lesional tissue, although viral load varies only slightly with clinical type of sarcoid.[2,23] However, intralesional viral load is directly associated with the severity of the disease.[24] It is thought that virus capsids of BVP are not found in equine sarcoids because papillomaviruses are usually host specific and the expression of virus capsids of the bovine papillomavirus requires the cellular environment of keratinocytes of the host species. Fibroblasts isolated from sarcoids are highly invasive, an attribute related to the high level of viral gene expression,[2,24] matrix metalloproteinase upregulation,[25] and production of viral oncoproteins.[26-28] Protein products of E5 and E6 enhance cell proliferation and, in vitro, increased invasion in EqS02a cells, and E7 enhances independence of cell anchorage independence, all attributes of neoplastic cells.[29] Elevated expression of phosphorylated p38 occurs in fibroblasts infected with BPV-1 as a result of the expression of BPV-1 E5 and E6 with enhancement of phosphorylation of the MK2 kinase, a substrate of *p38*, suggesting cellular mechanisms for the neoplastic transformation of infected cells.[30] Expression levels of FOXP3, interleukin-10, and interferon gamma mRNA (markers of regulatory T cells) and BPV-1 E5 copy numbers are significantly increased in lesional compared with tumor-distant skin samples from horses with sarcoids, suggesting local, regulatory, T-cell-induced immune suppression.[27]

Sarcoids do not regress, in contrast to the majority of papillomavirus infections, probably because expression of BPV in equine cells elicits immune evasion mechanisms.

CLINICAL FINDINGS

Sarcoids are localized proliferations of epidermal and dermal tissue that may remain small and dormant for many years and then undergo a stage of rapid, cancer-like growth. The lesions show moderate malignancy but do not metastasize to other sites, although there are sometimes (~2% of horses or 20% 30% of horses with sarcoids) multiple lesions.[10,20] Sarcoids occur as single or, more commonly, multiple lesions or clusters in the skin. The lesions occur anywhere on the body, but are more common on the head. Tumors on the head are 2.3 (95% CI, 2.0 to 2.7) times as likely to be sarcoids, compared with any other tumor type. Of 746 horses with sarcoids, 41% were on the head, 20% on the limbs, 16% on the neck or shoulder, 11% on the abdomen, 8% on the axilla or chest, and 5% in paragenital regions.[10]

Several forms of sarcoid are described:

- Verrucous (warty) sarcoid is a dry, horny, cauliflower-like surface that is usually partially or completely hairless. It may be broad based (sessile) or pedunculated. Verrucous sarcoids occur most commonly on the face, body, groin, and sheath area.
- Fibroblastic sarcoid has a similar appearance to that of proud flesh or excessive granulation tissue. It is often a firm, fibrous nodule in the dermis, although the surface may be ulcerated. It is found most commonly at sites of previous wounds and also the eyelid and limbs.
- A combination of both of the forms just described ("mixed")
- Occult sarcoid is typically an area of slightly thickened skin that has a roughened surface. It is usually partially hairless. Interference with these slow-growing sarcoids, including attempts at treatment, should be avoided; such interference can cause the tumor to proliferate. They occur most commonly around the mouth and eyes and on the neck.

CLINICAL PATHOLOGY

Confirmation of the diagnosis requires a **biopsy specimen** for histologic examination. Because sarcoids are usually associated with excessive granulation tissue and pyogranulomatous debris, the preferred specimen is a **transverse section of the excised tumor**. If punch biopsies are to be collected, then care should be taken that they include a representative section of the tumor, not just peripheral granulation tissue and edematous nontumor material. Examination by a pathologist accustomed to examining equine skin sections is important because the tumor has some features in common with papillomas and sarcomas and can be easily misdiagnosed.

PCR has been used to detect and quantitate BPV DNA.[31,32]

DIFFERENTIAL DIAGNOSIS

Cutaneous habronemiasis
Phycomycosis
Fibromas
Granulation tissue
Squamous-cell carcinoma, especially of the penis and eyelid
Other skin tumors, including melanoma, by examination of a biopsy of the lesion
Papillomatosis

TREATMENT

Surgical excision results in the return of the tumor in a significant proportion of animals within 6 months, often with overproliferation. BPV DNA can be detected in normal skin immediately surrounding sarcoids, and the recurrence has been speculated to reflect activation of latent BPV in normal tissue surrounding the tumor, although this interpretation is not supported by objective measurement of viral load in skin margins of the excised lesions.[33]

Intralesional administration of **cisplatin**, an oncolytic agent with in vitro activity against sarcoids cells,[34] by injection into the sarcoids or by electrochemotherapy, results in cure rates of 96% and 98%, respectively.[35,36] The protocol for intralesional injection of cisplatin in sesame seed oil is as follows:[36]

1. Crystalline lyophilized cisplatin powder is reconstituted with sterile water at a concentration of 10 mg/mL and mixed with medical-grade sesame seed oil (60%) and sorbitan monooleate (7%) by use of the pumping method just before administration (3.3 mg of cisplatin/mL of mixture).
2. Dosing objective is to deliver 1 mg of cisplatin per cubic centimeter of tumor. Tumor volume is calculated from the formula $V = \pi \times D1 \times D2 \times D3/6$, where D1 through D3 are tumor diameters measured with Vernier calipers.
3. Four intratumoral administrations of cisplatin are given at 2-week intervals of a series of intratumoral and peritumoral injections in 1 or 2 parallel planes, depending on the tumor size. The cisplatin emulsion is injected through narrow-bore needles (22 or 25 gauge). The spacing between injection rows is uniform, with a separation of 6 to 8 mm. The spacing between planes of injection is approximately 1 cm.

The largest dose of cisplatin to an adult horse should be not greater than 85 mg. Adverse reactions include moderate skin irritation. The treatment can be combined with surgical debulking of the lesion, with cisplatin administration begun when the surgical site has healed.[36]

Administration of **imiquimod** 5% cream to sarcoids three times weekly resulted in a cure rate of 60% in a study involving 15 horses.[37] Topical application of acyclovir (5%

cream) daily for 2 months to 47 sarcoids in 22 horses resulted in cure of 68%, with regression of tumor size in the remaining horses.[38]

Cryotherapy is associated with a much lower recurrence rate, but its use is limited by the anatomic location of the tumor. For instance, cryotherapy is not recommended for periocular lesions because of the risk of damaging nearby ocular tissues. The efficacy of cryotherapy may be enhanced by the use of thermocouples to monitor the temperature of the lesion to ensure adequate freezing. At least two or three freeze–thaw cycles are necessary.

Radiation therapy using radon-222, gold-198, radium-226, cobolt-60, or iridium-192 has been used and is indicated for recurrent or surgically inaccessible sarcoids such as periocular sarcoid. Radiation therapy is also useful for treating sarcoids of the body and legs. Local hyperthermia induced by a radiofrequency current of 2 MHz is also reported to be effective.

Immunotherapy, by injection of live organisms, killed bacilli, or cell-wall extract of the bacillus of Calmette and Guerin (BCG) have been successful on occasion, but their efficacy depends on the size of the lesion, its anatomic location, and possibly its type. Immunotherapy may work by inducing tumor-specific immunity. Adverse effects include local reactions characterized by edema and systemic anaphylactoid reactions after the second or third injections if commercial, whole-cell vaccines are used. Vaccines composed of cell-wall fractions in oil are free of such reactions and have given good results in periocular lesions, but sarcoids of the axilla did not react favorably. Large sarcoids or cases with multiple lesions may also respond poorly. Immunotherapy using mycobacterial cell-wall skeleton combined with trehalose dimycolate has resulted in total tumor regression.

Autogenous vaccines might result in the regression of existing sarcoids but have the risk of inducing new tumors and are not recommended for routine therapy. Use of acupuncture to treat sarcoids is reported, but there is little scientific justification for using this procedure.[39]

As yet, no single treatment modality is universally successful in the treatment of sarcoid. In a study in 92 horses comparing outcome, a successful outcome was obtained in 79% of horses treated with cryosurgery, 67% of those treated with BCG vaccination, 82% of those treated with conventional excision, and 71% of those treated using carbon dioxide laser. Greater success rates are reported for intralesional administration of cisplatin, and possibly for imiquimod and acyclovir.[35-38]

COWPOX AND BUFFALOPOX

SYNOPSIS

Etiology Cowpox and buffalopox virus are members of the genus *Orthopoxvirus* in the family Poxviridae. Buffalopox is a close variant of vaccinia virus.

Epidemiology Cowpox is endemic in the population of certain rodents in Europe and East Asia. Cattle are a rare and incidental host. Buffalopox is a (re) emergent disease occurring in buffaloes, cattle, and humans in India and neighboring countries. The natural host of buffalopox virus has not yet been identified. Spread of both viruses is by contact.

Clinical findings Typical pox lesions on the teats and udder. Erythema, papules with a zone of hyperemia around the base, vesiculation, pustular stage, and scab.

Clinical pathology Electron microscopy, polymerase chain reaction (PCR).

Diagnostic confirmation Electron microscopy, PCR, and virus isolation.

Treatment Palliative.

Control Sanitation to prevent spread between cows.

ETIOLOGY

Cowpox virus (CPXV) and buffalopox virus (BPXV) are members of the genus *Orthopoxvirus* in the family Poxviridae. Other orthopoxviruses infecting agricultural animals include horsepox, Uasin Gishu, and camelpox. All orthopoxviruses are antigenically extremely similar, but they can be identified by a combination of phenotypic and genetic tests.

CPXV received its name as a result of the association of this agent with skin lesions on the teat and udder skin of dairy cattle. Notwithstanding, it is probably a misnomer because infection of cattle is rare, whereas infection is widespread among rodents in Europe and western Asia.

EPIDEMIOLOGY

Occurrence

Infection with CPXV is **endemic in wild rodents** such as voles (*Microtus* spp.) in **Great Britain, Europe, and western Asia**, with infection in different rodent species acting as the reservoir host in different geographic areas. Domestic cats are commonly infected from hunting rodents, but CPXV infection can occur in a number of different mammalian species, one of which is cattle. The clinical syndrome of cowpox in cattle is now extremely rare, but it occurs sporadically in Europe. In recent decades, reemergence of CPXV infections in cats, zoo animals, and humans has been reported.[1]

BPXV was first isolated in India in the early 1930s, and disease outbreaks affecting buffaloes, cattle, and humans have been reported in India, Nepal, Pakistan, Egypt, and Indonesia since then.[2] BPXV is considered an important emerging or reemerging zoonotic viral infection in regions with a large buffalo population.[3] A similar but **distinct vaccinia-like virus** has been associated with disease outbreaks among cattle and humans in **Brazil.**[2]

Origin of Infection and Transmission

The origin of CPXV infection is most probably from infected farm cats or humans. **Transmission** from cow to cow within a herd is effected by milkers' hands or teat cups. Spread from herd to herd is probably effected by the introduction of infected animals, by carriage on milkers' hands, and in the absence of either of these methods, transport by biting insects is possible. In a herd in which the disease is enzootic, only heifers and new introductions develop lesions. Milkers recently vaccinated against smallpox may serve as a source of infection for cattle, although the **vaccinia virus**, the smallpox vaccine virus, is a different virus.

BPXV is most commonly isolated from buffaloes, cattle, and people having direct and frequent contact with these animals. Although a primary host species functioning as virus reservoir has not yet been identified for BPXV, peridomestic rodents have been incriminated as potential vectors.[4] Because disease outbreaks in buffalo herds are often associated with high disease occurrence among animal handlers and caretakers, transmission from animal to animal by means of people as vectors is considered to play an important role.[3]

It is generally assumed that the virus gains access to tissues through injuries to teat skin, and extensive outbreaks are likely to occur when the environment is conducive to teat injuries. Spread is rapid within a herd and immunity is solid, so that the disease tends to occur in sharp outbreaks of several months in duration, with subsequent immunity protecting the cattle for at least several years.

Economic Importance

Losses are a result of inconvenience at milking time because of the soreness of the teats and from occasional cases of mastitis, which develop when lesions involve teat sphincters and decreased milk production.

Zoonotic Implications

Human cowpox is not common, although the disease incidence has increased over the past decades, an observation that has been explained by increasing susceptibility of the human population to poxvirus infection following discontinuation of smallpox vaccination in most parts of the world.[5] Clinical cases in humans usually consist of one or a few lesions on the hand and face with minimal systemic reaction and are most commonly traced back to infected cats or occasionally rats rather than cattle.[1]

An increasing incidence of clinical cases of BPXV and Brazilian vaccinia-like virus infection has been reported in humans, particularly among animal caretakers and animal handlers in India but also in Brazil, and has become a serious public health concern in some countries.[2,3] Consumption of unpasteurized milk of affected animals has been incriminated as potential route of virus transmission from animal to human.

PATHOGENESIS

Five stages of a **typical pox eruption** can be observed. After an incubation period of 3 to 6 days, a roseolar erythema is followed by firm, raised papules light in color but with a zone of hyperemia around the base. Vesiculation, a yellow blister with a pitted center, follows. The subsequent pustular stage is followed by the development of a thick, red, tenacious scab.

In experimentally produced **vaccinia virus** mammillitis (produced by inoculation of smallpox vaccine), the lesions have three zones: a central brown crusty area of necrosis, surrounded by a gray–white zone of microvesicle formation, again surrounded by a red border as a result of congestion. The lesions are essentially hyperplastic.

CLINICAL FINDINGS

Typical **lesions** are similar for CPXV and BPXV infection and may be seen at any stage of development, but they are mostly observed during the scab stage, with the vesicle commonly having been ruptured during milking. True cowpox scabs are 1 to 2 cm in diameter and are thick, tenacious, and yellow–brown to red in color. In cows being milked, scab formation is uncommon, with the scab being replaced by a deep ulceration.

Distribution of the lesions is usually confined to the teats and lower part of the udder. Soreness of the teats develops, and milk letdown may be interfered with; the cow usually resents being milked. Secondary mastitis occurs in a few cases. Individual lesions heal within 2 weeks, but in some animals fresh crops of lesions may cause the disease to persist for a month or more. In severe cases, lesions may spread to the insides of the thighs, and rarely to the perineum, vulva, and mouth. Sucking calves may develop lesions around the mouth. In bulls, lesions usually appear on the scrotum.

Ulcerative skin lesions with raised edges frequently affected by secondary bacterial or fungal infection are commonly observed on the ears of nonlactating cattle and buffaloes infected with BPXV.[3]

CLINICAL PATHOLOGY

The virus can be propagated in tissue culture, and differentiation is possible by electron microscopy. The presence of virus-related DNA sequences can be identified by means of PCR.

DIFFERENTIAL DIAGNOSIS

A number of skin diseases may be accompanied by lesions on the udder and can easily be confused with cowpox if the lesions are advanced in age. Most outbreaks of teat skin disease that clinically resemble classical cowpox are associated with vaccinia virus from contact with a recently vaccinated person.

Pseudocowpox

Bovine ulcerative mammillitis associated with bovine herpesvirus-2 and bovine herpesvirus-4

Vesicular stomatitis and foot-and-mouth disease

Udder impetigo

Teat chaps and frostbite

Black spot

CONTROL

Prevention of spread is difficult because the virus responsible for the disease is readily transmitted by direct or indirect contact. Udder cloths, milking machines, and hands should be disinfected after contact with infected animals. Dipping of the teats in an alcoholic tincture of a suitable disinfectant, such as quaternary ammonium compounds, is usually satisfactory in preventing immediate spread. Although the prevalence and significance of CPXV infection in cattle is too low to warrant the development of vaccines, the emergence of buffalopox in buffalo and cattle herds and the ensuing zoonotic risk in some parts of the world may warrant considering the development of vaccines against BPXV for certain regions of the world.[3]

PSEUDOCOWPOX (MILKERS' NODULE)

SYNOPSIS

Etiology Parapoxvirus.

Epidemiology Primarily affects cows in early lactation. Low, but progressive, morbidity in herd. Spread during milking.

Clinical findings Vesicles, pustules, formation of a thick scab elevated by granulating tissue. Key distinguishing feature is horseshoe-shaped ring of small scabs surrounding granulating tissue on the teat.

Clinical pathology Vesicle fluid for electron microscopy.

Diagnostic confirmation Electron microscopy.

Treatment Antiseptics and emollient ointment.

Control Milking hygiene.

ETIOLOGY

Pseudocowpox virus is a member of the genus *Parapoxvirus*, with close similarity to the viruses of infectious papular stomatitis of cattle and contagious ecthyma of sheep and goats. It is possible that pseudocowpox virus (PCPV) might be identical to bovine papular stomatitis virus (BPSV).[1,2] The pseudocowpox virus was previously known as parapoxvirus bovis 2.

EPIDEMIOLOGY

Occurrence

Pseudocowpox is reported in **most countries**. In an affected herd the rate of spread is relatively slow and may result in the disease being present in the herd for up to a year. The **morbidity** rate approximates 100%, but at

any given time it varies between 5% and 10%, and occasionally up to 50%.

Origin of Infection and Transmission

The source of infection is **infected cattle**. The method of **transmission** includes physical transport by means of contaminated milkers' hands, washcloths, and teat cups. The virus cannot penetrate mucosa, and a preexisting discontinuity of it is necessary for the virus to gain entry. Transmission by biting insects seems likely. The virus can be isolated from the mouths of calves sucking affected calves, and from the semen of bulls.

Animal Risk Factors

Freshly calved and **recently introduced** cattle are most susceptible, but **all adult cattle** in a herd, including dry cows, are likely to be affected. The disease does not appear to occur in animals less than 2 years of age unless they have calved. There is no seasonal variation in incidence. Little immunity develops, and the disease is likely to recur in the herd within a short time.

Economic Importance

Pseudocowpox is relatively benign, with most losses occurring as a result of difficulty in milking and an increase in the incidence of mastitis.

Zoonotic Implications

The disease is transmissible to humans, with infection usually resulting in the development of milkers' nodule on the hand.

PATHOGENESIS

Transmission most commonly occurs at milking time and is mechanical, with the potential for transmission from cow to calf by suckling. The disease can be reproduced by the introduction of the virus onto scarified areas of skin. The lesions are characterized by hyperplasia of squamous epithelium.

CLINICAL FINDINGS

Acute and chronic lesions occur, and there may be up to 10 lesions on one teat (the udder is very rarely infected). **Acute lesions** commence as erythema followed by the development of a vesicle or pustule, which ruptures after about 48 hours, resulting in the formation of a thick scab. Pain is moderate and present only in the prescab stage. The scab, varying in size from 0.5 to 25 mm in diameter, becomes markedly elevated by developing granulating tissue beneath it; the scabs drop off 7 to 10 days after lesions appear, leaving a **horseshoe-shaped ring** of small scabs surrounding a small, wart-like granuloma, which may persist for months. The disease tends to disappear from a herd after 18 to 21 days but may recur cyclically about 1 month later. There are reports of lesions occurring occasionally in cows' mouths.

Chronic lesions also commence as erythema, but progress to a stage in which yellow–gray, soft, scurfy scabs develop. The scabs are readily rubbed off at milking, leaving the skin corrugated and prone to chapping. There is no pain, and the lesions may persist for months.

Milkers' nodules are clinically indistinguishable from human lesions associated with ecthyma virus. The lesions vary from multiple vesicles to a single, indurated nodule.

An outbreak of pseudocowpox infection occurred in Brazil, characterized by the presence of severe vesicular, papulopustular, and proliferative scabby lesions on the muzzle of 14 crossbred calves that did not have contact with dairy cattle.[2] The lesions started as macules and papules on the muzzle that progressed to vesicles, pustules, and scabs with a clinical course of 10 to 15 days, at which time the lesions spontaneously resolved. Nucleotide sequencing of the virus isolated from the lesions revealed 97% homology with pseudocowpox virus and only 84% homology with bovine popular stomatitis virus.[2]

CLINICAL PATHOLOGY AND NECROPSY FINDINGS

Material for examination by tissue culture or electron microscopic examination, the latter being highly recommended as a diagnostic procedure, should include fluid from a vesicle.

DIFFERENTIAL DIAGNOSIS

Differentiation of those diseases in which lesions of the teat are prominent is dealt with in the preceding section on cowpox.

TREATMENT

Locally applied ointments of various kinds appear to have little effect on the lesions. The recommended treatment includes the removal of the scabs, which should be burned to avoid contaminating the environment, application of an astringent preparation, such as triple dye, after milking and an emollient ointment just before.

CONTROL

Recommended measures, such as treatment and isolation of affected cows or milking them last, the use of disposable paper towels for udder washing, and disinfection of teat cups, appear to have little effect on the spread of the disease. An iodophor teat dip is recommended as the most effective control measure because it appears to exert some antiviral effect. An effort should be made to reduce teat trauma because infection is facilitated by discontinuity of the skin.

LUMPY SKIN DISEASE (KNOPVELSIEKTE)

SYNOPSIS

Etiology Lumpy skin disease virus, of the genus *Capripoxvirus* (closely related to sheep and goatpox viruses).

Epidemiology Previously enzootic in sub-Saharan Africa, but expanded into most of Africa in the 1970s. The disease is now actively spreading in the Middle East, with outbreaks in Israel, Lebanon, Turkey, Syria, Iran, Azerbaijan, and North Cyprus. Epizootics interspersed with periods of sporadic occurrence. Transmission by contact and a range of sucking/biting arthropod vectors.

Clinical findings Fever, nodular lesions on the skin and mucous membranes and lymphadenopathy. A proportion of cattle develop generalized infection, with high mortality. Losses accrue from damage to hides, decreased milk yield and growth, abortion, deaths, and disruption of international trade. Necrotic plugs of tissue highly susceptible to secondary infection and flystrike.

Clinical pathology Intracellular, eosinophilic inclusion bodies in biopsy material. Virus isolation. Fluorescent antibody, serum neutralization, and polymerase chain reaction (PCR) tests.

Necropsy findings Nodules in skin, upper alimentary tract, respiratory tract.

Diagnostic confirmation Biopsy and histology. Virus isolation to differentiate from pseudo lumpy skin disease caused by bovine herpesvirus-2.

Treatment Supportive.

Control Vaccination, control of movement of cattle from affected areas.

ETIOLOGY

Lumpy skin disease (LSD) is a severe systemic disease of cattle associated with the Neethling poxvirus, a *Capripoxvirus*. It has close antigenic relationship to sheeppox and goatpox viruses, which are in the same genus. There appears to be a difference in virulence between strains.

EPIDEMIOLOGY

Occurrence

The disease used to be confined to sub-Saharan Africa, but spread to many other African countries in the 1970s, then Egypt (outbreaks occurred in 1988 and 2006; the disease is now enzootic) and Israel (outbreaks in 1989, 2006-2007, and 2012). In Israel it was initially eradicated by slaughter of infected and in-contact animals, but vaccination using Sheeppox, and more recently Neethling strain vaccine, has since been used. The virus is actively spreading within and from the Middle East, with cases

confirmed in Kuwait (1991), Lebanon (1993), the United Arab Emirates (2000), Bahrain (2003), Oman (2010), Turkey and Syria (2013), Jordan (2013), Iran and Iraq (2013), Azerbaijan and North Cyprus.[1-3] There is a risk it could be introduced into European countries, mainly through the illegal movement of animals but also within vectors.[2,3]

Some outbreaks are associated with severe and generalized infections and a high mortality rate, whereas others have few obviously affected animals and no deaths. In general, outbreaks are more severe following introduction of the infection into a region and then abate, probably associated with the development of widespread immunity. Morbidity rates can reach 80% during epizootics, but typically range from 10% to 30% in enzootic areas. In Kenya, the disease is milder, with a lower morbidity rate and an average case fatality of 2%. Outbreaks in Israel produced no direct mortality from the disease. A resurgence of the disease in South Africa was associated with higher rainfall and a decrease in the use of vaccination.

Origin of Infection and Transmission

The virus is present in the nasal and lacrimal secretions, semen, and milk of infected animals. However, direct contact is not thought to be the major source of transmission, with most cases associated with transmission by an arthropod vector. LSD virus has been isolated from *S. calcitrans* and *M. confiscata* and transmitted experimentally using *S. calcitrans* and *Ablyomma* and *Rhipicephalus* ticks, with evidence that the virus may be transmitted vertically and overwinter in these tick species.[4,5] Other vectors are suspected, including *Biomyia*, *Culicoides*, *Glossina*, and *Musca* spp. However, although the virus was detected in mosquitoes (*Anopheles stephensi*, *Culex quinquefascuatus*), stable flies, and biting midges (*Culicoides nebeculosis*) after feeding on cattle with lumpy skin disease, infection did not transmit to susceptible cattle when these arthropods were subsequently allowed to feed on them.

Transmission via infected semen used in artificial breeding has been demonstrated experimentally.[6]

Risk Factors

Animal Risk Factors

All ages and types of cattle are susceptible, although very young calves and lactating and malnourished cattle develop more severe clinical disease. Recently recovered animals are immune for about 3 months.

British breeds, particularly Channel Island breeds, are much more susceptible than zebu types, both in numbers affected and the severity of the disease. Wildlife species are not affected in natural outbreaks, although there is concern that they might be reservoir hosts in interepidemic periods, such as African buffalo (*Syncerus caffer*) in the Kruger National Park in South Africa.[7] Typical skin lesions, without systemic disease, have been produced experimentally with Neethling virus in sheep, goats, giraffes, impalas, and Grant's gazelles, but wildebeests were resistant. Natural cases of lumpy skin disease were recorded in water buffalo (*Bubalis bubalis*) during an outbreak in Egypt in 1988, but morbidity was much lower than for cattle (1.6% vs. 30.8%).

Environmental Risk Factors

Outbreaks tend to follow waterways. Extensive epizootics are associated with high rainfall and high levels of insect activity, with peaks in the late summer and early autumn. Introduction of new animals and communal grazing have been identified as risk factors for LSD infection in Ethiopia.[8]

Pathogen Risk Factors

Capripoxviruses are resistant to drying and able to survive freezing and thawing, but most are inactivated by temperatures above 60° C (140 F).

Experimental Transmission

Experimental transmission can be achieved with ground-up nodular tissue, blood, or virus grown in tissue culture given by intranasal, ID, or IV routes. Although lumpy skin disease is characterized by generalized nodular skin lesions, less than 50% of natural or experimental infections develop generalized skin nodules. The length of viremia is not correlated with the severity of clinical disease.

Economic Importance

The mortality rate is usually low (although it can be 10% or more), but economic losses are high. There is reduced feed intake, a reduction in milk production, and occurrence of secondary mastitis associated with lesions on the teats. Losses also accrue from hide damage, reduced body condition, decreased fertility in bulls, and abortion in cows. There has always been a high risk of LSD spreading out of Africa, and it is now actively spreading in the Middle East. It is also a potential agent for agricultural bioterrorism.

PATHOGENESIS

In the generalized disease there is viremia and fever, followed by localization in the skin and development of inflammatory nodules. Following ID inoculation, local lesions develop at the challenge site but without viremia and systemic infection.

CLINICAL FINDINGS

The incubation period is typically 2 to 4 weeks in field outbreaks and 7 to 14 days following experimental challenge. In severe cases there is an initial rise of temperature, which lasts for over a week, occasionally accompanied by lacrimation, nasal discharge, salivation, and lameness. Multiple intradermal nodules appear suddenly about a week later, often initially on the perineum. They are round and firm, 1 to 4 cm in diameter, and flattened, and the hair on them stands on end. They vary from a few to hundreds and, in most cases, are confined to the skin. However, lesions can occur elsewhere, such as in the nostrils and on the turbinates, causing mucopurulent nasal discharge, respiratory obstruction, and snoring; in the mouth, as plaques and then ulcers, causing salivation; on the conjunctiva, causing severe lacrimation; and on the prepuce or vulva, spreading to nearby mucosal surfaces. In most cases the nodules disappear rapidly, but they may persist as hard lumps or become moist and necrotic, then slough.

Lymph nodes draining the affected area become enlarged, and local edema can occur, particularly of the limbs. When the yellow center of nodules slough, this can expose underlying tissues, including testicles or tendons. Lesions where skin is lost may remain visible for long periods. When lesions coalesce, large areas of raw tissue can be exposed, and these are susceptible to invasion with screwworm fly larvae. Lesions in the respiratory tract are often followed by pneumonia.

Convalescence usually takes 4 to 12 weeks, and pregnant cows may abort.

CLINICAL PATHOLOGY

The virus can be cultivated from lesions, and the viral antigen can be detected by a variety of PCR tests. Viral DNA can be detected in the skin up to 90 days after infection using PCR, which is much longer than the virus can be isolated. An antigen ELISA has also been used with samples collected early in the course of the disease, before the development of neutralizing antibodies. Electron microscopy will identify capripox virions in skin biopsies or scabs. This must be used in combination with the history of generalized nodular skin disease; capripox can be distinguished from parapoxvirus (the agent of bovine papular stomatitis) and pseudocowpox, but it is morphologically similar to cowpox and vaccinia viruses. Histopathology of lesions reveals a granulomatous reaction in the dermis and hypodermis, with intracellular, eosinophilic inclusion bodies in early lesions.

Virus neutralization is the most specific serologic test, but immunity is predominantly cell mediated, and thus it may fail to detect low concentrations of antibodies in many exposed cattle. The agar gel immunodiffusion (AGID) and indirect fluorescent antibody tests are less specific, producing false positives as a result of cross-reaction with bovine papular stomatitis and pseudocowpox viruses.

NECROPSY FINDINGS

The skin lesions are described under "Clinical Findings." Similar lesions are present in the mouth, pharynx, trachea, skeletal muscle,

bronchi, and stomachs, and there may be accompanying pneumonia. The superficial lymph nodes are usually enlarged. Respiratory distress and death are often the result of respiratory obstruction by the necrotic ulcers and surrounding inflammation in the upper respiratory tract, often with concurrent aspiration pneumonia. Histologically, a widespread vasculitis reflects the viral tropism for endothelial cells. Intracytoplasmic viral inclusion bodies may be seen in a variety of cells types.

Samples for Confirmation of Diagnosis

- **Histology**—formalin-fixed lesions from skin, alimentary and respiratory tissue, lymph node (LM)
- **Virology**—lymph node, skin lesion (ISO, EM)
- **Antigen detection**—affected tissue, blood, semen (PCR, antigen ELISA).

DIFFERENTIAL DIAGNOSIS

The rapid spread of the disease and the sudden appearance of lumps in the skin after an initial fever make this disease quite unlike any other disease of cattle.

Pseudolumpy skin disease (also known as Allerton virus infection and general infection of cattle with bovine herpesvirus-2), is associated with bovine herpesvirus-2, the agent of bovine mammillitis. It occurs primarily in southern Africa, although occasional cases occur in the United States, Australia, and the United Kingdom. Multifocal lesions are distributed over the body, are circular and up to 2 cm in diameter, and have an intact central area and raised edges, accompanied by loss of hair. Some lesions show a circular ring of necrosis around a central scab. The scabs fall off, leaving discrete hairless lesions that may be depigmented. The disease runs a course of approximately 2 weeks, and there is no mortality. Only the superficial layers of skin are involved. This is in contrast to the lesions of lumpy skin disease, which are often deep enough to expose underlying tissues. Herpesvirus can be isolated from the periphery of the lesions. Diagnosis can be made by polymerase chain reaction (PCR) on full-thickness skin biopsy.

TREATMENT

No specific treatment is available, but prevention of secondary infection with antibiotics or sulfonamides is recommended.

CONTROL

Lumpy skin disease moves into new territory principally by movement of infected cattle, and possibly by wind-borne vectors. Once in a new area, further spread probably occurs via insect vectors, and ticks have been implicated in maintaining the virus in between epidemics.[4,5] Control of cattle movement from uninfected to infected areas is an important measure to prevent the introduction of the virus. Once in an area, control is by vaccination.

Vaccination

Freeze-dried, live attenuated vaccines are commercially available and the most commonly used. There is antigenic homology between the *Capripoxviruses,* and thus vaccination of cattle with attenuated sheeppox virus has been used to protect against infection with LSD virus. This was used in countries previously free of LSD virus because it eliminated any risk of escape of attenuated live vaccine virus from vaccinated herds. However, incomplete protection with a vaccine based upon what was thought to be a Kenyan sheep and goatpox occurred during a 2006 outbreak of LSD in Egypt, and following the use of a sheeppox vaccine in Israel in 2006-2007 in which 11% of vaccinated cattle developed skin lesions.[3] Consequently, the attenuated Neethling strain vaccine of LSD virus was used in response to a serious outbreak of the disease in Israel during 2012. A battery of three molecular tests was able to differentiate infection with the vaccine strain, and a virulent virus was developed; no spread from vaccinated to nonvaccinated cattle was recorded.[9]

A small percentage of cattle vaccinated with the sheeppox virus do develop local granulomatous reactions, but there is no spread of the virus to sheep running with the cattle. However, the commonly used Kenyan sheeppox and goatpox vaccine virus (designated O-240) has been identified as an LSD virus; the low attenuation of this virus probably makes it unsafe for cattle because of its potential to cause clinical disease in vaccinated animals.[10] Other viruses capable of infecting sheep, goats, and cattle have been identified as potential candidates for vaccines against all capripox diseases.[10]

Vaccination of a herd at the start of an outbreak is of limited use. Most animals will already be incubating the disease, and poor needle hygiene in these circumstances may spread the disease. Slaughter of affected and in-contact animals, destruction of contaminated hides, and vaccination of at-risk animals is a common approach when the disease is introduced to a previously free country.

SHEEPPOX AND GOATPOX

SYNOPSIS

Etiology *Capripoxvirus*. Strains vary in virulence and host specificity.

Epidemiology Highly contagious, spread by aerosol, contact, and flies. Young and nonindigenous animals more susceptible. Morbidity and case-fatality rates are high.

Clinical findings Fever, generalized skin and internal pox lesions, lymphadenopathy, mucopurulent nasal discharge, high mortality.

Clinical pathology Fluorescent antibody and electron microscopy of biopsy material, serology, virus isolation.

Necropsy findings Pox nodular lesions in alimentary tract and respiratory tract.

Diagnostic confirmation Fluorescent antibody staining, virus isolation.

Control Vaccination.

ETIOLOGY

Sheeppox, goatpox and lumpy skin disease of cattle are members of the genus *Capripoxvirus*, one of six genera of poxviruses. The diseases produced by sheeppox and goatpox viruses are collectively called capripox infections. They are named on the basis of their host specificity in natural outbreaks and are usually highly host specific in natural infections, although exceptions exist. For example, Kenya sheeppox and goatpox viruses, and Yemen and Oman sheep isolates, infect both sheep and goats, although the disease caused by the same isolate can vary dramatically between the two hosts.[1] The viruses are closely related genetically, and hence they cross-react in serologic tests, and many can cross species barriers in experimental infections. Recombination may also occur naturally between isolates from different host species.

EPIDEMIOLOGY

Prevalence of Infection

Sheeppox and goatpox are prevalent in North and Central Africa north of the equator, the Indian subcontinent, the Middle East, China, Southwest Asia, and the former Soviet Union. Sporadic outbreaks occur in

southern Europe, including Turkey, Greece, and Bulgaria, and elsewhere.[2] The *Capripoxvirus* infections of small ruminants are the most serious of all the pox diseases in animals, characterized by fever and skin lesions.[3] In susceptible flocks and herds morbidity is 75% to 100%, with outbreaks often causing death in 10% to 85% of affected animals depending on the virulence of the infecting strain.

Methods of Transmission

Sheeppox and goatpox are highly contagious. The virus enters via the respiratory tract, and transmission commonly is by aerosol infection associated with close contact with infected animals. The virus is present in nasal and oral secretions for several weeks after infection and can live in scabs that have fallen off the animal for several months. Spread can also occur from contact with contaminated materials and through skin abrasions produced iatrogenically or by insects. Capripox has been shown to spread via the bites of *S. calcitrans* and the tsetse fly.

Experimental Reproduction

The disease can be transmitted by intradermal, intravenous, and subcutaneous inoculation and by virus aerosols. Capripox antigen is detected 6 and 8 days postinfection in skin and lungs, respectively.[4]

Risk Factors

Animal Risk Factors

Both sheeppox and goatpox affect sheep and goats of all ages, all breeds, and both sexes, but young and old animals and lactating females are more severely affected. In areas where sheeppox is enzootic, imported breeds such as Merinos or some European breeds may show greater susceptibility than the native stock. Young animals are more susceptible.

Pathogen Risk Factors

The virus is resistant to drying and survives freezing and thawing. It is sensitive to extremes of pH and 1% formalin. Sensitivity to heat varies between strains, but most are inactivated at 60°C (140 F) for 60 minutes. Isolates from most regions are host specific, but isolates from Kenya and Oman naturally infect both goats and sheep. Scabs shed by infected animals remain infective for several months.

Economic Importance

Loss is from mortality, abortions, mastitis, loss of wool, skin condemnation, and loss of exports. In ewes and does, severe losses may occur if the udder is invaded because of the secondary occurrence of acute mastitis. In some outbreaks, adult sheep are affected with the more severe form of the disease. Sheeppox is a potent threat to countries that have large sheep populations, and where the disease does not occur, because it is difficult to eradicate and has a high mortality rate.

In a natural outbreak in an intensive sheep dairy in Israel, losses accrued from acute illness, deaths, reduced milk production, and reduced fertility. Milk production declined for 8 weeks after the index cases and was accompanied by an increased somatic cell count.[5]

Zoonotic Implications

Human infections in people handling infected animals are not a consideration.

PATHOGENESIS

During an initial viremia, the virus is carried by infected monocytes/macrophages to many tissues, particularly the skin, respiratory tract, and gastrointestinal tract.[4] Syncytial cells are seen in skin, and these probably facilitate local spread of the virus. The development of typical pox lesions, as in vaccinia, is characteristic of the disease. The virus is present in greatest quantities from 7 to 14 days after inoculation. Passive protection by serum will protect against challenge. Circulating antibody limits spread of infection, but does not prevent replication of the virus at the site of inoculation.

CLINICAL FINDINGS

In sheep, sheeppox has an incubation period of 12 to 14 days, with the malignant form being the most common type in lambs. There is marked depression and prostration, a very high fever, and discharge from the eyes and nose. Affected lambs may die during this stage before typical pox lesions develop. When pox lesions develop, they appear on unwooled skin and on the buccal, respiratory, digestive, and urogenital tract mucosae. They commence as papules, then become nodular, occasionally vesicular, and pustular, then finally scab. Some progress from nodules to tumor-like masses. The mortality rate in this form of the disease may reach 50%. In the benign form, more common in adults, only skin lesions occur, particularly under the tail; there is no systemic reaction, and animals recover in 3 to 4 weeks. Abortion and secondary pneumonia are complications. In sheep, infection with goatpox is more severe than with sheeppox, with lesions on the lips and oral mucosa, teats, and udder.

Goatpox in goats is very similar clinically to sheeppox in sheep. Young kids suffer a systemic disease, with lesions spread generally over the skin and on the respiratory and alimentary mucosae. Adult goats may have systemic disease and extensive lesions, but in adult goats the disease is usually mild, and lesions are as described previously for the benign form in sheep. A flat hemorrhagic form of capripox is seen in some European goats, and this form has a high case-fatality rate.

CLINICAL PATHOLOGY

Antigen Detection

Diagnosis is based on typical clinical signs combined with laboratory confirmation of the presence of the virus or antigen. Using electron microscopy, large numbers of characteristic "sheeppox cells" containing inclusion bodies and typical capripox virions can be seen in biopsies of the skin. The virus can be cultured in tissue culture, but virus isolation as a method of rapid diagnosis is limited by the extended time it takes for virus cytopathic effects to develop and the need, with some strains, for several blind passages before this occurs. Direct fluorescent antibody testing is used to detect the presence of poxvirus in the edema fluid, and the antigen can be detected in biopsies of lymph glands by AGID using specific immune sera. An antigen detection ELISA is also available.

Serology

Serologic testing can be by virus neutralization, which is 100% specific, or by an indirect fluorescent antibody or an agar gel precipitation test (AGPT), both of which cross-react with antibody to orf virus. An indirect ELISA has a similar diagnostic sensitivity and slightly lower specificity than the virus neutralization assay.[6] Virus-specific analysis of antibody response by Western blot can differentiate the infections.

PCR and melt-point analyses for the detection of capripox antigen have been developed, some as duplex or multiplex assays to differentiate capripox infections from orf virus.[7] These are suitable for use in countries that do not have the disease and do not hold live capripox virus. Loop-mediated isothermal amplification (LAMP) assays are potentially a cost-effective test to rapidly differentiate sheeppox and goatpox during outbreaks.[8]

NECROPSY FINDINGS

In the malignant form, pox lesions extend into the mouth, pharynx, larynx, and vagina, with lymphadenopathy and a hemorrhagic spleen. Lesions may also appear in the trachea. Lesions in the lung are severe, manifesting as lentil-sized white pox nodules to a consolidating and necrotizing pneumonia. Lesions occasionally reach the abomasum and are accompanied by hemorrhagic enteritis.

Histologically, cells infected with capripox virus have a characteristic appearance with vacuolated cytoplasm and nuclei, marginated chromatin, and multiple inclusion bodies ("sheeppox cells"). With the use of double immunohistochemical labeling, the viral antigen appears in cells of the monocyte/macrophage lineage within 6 to 8 days of infection, and later in pneumocytes.[4]

DIFFERENTIAL DIAGNOSIS
Contagious ecthyma (orf)
Bluetongue

TREATMENT

No specific treatment is advised, but palliative treatment may be necessary in severely affected animals.

CONTROL

Control in countries or regions that are free of this disease centers around prohibiting the importation of live animals and unprocessed produce from infected areas and, if the infection is introduced, ring vaccination, the destruction of affected flocks, and the quarantine of infected premises.

Vaccination with natural lymph has been used in some affected areas, but it can spread the disease. Natural infection with one capripox strain imparts immunity to all capripox infections, and vaccination with a single capripox vaccine will give protection across all species and against all capripox infections.

A variety of commercial vaccines are available, and there is no easy basis for comparison. Killed virus vaccines elicit only temporary protection, but live attenuated vaccines protect against infection for more than 1 year. Colostral antibody can interfere with vaccination until 6 months of age. Vaccination programs in endemic areas recommend vaccination of lambs at 2 and 10 weeks, followed by an annual booster.[5] A subunit capripox virus vaccine has been developed.

Vaccination in the face of outbreak is unlikely to prevent deaths during the subsequent 2 weeks and, if needle hygiene is poor, may facilitate the spread of the disease.

CONTAGIOUS ECTHYMA (CONTAGIOUS PUSTULAR DERMATITIS, ORF, SCABBY MOUTH, SOREMOUTH)

SYNOPSIS

Etiology Orf virus. Genus *Parapoxvirus*. Family Poxviridae.

Epidemiology Primarily young lambs and kids. Morbidity may reach 100% and case-fatality rate 5% to 15%. Rapid spread in flock by contact or via inanimate objects such as feed troughs, eartag equipment, and emasculators. Scabs from lesions remain infective in the environment for a long time. Orf infections can cause considerable setback in young lambs and has economic importance as a result of restriction of movement and trade of affected sheep. May infect humans.

Signs Papules, pustules, scabs covering ulceration, granulation, proliferation, and inflammation. Lesions begin at oral mucocutaneous junction and oral commissures and spread to muzzle and oral cavity. Lambs cannot suck or graze. Malignant form occurs with invasion of alimentary tract. Severe systemic reaction can occur and lesions on coronets, ears, anus, and vulva. Lesions can be multifocal in goats.

Clinical pathology Electron microscopy, polymerase chain reaction (PCR)

Lesions Scabs, pustules, granulation tissue, and secondary lesions. Eosinophilic cytoplasmic inclusion bodies.

Diagnostic confirmation Clinical signs, differentiate virus by PCR.

Differential diagnosis list:

Ulcerative dermatosis

Proliferative dermatitis (strawberry footrot)

Blue tongue

Foot-and-mouth disease

Sheeppox and capripox

Treatment. Nothing specific; general care of lesions.

Control. Isolation of affected animals. Vaccination.

ETIOLOGY

Orf is associated with the orf virus, a type species of the genus *Parapoxvirus* (family Poxviridae). In addition to the orf virus (parapox ovis), the genus includes the viruses of bovine papular stomatitis (parapox bovis 1), pseudocowpox (parapoxvirus bovis 2), and a parapox virus of deer. The orf virus withstands drying and is capable of surviving at room temperature for at least 15 years. Restriction endonuclease digests of DNA shows considerable heterogeneity between different field isolates.

EPIDEMIOLOGY

Occurrence

The disease occurs worldwide in sheep and goats.[1] It causes unthriftiness, varying degrees of pain, and some economic loss. It occurs most commonly in 3- to 6-month-old lambs at pasture, although lambs 10 to 12 days of age and adult animals can be severely affected. Outbreaks involving the lips and face of young lambs and the udders of the ewes are common. This disease can occur at any time, but outbreaks are most common in grazing sheep during dry conditions, lambs in feedlots, and penned sheep being fed from troughs. The disease has occurred in musk ox, in which it causes heavy losses, and in reindeer, mountain goats and bighorn sheep, chamois, caribou, Dall sheep, buffalo, wild goats, and camels. The virus can be passaged in rabbits if large doses are placed on scarified skin or injected ID. Mild lesions develop on the chorioallantois of the 9- to 12-day-old chick embryo. Guinea pigs and mice are not susceptible.

The disease also occurs in humans working among infected sheep. In abattoir workers it is most common in those handling wool and skins.

Morbidity and Case Fatality

Outbreaks may occur in sheep and goats, with morbidity rates approaching 100% and case-fatality rates from 5% to 15%. The deaths that occur are a result of the extension of lesions in the respiratory tract, but the case fatality rate may reach 15% if severely affected lambs are not provided with adequate care and support, or if secondary infection and cutaneous myiasis (flystrike) are allowed to occur. In the rare outbreaks where systemic invasion occurs, the case-fatality rate averages 25% and may be as high as 75%. Under field conditions, recovered animals are immune for 2 to 3 years, but no antibodies appear to be passed in the colostrum, and newborn lambs of immune ewes are susceptible.

Methods of Transmission

Scabs that fall off from healing lesions contain the virus and remain highly infective for long periods in dry conditions, but survival of the disease in a flock may be the result of chronic lesions that exist for long periods on individual animals. Infection can be from environmental persistence of the virus or from infected sheep. Spread in a flock is very rapid and occurs by contact with other affected animals or by contact with contaminated inanimate objects, such as feed troughs or ear-tagging pliers. An outbreak of lesions on the tail has been recorded in association with the use of docking instruments.

It has been assumed that natural infections on pasture are the result of invasion of the virus after skin damage induced by prickly plants or stubble; application of a viral suspension to scarified skin is the established method of inducing orf. However, an outbreak has occurred in groups of lambs collected from several farms and transported in a vehicle over a period of 23 hours when there was no evidence of injury to their mouths.

Experimental Reproduction

The disease is readily reproduced by introduction of the virus onto scarified areas of

skin. Immunity to reinfection is relatively solid at the site of initial infection, but shorter-duration lesions can be reproduced by rechallenge of these sheep at other sites.

Risk Factors

The primary risk factors are the presence of the virus and the immune status of the sheep. Mixing of sheep, such as occurs in a feedlot with sheep originating from several sources, allows transmission of the infection. Intercurrent infections may exacerbate the occurrence of disease on rare occasions. For example, the disease has spread from clinically normal ewes to susceptible 2- to 4-year-old ewes that were persistently infected with border disease virus. Lambs experimentally infected with *Ehrlichia phagocytophilia* and subsequently challenged with orf virus developed more severe lesions with a longer course than those in control lambs.

Economic Importance

The disease produces only a minor setback, except when it affects young sucking lambs with associated lesions on the teats and udders of their ewes. Loss from lamb mortality and secondary mastitis in these circumstances can be significant.

The disease assumed economic importance for Australia when shipments of sheep exported from Australia in 1989 to 1990 were rejected at some ports in the Middle East because of scabby mouth. Litigation is also a potential concern when zoonotic infections occur at petting zoos or fairs.

Zoonotic Implications

Orf virus is readily transmitted to humans and historically has been a risk for industrial workers handling raw wool.

Lesions occur at the site of infection, usually an abrasion infected while handling diseased sheep for shearing, crutching, or drenching, or by accidental inoculation with live scabby mouth vaccine. Lesions progress from macular to papular stages, are usually single, and are localized on the hands, arm, or face. The lesions are self-limiting and heal without scaring after 6 to 7 weeks. They are pruritic and respond poorly to local treatment. Orf is also a zoonotic consideration in petting zoos and fairs where children allow lambs to suck their fingers or otherwise become infected from handling sheep in interactive exhibits.

PATHOGENESIS

Damage to the skin is essential for the establishment of orf infection and the development of typical lesions. Following viral challenge of mildly abraded skin, the virus does not establish in the damaged epidermis, but instead replicates in the cells of an underlying replacement epidermal layer derived from the walls of the wool follicles. Following scarification of ovine skin and topical application of the orf virus, antigen cannot be detected in the skin during the period when the epidermis is being renewed. The virus can first be detected in the center of the newly differentiated epidermis immediately below the stratum corneum, 72 hours after infection. The location of the virus during the eclipse stage is unknown. The infection spreads laterally and uniformly from the new epidermis, initially in the outer stratum spinosum and subsequently throughout the entire depth of the epidermis. The skin reaction consists of a cellular response with necrosis and sloughing of the affected epidermis and underlying stratum papillare of the dermis. The cutaneous response to infection includes a delayed-type hypersensitivity reaction and an influx of inflammatory cells involving neutrophils, basophils, and possibly mast cells. Class II dendritic cells are also involved and appear to form the basis of a highly integrated local dermal defense mechanism. The lesions evolve through the stages of macule, papule, vesicle, pustule, scab formation, and resolution. The pustules develop within a few days and then rupture, resulting in ulcers and subsequently the formation of a thick overlying crust or scab that is shed within 3 to 4 weeks, leaving no scar. Immunity is solid but will last only about 8 months. Although there is an antibody immune response to the virus, recovery is the result of cell-mediated immune mechanisms. Experimentally, a secondary infection, following recovery from a primary infection, is milder and accelerated. During the secondary challenge, pustules and scabs develop earlier, the lesions resolve more rapidly, and no vesicular stage may occur.

CLINICAL FINDINGS

Sheep

Lesions develop initially as papules and then pustules, stages that are not usually initially seen, and progress to a raised and moderately proliferative area of granulation and inflammation covered with a thick, tenacious scab. Time from the initial lesions to the formation of scabs is approximately 6 to 7 days. New lesions will develop during the first 10 days of infection. The first lesions develop at the oral mucocutaneous junction, usually at the oral commissures, and are accompanied by swelling of the lips. From here they spread to the muzzle and nostrils, the surrounding haired skin, and, to a lesser extent, o the buccal mucosa. They may appear as discrete, thick scabs 0.5 cm in diameter, or coalesce and be packed close together as a continuous plaque. Fissuring occurs, and the scabs are sore to the touch. They crumble easily but are difficult to remove from the underlying granulation. Affected lambs suffer a severe setback because of restricted sucking and grazing. In benign cases the scabs dry and fall off, and recovery is complete in about 3 weeks.

Affected lambs sucking ewes may cause spread of the disease to the udder, where a similar lesion progression is seen on the teats

Fig. 16-6 Contagious ecthyma on the teat of an ewe. The ewe contracted the infection by being suckled by a lamb with orf lesions on the commissures of its mouth.

(Fig. 16-6). Lesions on the teats predispose to mastitis, and secondary infection of the skin lesions by bacteria or fly larvae occurs in some cases. In rams, lesions on the scrotum may be accompanied by fluid accumulation in the scrotal sac and associated temporary infertility. A high incidence of infection can also occur where the dominant lesions are on the feet, occurring around the coronary band, the dew claws, and on the volar areas of the intervening skin.

Occasionally severe edema of the face can occur in association with oral lesions. In a severe case, over 50% of 4-month-old Texel lambs grazing good-quality pastures in Ireland were affected.[2] The edema resolved after 10 days but appeared quite similar to that seen with experimental bluetongue infections.

Rarely, systemic invasion occurs and lesions appear on the coronets and ears, around the anus and vulva or prepuce, and on the nasal and buccal mucosae. There is a severe systemic reaction, and extension down the alimentary tract may lead to a severe gastroenteritis; extension down the trachea may be followed by bronchopneumonia. Lesions may also occur in the mouth, involving the tongue, gums, dental pad, or a combination of those sites. These are more commonly seen in outbreaks affecting lambs less than 2 months of age. In the mucosa of the mouth these lesions do not scab but are papular erosive and surrounded by an elevated zone of hyperemia. Extensive painful and proliferative lesions occur on the gingival margins of the incisor teeth.

In some outbreaks the lesions on the skin are highly proliferative and present as raw, raised, granulating lesions without an overlying scab. This manifestation appears more common in Suffolk sheep, and lesions are present on the lips, bridge of the nose, and around the eyes (Fig. 16-7). Cases of this proliferative form involving the feet are also recorded.

A malignant form of the disease has also been observed in sheep. It begins with an acute episode manifested by oral vesicles, followed by extension of these lesions down the gastrointestinal tract, followed later by granulomatous lesions and shedding of hooves.

An atypical case of the disease in sheep after extensive cutaneous thermal injury has been described. The virus was present in proliferative verrucous tissue lesions at the periphery of the original thermal injury. The lesions consisted of tightly packed 0.5-mm-diameter papillary projections.

Goats

An unusual case in a group of female goats has been described, with multifocal lesions over the head, neck, thorax, and flanks of each animal. The lesions developed approximately 2 weeks after the animals returned from a show at which the does were housed for 3 days in pens previously occupied by sheep. The lesions began as plaques, followed by epidermal proliferation and severe encrustation. Affected areas were discrete and approximately 2 to 7 cm in diameter. There were no lesions of the muzzle, lips, udders, or teats. Recovery occurred uneventfully within 3 to 6 weeks without treatment. The skin crusts gradually dried and fell off, leaving areas of alopecia and depigmented skin. Regrowth of hair followed.

Persistent orf occurred in a proportion of Boer goats following an outbreak. In most animals the disease ran a typical clinical course of 3 to 4 weeks, but in 2% of animals it persisted for several months, with lesions disseminated over the body. There were no particular distinguishing differences of the virus genome compared with those of other orf viruses, and the persistence was possibly a result of individual host-susceptibility factors.

CLINICAL PATHOLOGY

Electron microscopic identification of the virus is quick and generally reliable with multiple samples from an affected herd or flock. Viral DNA can also be detected by a number of PCR assays, including real-time PCR and a multiplex PCR to differentiate orf, sheeppox, and capripox viruses.[3] LAMP assays have also been developed.[4] These are comparable to a real-time PCR but require less sophisticated equipment and thus may be a suitable test where resources are limited but rapid differentiation of orf virus and poxviruses is necessary.

Recovered animals have elevated neutralizing antibodies in their serum that are detectable by a gel diffusion test. Other serologic tests have been developed but are not widely available and probably of little clinical value.

NECROPSY FINDINGS

In malignant cases there are irregularly shaped lesions with a hyperemic border in the oral cavity and the upper respiratory tract, with rare involvement of the mucosae of the esophagus, abomasum, and small intestine. Typical lesions are actually proliferative, with subsequent loss of centrally located cells creating an ulcer-like appearance. Microscopically, the hyperplastic epithelium contains swollen degenerate cells, some of which may house eosinophilic cytoplasmic inclusion bodies.

Samples for Confirmation of Diagnosis

- **Histology**—formalin-fixed lesions (LM)
- **Virology**—vesicle fluid, scraping from lesion (EM)

DIFFERENTIAL DIAGNOSIS

In most outbreaks of ecthyma, the cases are sufficiently mild to cause no real concern about losses or about diagnosis.

Dramatic outbreaks of a very severe form of the disease may occur and may be confused with bluetongue. Very severe cases are also commonly seen in housed experimental sheep, especially colostrum-free lambs.

Ulcerative dermatosis is sufficiently similar to cause confusion in diagnosis, but this disease has not been reported for many years.

Mycotic dermatitis usually occurs on woolled skin, but lesions can occur on the lips and feet (strawberry footrot), have a thick dry asbestos-like scab, and are easily differentiated by laboratory culture.

Facial eczema is distinguished by diffuse dermatitis and severe edema and damage to the ears.

Papillomatosis (warts) need also to be considered in the differential diagnosis for the proliferative manifestations of contagious ecthyma, although warts are extremely uncommon in sheep.

Bluetongue is always accompanied by a high mortality rate and a severe systemic reaction, and lesions occur on the muzzle, the coronets, and extensively on the buccal mucosa. It is more common in adults than sucking lambs. Because it is transmitted by insect vectors, the morbidity rate is usually much less than the 90% commonly seen in contagious ecthyma.

Sheeppox may present a rather similar clinical picture, but the lesions are typical and there is a severe systemic reaction and heavy mortality rate.

Foot-and-mouth disease. The classic developed lesions of orf are easily differentiated from foot-and-mouth disease, but the papular and vesicular stages seen early in the course of orf, particularly lesions in the mouth, can be difficult to differentiate, especially when a prompt on-farm differentiation is required. The raised, firm, papular erosive nature of the lesion with the surrounding zone of hyperemia is a crucial differentiating feature in the field.

Fig. 16-7 Extensive chronic lesions as a result of chronic orf infection in a Suffolk ewe lamb. These facial lesions are often accompanied by similar lesions on the distal limbs.

TREATMENT

Removal of the scabs and the application of ointments or astringent lotions are practiced but delay healing in most cases. Antiviral drugs have been combined with emollients in gels and sprays (e.g., cidofovir and sucralfate).[5] These formulations can decrease the time to healing and amount of virus shed in scabs, but will be impractical and not cost-effective in most flocks. Supportive treatment, such as providing soft, palatable food, may be helpful.

CONTROL

In the early stages of an outbreak, the affected animals should be isolated and the remainder vaccinated. Vaccination is of little value when a large number of animals are already affected. Persistence of the disease from year to year is common. If lesions are severe and consistently provide a setback, lambs should be vaccinated at 6 to 8 weeks of age. Vaccination when a few days old evokes a protective response. However, prelambing vaccination of the ewe is of no benefit for the lamb and so is not recommended. Vaccination of housed lambs should be given before the time that lesions have been observed in previous years.

Commercially available vaccines are typically a suspension of live tissue culture virus, often with a blue dye. An autogenous vaccine can also be prepared from a suspension of scabs in glycerol saline. The vaccine is scratched in a 5-cm line onto bare skin, usually the inside of the foreleg, brisket, or inner thigh. Alternative methods are to apply autogenous vaccine to a small area of scarified skin or to prick the ear with a needle dipped in the vaccine. Vaccination is effective for at least 2 years, but the lambs should be inspected 1 week after vaccination to check that a local reaction has occurred. A small proportion of vaccinated lambs may develop mild lesions around the mouth because of nibbling at the vaccination site. Absence of a local reaction signifies either a lack of viability of the vaccine or the existence of prior immunity. Immunity is not complete until 3 weeks after vaccination. As a further protective measure, removal of abrasive material from the environment is recommended but is not usually practicable. For the live-sheep export trade from Australia to the Middle East, sheep should be vaccinated at least 3 weeks before shipment to allow immunity to develop.

Because the vaccines are live virus vaccines and the shed scabs contain live virus, routine vaccination against orf in flocks that have not experienced the disease is not recommended. Outbreaks have occurred from vaccine virus.

ULCERATIVE DERMATOSIS OF SHEEP

Ulcerative dermatosis of sheep is an infectious disease characterized by the destruction of epidermal and subcutaneous tissues and the development of raw, granulating ulcers on the skin of the lips, nares, feet, legs, and external genital organs. The lesions on the lips occur between the lip and the nostril, those on the feet occur in the interdigital space and above the coronet, and the genital lesions occur on the glans and the external opening of the prepuce of rams and the vulva of ewes.

A virus, very similar to but antigenically different from the ecthyma virus, is the cause of the disease, which is likely to be confused with contagious ecthyma. However, the lesions are ulcerative and destructive, rather than proliferative as in ecthyma, and bleed easily. It is not highly infectious like bluetongue or sheeppox, and the "lip-and-leg" distribution of the lesions differentiates it from balanoposthitis of wethers, strawberry footrot (dermatophilosis), footrot, and interdigital abscess. The presence of lesions on the glans penis and their absence from mucosae, the typical ulcerative form of the lesion; the absence of pus; and the susceptibility of recovered animals to infection with ecthyma virus are diagnostic features of ulcerative dermatosis.

The typical morbidity rate is 15% to 20%, but up to 60% of a flock may be affected. Mortality is low if the sheep are in good condition and the lesions don't get secondary bacterial infection or flystrike. Physical contact at breeding time seems to be the most probable method of spread.

The lip cutaneous form of this disease is very rare and possibly has disappeared since its original description, or is very uncommon. A clinically similar disease to the genital infection of ulcerative dermatosis, with balanoposthitis and vulvovaginitis, is associated with *Mycoplasma mycoides*.

POXVIRUS INFECTIONS IN HORSES (HORSEPOX, UASIN GISHU, VIRAL POPULAR DERMATITIS, EQUINE MOLLUSCUM CONTAGIOSUM)

Equids can be infected by horsepox virus or vaccinia virus. Infection is associated with classical horsepox, equine molluscum contagiosum, viral papular dermatitis, or Uasin Gishu disease and possibly a form of "greasy heel" in horses and donkeys. Classical horsepox, caused by infection of horses by a specific poxvirus (horsepox virus, HSPV), was common before the twentieth century and was considered a rare, if not extinct, disease of horses until it was again identified in Brazil in 2010.[1] The genome of HSPV has been determined and demonstrates that although it is closely related to vaccinia viruses, it contains additional genetic material that appears to confer some host specificity and pathogenicity.[2] HSPV, with cowpox virus, was used for vaccination of humans against smallpox before introduction of use of vaccinia virus.[3] Whereas most poxviruses are highly host adapted and do not cross species lines (e.g., variola virus causing smallpox in humans does not naturally infect animals), this is not the case with cowpox, horsepox, and vaccinia viruses, which can be zoonoses or anthroponoses. Widespread use of vaccinia virus live vaccines in humans was associated with a pox-like disease in horses.[3] This disease has largely not occurred since the cessation of the smallpox vaccination program, but other poxvirus diseases in animals are reported, and infection appears to have the potential to be zoonotic for horsepox and cowpox viruses, or anthroponotic (reverse zoonosis) for vaccinia viruses.[3-5]

The eradication of smallpox and the discontinuation of human vaccination in most countries were accompanied by a gradual reduction of the number of horse cases,[1–3] although the disease is not eradicated, and infections involving cattle, horses and humans occur in Brazil.[4] The virus isolated from horses (Pelotas 1 virus [P1V] and Pelotas 2 virus [P2V]) in Brazil is highly pathogenic in rabbits.[6,7] The source of the vaccinia virus in these outbreaks has not been determined (e.g., wildlife, rodents).[4]

Horses infected with the **vaccinia virus** used in human vaccine programs develop a transient and self-limiting disease characterized by pox-like lesions (papulopustular) in the mucous membranes of the mouth and in the skin of the lips and nose. Infection by particular strains of the vaccinia virus (P1V and P2V)) in Brazil causes papules and vesicles progressing to proliferative and exudative lesions on the muzzle, external nares, and external and internal lips (Fig. 16-8).[1] The vesicles erode, and the proliferative lesions progress to moist crusts and scars.

Fig. 16-8 Muzzle of an affected mare during acute disease associated with infection by vaccinia-like virus. Multiple, confluent papules and proliferative lesions in the muzzle, between and surrounding the nares, and extending aborally. (Reproduced with permission, Brum MCS et al. *J Vet Diagn Invest* 2010; 22:143.)

Clinical signs last approximately 6 to 12 days. The overall duration of the outbreak is 90 days.

Infection by classical HSPV causes either a relatively benign disease or a more severe, sometimes fatal, disease.[1,2] The benign or localized form (contagious pustular stomatitis) causes lesions in the muzzle and buccal cavity. The more severe form (equine papular stomatitis) is a generalized, highly contagious disease causing fever, skin lesions that can involve the udder, and death in some animals. Both adults and foals are susceptible.[2] Immunity after an attack is solid.

Typical pox lesions develop in a **leg form** or in a **buccal form.** In the **leg-form** nodules, vesicles, pustules, and scabs develop, in that order, on the back of the pastern and cause pain and lameness. There may be a slight systemic reaction, with elevation of temperature. In the **buccal form,** similar lesions appear first on the insides of the lips and then spread over the entire buccal mucosa, sometimes to the pharynx and larynx and occasionally into the nostrils. In very severe cases, lesions may appear on the conjunctiva, the vulva, and sometimes over the entire body. The buccal lesions cause a painful stomatitis, with salivation and anorexia as prominent signs. Most cases recover, with lesions healing in 2 to 4 weeks.

Uasin Gishu is a skin disease of nonindigenous horses of the Uasin Gishu plateau of Kenya and neighboring areas associated with a poorly documented poxvirus. The source of the virus, and its method of transmission, are unknown, although a wildlife host is presumed. Concerns have been raised of the potential for zoonotic spread or anthroponosis (reverse zoonosis) of horsepox viruses or vaccinia virus, respectively.[4,5] Lesions of Uasin Gishu occur on the head, neck, and flanks and resemble papillomas. Various stages of the lesions can be present in the same horse, and lesions can develop and regress intermittently for years. There is no specific treatment, and no control methods are reported.

Viral popular dermatitis is a disease of horses in the United States, the United Kingdom, and Australia. It is a contagious disease characterized by cutaneous lesions in the form of firm papules 0.5 to 2 cm in diameter. No vesicles or pustules are formed, but after 7 to 10 days a dry crust is detached, leaving small circumscribed areas of alopecia. The lesions are not itchy, there is no systemic disease, and the distribution of the lesions, and the way in which they can develop simultaneously in large numbers in introduced horses, is suggestive of an insect-borne disease.

The course of the disease varies between 10 days and 6 weeks. The disease is strongly suspected to be caused by a poxvirus.[1,2] A febrile reaction, up to 40.2° C (104.5° F), precedes the appearance of skin lesions by about 24 hours. There is no histologic description. Recovery is usually complete and uncomplicated. The disease is clinically similar to **molluscum contagiosum** in horses associated with poxvirus. This disease has similar papular lesions, which are hypopigmented and covered by tufts of raised hair, but the disease has a long clinical course. Histologically, these lesions show proliferation of keratinocytes containing large intracytoplasmic inclusions, known as molluscum bodies, which are composed of numerous pox virions.

Differential diagnoses include greasy heel, vesicular stomatitis, viral papular dermatitis, molluscum contagiosum, and Uasin Gishu. See Tables 16-3 and 16-4.

There is **no specific treatment**. Local wound care is indicated. Because of the contagious nature of the disease, rigid isolation and hygiene in the handling of infected horses is essential. No vaccine is available.

SWINEPOX

SYNOPSIS

Etiology Swinepox virus.

Epidemiology Widespread sporadic disease that is generally benign with low morbidity and low **mortality** in older pigs. High case fatality in congenitally infected and very young sucking piglets. Transmitted mechanically and by the hog louse.

Clinical findings Characteristic pox lesions mainly on skin of head, legs, and belly.

Clinical pathology Demonstration of typical lesions by histology and virus by electron microscopy.

Lesions Typical pox lesions.

Diagnostic confirmation Demonstration of typical lesions by histology and virus by electron microscopy.

Treatment None.

Control Control of hog louse.

Swinepox virus causes a mild, acute disease of swine characterized by typical poxvirus lesions of the skin. There are no public health concerns.

Table 16-3 Differential diagnosis of diseases of horses characterized by discrete lesions of the skin only

	EPIDEMIOLOGY			
Disease	**Method of spread**	**Behavior in herd**	**Lesions**	**Clinical pathology**
Horsepox	Extremely rare, usually benign. Can be severe. Spread by contact, rugs, grooming tools.	Solid immunity after attack. No recurrence. Lesions heal 2–4 weeks.	Typical pox lesions in mouth or behind pasterns. Rare cases have lesions in mouth, nostrils, vulva.	Electron microscopy of swab from lesion. Poxvirus present—horsepox virus or vaccinia virus. Polymerase chain reaction (PCR).
Vesicular stomatitis	Occurs in horses, cattle, and pigs. Spread by insert or contact. Clustered outbreaks summer and autumn.	Lesions last only 3–4 days. Solid immunity for 6 months.	On tongue and lips. Uncommon on udder or prepuce. Vesicles up to 2 cm rupture, leaving raw area; profuse ropey saliva. Heal quickly.	Virus isolation, PCR. Many serologic tests available.
Viral papular dermatitis	Insect vector. May affect many horses at one time. Local horses immune. Summer and autumn.	Recovered in 10 days to 6 weeks. Benign, disappears without trace.	Generalized cutaneous papules 0.5–2 cm in diameter, dry crust at 7–10 days, then spot of alopecia.	Assumed poxvirus.
Staphylococcal dermatitis	Sporadic. Lesions under harness suggest pressure or spread by contact. A common disease.	No information, does not spread much. Very difficult to cure in individual. Horse will not work under harness.	5-mm nodules then pustules. Slough, taking small scab and hair. Very painful to touch.	*Staphylococcus aureus* culture from swab of lesion.
Deep ringworm	Diffuse ringworm more common. Spread easily by direct contact or harness or tools.	Sporadic usually. Difficult to cure.	3-mm-diameter follicular nodule, hair loss leaving bald patch. No extensive lesions. Sore to touch, itchy. Spreads from axilla.	*Trichophyton* or *Microsporum* spp. on swab.
Demodectic mange	Spread via grooming tools and rugs. Rare.	Slow spread.	Lesions around face and eyes initially.	*Demodex* spp. in scraping.
Mycotic dermatitis	Wet, humid weather predisposes. Prolonged wetness. Mud leads to foot lesions. Biting flies may spread other forms.	May be number affected if weather conditions suitable.	Lesions commence on head at muzzle and around eyes, with lacrimation and mucopurulent nasal discharge, on lower legs or generalized. Not itchy; may be sore. Matted hair and scab can be lifted off an ovoid, slightly bleeding area.	Branching filamentous *Dermatophilus congolensis* on smear of lesion.
Tyroglyphosis	In horses fed recently harvested, infested grain, or at pasture.	Transient, self-limiting disease.	Dermatitis, itchy, scaly; with rubbing get alopecia and scab formation on muzzle and face, lower limbs at flexures.	Larvae of chigger mites *Pediculoides* and *Trombicula* spp. in scraping.
Photosensitization	Rare in horses. Feeding on St. John's wort or hepatotoxic plants; secondary to cholangiohepatitis or cholelithiasis.	Occurs only in sunlight. Disappears on removal from damaging feed and sun.	Extensive edema, weeping dermatitis, or skin sloughing on white parts. May also be signs of hepatic insufficiency.	Nil.
Queensland itch	Sporadic. During insect season. Only in horses outdoors.	Only hypersensitive horses affected. Disease persists as long as insects present. Interferes with work and grazing.	Intensely itchy. Lesions at tail butt, along back, withers, crest, poll, ears, down sides. Papules, hair rubs off. Pachydermia, no weeping.	Hypersensitivity indicated by eosinophilia in skin biopsy.
Ringworm	Ready transmission by contact and with equipment and premises. Most serious in winter.	Spontaneous recovery in about 3 months. Spread in herd can be very rapid.	Thick, dry, crumbly scab, 2-3 cm diameter, or diffuse alopecia with scaliness begin at girth or under head stall.	*Trichophyton* and *Microsporum* spp. on scraping.

Note: See also discussions of cutaneous globidiosis, multiple abscess caused by Corynebacterium pseudotuberculosis, anhidrosis, congenital absence of skin.

Table 16-4 Differential diagnosis of diseases of horses characterized by lesions of the skin of the lower limbs only

	EPIDEMIOLOGY			
Disease	**Method of spread**	**Behavior in herd**	**Lesions**	**Clinical pathology**
Glanders	Contact with infected horses. Ingestion from contaminated environment.	This is chronic form. Other cases of classical glanders with pulmonary and nasal mucosal involvement.	Nodules and ulcers on nasal mucosa, purulent discharge. Stellate scars on septum. Limb lesions mostly at hock (medial aspect): nodules 1–2 cm, discharge honey-like pus.	Mallein test. Complement fixation tests on serum. Transmission to guinea-pigs. *Burkholderia mallei* in smears.
Epizootic lymphangitis (equine blastomycosis)	Occurs in outbreaks. Spread by spores on contaminated bedding. May survive in soil. Entry through skin abrasions.	Horses cannot be worked. Common in large groups (e.g., military horses).	Ulcers at hocks, lymph nodes at hocks swell and discharge creamy pus. Lymphangitis. Some cases generalized with pulmonary abscesses.	*Histoplasma farciminosum* in smears of pus. Skin sensitivity test.
Sporotrichosis	Slow spread. Sporadic cases. Spread by contact and contamination.	Lesions heal 3–4 weeks, but new crops keep disease going.	Painless nodules at fetlocks ulcerate then heal. Lymphangitis in some animals.	*Sporotrichum schenckii* on smear.
Swamp cancer (pythiosis)	Sporadic. Infection or invasion of wound.	Does not spread.	On lower limbs, ventral abdomen, or below medial canthus of eye, lips. Papules to plaques 1 cm thick, connective tissue with ulcers up to 20 cm, with inspissated pus in pockets.	Biopsy and scrapings for hyphae of *Pythium insidiosum*, *Entomophthora coronata*, larvae of *Habronema megastoma*.
Greasy heel	Sporadic cases only. Horses standing in manure and urine.	Not contagious, but can be chronic and incapacitating.	Horizontal cracks and fissures behind pastern, very lame. Much sebaceous exudate. May develop cellulitis.	Nil.
Ulcerative lymphangitis	Infection of skin wounds in dirty stable.	Lesions heal in 1–2 weeks. New lesions develop for up to 12 months.	Painful nodules around pastern rupture; creamy green pus. Lame. Lymphangitis with ulcers.	No lymph node involvement. *Corynebacterium pseudotuberculosis* in pus. Other organism can cause similar disease.
Chorioptic mange	Widespread. Mostly draft and other working horses.	Most horses in group affected.	Violent stamping; rubs back of pasterns; swollen, scabby, cracked, greasy, painful to touch; lame.	Scrapings reveal mites, *Chorioptes equi*.

Note: See also horsepox (Table 16-3).

ETIOLOGY

The cause is swinepox virus, the sole member of the genus *Suipoxvirus* in the family Poxviridae.

EPIDEMIOLOGY

Occurrence

Swinepox (pigpox) occurs worldwide where swine are raised and is more common in swine units where there is poor sanitation.

Methods of Transmission

Transmission is not well understood. It is by contact transmission and mechanically by the pig louse (*Haematopinus suis*), and because these cannot always be found, it is suspected that possibly flies and other insects may also be involved. Young sucking pigs may have lesions on the face, with similar lesions on the udder of the sow, so there is evidence of spread by direct contact. Vertical transmission is also possible; there are reported cases of congenital infection. The virus can survive in scab material for several months and in dust and dried secretions.

Animal Risk Factors

The virus infects only swine and can infect all ages, but clinical disease is most commonly seen in young piglets. It is usually a sporadic disease, with occasional outbreaks affecting a cluster of litters within a herd, and of short duration. Some or all pigs in a litter may show clinical signs. The disease may appear apparently spontaneously or may occur only in pigs brought into the contaminated environment of a herd in which the indigenous pigs are immune.

The incidence in individual herds may be high. Mortality is usually low except in very young piglets and congenitally affected piglets, where mortality rates can be high. Congenital infection presents with low morbidity but high case fatality. Older animals seem to suffer few ill-effects.

PATHOGENESIS

The virus may enter the skin through preexisting skin lesions and then replicates in the keratinocytes of the stratum spinosum. It rarely affects other tissues. It can be isolated from the skin as soon as 3 days following intradermal inoculation. In field cases, the lesions progress through the classical phases of poxvirus infections but do not usually proceed past the pustular or vesicle stage. At this time there is rupture and the formation of scabs, which heal and drop off. Congenital infection is thought to occur when naïve pregnant sows become infected and develop viremia with infection of the fetal membranes. Not all fetuses are born affected, and compartmentalization of placentas may restrict further uterine spread as occurs with parvovirus infections.

CLINICAL FINDINGS

The morbidity may be high in individual herds where young pigs are affected, but the mortality is usually very low. The incubation period may be from 4 to 14 days. Small 1- to 1.5-cm-diameter papules develop first and may pass through the pustular and vesicular stage very quickly with the formation of red–brown, round scabs. In neonatal pigs, the rupture of many vesicles at one time may

cause wetting and scab formation over the cheeks, and conjunctivitis and keratitis are present in many affected animals. In most cases the lesions are restricted to the belly and inside the upper limbs, but they may involve the back and sides and sometimes spread to the face. Lesions may coalesce. A slight febrile reaction may occur in the early stages in young animals, and in sucking pigs, deaths are observed. In adult pigs, detectable skin lesions are less well defined, restricted to the nonhaired softer skin areas, and frequently do not progress through the developmental stages to form scabs. Congenital swinepox is characterized by striking lesions present in piglets at birth, involving the skin and also commonly the tongue and hard palate. Affected piglets are born from healthy sows. Affected piglets may be stillborn or die within a few days after birth.

CLINICAL PATHOLOGY

The diagnosis is confirmed by examination of skin biopsies, which show hydropic degeneration of the stratum spinosum keratinocytes. Focal superficial erosions, marked epidermal hyperplasia with acanthosis, ballooning of epidermal cells, and occasional large eosinophilic intracellular inclusion bodies are present on histologic examination. Hydropic degeneration can also be seen in the outer sheaths of the hair follicles. There is no fluid accumulation between the keratinocytes. Necrosis may occur later. Inflammatory cells invade the underlying dermis. Electron microscopy can be used to detect the viral particles, and the virus can be cultivated in primary pig kidney cell tissue culture with at least seven passages. Crusts, papules, or pustules are best for this. Pigs will develop virus-neutralizing and virus-precipitating antibodies but not at high enough levels to make antibody tests reliable. There is strong immunity in recovered animals.

DIFFERENTIAL DIAGNOSIS

The distribution of the pox-like lesions and the association of the disease with louse infestations suggest the diagnosis. Swinepox may resemble swine vesicular disease, which is characterized by vesicles on the coronary bands, lips, tongue, and snout.

Lesions associated with *Tyroglyphus* spp. mites are usually larger, occur anywhere on the body, and, like those of sarcoptic mange, are usually accompanied by itching. The causative mites are detectable in skin scrapings. Ringworm and pityriasis rosea have characteristic lesions that do not itch, occur in older pigs than typically does swinepox, and fungal spores are present in scrapings in the former disease.

A vesicular disease with necrosis resembling swinepox has been attributed to infection with parvovirus, but there is little evidence that parvovirus is a primary skin pathogen.

TREATMENT

No specific treatment is available, and lesions cause so little concern to the pig, and heal so rapidly, that none is attempted.

CONTROL

Vaccination is not usually practiced, and control of the pig lice is the principal prophylactic measure attempted in most outbreaks.

Dermatomycoses

RINGWORM

SYNOPSIS

Invasion of cutaneous keratinized epithelial cells and hair fibers by dermatophytes.

Etiology *Trichophyton*, *Microsporum* spp. fungi.

Epidemiology Carrier animals are the source; spread is via direct contact or contact with infected inanimate objects. Housed animals most susceptible.

Clinical signs Circumscribed areas of hairless skin; thick gray crumbly crusts (cattle) or shiny, bald areas (horses); heavy pityriasis; common locations where infection likely to contact (e.g., neck, sides).

Clinical pathology Spores and mycelia in skin scraping, or in culture.

Necropsy lesions Mycelia identifiable in skin sections.

Diagnostic confirmation Laboratory typing of fungus in scraping or tissue.

Treatment Spontaneous recovery usual. Topical ointments such as Whitfield's ointment, systemic griseofulvin. Vaccination widely used in European countries and supportive treatment.

ETIOLOGY

The associated fungi that grow on the hair, skin, or both are as follows:

- **Cattle:** *Trichophyton verrucosum* (most commonly), *T. mentagrophytes*, *T. megninii*, *T. rubrum*, *T. simii*, *T. verrucosum* var. *album*, *T. verrucosum* var. *discoides*, *Microsporum gypseum*
- **Sheep:** *T. verrucosum* var. *ochraceum*, *T. quinckeanum*, *T. mentagrophytes*, *M. gypseum* ("club lamb fungus" in show lambs in the United States), *Microsporum canis*
- **Goat:** *T. verrucosum*
- **Horse:** *T. equinum*, including a dark variant able to perforate hair in vitro (*T. equinum* var. *equinum*), *T. quinckeanum*, *T. mentagrophytes*, *T. verrucosum*, *Microsporum equinum* (syn. *M. canis*), *M. gypseum*, *Equicapillimyces hongkongensis*
- **Donkey:** *T. mentagrophytes*, *T. verrucosum*
- **Pig:** *T. mentagrophytes*, *T. rubrum*, *T. verrucosum* var. *discoides*, *M. canis*, *Microsporum nanum*

Uncommon dermatophytes also found in skin lesions in farm animals and horses include the following: *M. gypseum* and *Keratinomyces allejoi* in horses; *Malaessezia* spp. yeasts causing superficial mycoses in immunocompromised horses; *Scopulariopsis brevicaulis* in cattle; *M. nanum* in adult pigs, in which it is most common and in which the lesions are often so mild as to go unnoticed by the farmer; and *Alternaria alternata* in horses, goats, pigs, sheep and cattle.

A rare but similar disease is tinea versicolor, a fungal dermatomycosis associated with *Malassezia furfur* (syn. *Pityrosporum orbiculare*) on the teats of goats. The lesions are circular, discrete, slightly thickened, and scaly at the edges, but not painful. They are characterized by an alteration in the color of the surrounding skin, either darker or lighter. The infection persists on a patient for at least a year and in a flock for a longer period. Hyphae are distinguishable in sections of the lesions.

EPIDEMIOLOGY

Occurrence, Source of Infection, and Transmission

Ringworm occurs in all animal species in all countries but more commonly where animals are accommodated in dense groups, especially indoors.

Direct contact with infected animals is the common method of spread of ringworm, but indirect contact with inanimate objects, particularly bedding, harnesses, grooming kits, and horse blankets, is probably more important. Spores can exist on the skin without causing lesions, and up to 20% of normal animals in an infected group will act as carrier animals. Premises and harnesses may remain infective for long periods because fungal spores remain viable for years if they are kept dry and cool. Moderate heat and desiccation destroy them.

A dermatophytosis in lambs in the United States, called **club lamb fungus,** affects lambs during lamb show season. Approximately one-third of families reported that children or owners involved in showing these lambs developed skin lesions consistent with dermatophytosis.

Ringworm in yearling horses can interfere with training, causing economic losses because of the isolation required to prevent spread of infection to other horses and humans and to decrease environmental contamination.

Risk Factors

Pathogen Factors

M. gypseum, *K. allejoi*, and *M. nanum* are soil saprophytes, and the reasons for their assumption of pathogenicity are not understood.

Environment and Host Factors

A high incidence of clinical cases in the winter and of spontaneous recovery in the spring is common, but outbreaks also occur during the summer months, so that close confinement and possibly nutrition seem to be more important in the spread of the disease than other environmental factors such as temperature and sunlight. Humidity is known to be important, with high humidity being conducive to multiplication of the fungus. In calf-rearing and vealing units the prevalence is greater in units that continuously add or remove calves from the stock; an "all-in all-out" program is less conducive to spread of the disease.

Animal susceptibility is determined largely by immunologic status, and thus young animals are most susceptible.

Zoonotic Considerations and Economic Importance

Spread between species occurs readily, and in rural areas 80% of human ringworm may derive from animals. *Trichophyton* spp. infections are commonly contracted from horses and cattle[1] and *M. canis* infections from dogs. Ringworm of animal origin affects adult humans and children, and diagnosis and treatment are often very difficult.[2]

Injury to affected animals is of a minor nature, but sufficient damage to hides occurs to warrant some attempt at control of the disease.

PATHOGENESIS

Ringworm fungi chiefly attack keratinized tissues, particularly the stratum corneum and hair fibers, resulting in autolysis of the fiber structure, breaking off of the hair, and alopecia. Exudation from invaded epithelial layers, epithelial debris, and fungal hyphae produce the dry crusts that are characteristic of the disease. The lesions progress if suitable environmental conditions for mycelial growth exist, including a warm and humid atmosphere and a slightly alkaline pH of the skin. Ringworm fungi are all strict aerobes, and the fungi die out under the crust in the center of most lesions, leaving only the periphery active. It is this mode of growth that produces the centrifugal progression and the characteristic ring form of the lesions.

The significance of skin pH in the development of ringworm is widely known. The susceptibility of humans to ringworm infection is much greater before puberty than afterward, when the skin pH falls from about 6.5 to about 4.0. This change is largely attributable to excretion of fatty acids in the sebum, and these fatty acids are often highly fungistatic. Calves are more commonly infected than adult cattle, but whether this is a result of increased susceptibility in calves or the development of immunity in adults has not been determined.

There is some experimental evidence that traumatic injury of the skin is an important factor for the development of ringworm lesions in calves. Different numbers of microconidia of *T. verrucosum* are required to induce ringworm depending on the degree of shearing of the hair and scarification of the skin. *T. mentagrophytes* secretes a small peptide (hemolysin) that is suspected to result in cell-membrane damage and facilitate infection of the skin.[3]

Secondary bacterial invasion of hair follicles is common. The period after experimental infection before distinct lesions appear is about 4 weeks in calves, but considerably less in horses. Spontaneous recovery occurs in calves in 2 to 4 months, with the duration and severity of the disease often depending on the nutritional status of the host. A resistance to reinfection occurs after recovery from experimental or natural infection even though a local mycotic dermatitis may occur at the reinfection site. The immunity is specific to the fungal species concerned, and in horses immunity lasts up to 2 years.

CLINICAL FINDINGS

Cattle

The typical lesion is a heavy, gray–white crust raised perceptibly above the skin. The lesions are roughly circular and about 3 cm in diameter. In the early stages the surface below the crust is moist; in older lesions the scab becomes detached, and pityriasis and alopecia may be the only obvious abnormalities. Lesions are most commonly found on the neck, head, and perineum, but a general distribution over the entire body may occur, particularly in calves, and in severe cases the lesions may coalesce. Itching does not occur, and secondary acne is unusual.

Sheep

In sheep the lesions occur on the head and rarely in the fleeced areas, and although lesions usually disappear in 4 to 5 weeks, the disease may persist in the flock for some months. The lesions are discrete, round, nearly bald patches covered with a grayish crust. Similar lesions occur in goats, but they are distributed generally over all parts of the body. The exception to this description is a new ringworm associated with an unidentified *Trichophyton* that has appeared in sheep in the western U.S. states, plus Georgia and Kentucky, since 1989. Lesions occur extensively in fleeced areas and are characterized by shedding of the wool staple and exudation from the skin surface. Serious spread of the infection to human attendants occurs.

Outbreaks of ringworm in sheep flocks associated with *T. verrucosum* have been reported in Scotland. The outbreaks have been unusual because of the high morbidity rates and persistence of active lesions for up to 6 months. The presence of ringworm lesions precluded the sale of rams in affected flocks.

In club lamb fungus in show lambs in the United States, gross lesions typical of ovine dermatophytosis were located on all parts of the body and consisted of circular areas of matted wool, crusts, and discoloration.

Horses

The lesions may be superficial or deep. Superficial infections are more common. Lesions resulting from *T. equinum* commence as round patches of raised hair and soreness of the lesions to touch. This stage is followed about 7 days later by matting of the hair, which becomes detached, leaving a bald, gray, shining area about 3 cm in diameter. Fine scabs appear, and recovery with regrowth of hair commences in 25 to 30 days. Heavier scabs and larger lesions are usually a result of rubbing by the harness. Lesions associated with *M. gypseum* are smaller, about 10 mm in diameter, and are manifested either by the development of thick crusts or, more generally, a diffuse moth-eaten appearance with desquamation and alopecia. Less commonly, deeper structures are infected through the hair follicles, causing small foci of inflammation and suppuration. A small scab forms over the follicle and the hair is lost, but extensive alopecia and crust formation do not occur. Some irritation and itching may be caused by this type. The distribution of lesions in the horse differs from that in cows, with lesions usually appearing first on the axillary girth area and spreading generally over the trunk and over the rump; lesions may spread to the neck, head, and limbs. Some cases are clinically impossible to differentiate from dermatophilosis.

Chromoblastomycoses is a sporadic, slow-developing chronic granulatous fungal infection of skin following traumatic injury that has been reported occasionally in horses. Nodular granuloma-like nodules gradually appear that are clinically indistinguishable from habronemosis.

Brittle-tail syndrome of horses is a newly reported disease of horses in Hong Kong caused by a keratinolytic fungus, *Equicapillimyces hongkongensis.* Affected horses develop short, stumpy tails as a result of breakage of hairs in the dorsal layers of the tail.[4] The disease is contagious, and environmental or animal reservoirs (apart from horses) are unknown.

Pigs

Ringworm is not common in pigs. Regular ringworm lesions in pigs develop as a centrifugally progressing ring of inflammation surrounding a scabby, alopecic center. The lesion produced by *M. nanum* is different—there is no pruritus or alopecia and cutaneous reaction is minimal, but the centrifugal enlargement of each lesion may cause it to reach an enormous size.[5] Superficial, dry,

brown crusts cover the affected area but are not obviously raised, except at the edges in some cases. The crusts are formed of flakes or dust composed of epithelial debris. Most lesions occur on the back and sides. Spontaneous recovery does not occur in adult pigs.

CLINICAL PATHOLOGY

Laboratory diagnosis depends on the demonstration of spores and mycelia in skin scrapings from the edge of the lesion and in culture. Skin scrapings should be made after decontaminating the skin with 70% ethyl alcohol, placing the scraping in a 10% solution of potassium hydroxide, and potentially adding lactophenol cotton blue before microscopic examination is performed. Spores are the diagnostic feature and appear as round or polyhedral, highly refractive bodies in chains (*Trichophyton* spp.) or mosaics (*Microsporum* spp.) in hair follicles, in epithelial scales, and in or on the surface of hair fibers. A hair perforation test, which measures the capacity of a fungal isolate to perforate human hair fibers in the laboratory, is used in the differentiation of dermatophytic species. Culture can take 2 to 6 weeks to provide a diagnosis; consequently, a PCR test using the primer pair for chitin synthase 1 (CHS1) gene has been developed for use in horses.[6] An ELISA for serodiagnosis has been developed for cattle, but it appears it will be most successful in monitoring response to vaccination and epidemiologic studies.[7]

The most useful technique for the early diagnosis of ringworm in cattle uses a small sterilized hairbrush. The skin lesion is first swabbed with a cotton swab containing 70% to 90% ethyl alcohol to remove environmental contaminants and allowed to dry. The lesion is then brushed; the brush is placed in a sterile plastic bag for immediate transportation to the laboratory[8] and subsequent culture within a few hours.

Examination of the skin of infected animals to detect the fluorescence associated with some fungal infections can also be a useful clinical aid, but many trichophyton fungi do not fluoresce, whereas petroleum jelly and other oily skin dressings may do so. Fungal hyphae in tissues can be identified, even down to the genus, by the use of immunofluorescent staining. The technique was devised for use on necropsy material but should have application for biopsy material and scrapings. Specimens to be sent for laboratory examination should be packed in envelopes because airtight jars and cans favor the growth of nonpathogenic fungi during transportation.

DIFFERENTIAL DIAGNOSIS

The diagnosis of ringworm depends on evidence of infectivity, the appearance of characteristic lesions, and the presence of fungal mycelia and spores. Diagnostic confirmation is by demonstration of fungal elements in a scraping or biopsy.

The differential diagnosis list of ringworm, which may be confused with diseases with similar clinical profiles, follows.

Cattle

Mycotic dermatitis, which has tenacious scabs that cover a raw area of skin.

Inherited parakeratosis, characterized by tenacious thick crusts that respond quickly and completely to dietary supplementation with zinc.

Sarcoptic mange, in which mites can be demonstrated in scrapings; there is intense pruritus and a quick response to standard insecticides.

Psoroptic mange, identifiable by the presence of mites in scrapings, pruritus, occurrence in housed cattle, and the location of the lesions over the hindquarter.

Horses

Mycotic dermatitis, which is limited in its distribution to the back of the horse, and *Dermatonomus congolensis* can be cultured.

Queensland itch diagnosable on its occurrence only in summer, only along the back, and the associated intense pruritus.

Other equine dermatitides.

Pigs

Pityriasis rosea, in which no mites can be demonstrated, and the disease is limited to a particular age group.

Exudative epidermitis has extensive lesions with a characteristic greasy covering.

Tyrogliphosis is self-limiting, associated with a new source of grain, and characterized by pruritus.

Sarcoptic mange, identifiable by the mites in scrapings, the intense pruritus, and the prompt response to treatment with insecticide.

TREATMENT

Many recorded cures are no doubt a result of strategic treatment just before spontaneous recovery, but treatment is widely practiced and recommended because it greatly reduces contamination of the environment by infected animals. Local or systemic treatments are used, the latter when lesions are widespread. Gloves and protective clothing should be worn when treating affected animals because of the potential for zoonotic spread.[2] Administration of a live attenuated *T. verrucosum* vaccine to cattle with ringworm is effective in hastening the resolution of lesions.[9] Vaccination with an inactivated lyophilized *T. verrucosum* vaccine twice at a 14-day interval has been reported to be an effective treatment in horses with multiple ringworm lesions.[10]

Local Application

The crusts should be removed by scraping or brushing with a soft wire brush and burned; the selected medicament should be brushed on or rubbed in vigorously. Clipping of the hair may facilitate treatment application. Suitable topical applications include Whitfield's ointment (a mixture containing 6% benzoic acid and 3% salicylic acid);[11,12] propionic and undecylenic acid ointments; povidone–iodine, thiabendazole 1% to 5%, and captan ointments; ointments containing one of the azole compounds, such as imidazole, miconazole, or tioconazole (1%),[13] or enilconazole (0.2%),[5] and a 10% ammoniated mercury ointment; propolis (a resinous substance collected by honeybees from plants[11]); homeopathic remedies;[12] burnt motor oil;[14] a 10% solution of povidone–iodine; 5% to 10% copper sulfate solution;[14,15] solutions of quaternary ammonium compounds (1:200 to 1:1000); solutions of 0.25% hexadecamethylene-1, 16-bis-isoquinolinium chloride (Tinevet), and Hexetidine (bis-1,3 beta-ethylhexyl-5 methyl-5-amino-hexahydropyrimidine) borotannic complex; and ivermectin (SC, 200 µg/kg BW).[16] The long list of potential treatments indicates the lack of a definitive, large-population, randomized clinical trial using objective measures of treatment efficacy and a negative control group. Whitfield's ointment appears to have the strongest evidence of efficacy and is considered to have keratolytic, antimicrobial, and antifungal effects. Topical treatments are probably of greater value in the early stages of an outbreak when the lesions are small and few in number, and spontaneous resolution is likely in younger animals.

Sprays, Washes

When infection in a group is widespread, washes or sprays that can be applied over the entire body surface of all animals are used, although the efficacy of the preparations is less than that of ointments, and daily application for at least 5 days is required. Sprays have a big advantage if prophylactic treatment of all in-contact animals is recommended. Examples are agricultural Bordeaux mixture, 5% lime sulfur (20% w/v polysulfides diluted 1:20), captan (N-(trichloromethylthio)-cyclohex-4-ene-1, 2-dicarboxamide) 3%, N-trichloromethylthio-tetrahydrophthalimide, iodofors, 0.5% sodium hypochlorite, and natamycin (100 ppm). These treatments may not be available or permitted in every country.

Systemic Treatment

Systemic treatments recommended for use in farm animals include the IV injection of sodium iodide (1 g/14 kg body weight) as a 10% solution repeated on several occasions, and, if the high cost of the treatment can be overlooked, the oral administration of griseofulvin has been empirically recommended at 7.5 to 10 mg/kg BW once daily, with no

strong evidence to support or refute this dosage protocol.

Spontaneous recovery is common in individual animals within 90 days, and careful appraisal of results in clinical trials is necessary. Many farmers overtreat their animals with irritant preparations administered daily for long periods. A crusty dermatitis, or even a neoplastic acanthosis, may result.

CONTROL

Hygiene

Failure to control an outbreak of ringworm is usually a result of the widespread contamination of the environment before treatment is attempted. Isolation and treatment of infected animals; the provision of separate grooming tools, horse blankets, and feeding utensils; and disinfection of these items after use on affected animals are necessary if the disease is to be controlled. All grooming equipment should be carefully washed and treated with a solution of enilconazole or 1:10 dilution of household bleach. Cleaning and disinfection of stables with a commercial detergent or a strong solution (2.5% to 5%) of phenolic disinfectant, 5% lime sulfur, 5% formalin, 3% captan, or 5% sodium hypochlorite is advisable where practicable. Good results are also claimed for the disinfection of buildings with a spray containing 2.0% formaldehyde and 1.0% caustic soda. Sunlight and a low stocking rate provide very effective control measures, which is why ringworm occurs at a much lower incidence in suckling beef calves in pasture than dairy calves raised in group housing with no direct sunlight.

Vaccination

A vaccine developed in the former Soviet Union has achieved a great deal of success in preventing infection in cattle and horses in most countries of Europe and Scandinavia. The nonadjuvanted vaccine includes lyophilized microconidia and hyphal elements of a highly immunogenic, nonvirulent strain of *T. verrucosum*. Small injection-site skin lesions are present for a few weeks in vaccinated calves.[17] Vaccination of all animals in the group is recommended, and isolation and treatment of infected animals and disinfection of premises and gear must be carried out at the same time.

The vaccine is almost totally without side effects except for very rare deaths as a result of anaphylaxis, apparently related to keeping reconstituted vaccine for too long a period. National vaccination campaigns have been successful in eradicating *T. verrucosum* from cattle herds.[17]

Nutrition

Although ringworm occurs in well-nourished and poorly fed animals, there does seem to be a tendency for the latter to become infected more readily and to develop more extensive lesions. Supplementation of the diet, particularly with vitamin A to young housed animals, should be encouraged as a preventive measure. The adequacy of dietary selenium and zinc intake should be determined.[18]

TREATMENT AND CONTROL

Treatment

Discrete lesions in calves or horses

- Whitfield's ointment (6% benzoic acid, 3% salicylic acid) applied topically daily (R-2)
- 5% to 10% copper sulfate solution, daily for 15 days or 4 times at 5-day intervals (R-2)
- 1% tioconazole ointment, 2% miconazole ointment, 0.2% enilconazole solution (R-2)
- Ivermectin (200 µg/kg BW, SC) (R-2)

Widespread multiple lesions

- Topical 2% ketoconazole shampoo twice a week for 4 weeks in horses (R-2)
- Consider oral griseofulvin (7.5 to 10 mg/kg BW once daily) in all species, but excessive cost and may not be permitted in many countries (R-2)

Control

Calves

- Vaccinate with modified live *Trichophyton verrucosum*. (R-1)

All animals

- Don't share grooming equipment between animals (R-1).
- Ensure adequate sunlight and house on pasture with low stocking density. (R-2)
- Ensure adequate vitamin A, selenium, and zinc status. (R-2)

MUCORMYCOSIS

Mucormycosis is a rare disease of humans, horses, cattle, and pigs caused by coenocytic fungi of the order Mucorales. *Lichtheimia corymbifera* (formerly *Absidia corymbifera, Mycocladus corymbiferus*) causes severe disease and death of horses, abscessation of lymph nodes in pigs, and mastitis and abortion in cattle.[1,2] The disease is usually acute and progressive, and antemortem diagnosis is difficult. Clinical signs include fever, diarrhea, circling, convulsions, and acute death. Horses can have ulcerating skin lesions of the muzzle, nostrils, knees, and hocks, which can develop in animals that survive the acute disease. Necropsy examination reveals demarcated necrotic or hemorrhagic lesions in the respiratory and gastrointestinal mucosa, lungs, spleen, and brain. Thin-walled hyphae are visible in routine sections of tissue examined microscopically. There is no effective treatment or control. Zygomycotic lymphadenitis attributable to *Rhizomucor pusillus* or *Lichtheimia corymbifera* (formerly *Absidia corymbifera*) was detected in 0.04% of feedlot steers slaughtered in California. Lesions most commonly affected the mesenteric lymph nodes.[3]

MALASSEZIA SPP. DERMATITIS

Malassezia spp., formerly known as *Pityrosporum*, is a genus of fungi. Dermatitis associated with *Malassezia* spp. is described in goats and horses. A number of species of *Malassezia*, including *M. furfur*, *M. obtusa*, *M. globosa*, *M. pachydermatis*, *M. restricta*, *M. slooffiae*, *M. sympodialis*, and *M. equina*, are present on normal and abnormal skin of horses.[1,2] *Malassezia* spp. were cultured from 5 of 44 swabs and detected on microscopic examination in 40 of 44 swabs of preputial or mammary skin from 11 healthy horses, indicating the need for caution when ascribing etiologic importance to detection of this organism in samples of skin of horses with dermatitis.[1]

Lesions in a horse with alopecia areata included scaling and crusting dermatitis characterized histologically by mild to moderate hyperplasia, mild lymphocytic exocytosis, mild eosinophilic dermatitis, and diffuse parakeratosis with numerous budding yeasts. Alopecia areata might have predisposed the horse to infection, and disease caused by *Malassezia* spp., or the organism might have been an incidental finding.[2] The putative disease in goats is not well characterized.[3]

SPOROTRICHOSIS

Sporotrichosis is a contagious disease of horses, dogs, cats, cattle, and humans characterized by the development of **cutaneous nodules and ulcers** on the limbs that may be accompanied by lymphangitis.

ETIOLOGY

Sporotrichum schenckii (*Sporothrix beurmanii, S. schenckii, S. equi*) is a gram-positive dimorphic fungus that forms single-walled spores. The organism survives in a mycelial phase on living or decaying plant material but changes to a yeast phase when it enters a mammalian body through a puncture wound or bite.

EPIDEMIOLOGY

The disease is reported to occur in Europe, India, Africa, and the United States and likely occurs throughout the world.[1] The host range includes humans, horses, cattle, cats, camels, mice, rats, and chimpanzees. Economic loss caused by sporotrichosis is not great because the disease spreads slowly, the case fatality rate is low, and treatment is effective. Outbreaks of sporotrichosis in dairy cattle causes reduced milk production.

The causative agent persists in organic matter, and contamination of cutaneous wounds can occur either by contact with discharges from infected animals or from contaminated surroundings. The disease is readily spread from affected cats to humans. Transmission from horses to humans has not been reported.

Pathogenesis, Clinical Findings and Clinical Pathology

Local invasion through wounds results in the development of abscesses and discharging ulcers. Multiple, small, cutaneous nodules develop on the lower parts of the legs, usually near the fetlock. The nodules may follow lymphatics and extend to the proximal limb. The nodules are painless, develop a scab on the summit, discharge a small amount of pus, and heal in 3 to 4 weeks. Succeeding crops of lesions may cause the disease to persist in the animal for months. Lymphangitis, causing cording of the lymphatics, occurs.

Demonstration of gram-positive spores in discharges is diagnostic, but it is difficult because of their low number in horses and cattle, as opposed to the high number of spores present in lesions in cats. The organism can be demonstrated in air-dried smears of exudate stained with Wright stain or Romanowsky stain. The hyphal stage is rare in tissues. Injection of pus into rats or hamsters produces a local lesion containing large numbers of the yeast-like cells. The organism can be **cultured** on Sabourard agar.

DIFFERENTIAL DIAGNOSIS

Glanders
Epizootic lymphangitis
Ulcerative lymphangitis

TREATMENT AND CONTROL

Systemic treatment with **iodides** (potassium iodide orally or sodium iodide IV) is the most effective treatment. Local application of tincture of iodine daily to ulcers may suffice in mild cases. **Itraconazole** might be effective.

Prophylactic treatment of all cuts and abrasions, isolation and treatment of clinical cases, and disinfection of bedding, harnesses, and gear will prevent spread of the disease in enzootic areas. Thorough washing of hands and arms with povidone iodine or chlorhexidine is recommended for humans handling infected animals or plant material.

EPIZOOTIC LYMPHANGITIS (PSEUDOGLANDERS, EQUINE BLASTOMYCOSIS, EQUINE HISTOPLASMOSIS)

SYNOPSIS

Etiology Histoplasma capsulatum var. farciminosum, a fungus.

Epidemiology Epizootic disease of low mortality of horses in Asia, Africa, and the Mediterranean. The disease has important adverse effects on the horse, the owner, and wider society in communities that rely on horses as draft animals.

Clinical signs Nodules, lymphadenopathy, and lymphangitis, usually of the hindlimbs. Nodules discharge creamy pus. Conjunctivitis and pneumonia may occur. Spontaneous resolution after a long course is usual.

Clinical pathology Organism in pus, fluorescent antibody test. Histofarcin skin test.

Lesions Lymphangitis, lymphadenitis.

Differential diagnosis Glanders (farcy), ulcerative lymphangitis, sporotrichiosis.

Diagnostic confirmation Demonstration of organism in pus. Clinical characteristics of the disease.

Treatment Parenteral iodides. Amphotericin.

Control Hygiene, slaughter, vaccination.

The disease is important in developing countries, such as Ethiopia, that have a dependence on use of equids as draft animals. In these communities, the disease has an adverse impact on affected equids beyond that caused by the lesions, because affected equids continue to be used as draft animals, because of lost utility of affected animals to owners, and because of the wider societal impact of the loss of availability of large numbers of draft animals.[1] Income generated from providing a cart-horse service is often the sole source of income for families in developing countries, and the presence of the disease reduces the utility of the equid and therefore the income of the family.[1,2]

ETIOLOGY

The cause is a fungus, *Histoplasma capsulatum* var. *farciminosum,* a dimorphic fungal soil saprophyte. The organism has also been classified by the genus name *Zymonema, Cryptococcus, Saccharomyces,* or *Blastomyces.*

The disease is listed by the OIE as a notifiable disease.

EPIDEMIOLOGY

The disease occurs as outbreaks in horses, donkeys, and mules in parts of Iran, Asia, India, northern Africa, and the Mediterranean littoral. Most outbreaks occur in autumn and winter or when large numbers of horses are gathered together for military or other purposes. The disease was detected 19% of cart horses in Ethiopia over an 18-month period, with the prevalence of the disease varying by geographic region from 0% to 39%.[3] The disease was more prevalent in areas with higher mean temperature.[3] The case-fatality rate is 10% to 15%, but the course is prolonged. Cattle and camels are rarely affected.

Fungal spores are carried from infected animals by direct contact or on bedding, grooming utensils, horse blankets, or harnesses, and gain entry through abrasions, usually on the lower limbs. A saprophytic stage in the soil has been suggested to account for the difficulty experienced in eradicating the disease. The organism has been isolated from the alimentary tract of biting flies, and they may play a role in the transmission of the disease.

Zoonotic Potential

Infection is reported in humans.

PATHOGENESIS

After gaining entry through wounds, the fungus invades subcutaneous tissue, sets up a local granuloma or ulcer, and spreads along the lymphatic vessels. The ocular form of the disease results from inoculation of the organism into the eye, likely by biting flies.

CLINICAL FINDINGS

The disease is primarily an ulcerating, suppurative, pyogranulomatous dermatitis, and, in most cases, lymphangitis. An ocular form of the disease is characterized by ulcerating conjunctivitis. Of 65 cases in cart mules in

Ethiopia, 92% had cutaneous lesions, 5% lung lesions, and 3% ocular lesions.[4] The incubation period in two horses experimentally infected varied from 4 weeks to 3 months.[5]

In the **cutaneous form** of the disease an indolent ulcer develops at the portal of entry, making its appearance several weeks to 3 months after infection occurs. The affected skin and subcutaneous tissues are thickened and firm.[4] Nodules that do not rupture are hairless. A spreading dermatitis and lymphangitis, evident as corded lymphatics with intermittent nodules, develops. Nodules rupture, discharging a thick, creamy pus. Local lymph nodes also enlarge and can rupture. Thickening of the skin in the area and general swelling of the whole limb are common. The lesions are painless.

The lesions usually develop on the limbs, particularly around the hocks, but may also be present on the back, sides, neck, vulva, and scrotum. Occasionally lesions appear on the nasal mucosa just inside the nostrils and do not involve the nasal septum. Ocular involvement is manifested by keratitis and conjunctivitis. Sinusitis and pneumonia occur in other forms of the disease.

The disease is chronic, persisting for 3 to 12 months. Spontaneous recovery occurs, and immunity is solid after an attack, but many animals are destroyed because of the chronic nature of the disease.

CLINICAL PATHOLOGY

Gram-positive, yeast-like cells, with a characteristic double-walled capsule, are easily found in discharges. The organisms are located both extracellularly and intracellularly in giant cells and macrophages. The agent can be cultured on special media, but the fungus dies quickly in specimens unless these are collected in antibiotic solutions, refrigerated, and cultured promptly. The specimen should be collected into a solution containing 500 units/mL penicillin.

The mallein test is negative, but a sterile filtrate of a culture of *H. capsulatum* var. *farciminosum* has been used in a cutaneous sensitivity test, and several serologic tests, including a fluorescent antibody test, are available. Antibodies to *H. capsulatum* var. *farciminosum* are detectable in serum before or at the time of development of lesions.

NECROPSY FINDINGS

Lesions are usually confined to the skin, subcutaneous tissues, and lymph vessels and nodes. In some cases, granulomatous lesions may be found in the lungs, liver, and spleen. Histologically, the lesion is quite characteristic and consists of pyogranulomatous inflammation with fibroplasia. Langerhans giant cells are common. The presence of numerous organisms, some of which show budding, in both intra- and extracellular tissue sections stained with H&E, Periodic acid–Schiff reaction, and Gomori methenamine–silver stain is of diagnostic value.

DIFFERENTIAL DIAGNOSIS

See Table 16-4.

Glanders (*Burkholderia mallei)*

Ulcerative lymphangitis (*Corynebacterium pseudotuberculosis*)

Sporotrichosis (*Sporothrix schenckii*)

Histoplasmosis (*Histoplasma capsulatum*)

TREATMENT AND CONTROL

Many treatments have been tried, largely without success. Parenteral iodides have been reported as effective in some cases, as has amphotericin. Sodium iodide is administered as a 10% solution at a dose of 1 mL per 5 kg IV once weekly for 4 weeks. Amphotericin is administered at a dose of 0.2 mg/kg body weight every 48 hours for three treatments, but it might not be economically feasible for use in developing countries.

Outbreaks in uninfected areas are probably best controlled by **slaughter of affected animals**. In enzootic areas, severe cases should be destroyed and less severe cases kept in strict quarantine while undergoing treatment; however, the high prevalence of the disease in some areas (39%) and economic importance to the horse owner of the animal continuing to work make this a difficult recommendation to enforce. All infected bedding, harnesses, and utensils should be destroyed or vigorously disinfected. Formalinized aluminum hydroxide adsorbed and heat-attenuated vaccines have been widely used, apparently with success.

EQUINE PHYCOMYCOSIS (SWAMP CANCER, PITHYOSIS, HYPHOMYCOSIS DESTRUENS, FLORIDA HORSE LEECH, BURSATTEE)

SYNOPSIS

Etiology Pithyium insidiosum, Basidiobolus haptosporus, or Conidiobolus coronatus

Epidemiology Tropical and subtropical areas of the world. Pythiosis occurs during the wet time of the year, but there is no seasonal distribution for B. haptosporus or C. coronatus.

Clinical signs All cause ulcerative granulomas. P. insidiosum causes lesions on the legs and ventral abdomen; B. haptosporus causes lesions on the side of the body, neck, and head; C. coronatus causes lesions in the oral, nasal, pharyngeal, and tracheal mucosae.

Clinical pathology Agar gel double diffusion test and histologic examination and immunohistochemical staining of tissue sections.

Lesions Ulcerative granulomas with sinus tracts containing yellow coagulated material.

Diagnostic confirmation Histologic examination of tissue.

Treatment Surgical excision. Sodium or potassium iodide. Vaccination.

Control None.

ETIOLOGY

The causes are fungi, including *Pythium insidiosum* (syn. *Hyphomyces destruens*), *Basidiobolus haptosporus* (syn. *B. haptosporus* var. *minor*), *Conidiobolus coronatus* (syn. *Entomophthora coronata*), and *Rhinosporidium* spp. *Pseudoallescheria boydii* causes granulomatous lesions of the nasal cavity. *Alternaria alternata* causes small granulomatous lesions on the head of horses, especially young horses.[1] *Scedosporium prolificans* has been associated with conjunctival lesions, arthritis, and osteomyelitis in horses.[2] Unidentified fungi also cause lesions containing black-colored granules or grains, the so-called "black-grain mycetomas."

Skin lesions in horses have been associated with infection by wide variety of fungi, including:[3] *Madurella mycetomatis, Curvularia erruculosa, Bipolaris speciferum, Cladosporium* spp., and *Exserohilum rostratum.* Nonpigmented fungi that cause localized fungal infections in horses include *P. boydii, Aspergillus versicolor, Alternaria tenuis,* and *Scedosporium apiospermum.*[3] *B. haptosporus* is a terrestrial fungus that lives in decaying vegetation.

EPIDEMIOLOGY

Occurrence

The disease occurs most commonly in **tropical and semitropical climates** but can occur in animals housed in temperate climates. Although the disease is recorded most commonly in horses, it does occur in young cattle, dogs, and humans.[4] Fungal disease, excluding that caused by the dermatophytes, accounted for 2.5% of nonneoplastic diagnoses of nodule skin lesions examined in Colorado and the prairie provinces of Canada.[5]

Pythiosis occurs mostly during the monsoon season in tropical areas, whereas infection by *B. haptosporus* and *C. coronatus* occurs year round. A survey in tropical northern Australia showed that granulomas of horses were caused by *P. insidiosum* in 77%, *B. haptosporus* in 18%, and *C. coronatus* in 5% of cases.

Animal Risk Factors

The fungi gain access to the subcutaneous tissues through wounds or other disruptions of the integrity of the skin or mucosa. A strong correlation between the occurrence of the lesions and frequent wetting and exposure to water is reported and is consistent with the concept of an aquatic life cycle and **motile zoospores** of *P. insidiosum.* There is no breed, age, or sex predilection. Multiple cases can occur in horses maintained in the same enclosure.

Zoonotic Potential

Many of these fungi cause disease in humans, for instance, *P. boydii* infection causes granulomas of the lower extremities of people in tropical regions and is referred to colloquially as Madura foot. However, there is no evidence of spread of infection from horses or other infected animals to humans, although appropriate caution should be exercised when handling infected tissues, especially by individuals with compromised immune function.

PATHOGENESIS AND CLINICAL FINDINGS

The **life cycle** of *P. insidiosum* involves colonization of leaves of aquatic plants where the organism undergoes sexual reproduction and produces sporangia. Motile zoospores, released from the sporangia, are attracted to plant and animal tissue, to which they adhere. Zoospores are attracted to damaged tissue, on which they encyst and develop germ tubes. The hyphae invade tissue and produce the granulomatous reaction and ulceration. Ejected kunkers (necrotic material infected with hyphae) may produce sporangia.

The large (20-cm), rapidly growing, circular, fibrotic, ulcerative granulomas caused by *P. insidiosum* usually develop on the lower limbs, ventral abdomen, or thorax and contain yellow concretions in sinus tracts (leeches or kunkers).[4,6,7] The lesions are pruritic and grow rapidly, often becoming greater 20 cm in diameter in 1 month. *P. insidiosum* lesions may involve underlying bone, and **osteomyelitis** may be a common feature of chronic pithyosis of the lower limbs. *Pithyium* spp. infection of the small intestine causes **eosinophilic enteritis** and granuloma formation, resulting in colic and the need for surgical resection. Dissemination of infection from subcutaneous sites to the liver, lung, and spleen occurs and results in a progressive weight loss and eventual death.

C. coronatus causes lesions similar to, but smaller than, those of pithyosis.[8] However, lesions are only on the nares, nasal passages, oral cavity, pharynx, or trachea. The lesions can be very slow growing and take 1 to 2 years to become invasive, whereas others grow rapidly. *P. boydii* causes granulomatous lesions of the nasal cavity in horses. *B. haptosporus* causes ulcerative, granulating lesions that have a hemorrhagic, edematous surface, in contrast to the fibrotic lesions caused by *Pithyium* spp., on the sides of the **trunk, thorax, neck, and head**. Lesions caused by *B. haptosporus* are pruritic.

A. alternata causes cutaneous nodules that are not painful or pruritic on the head of horses. The nodules may be solitary but are usually multiple and slowly progressive.[1]

S. prolificans causes infection of musculoskeletal structures, including joints and bone, usually secondary to puncture wounds or surgery. This organism causes disseminated lesions and a fatal disease in immunosuppressed humans.

CLINICAL PATHOLOGY

Culture of the causative fungus is a laborious task but is necessary to demonstrate presence of the organism, although PCR detection is becoming available and could replace culture as the definitive diagnostic test. A PCR test has been developed for the identification of *Pythium* spp., and this test also is useful for the detection of *C. coronatus.* Horses infected with *P. insidiosum* have a positive reaction to an **agar gel double-diffusion test**, and complement fixation and intradermal hypersensitivity tests are also of diagnostic value.

Examination of a biopsy specimen is also of value, but care is needed to include a portion of necrotic tissue in which hyphae are most likely to be found. *P. boydii* is indistinguishable from *Aspergillus* spp. on microscopic examination of tissue. **Immunohistochemical** staining methods, using indirect peroxidase techniques, are of value in distinguishing *Pythium* spp. from other fungi in swamp cancer lesions.

Necropsy examination of horses with disseminated pythiosis reveals small, firm, irregularly branched, yellow–white masses in the regional lymph nodes draining cutaneous lesions and in the liver, lungs and spleen. Histologically the masses are eosinophilic granulomas containing hyphal elements of *Pythium* spp.

DIFFERENTIAL DIAGNOSIS

- Habronemiasis
- Granulation tissue
- Sarcoid
- Fibrosarcoma
- Amyloidosis of the nasal septum
- Squamous cell carcinoma
- Aspergillosis of the nasal septum
- Osteomyelitis

TREATMENT

The most **efficacious treatment** for pythiosis and conidiobolomycosis is excision, although recurrence is common (30%) with larger lesions. Laser ablation of the bed of the granuloma may reduce the rate of recurrence. Larger lesions are usually treated medically. Fungal lesions respond to treatment of **sodium iodide** (20 to 40 mg/kg BW IV, q 24 h, as a 20% solution), followed by oral administration of **potassium iodide** (10 to 40 mg/kg po q 24h for 7 to 120 days). Potassium iodide can also be administered at a dose of 10 g/425 kg once daily, with the dose increasing by 2 g/day until the horse exhibits feed refusal or a dose of 20 g/day is achieved. Treatment should continue until signs of mycotic disease have resolved, which is often weeks to months. An alternative to potassium iodide is ethylenediamine dihydroiodide (1.3 mg/kg, oral q 12 hours for up to 4 months and q 24 hours for up to 1 year). Iodinism is a potential adverse effect of administration of sodium or potassium iodide, although this is rarely observed.

Amphotericin also gives good results as a systemic treatment (intravenously 0.4 mg/kg BW increasing to 1.5 mg/kg per day for 10 to 40 days) combined with local infiltration and after surgical excision in extensive lesions. Administration of amphotericin can be limited by its nephrotoxicity, which should be monitored during treatment. **Itraconazole** (3 mg/kg orally every 12 hours for 3 to 4 months) is effective in the treatment of *C. coronatus* infections of the nasal septum. **Fluconazole** (14 mg/kg oral loading dose followed by 5 mg/kg q 12 hours orally for 6 weeks) is effective in the treatment of nasal conidiobolomycosis in horses. The pharmacokinetics of fluconazole in horses have been determined, permitting rational dosing of this drug. Ketoconazole is not effective for the treatment of *C. coronatus* in horses.

Miconazole (5 grams of 2% solution) infused for 4 weeks into lesions in the nasal cavity, in combination with systemic administration of iodides, was effective in treatment of nasal lesions caused by *P. boydii.*

S. prolificans is resistant to commonly used antifungal drugs.

A **vaccine** composed of elements of *P. insidiosum* causes recovery or improvement in most cases. It also causes a severe reaction, sometimes a cold abscess, at the injection site. Other complications include osteitis and laminitis, which necessitate euthanasia.

MADUROMYCOSIS

Maduromycosis is a skin disease of horses characterized by cutaneous granuloma caused by a variety of fungi, including *Helminthosporium spiciferum, Brachycladium spiciferum, Curvularia geniculate,* and *Monosporium apiospermum*. One or more lesions 1 to 2.5 cm in diameter appear anywhere on the skin but with a special frequency at the coronet. The incised lesion has a mottled appearance and drains pus containing the fungus.

Protozoal Diseases of the Skin

BESNOITIOSIS (ELEPHANT SKIN DISEASE)

SYNOPSIS

Etiology Intermediate host-specific tissue cysts of *Besnoitia besnoiti*, *B. caprae*, and *B. bennetti.*

Epidemiology Endemic disease in some tropical and subtropical areas, with high morbidity and low mortality. Rare disease elsewhere. Definitive host not known. Disease occurs in donkeys in the United States. Possible insect transmission of disease to cattle and goats.

Clinical findings Anasarca, alopecia, hyperpigmentation and scleroderma, and infertility.

Inspiratory dyspnea and loss of condition Pin-point nodules (cysts) on the scleral conjunctiva and nasal, pharyngeal, and/or laryngeal mucosa.

Lesions Parasitic cysts in dermis, subcutaneous, and other fascia.

Diagnostic confirmation Demonstration of bradyzoites in skin biopsy or scleral conjunctival scrapings.

Treatment and control Little information available.

Besnoitiosis is a parasitic disease of cattle, goats, horses, and certain wild animals. Infections in the chronic cystic stage can result in severe disease and/or production loss.[1-5]

ETIOLOGY

Besnoitia are cyst-forming coccidian (apicomplexan) parasites. The life cycle involves a definitive host and an intermediate host. There are seven classified species, of which three occur in domestic livestock. These are *B. besnoiti* in cattle, *B. caprae* in goats, and *B. bennetti* in horses, donkeys, and mules. The other four known *Besnoitia* species infect wildlife species. Cats are the definitive host for some *Besnoitia* infecting wildlife, but the definitive host(s) for the three domestic livestock species are unknown. Recent evidence suggests that *B. besnoiti* and *B. capri* are the same genetically, that they also have the same bradyzoite ultrastructure, and that they may not be separate species.[2,3]

EPIDEMIOLOGY

Occurrence

Besnoitiosis of livestock animals occurs as outbreaks in some tropical and subtropical regions, and sporadically in other areas. In endemic areas, the disease can affect a large proportion of the herd and cause significant economic loss.[1-3] **Bovine** besnoitiosis is recorded in the African continent, southern Europe,[1] South America, Israel, Asia, and the Russian Federation; **caprine** besnoitiosis in Kenya, Uganda, Iran, and Kazakhstan; and besnoitiosis is found in equids in Africa and has recently emerged in donkeys in the United States.[4,5]

Risk Factors

Besnoitia are relatively host specific. *B. besnoiti* infects cattle and in Africa also infects goats and wild ruminants. The Kenyan species of *B. caprae* does not infect cattle or sheep. The natural means of transmission is not known, but is presumed to be by ingestion of oocysts from the definitive host(s). Infection with *B. besnoiti* and *B. caprae* can be transmitted experimentally with endozoites and bradyzoites, and mechanically by infections or biting flies. Outbreaks of disease in cattle or goats occur in fly seasons, and it is postulated that biting insects may be important vectors. Transmission via semen from infected males is also suggested.

Economic Importance

B. besnoitia is an economically important parasite of cattle in Africa and Israel.[2,3] Although mortality is generally low, morbidity can approach 10% in the chronic stages. There is a loss of condition, and the fertility of male cattle and goats can be significantly impaired from chronic scrotal skin lesions. Skins have no value for tanning. Besnoitiosis in equids appears to have a rare occurrence, but there is evidence of an emergence in donkeys in the United States.[4,5]

PATHOGENESIS

Following infection of the intermediate host, the endozoites (tachyzoites) proliferate in macrophages, fibroblasts, and endothelial cells, causing **vasculitis** and thrombosis, particularly in capillaries and small veins of the dermis, subcutis, and testes. They then mature to form bradyzoite cysts (cystozoites) within fibroblasts. Replication is accompanied by cellular destruction and the release of inflammatory mediators, resulting in anorexia, lethargy, testicular degeneration, generalized edema of the skin, alopecia, and scleroderma.[2-5] *Besnoitia* cysts form in high numbers in the dermis and subcutaneous tissue. Inspiratory dyspnea is associated with infection in the upper respiratory tract.

CLINICAL FINDINGS

Bovine Besnoitiosis

Typical signs occur in two stages: the acute anasarca stage associated with the proliferation of endozoites and the chronic scleroderma stage associated with cyst formation.[2,3]

Acute Stage

In the acute stage there is fever and an increase in pulse and respiratory rates; warm, painful swellings appear on the ventral aspects of the body, interfering with movement. There is also generalized edema of the skin. The superficial lymph nodes are swollen, diarrhea may occur, and pregnant cows may abort. Lacrimation and an increased nasal discharge are evident; small, whitish, and elevated macules may be observed on the conjunctiva and nasal mucosa. The nasal discharge is serous initially, but it becomes mucopurulent later and may contain blood.

Chronic Stage

As the disease becomes chronic, the skin becomes grossly thickened and corrugated, and there is alopecia. A **severe dermatitis** is present over most of the body surface. Affected bulls often become sterile for long periods, particularly if the scrotal skin is affected. Cystic stages of the *Besnoitia* have been found in vascular lesions in the testes of affected animals and may be a major contributor to the sterility. **Cysts on the scleral conjunctiva** are considered to be of particular diagnostic importance.[3]

In endemic areas, the signs that attract clinical attention are alopecia and severely thickened and wrinkled skin, which is often thrown into folds around the neck, shoulder, and rump region and the carpal and tarsal areas. Small, subcutaneous, seed-like lumps can be palpated. In cattle, infections of the teat skin may result in lesions around the mouth in suckled calves. The case fatality rate can be ~10%, and the convalescence in survivors is protracted over a period of months.

Caprine Besnoitiosis

The acute stage is not commonly seen in goats; the disease presents like the chronic stage in cattle,[3] with dyspnea and cutaneous lesions. The cutaneous lesion is a chronic dermatitis of the legs, particularly the carpal and tarsal regions, and the ventral surface of the abdomen. It varies from mild thickening with superficial scaling, to marked thickening with hyperpigmentation and a serous discharge. The hair is sparse.

Equid Besnoitiosis

The clinical signs are similar for different species of equids (horses and donkeys).[4,5] Animals may show exercise intolerance, nasal discharge, and inspiratory dyspnea.

Skin lesions, like those in cattle and goats, are present on the ventral abdomen and legs or the whole body surface. Pin-point white nodules can be seen on the nares and sclera, and by endoscopy on the soft palate, pharynx, and/or larynx.[4,5]

CLINICAL PATHOLOGY

There is little information on hematology and blood chemistry. Hypergammaglobulinemia has been reported in one horse. Cysts containing a number of banana- or spindle-shaped zoites can be detected in scrapings or sections of skin or scleral conjunctival scrapings. Ear-tip biopsies are commonly used in surveys of goats, and many infected animals show no clinical signs of infection. Serum antibodies to *Besnoitia* spp. can be detected using an indirect immunofluorescence technique or ELISA, but such tests likely have inadequate sensitivity and specificity.

NECROPSY FINDINGS

At necropsy, apart from any lesions detected upon clinical examination, animals that die in the acute stage of disease usually have widespread petechiae and ecchymoses in the subcutis and edema in the lymph nodes and in the testis in males. In the chronic stage, small white granules (the size of sugar granules) may be found in multiple muscles, intermuscular fascia, and tendons, particularly in the limbs, neck, and nasal mucosa. Parasite stages are evident in lesions upon histologic examination, and they are found in endothelial cells and the intima of blood vessels, often associated with necrosis and a mild inflammatory reaction.

DIAGNOSTIC CONFIRMATION

The most efficient and cost-effective method of diagnosis of clinical disease is the demonstration of *Besnoitia* bradyzoites in skin biopsy smears or scleral conjunctival scrapings. PCR-based techniques might also be used.[5,6]

TREATMENT AND CONTROL

There is little information on treatment. Clinical cure of a donkey with a 9-month history of chronic skin disease is reported following prolonged oral administration of trimethoprim–sulfamethoxazole.[1] Animals should receive supportive therapy and be treated symptomatically for enteritis or dermatitis. A vaccine containing *Besnoitia besnoiti*, grown on tissue culture and originally isolated from blue wildebeest, has been used to vaccinate cattle. A durable immunity to the clinical form of the disease was reported, but low-level subclinical infection did occur.[1]

Nematode Infections of the Skin

SUMMER SORES IN HORSES (HABRONEMOSIS)

SYNOPSIS

Etiology Three nematode species, *Habronema muscae*, *H. majus* (syn. *H. microstoma*), and *Draschia megastoma*, infect the horse.

Epidemiology Larvae from eggs in the feces are ingested by fly larvae; adult flies deposit infective larvae on skin.

Signs Larvae deposited in wounds or in eye cause local inflammation and the development of extensive granulation tissue.

Clinical pathology Larvae may be found in skin scrapings, biopsies, or discharge; marked local eosinophilia.

Lesions Adult *D. megastoma* cause tumorlike lesions in stomach; other species cause a catarrhal enteritis.

Diagnostic confirmation *Gastric form:* eggs difficult to find in feces; *cutaneous form:* demonstration of larvae, eosinophils in biopsy or scraping.

Treatment Ivermectin.

Control Protect horses from flies; treat all skin wounds promptly.

ETIOLOGY

The various forms of cutaneous habronemosis, with local names such as "summer sores," "swamp cancer," and "bursattee," involve three nematode species, *Habronema muscae*, *Habronema majus* (syn. *microstoma*), and *Draschia megastoma*, the adults of which infest the stomach of horses.

LIFE CYCLE

Habronema spp. adults are larger (1 to 2.5 cm long) than those of *D. megastoma* (1.25 cm). The life cycles are indirect; all species use flies as their intermediate hosts. *H. muscae* and *D. megastoma* mainly use the housefly (*Musca domestica*)[1] but can use other muscid species, whereas *H. majus* usually passes through the stable fly (*Stomoxys calcitrans*),[2] although *Haematobia irritans exigua*, *Sarcophaga melanura*, and the housefly can also be used. The thin-walled larvated eggs hatch in the manure and are ingested by maggots, in which they develop. The infective form is reached at about the time the adult fly emerges from the puparium. Horses become infected by swallowing dead flies with feed or water, or, alternatively, infective larvae may pass through the proboscis of the fly when it is feeding on the lips or on wounds.[3] Larvae that are swallowed reach maturity in the stomach, whereas those deposited in wounds cause cutaneous habronemosis. Stray larvae may be found anywhere throughout the body but occasionally massive invasion of the lungs is seen.

EPIDEMIOLOGY

Habronema and *Draschia* have a worldwide distribution. They are of importance only in warmer climates, where they are commonly found, especially in wetter areas where the intermediate hosts are common.[4-6] Elsewhere they tend to be a sporadic nuisance. Gastric granulomas and most cutaneous lesions appear to be associated with *D. megastoma*, although typical cutaneous lesions do occur naturally and have been produced experimentally by the cutaneous implantation of *H. majus* or *H. muscae* larvae. The latter, however, only cause a transitory reaction. Horses of all ages are susceptible, but the disease is most common in adults.

PATHOGENESIS

Two types of gastric habronemosis occur. The more serious is associated with *D. megastoma*. Larvae invade the gastric mucosa and cause the development of large granulomatous masses that later fibrose. These tumors contain adult worms and have a central orifice through which eggs and larvae escape into the lumen. In many horses, the lesions cause only a mild chronic gastritis. In rare cases perforation occurs and is followed by a local peritonitis, which may involve the intestine, causing constriction, or the spleen, causing abscesses. *H. majus* and *H. muscae* do not cause tumors but penetrate the stomach glands and cause a catarrhal gastritis with the production of a thick tenacious mucus. Heavy burdens may cause ulceration. In donkeys, hyperoxemia, edema, erosions, and ulcers in addition to parasitic lesions have been observed.[7]

In cutaneous and conjunctival habronemosis, *Habronema* spp. larvae deposited in wounds cause local inflammation and the development of extensive granulation tissue.[5] Secondary bacterial or mycotic invasions may occur. In the eye, similar lesions form on the inner canthus, the nictitating membrane, or the eyelid. These can cause profuse lacrimation and other signs of local irritation.

CLINICAL FINDINGS

Gastric habronemosis does not usually provoke clinical signs, but affected animals may, on occasion, have a poor coat and a

variable appetite. Large tumors may cause pyloric obstruction and gastric distension. When perforation occurs, there is depression, a fever of 39.5° to 40.5° C (103° to 105° F), and pain and heat on the left side just behind the costal arch. Mild to moderate colic may be evidenced when intestinal stenosis is present. If the spleen is involved, there is marked anemia and a gross increase in the total leukocyte count with a shift to the left.

Cutaneous habronemosis is manifested by the appearance of lesions on those parts of the body where skin wounds or excoriations are most likely to occur and where the horse cannot easily displace the vector flies. Thus they are most common on the face below the medial canthus of the eye and on the midline of the abdomen, extending in males onto the prepuce and penis. Less commonly, lesions may be found on the legs and withers, but those occurring in the region of the fetlocks and coronary band are especially serious. The cutaneous lesions commence as small papules with eroded, scab-covered centers. Development is rapid, and individual lesions may increase to 30 cm in diameter in a few months. The center is depressed and composed of coarse, red granulation tissue covered with a grayish necrotic membrane, and the edges are raised and thickened. Although the lesions do not usually heal spontaneously, they may regress in colder weather and recur the following summer. There is little discharge. The sores are unsightly, are inconvenient, and cause some irritation.

In **conjunctival habronemosis**, lesions on the nictitating membrane may be as large as 5 mm in diameter. The conjunctivitis is manifested by small, yellow, necrotic masses about 1 mm in diameter, accompanied by soreness and lacrimation, which do not respond to standard treatments for bacterial conjunctivitis.

CLINICAL PATHOLOGY

Diagnosis is difficult in the gastric form of the disease because the eggs and larvae are not easy to find in the feces. Biopsy of a cutaneous lesion reveals connective tissue containing small, yellow caseous areas up to 5 mm in diameter. Larvae may be found in skin scrapings or biopsies, and ocular lesions can be found in the conjunctival sac or discharge. A marked local eosinophilia occurs.

NECROPSY FINDINGS

Tumor-like lesions of *D. megastoma* bulge into the lumen of the stomach and may reach the size of a golf ball. Adult *Habronema* are stout worms, but their presence is often masked by a thick, tenacious layer of mucus. This is on the glandular part of the stomach and often close to the margo plicatus.

Granulomatous lesions may be found in all the sites mentioned in the description of clinical signs, and although varying in size, they are of essentially the same composition as described earlier under "Biopsy." Horses that have had the cutaneous form of the disease may have small nodules in the parenchyma of the lung. These are hard and yellowish and contain inspissated pus and larvae.

DIAGNOSTIC CONFIRMATION

A biopsy will confirm clinical diagnosis of the cutaneous and conjunctival forms of the condition. Experimentally, PCR assays targeting the application of the Internal transcribed spacer 2 (ITS2) of ribosomal DNA for specific identification of *Habronema* spp. in feces and biopsies have been developed.[8,9]

DIFFERENTIAL DIAGNOSIS

The gastric form of habronemosis is difficult to differentiate from infestation with stomach bot (*Gasterophilus*) larvae or *Trichostrongylus axei.* These parasites often coexist in the same animal. Cutaneous habronemosis must be distinguished from:

- Fungal granulomata associated with *Hyphomyces destruens*
- Overgrowth of granulation tissue following a wound
- Equine sarcoids

TREATMENT

TREATMENT
Ivermectin (0.2 mg/kg SQ) (R-1)
Moxidectin (0.4 mg/kg) (R-1)
Fenbendazole (10 mg/kg, q.1d. for 5d) (R-2)

Few anthelmintics have been adequately tested against *Habronema* spp. and *D. megastoma.* Ivermectin 0.2 mg/kg will remove these species from the stomach with a single SC treatment,[10] but a second dose is sometimes necessary to promote healing in cutaneous lesions. Moxidectin (0.4 mg/kg) is active against adult *Habronema muscae.* Fenbendazole used at 10 mg/kg PO once daily for 5 days is reported to have high efficiency against *D. megastoma* and possibly *Habronema* spp.

CONTROL

Interruption of the life cycle by careful disposal of horse manure and control of the fly population are obvious measures. In enzootic areas all skin wounds and excoriations should be treated promptly to promote healing and protect them against flies.

RHABDITID DERMATITIS

Pelodera is a subgenus of the soil nematode *Rhabditis.* Dermatitis associated with the larvae of *P. strongyloides* is rare. It is recorded most commonly in the dog,[1] but outbreaks have been observed in cattle, sheep, and horses. It has also been an incidental finding in other skin diseases associated with poor husbandry practices. Alopecia is marked, particularly on the neck and flanks. In moderate cases the skin on affected areas is thickened, wrinkled, and scurfy, and some pustules are present on the ventral abdomen and udder. Pustules are up to 1 cm in diameter and contain thick, yellow caseous material and worms. There is marked irritation and, in severe cases, affected areas are swollen and raw and exude serum.

Pelodera strongyloides is a free-living soil nematode found particularly in decaying leaf mold and similar material. When warm-blooded animals lie on its habitat for prolonged periods, it takes the opportunity to invade the skin. Thus infestation is encouraged by housing animals on warm, wet bedding. Under favorable conditions, the disease may spread rapidly. In these circumstances the lesions occur most commonly where the skin contacts the bedding. The nematodes are easily detected in skin scrapings or biopsy specimens and in samples of the bedding, preferably taken from the top few centimeters in the pen.

Control measures include the regular removal of soiled bedding and steps to ensure that the litter is kept dry. Spontaneous recovery usually occurs if these precautions are taken, but local application of a parasiticide and symptomatic therapy will speed recovery.

ONCHOCERCIASIS (WORM NODULE DISEASE)

Onchocerca spp. are filamentous, thread-like nematodes found mostly as convoluted masses in fibrous tissues. They vary in length; those of the horse are 15 to 18 cm long, whereas bovine species may be as long as 75 cm. They are filarial worms, and the females produce motile embryos (microfilariae). These congregate in the skin and subcutaneous tissues at the favored feeding site of their intermediate host. Each *Onchocerca*

species uses a particular biting fly, usually a species of *Culicoides* (midge) or *Simulium* (blackfly). Transmission takes place when infective larvae that develop in the fly are deposited on the skin of their host at a subsequent feed.

Infestation by adult worms is often symptomless, and prevalence tends to increase with age. Relatively nonpathogenic species of widespread occurrence in cattle include *O. gutturosa* in the ligamentum nuchae and *O. lienalis* in the gastrosplenic ligament, whereas horses often harbor *O. cervicalis* in the ligamentum nuchae and *O. reticulata* around the flexor tendons. In horses *O. cervicalis* can cause recurrent fluid-filled masses over the withers that lead to mild bone lysis of the dorsal spinous processes and mineralization within the soft tissue swelling.[1,2] Some cause rejection of meat for human consumption. *O. gibsoni* in Australian cattle, for example, provokes nodules up to 3 cm across in subcutaneous tissues, especially in the brisket. *O. ochengi* produces subcutaneous nodules in African cattle,[3,4] most commonly on the scrotum and udder. Other species may be more pathogenic, such as *O. armillata*, which lives in the aorta of cattle, buffalo, and goats in India and Iran.

Losses caused by adult worms are slight, although *O. gibsoni* in cattle causes unsightly lesions and rejection of beef carcasses from the high-class meat trade. The characteristic nodules of *O. gibsoni* are usually freely movable and consist of fibrous tissue canalized by the long body of the worms. With *O. armillata*, the inner wall of the aorta may be corrugated and swollen. In horses, new infections with *O. reticulata* may cause swelling of the suspensory ligament and a hot edematous swelling of the posterior part of the cannon that persists for 3 to 4 weeks. After the swelling subsides, the suspensory ligament remains thickened, and small caseated or calcified nodules may be palpated. Affected animals are lame while the area is edematous and swollen, but many recover when the swelling disappears. *O. cervicalis* causes fibrotic, caseous, and calcified lesions in the ligamentum nuchae, but clinical signs are not seen. The conditions known as "poll evil" and "fistulous withers" are no longer thought to be associated with this parasite.

Microfilariae may sometimes be damaging. Those of *O. cervicalis*, for example, are occasionally observed in the cornea of horses, but the proposed causal relationship with periodic ophthalmitis is no longer thought to be valid. They can, however, induce hypersensitivity reactions in the skin of some individuals. Lesions are characterized by alopecia, scaliness, and pruritus, particularly along the ventral abdomen. They may extend between the forelegs and backlegs to include the thigh, and in severe cases they may extend up the lower abdominal wall. Some horses have lesions on the face, neck, or thorax. The lesions may be confused with those associated with horn-fly feeding, but these are more likely to include crusting and ulcerating dermatitis. In onchocercosis, microfilariae are not detectable in the bloodstream but may be found in skin biopsies. *O. ochengi* in African cattle has been associated with a dermatitis resembling demodectic mange and pox, and in Turkey microfilariae of *O. gutterosa*, *O. lienalis*, and an unidentified species have recently been reported in association with teat lesions, including sores, chaps, and nodules.[5] In cattle, sheep, and horses common pathologic lesions that have been observed in muscle fasciae and connective tissues include greenish-gray coloration, edema, and small (3 to 10 mm) pale granulomatous nodules on fasciae. In the liver there are multifocal, small (2 to 6 mm), clustered pale or yellowish nodules. Histopathological examination of the nodules shows mild to intense infiltration with eosinophilic granulocytes and multifocal nodular lymphoplasmacytic aggregations.[5]

TREATMENT

Ivermectin (0.2 mg/kg, PO) (R2)
Moxidectin (0.4 mg/kg, PO) (R2)

Control of the intermediate hosts is virtually impossible, but valuable horses prone to hypersensitivity to *O. cervicalis* microfilariae can be partially protected by housing at night because most *Culicoides* species feed during twilight hours and/or at night. The use of insect repellents and avoidance, if possible, of grazing areas where the insects are likely to be in large numbers will also be beneficial. There is no specific treatment for the adult worms. A novel approach has been the experimental use of tetracycline to eliminate *O. ochengi* by killing the symbiotic bacterium *Wolbachia*, which is found in many, but not all, filarial species.[6,7] An experimental multivalent subunit vaccine based on recombinant proteins of *O. volvulus* has shown partial protection against patent *O. ochengi* infection in cattle.[8,9] Experimental treatment with three doses of 4 mg/kg melarsomine hydrochloride in aqueous solution by slow IV injection on alternate days has been shown to be macrofilaricidal in cattle with *O. ochengi* infection.[10] Oral ivermectin 0.2 mg/kg or moxidectin 0.4 mg/kg can be used to eliminate microfilariae in horses, but recurrence of microfilariae and lesions has been observed even after repeated treatment with ivermetin.[1,11] About 10% of treated horses develop an edematous reaction within 24 hours. This is usually restricted to the area of the lesion, but some may develop a pruritic ventral edema.

PARAFILARIOSIS

Horses in Europe, particularly eastern Europe, China, South America, and North Africa, are sometimes infected with *Parafilaria multipapillosa*, a 3- to 6-cm-long nematode. The female lives in a nodule in the skin, which it pierces to lay eggs on the surface. The subcutaneous nodules ulcerate, bleed, heal, and disappear spontaneously. The hemorrhagic exudate from the lesion attracts bloodsucking flies such as *Haematobia*, which ingest the eggs and act as the intermediate host. The condition is relatively benign, occurring in the spring, summer, and autumn. Many nodules may occur on a horse, but although unsightly, they do little harm unless they interfere with harness straps.

Similar lesions in cattle are associated with *P. bovicola*, which is endemic in eastern and some western European countries,[1-4] India, the Philippines, Japan, and South Africa. It has recently become established in Canada, Ireland, and Sweden, where it spread at a rate of 50 km/year. Muscid flies, for example, *Musca autumnalis* in Sweden and Belgium,[1] act as the intermediate host, and the prepatent period in cattle is 7 to 9 months.[1] The condition is seen mostly in late winter, spring, and summer and causes widespread economic losses as a result of carcass trimming and hide damage. The majority of lesions are superficial and localized, but sometimes they cover the whole carcass. In such cases intermuscular lesions will be found within the fascia of adjacent muscles. Subperitoneal, abdominal, subpleural, and thoracic lesions may also occur and cause condemnation of the whole carcass. *Suifilaria suis* causes similar lesions in the pig in South Africa.

Clinical signs are restricted to the presence of bleeding points, and a diagnosis may be made by examining a smear of the exudate microscopically for larvated eggs.[1]

DIFFERENTIAL DIAGNOSIS

- Insects bites (mainly tabanids)[1]
- Injuries[1]
- Warbles, bacterial or fungal granulomas[1]

TREATMENT

Ivermectin (0.2 mg/kg IM) (R-1)
Nitroxynil (20 mg/kg SQ q72 twice) (R-2)

Ivermectin markedly reduces the area of the lesions and the mass of affected tissue.[1] A control program for *P. bovicola* using ivermectin has been evaluated. Blood spots were dramatically reduced, but transmission was not stopped. Nitroxynil 20 mg/kg twice at 72-hour intervals is effective in reducing the number and area of lesions, but care must be taken to ensure accuracy of dosing or toxic signs of drug overdose may be seen.[5] Topical levamisole may also be effective.

STEPHANOFILARIASIS

Stephanofilaria spp. are very small (up to 8 mm) filarial nematodes living in cysts at the base of hair follicles. They are associated with subcutaneous tissue lesions in cattle and buffalo. There are a number of species, including *S. dedoesi* (synonyms *S. assamensis*, *S. kaeli*, and *S. okinawaensis*), which provokes a dermatitis ("cascado") affecting the eyes, neck, withers, shoulders, and dewlap in cattle in parts of Asia, in addition to '"humpsore" in India, leg sores on cattle in Malaysia, and muzzle and teat lesions in Japan. *S. zaheeri* causes "earsore" in India, and *S. stilesi* is responsible for dermatitis of the ventral abdomen in parts of the United States and Russia. A similar species in Queensland, Australia, affects the head, neck, dewlap, and sternum. *S. boomkeri* has recently been described in pigs in Africa. The adult worms release microfilariae that later develop into flies that feed on the sores. The vector for *S. dedoesi* is *Musca conducens*, whereas the horn fly *Haematobia irritans* is the intermediate host for *S. stilesi* in the United States. The Australian species is probably spread by the buffalo fly, *Haematobia irritans exigua*.

Cutaneous stephanofilariosis starts with small papules that later coalesce to produce lesions varying from 3 to 15 cm in diameter. They are an extreme irritant, and evidence of rubbing is present. Part but not all of the hair is lost, and dried exudate forms a thick, crumbly scab that may crack to expose blood-stained fluid. Skin scrapings taken from beneath the scab may reveal worm fragments. If healing occurs, the scab disappears, leaving a scar. Infection does not affect growth rate, and treatment and control are required only in stud cattle in which lesions are esthetically undesirable.

TREATMENT
Levamisole (7.5 mg/kg PO) (R-2)

Ivermectin is an effective microfilaricide in buffaloes and reduces the number of adult worms. Oral levamisole 7.5 mg/kg once or twice at 3 -to 4-week intervals is reported to be effective. Ointments containing insecticides may aid control. The Asian species require a preexisting wound for infection to take place. Simple wound prevention and treatment would therefore reduce the risk of disease in this region.

Cutaneous Myiasis

Cutaneous infestation by fly larvae or maggots (known as myiasis) causes serious loss to the livestock industries across the world. Losses include mortality, increased morbidity, and reduced production of meat, milk, and fiber. The disease is associated with larvae of flies in two major dipteran families, Calliphoridae and Sarcophagidae.

Two types of cutaneous myiasis can be distinguished: primary, in which the fly larvae are obligate parasites feeding on living tissues, and secondary, in which the larvae feed primarily on necrotic tissues and only secondarily invade uninjured tissue. Clearly, primary myiasis is most significant to animal health and therefore the most costly, not only in terms of mortality, morbidity, and reduced productivity, but also in terms of cost of control. However, it may be difficult to differentiate primary from secondary myiasis because the larvae are superficially similar.

Three primary fly-strike disease states, resulting from the activities of different species, are well known and described. Blowfly strike by calliphorids such as *Lucillia cuprina* and *Lucillia sericata* is a major problem, particularly for sheep producers, in Australia, New Zealand, and Great Britain. The second group are the screwworms, *Cochliomyia hominivorax* (in the New World) and *Chrysomyia bezziana* (in southern Europe, Africa, and Asia), which are of importance across the livestock species and result in great costs for control. The sarcophagid (flesh fly) *Wohlfahrtia magnifica* causes traumatic myiasis in a wide range of livestock species, but has the greatest effect on goat and sheep production. This species occurs in southern Europe, particularly the Mediterranean and the steppe regions of the continent. Because of differences in the nature of the disease state and control practices for each of these three groups, they will be dealt with as separate entities.

BLOW-FLY STRIKE OF SHEEP

Blow-fly strike ("strike") is a very important cause of production and economic loss in most countries where large numbers of sheep are kept. In bad years many sheep may die (up to 30% of a flock), and the expense of controlling the flies and failure of wool to grow after recovery may be a serious cost, both for individual farmers and the overall industry. For example, in Australia the annual cost of blow-fly control and production losses in 2014 was estimated at around A$170 million.[1] Merino sheep, especially those with heavy skin wrinkles and fecal soiling, are by far the most susceptible breed.

SYNOPSIS

Etiology *Lucilia cuprina* and *L. sericata* are the most important primary flies; other calliphorids act as secondary invaders.

Epidemiology Fly numbers depend on temperature and moisture. Flies are attracted to wool that has been wetted or to areas affected by fleece rot, mycotic dermatitis, diarrhea, or urine staining. Incidence of strike is positively correlated with fly numbers, rainfall, humidity, cloud cover, and pasture growth. Covert (unnoticed) strikes provide larvae for future generations.

Clinical signs Sheep are restless, bite at the affected area, and wriggle their tails. Affected area is moist and malodorous, body temperatures may reach 42°C (107.6F), pulse and respiratory rates increase.

Clinical pathology A clinical examination is all that is necessary. The larvae of the primary and secondary flies can be differentiated, but this is of little use and rarely done.

Lesions Moist, malodorous areas containing active larvae. Predisposing diseases such as dermatophilosis, fleece rot, parasitic gastroenteritis, and footrot are easily identified.

Diagnostic confirmation Clinical signs are diagnostic.

Differential diagnosis Lice, sheep scab, screwworm fly infestations.

Treatment Insect growth regulators (principally cyromazine and dicyclanil), macrocyclic lactone endectocides, spinosad, or organophosphates (although the latter are restricted or no longer registered in many countries because of environmental and occupational health and safety concerns).

Control Dicyclanil protects from flystrike for up to 18 weeks, depending on the formulation; cyromazine and ivermectin for 10 to 12 weeks. Spinosad is an option for organic treatment and has short or no withholding period, but protects for only 2 to 3 weeks. The insect growth regulators do not kill existing larvae until they molt to the next stage; thus, ivermectin, spinosad, or an organophosphate (if permitted) need to be used if a rapid kill is desirable. Breeding and managing sheep to be less susceptible to strike, including the strategic or timely application of insecticide, form an integrated control program. For breech strike this is predominantly by genetic selection for decreased breech wrinkle and

Continued

reduced susceptibility to diarrhea, and control of predisposing diseases, especially gastrointestinal nematodes. The Mules operation reduces susceptibility by dramatically reducing breech wrinkle, but it remains controversial because of the pain and initial lost production associated with the procedure. Docking tails to the correct length and strategic timing of crutching and shearing are other important management factors. For body strike, reducing susceptibility of sheep to fleece rot by genetic selection and controlling mycotic dermatitis by appropriate management, such as not mustering or crowding wet sheep, are important.

ETIOLOGY

Despite there being a large number of species capable of causing the disease, there are two species that initiate most strikes and are of primary concern: *Lucilia cuprina* and *Lucilia sericata*. Locations of typical species are as follows:

- Australia: *L. cuprina*, *L. sericata* (secondary flies include *Calliphora stygia*, *Calliphora novica*, *Calliphora augur*, *Calliphora hilli*, *Calliphora albifrontalis*, *Chrysomyia rufifacies*, and *Chrysomyia varipes*)
- New Zealand: *L. sericata*, *L. cuprina* (*C. stygia*)
- Great Britain and northern Europe: *L. sericata* (secondary flies include *Calliphora erythrocephala*, *Calliphora vomitoria*, and *Phormia terra-novae*)
- North America: *Phormia regina*, *P. terra-novae*

LIFE CYCLE AND EPIDEMIOLOGY

The primary agents of flystrike are obligate parasites. *L. cuprina* is overwhelmingly important in the initiation of strike in sheep from Australia and South Africa. *L. cuprina* was confirmed to be present in New Zealand in 1988. and flystrike from this species is now a major disease in that country. In northern Europe the primary agent of flystrike is *L. sericata*, although there are some other minor species that have been reared from struck sheep.

The incidence varies widely, depending largely on the climate, with warm, humid weather being most conducive to a high incidence. In summer-rainfall areas flystrike may be seen most of the year, being limited only by dry winter conditions. In winter-rainfall areas it is usually too cold in the winter and too dry in the summer for outbreaks to occur.[2] Under these conditions abnormally heavy summer or autumn rains may be necessary before an outbreak will occur.

The Fly Population

Primary flies are of particular importance because they initiate the strike and provide suitable conditions for subsequent invasion by secondary flies. These latter flies are not of economic importance but may infest wool matted with dried exudate or feed on necrotic tissue surrounding a healing strike. In warm areas, pupal development may continue throughout the year, but as soil temperatures fall an increasing number of larvae fail to pupate, and larvae may overwinter until the following spring. Adult flies emerge in the spring, and after one to two breeding cycles, numbers increase to a peak in summer.[3] Numbers may remain high if climatic conditions are suitable, with adequate moisture being of prime importance, but fall dramatically in hot and dry conditions during the summer. An increase in numbers may occur again in the autumn.

All adult flies require carbohydrate and water, but females require protein for ovarian development. The flies are attracted to sheep that have undergone prolonged wetting such that bacterial growth and decomposition of the skin occurs. The association of breech strike with diarrhea and urine staining, and body strike with fleece rot, mycotic dermatitis, and footrot, is related to the excessive moisture deposited on the skin or to the production of serous exudates. Fleece-rot-affected wool with *Pseudomonas aeruginosa* has been shown to stimulate oviposition.

L. cuprina deposit eggs in batches of up to 300, the actual number depending on the fly's size and its ability to locate sufficient protein for egg development. Similarly, *L. sericata* deposit eggs in batches of approximately 200.

The average female longevity in the field in Australia is about 2 weeks, and females rarely live long enough to mature more than two or three batches of eggs. In the United Kingdom, mean female longevity is shorter at 5 days.

The eggs hatch in 12 to 24 hours, and the first instars feed on protein-rich serous exudate that has been provoked by bacterial damage or some other irritation. Larval mouth hooks and enzymes present in the saliva and excreta will further digestion of the skin. Large groups of larvae, particularly second and third instars, further damage of the skin, which extends the lesion and ensures a continuing supply of food. The second and third instars are 6 to 12 mm long, thick, and yellow and white in color, and they move actively. Larvae reach maturity after approximately 72 hours. They leave the feeding lesion, fall to the ground, wander briefly, and then burrow into the earth to pupate. The length of the life cycle is highly temperature dependent; it can be completed in as little as 8 days but may require up to 6 weeks in temperate regions such as the United Kingdom. Egg and larval stages are highly susceptible to desiccation, and mortality will be high if the relative humidity in the fleece falls below 60%. In temperate climates when the temperature declines in autumn, wandering larvae that have left the sheep will burrow into the ground but cease development, thereby overwintering as arrested mature larvae.

A few generations of primary flies are necessary before numbers are high enough to cause severe outbreaks, and so warm, humid weather must persist for a reasonable time before severe outbreaks occur. The incidence of body strike increases with the increase in the number of gravid flies and is positively correlated with rainfall, cloud cover, and rate of pasture growth. Other primary flies are not as effective as *L. cuprina* in initiating a strike, and in Australia and South Africa 85% to 90% of all primary strikes are a result of *L. cuprina*. Larvae of primary flies, other than *L. cuprina*, and secondary flies develop in carrion or in rotting vegetation, and their main role is to invade and extend the primary strike. *Ch. rufifacies* is the most important secondary fly in Australia. It requires higher temperatures than the other flies, is found later in the season, and is the first to disappear as temperatures fall.

Detailed population models have been developed for the strike by *Lucilia* spp. in Australia and northern Europe, and both have been used to predict onset of flystrike in sheep populations.[4,5] The latter model has been extensively validated and is sufficiently accurate to establish an early warning system for alerting producers of the impending onset of flystrike, and hence the optimum time for prophylactic treatment.

Distribution of flystrike in flocks is highly aggregated, with a small number of sheep having high numbers of larvae in lesions, a moderate number of sheep with low numbers of larvae, and the majority of sheep being unstruck. In part this is a result of the attractiveness of already-struck sheep to ovipositing flies, although other factors, such as innate attractiveness to flies, shown by the propensity of some sheep to be restruck within the same fly season, also play a role.

Susceptibility of Sheep

By far the most common site for flystrike is the breech, resulting from soiling and excoriation by soft feces and the urine of ewes. Lush pasture, parasitic gastroenteritis, and fleece length are predisposing factors, but individual sheep are predisposed because of their breech conformation. Excessive wrinkling of the skin on the back of the thighs and perineum, a narrow perineum and crutch, and an excessively long or short tail favor continuous soiling of the area and encourage "breech strike" or "tail strike."

"Body strike" occurs along the dorsum of the body, especially in young sheep in wet seasons when fleece rot or dermatophilosis is common. Less common sites for infestation are around the prepuce ("pizzle strike") and

on the dorsum of the head when there is excessive folding of the skin ("poll strike"). Sheep grazing on tall, dense pasture are commonly affected by body strike because wet plants keep the fleece on the lower part of the body wet. Footrot lesions and wounds, especially castration incisions, docking wounds, and head wounds on rams caused by fighting, are also likely to provide good sites for blow-fly strike. Young sheep are more susceptible.

PATHOGENESIS

The first instars feed on the exudate produced by the bacterial infection on the skin, but the larvae also produce excretory/secretory enzymes that may cause some skin degradation after egg hatch and provide soluble molecules on which the first instars can feed. Later instars can cause severe skin damage when feeding. Larvae may also migrate from the original area of strike, along the surface of skin, to establish additional focal lesions.

Many primary strikes remain small and are unnoticed by the farmer. Such "covert" strikes may outnumber obvious strikes and are important as a source of future generations of flies. Once the initial strike is made, the site becomes suitable for the secondary flies, which invade and extend the lesion. The effects of strike include toxemia as a result of absorption of toxic products of tissue decomposition, loss of skin and subsequent fluid loss, and secondary bacterial invasion.

CLINICAL FINDINGS

Individual sheep may be struck at any time provided they are in a susceptible condition. Massive outbreaks tend to be confined to periods of humid, warm weather and are therefore in temperate areas usually limited in length to relatively short periods of 2 to 3 weeks, but in subtropical areas characterized by summer rainfall, severe strikes may occur over many months.

The clinical effects of blow-fly strike vary with the site affected, but all struck sheep have a basic pattern of behavior caused by the irritation of the larvae. The sheep are restless, moving about from place to place with their heads held close to the ground, and they become anorexic. They tend to bite or kick at the struck area and continually wriggle their tails.

If the area is large, there is an obvious odor, and the wool can be seen to be slightly lifted above the normal surrounding wool. The affected wool is moist and usually brown in color, although in wet seasons (when fleece rot is prevalent) other colors may be evident. In very early cases, the maggots may still be in pockets in the wool and not yet in contact with the skin. When they have reached the skin, it is inflamed and then ulcerated, and the maggots begin burrowing into the subcutaneous tissue.

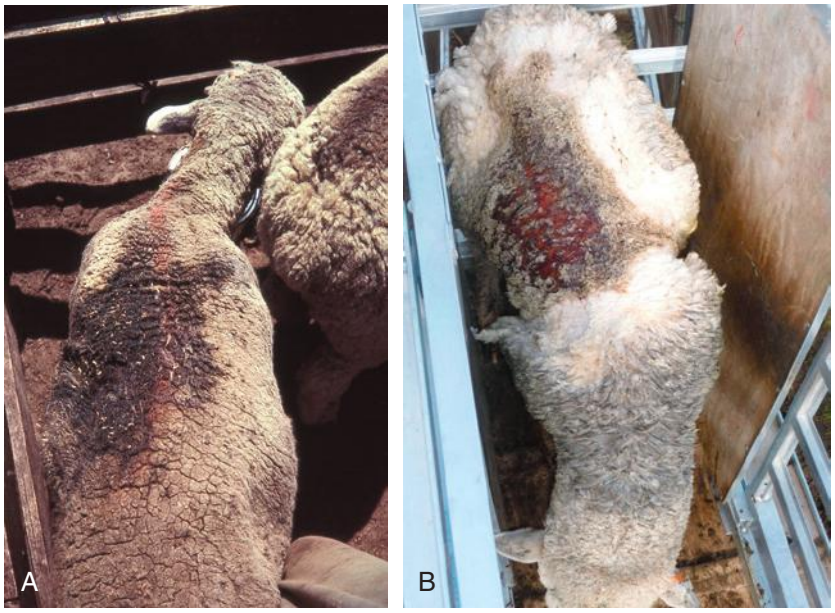

Fig. 16-9 **A, Body strike on a wether as viewed from above. The wether is depressed, and maggots (white) are visible on the surface of the struck area (blackened area of wool). B, Body strike on a weaned sheep as viewed from above. The wool has been clipped away from the edges of the lesion before application of treatment.**

Three days after the primary oviposition feed intake is reduced, rectal temperature rises to about 42°C (108°F), and pulse and respiratory rates increase. There is a reduction of feed intake and loss of body weight, and some sheep may die.[6] The wool may be too hot to handle as a result of the inflammation caused by the mass of maggots that can be seen when the wool over the strike is opened. When primary strikes are invaded by secondary flies, particularly *C. rufifacies*, the affected area is extended, and the maggots may burrow deeply into the tissues. Affected sheep may lose their fleece over the affected area (Fig. 16-9) and may suffer a break in the remaining fleece. Tracts of discolored wool may lead to other affected areas of skin. As the struck area extends, a scab forms over the center, the wool falls out, and the maggots are active only at the periphery.

CLINICAL PATHOLOGY AND NECROPSY FINDINGS

A clinical examination is all that is necessary to make the diagnosis, but identification of the flies responsible may be important if epidemiology is being considered. Identification of larvae should be carried out by a specialist. Molecular techniques for accurate identification are available but are a specialized research technique rather than routine diagnostic tool. Preservation of the larval stages is critical to these techniques, and larvae should be rapidly frozen or preserved in 70% ethanol. Fly trapping may not correlate with larval findings because not all flies are attracted equally by the commonly used baits.

DIFFERENTIAL DIAGNOSIS

Attention will be drawn to affected sheep by their foot stamping, tail twitching, and biting at the affected part. Affected sheep can easily be diagnosed by finding the moist, malodorous, maggot-infested area. Many covert strikes may be present without producing clinical signs. Predisposing diseases such as footrot, wound infections, dermatophilosis, and diarrhea resulting from parasitic gastroenteritis are usually easily detected, and fleece rot is indicated by matting of the wool and discoloration.

TREATMENT

Removal of wool from the surrounding area removes most of the maggots, and applying a dressing prevents reinfestation of the wound. Dressings containing cyromazine, spinosad, ivermectin, or an organophosphate such as diazinon, tetrachlorfenvinphos, or propetamphos (if permitted), are the most commonly used. Cyromazine is an insect growth regulator, and thus live larvae will be seen in the fleece for some days after treatment. Thus other chemicals need to be included in a dressing if immediate killing of larvae is desirable. Ivermectin at 0.3 mg/kg is highly effective in killing all larval stages, and no resistance has yet been reported. However, resistance to organophosphates is widespread in Australia; many products do not kill all the resistant larvae, with some performing poorly even against susceptible larvae. Preventing reinfestations is important, and thus application of the larvicide to the wool surrounding the treated area is essential.

CONTROL

In Australia, practical control of breech strike of Merino sheep in extensive farming areas has relied on the use of the Mules operation, which removes breech wrinkle and extends the bare areas around the perineum and tail. This has been integrated with other strategies to reduce the susceptibility of Merino sheep to strike, such as effective worm control to reduce diarrhea, and hence contamination of the perineal region with feces ("breech soiling"), correct tail length, strategic timing of crutching and shearing, and timely application of insecticides (an integrated pest management approach).[2,7] Control of strike in other situations is based on insecticidal treatment and treatment of wounds as they occur.

Under conditions of extensive sheep rearing, such as occur in Australia, New Zealand, and South Africa, and where climatic conditions are conducive to the development of the disease, the control of blow-fly strike is a major challenge. An extensive literature on the subject is available, so only a summary is given here.

Control programs can be thought of as having three components: reduction in fly numbers (mainly by strategic application of insecticide and fly trapping), prediction of risk periods (to most appropriately time activities such as crutching, shearing, or the application of insecticide), and reduction in susceptibility of sheep (mulesing of Merinos, genetic selection for plain breeches and/or reduced breech cover; control of predisposing factors, particularly diarrhea and fleece rot).

Reduction of Fly Numbers

Reducing the fly population has been of limited value because there are usually enough flies present to strike all susceptible sheep if suitable conditions are present. Nevertheless, if the primary fly responsible for initiating strikes can be controlled, the buildup of primary flies and involvement and importance of secondary flies is greatly reduced. Measures include early insecticide treatment, just before or after the first generation of primary flies emerge in areas that have a seasonal pattern of fly emergence; trapping of flies; early treatment of clinical cases; and the proper disposal of carcasses and wool waste. Biological control by the use of insects parasitizing blow flies has been proposed but has yet to be exploited.

A weather-driven model of flystrike risk in southeastern Australia predicted that strategic early treatment would reduce the number of treatments and have a positive cost-benefit outcome in high-risk areas where preventive treatments were routinely given, but there was less benefit for low-risk areas because treatments were not needed every year.[8] A large-scale field study comparing early strategic treatment of unmulesed Merino sheep with mulesed ones not given an insecticide found a similar prevalence of strike in both groups and concluded that this was a potential medium-term strategy for the control of strike in unmulesed Merinos in this area.[2,9]

Trapping, provided the traps are carefully tended and satisfactory baits are used, can reduce the number of blow flies. However, the benefits in reducing the prevalence of strike are mixed. The use of a trap designed specifically for *L. sericata*, the primary fly in the United Kingdom, reduced strikes by 55%.[10] However, despite reducing the numbers of *L. cuprina* by 60% to 80%, the use of a trap specific for this species (LuciTrap™) has not consistently reduced the prevalence of strikes in Australia or South Africa.[7,11] In addition, it is expensive and logistically difficult to use these traps in large flocks at the suggested distribution of 1 trap per 100 sheep. Nevertheless, trapping can still be useful to indicate the presence and abundance of blow flies and the most appropriate time to apply a strategic early treatment.[11]

It is also important to identify clinically affected sheep, particularly those affected early in the season, and to treat these infestations. If early-season strikes are not treated, they can propagate a larger second and third generation of flies on a farm, given that *L. cuprina* doesn't travel large distances. Thus large farms breed most of their own flies, and so outbreaks of strike will be potentially more problematic later in the season. When affected areas are clipped, the clippings should be treated with a suitable dressing to kill the larvae, then burned or buried.

Control by genetic manipulation of the fly offers some promise for long-term control, but this strategy has yet to be exploited with either *L. cuprina* or *L. sericata*. For example, reduced fertility in male flies and lethal mutants, such as flies that will be blind under field conditions and die, have been reported. The sequencing of the draft genome of *L. cuprina* may facilitate these and other developments, such as exploring genetic mechanisms of insecticide resistance, the design of novel insecticides, and other strategies.[12]

Prediction of Risk Periods

Flystrike results from a complex interaction between fly abundance and sheep susceptibility, both of which are directly related to weather, geography, and animal husbandry. Predictive models incorporating climatic and production components have been developed in the United Kingdom and are used to give producers warning of impending flystrike.[5] In Australia, models have been incorporated into tools on an advisory website for farmers and advisers (Flyboss), enabling them to compare management systems for flystrike risk.

Outbreaks of breech strike will occur if sheep have diarrhea or if ewes have urine wetting of the breech area because their tails are docked too short or too long. If an outbreak is routinely expected, such as during spring in a winter- or uniform-rainfall area, removal of breech wool by crutching or shearing, and/or the prophylactic application of insecticides, will largely eliminate or reduce the severity of strike. Crutching is routinely carried out before lambing or an expected increase in fly numbers and provides protection from strike for around 6 weeks in crossbreeds and mulesed Merinos but for a shorter period in unmulesed Merinos. It has a significant cost as a result of the labor and loss of wool involved, and thus many sheep farmers use prophylactic treatment with an insecticide.

Sporadic cases of body strike may occur in sheep at any time and cannot always be prevented, but if environmental circumstances conducive to high fly populations and high susceptibility of sheep are recognized, then short-term prophylactic measures can be taken. Warm, showery weather extending over several weeks allows several generations to be completed and sufficient flies to be available to cause an outbreak of strike. Once sufficient flies are present, an outbreak of flystrike may occur whenever the sheep become susceptible. Warm, humid weather, rain over 2 to 3 days, or grazing in long and wet grass may provide suitable conditions for the sheep to become susceptible to body strike. Sheep with poor physical conformation (e.g., high shoulder blades), fleece that is yellow with high suint and low wax content, and a wool staple structure more prone to wetting (pointed, thin staples that are less tightly packed) are most susceptible. The time of year when shearing is carried out also exerts a strong influence on the frequency and severity of outbreaks of body strike because the staple length when sheep are wetted determines the degree of wetting and rapidity of drying. It also influences susceptibility to breech strike, with a longer staple length usually facilitating a greater accumulation of feces ("dag").

Treatment and Prevention

Prophylactic treatment with insecticide has been a major part of blow-fly control for many years, and surveys in countries with significant sheep populations show that up to 90% of farmers in high-risk areas routinely treat their sheep. Currently available chemicals include the insect growth regulators (dicyclanil and cyromazine), macrocyclic lactones (ivermectin), and spinocyn (spinosad). Organophosphate chemicals have also been heavily used, but resistance is widespread, and thus the period of protection is reduced to as little as 3 to 5 weeks. There is also increasing concern over their environmental effects and occupational health and safety, and thus their use is restricted or prohibited in many jurisdictions. Resistance by *L. cuprina* to cyromazine has been detected in Australia, but application of this chemical at the recommended

concentration is still effective in preventing reinfestations.[13]

Depending on the formulation used, the insect growth regulators can provide 10 to 12 (cyromazine) and 18 to 24 (dicyclanil) weeks of protection, and can be applied by high-volume jetting (cyromazine) or a low-dose spray (both). Their action is specific to dipteran larvae, although they inhibit chitin synthesis and thus larvae do not die until they molt.

The methods of application include dipping, jetting, and tip spraying. However, dipping requires specialized equipment, has higher labor costs, and is much slower and thus is not recommended unless lice are also present. Jetting is recommended for breech strike, and if the jetting piece is combed through the wool from the poll to the rump with the solution at high pressure (500 to 900 kPa), this method will also prevent body strike.

Reducing the Susceptibility of Sheep

The primary method for reducing the susceptibility of Merino sheep to breech strike has been the modified Mules and tail-strip operation.[14] Mulesing, originally developed to remove the wrinkled region of the breech, has been modified by incorporating pain relief to address concerns regarding animal welfare, which must be balanced against the effects of strike. Although still permitted by codes of practice in Australia, the technique remains controversial because of ongoing opposition from animal welfare activists and concern over production losses. The latter accrue following a significant growth setback when lambs are mulesed at a young age (6 to 10 weeks old), often leading to reduced weaning weights and higher mortality rates after weaning. The protection gained by mulesing surpasses that afforded by breeding and is immediate and permanent.

The Mules operation is often supplemented by a tail-strip operation, whereby a thin strip of woolled skin is removed from each side of the tail. This stretches the bare skin over much of the tail, reducing fecal and urinary contamination. Unfortunately, some contractors dock tails too short, leaving a "butted" tail that the sheep is unable to elevate when defecating, thereby increasing the degree of breech soiling (dag). When butted tails are combined with mulesing, there is often a high prevalence of squamous-cell carcinoma of the vulva. Consequently, docking tails to the correct length (tip of the vulva in ewes) and leaving a V-shaped flap of wool bearing skin on the tip of the tail is important.

Alternatives to mulesing have been developed and investigated in an ongoing research program funded by Australian woolgrowers.[15] These methods include plastic breech clips, applied to the breech of lambs at a similar age to mulesing, and the intradermal injection of compounds, such as sodium lauryl sulfate, into the breech area.[16] Unfortunately, to date no alternative has produced the degree of breech modification achieved by mulesing, nor have they significantly reduced the prevalence or risk of breech strike compared with unmulesed sheep. For example, in a field study involving over 6000 sheep there was a significant reduction in the breech wrinkle scores of hoggets and ewes that had clips applied as lambs, but these changes were only a fraction of the reduction seen in mulesed sheep. Compared with mulesed sheep, the clipped ones had from 3 to 27 times the risk of breech strike as hoggets, and 2 to 8 times the risk of strike as maiden ewes.[2,9]

Consequently, selective breeding to reduce the susceptibility of Merino sheep to breech strike is being recommended. This possibility was first noted in the 1930s, when sheep with certain breech characteristics were found to have a far higher risk of breech strike, whereas others were relatively immune.[14] However, these investigations were discontinued as a result of the effectiveness and widespread adoption of mulesing, plus the development of highly effective insecticides. Genetic selection offers cumulative and permanent chan ges, although not total reduction in risk. Several risk factors for breech strike were identified in a large-scale study in western Australia involving over 2800 unmulesed lambs sired by 49 rams.[17] The most important of these were breech soiling (dag), urine staining, and breech "cover" (the reverse of bare area), which had genetic correlations with breech strike of 0.64 to 0.81, 0.54, and 0.32, respectively. Breech wrinkle was not identified as a risk factor because these were a plain-bodied genotype of sheep. However, a similar study of typical wrinkly fine-woolled Merinos in a summer-rainfall area confirmed a strong relationship between breech strike and breech wrinkle.[18] This research has been summarized and published on an open-access website called Flyboss.[19] A similar genetic and phenotypic relationship of breech soiling with breech strike has been demonstrated for New Zealand Romney sheep and in the United Kingdom.[20]

Other good management practices are essential to prevention of flystrike. These include management of gastrointestinal nematodes to prevent diarrhea ("scouring"), docking of tails to the correct length, and crutching before a risk period (typically before lambing with ewes) to reduce breech soiling that predisposes animals to breech strike.

Pizzle strike can be dramatically reduced or eliminated by the use of testosterone implants to prevent posthitis ("pizzle rot"), and "ringing" (shearing of the pizzle area) provides 6 to 8 weeks of protection from strike. Pizzle dropping (the surgical separation of the preputial sheath from the belly) also provides good protection. However, treated sheep can be more difficult to shear, and it will no longer be an approved practice when draft Australian animal welfare standards are endorsed.[21] Fleece rot occurs most commonly on the withers of sheep, and the conformation that allows accumulation of moisture and the development of fleece rot and flystrike is heritable, so sheep with these faults should be culled. Although control is mainly centered on management, the application of an insecticide may be needed when weather conditions are particularly suitable for body strike, such as summer storms.

SCREWSWORM (*COCHLIOMYIA HOMINIVORAX* AND *CHRYSOMYIA BEZZIANA*)

Cutaneous myiasis associated with the screwworm maggots has been a cause of great financial loss in livestock in the western hemisphere, Africa, and Asia. Deaths may be heavy in groups of livestock that are at range and seen infrequently.

SYNOPSIS

Etiology *Cochliomyia hominivorax* in the New World (New World screwworm) and

Continued

Chrysomyia bezziana (Old World screwworm) in Africa and Asia.

Epidemiology Eggs laid in fresh wounds. Flies most active at 20° to 30°C (68 to 86F). Disease spread by dispersal of flies or transport of infested animals.

Clinical signs Larvae invade the tissue, producing characteristic large lesions containing mature larvae and foul-smelling brown exudate.

Clinical pathology Not applicable.

Lesions Deep wound containing foul-smelling brown material and third instars.

Diagnostic confirmation Rows of spines are present on the anterior part of each segment of the third instar.

Differential diagnosis No other disease causes such lesions.

Treatment Ivermectin 0.2 mg/kg subcutaneously kills many larvae and provides protection for 16 to 20 days. Other insecticides used as gels or ointments twice weekly are also effective. Doramectin subcutaneously.

Control Eradication has been achieved in North and Central America by the mass release of sterile males. Chemical attractant baits will reduce the prevalence of flies and strikes. Breeding and management procedures such as castration and shearing should be carried out in the cold weather.

ETIOLOGY

Larvae of the flies *C. hominivorax* and *C. bezziana* cause myiasis or "screwworm disease" of animals. The flies are typically blowflies, *C. hominivorax* (New World screwworm), which is blue–green with an orange head, or *C. bezziana* (Old World screwworm), which is of similar coloring. *C. hominivorax* occurs in the Americas, and *C. bezziana* occurs in the Persian Gulf, Africa, and Asia. The occurrence of *C. bezziana* in Papua New Guinea provides a constant threat to livestock on the Australian mainland. A similar fly is *Callitroga* (*Cochliomyia*) *macellaria*, which is not a true "screw-fly" in that the larvae feed only on carrion or necrotic tissues.

EPIDEMIOLOGY

The screwworm maggots are obligatory parasites with no host specificity. Thus all domestic and wild mammals, marsupials, and birds are potential hosts. Females are attracted to fresh wounds, where they will oviposit. The navel of a newborn animal is a favored site, but fresh accidental or surgical wounds, such as those produced by castration, docking, and dehorning, are readily infested. Wounds that have already been infested are markedly attractive to the flies because of their odor. In bad seasons the flies will lay eggs on minor wounds such as areas of excoriation, tick bites, running eyes, peeling brands, and on the perineum soiled by vaginal and uterine discharges in animals that have recently given birth. Injury is not necessarily a prerequisite for screwworm strike in sheep, which can be struck in the intact infraorbital fossa and vulva. Wool loss and tenderness may occur, and the remaining fleece may be stained.

The development of the fly is favored by hot, humid weather. The optimum temperature range for *C. bezziana* is 20° to 30°C (68° to 86°F). Below this temperature, the flies become sluggish, and at 10°C (50°F) and below the flies will not move. Temperatures above 30°C (86°F) can be tolerated, provided shade is available. *C. hominovorax* is active all year in areas where temperatures exceed 16°C (61F) and disperses rapidly from these areas as the temperature increases in the neighboring colder areas. The disease can be spread either by migration of flies or their carriage in livestock ships or commercial aircraft, by shipment of infested cattle or other livestock, and by movement of affected wildlife. The mean distance that *C. bezziana* can travel and deposit eggs is 11 km. The maximum distance is 100 km, but long distances are probably wind assisted. In the new environment the flies may die out if the climate is unsuitable or persist to set up a new enzootic area. Persistence of the fly in an area may depend on persistence in wildlife or in neglected domestic animals, although the latter do not usually survive unattended for more than about 2 weeks.

In many enzootic areas it is common for the fly to persist in neighboring warmer areas during winter, returning to its normal summer habitat as the temperature rises. This pattern is exemplified by the introduction of screwworms into the southeastern United States in 1933 where they had not previously occurred. The flies died out in most areas in winter but persisted in southern Florida. In succeeding summers migrations of flies northward caused outbreaks. The disease has since been eradicated from the area.

The disease is of importance in tropical and subtropical areas of Africa, Asia, North and South America, the Caribbean islands, Mexico, American states bordering on Mexico, and especially Central America. The prevalence of the fly in enzootic areas places severe restriction on the times when prophylactic surgical operations can be carried out.

The potential worldwide geographic distribution and abundance of *C. bezziana* has been assessed using a computer program. The differences in the observed global distribution and the potential predicted distribution indicate the areas at risk of colonization.

LIFE CYCLE

The screwworm flies have a typical fly life cycle with eggs, three larval instars, and a pupal stage. Females lay 150 to 500 white eggs in shingle-like clusters at the edges of fresh wounds. Larvae hatch in about 12 hours and penetrate the tissues surrounding the wound. The larvae preferentially feed on fresh, living tissue, which is digested by regurgitation of a wide variety of salivary enzymes. Oviposition by other screwworm flies is encouraged by the presence of larvae already in the wound. The larvae feed as a group and at their time of maturation will have created a deep lesion 10 to 12 cm in diameter. Larval development is complete in 5 to 7 days, after which they leave the wound and fall to the ground. These mature third instars burrow into the upper soil layers and pupate. On the ground, pupal development is highly temperature dependent, requiring from 3 to 60 days. Emerging flies commence egg-laying in about 1 week, having completed the life cycle, under optimum environmental conditions, in less than 3 weeks. There may be 15 or more generations per year.

The temperature sensitivity of the pupal stage, which is unable to survive freezing for more than short periods, limits the distribution of this parasite. As with all flies, pupal development is highly temperature regulated. The screwworm pupal development is inhibited at soil temperatures below 15°C (60°F). Temperatures below this point for more than 2 months cause death of the pupa. Thus the occurrence of the disease is limited to warm climates. Pupae are also affected by the moisture content of the soil. The emergence of adults is reduced when the moisture content is more than 50%, whereas temporary floods can drown pupae.

PATHOGENESIS

Following invasion of the wound a cavernous lesion is formed, characterized by progressive liquefaction, necrosis, and hemorrhage. Anemia and decreased total serum protein result from hemorrhage into the wound. Secondary bacterial infection, toxemia, and fluid loss contribute to the death of the animal. Surviving calves frequently develop infectious polyarthritis.

CLINICAL FINDINGS

The young larvae invade the nearby healthy tissues vigorously and do not feed on necrotic superficial tissue. A profuse brownish exudate, composed of larval excreta and host fluids, pours from the wound, and an objectionable odor is apparent. This is highly attractive to other flies, and multiple infestations of a single wound may occur within a few days. The resulting tissue damage may be so extensive that the animal is virtually eaten alive. Affected animals show irritation in the early phase of the infestation and by day 3 show pyrexia. Animals do not feed but wander about restlessly, seeking shade and shelter.

CLINICAL PATHOLOGY

It is imperative to differentiate screwworm infestation from infestation with other fly larvae. The appearance and smell of the wound are significant, but careful examination of the larvae is necessary to confirm the diagnosis. Mature larvae are 1 to 2 cm long and pink in color; they are pointed anteriorly and blunt posteriorly; two dark lines are visible reaching from the blunt posterior to the middle of the body, and they have rows of dark fine spines on the anterior part of each segment. Specimens forwarded to a laboratory for identification should be preserved in 70% alcohol.

NECROPSY FINDINGS

Superficial examination of infested wounds is usually sufficient to indicate the cause of death.

DIFFERENTIAL DIAGNOSIS

The presence of maggots in the wound is usually apparent. It is important to differentiate them from blow-fly larvae as described previously.

TREATMENT

Affected wounds should be treated with a dressing containing an efficient larvicide and preferably an antiseptic. The larvicide should be capable of persisting in the wound for some time to prevent reinfestation. An ointment or gel base is preferred so that as much of the active ingredient as possible is left in the site. It should be liberally and vigorously applied with a paint brush to ensure that larvae in the depths of the wound are destroyed. To avoid reinfestation in extensive lesions or in bad seasons, the treatment should be repeated twice weekly.

Thirteen acaricides, commonly used for *Boophilus microplus* control, have been tested against *C. bezziana* larvae. Although they are not sufficiently active to use as a primary treatment, their continued use for tick control would reduce screwworm populations.

Ivermectin 200 mcg/kg given subcutaneously kills all *C. bezziana* larvae up to 2 days old and many older larvae. It provides residual protection for 16 to 20 days. Bull calves treated with ivermectin at the time of castration were completely protected against strike. A preliminary study showed that closantel at 15 mg/kg body weight was effective, with a residual protection of 8 to 15 days. Doramectin 200 mcg/kg subcutaneously caused complete expulsion of *C. hominivorax* larvae within 8 days. Prophylactic use of ivermectin and doramectin significantly reduced occurrence of screwworm strike in cattle. Fipronil had a prophylactic effect, reducing occurrence of screwworm infestations in cattle and providing efficacious treatment in those that did become infested.[1]

CONTROL

In an enzootic area the incidence of the disease can be kept at a low level by the general institution of measures designed to break the life cycle of the fly. Surgical procedures should be postponed where possible until cold weather. In the warm months all wounds, including shearing cuts, must be immediately dressed with one of the preparations described under "Treatment." All range animals should be inspected twice weekly and affected animals treated promptly. Infestation of fresh navels is common, and newborn animals should be treated prophylactically. If possible, the breeding program should be arranged so that parturition occurs in the cool months. The routine use of ivermectin for internal parasite control provides protection for about 2 weeks.

In the United States, the Caribbean, and Central America, an eradication program has been successfully carried out against *C. hominivorax* using the sterile insect technique (SIT).[2] Huge numbers of pupae are mass reared on semiartificial media and exposed to the sterilizing effects of cobalt 60. The resulting sterile male flies are released over large areas, primarily by aerial drops, where they compete with wild males for available females, which mate only once. *C. hominivorax* has now been eliminated from the United States, the Caribbean, and all of Central America, up to the Darien Gap in Panama. *C. hominivorax* appeared in Libya in 1988, apparently with a load of sheep transported from South America, but has been eradicated using sterile male flies from the United States.[3]

Attractants may also be used to reduce the fly population. A chemical bait has been developed that, when combined with an insecticide, forms a screwworm adult suppression system (SWASS) that reduces the fly population and the incidence of strikes. An examination of the efficacy of various methods of baiting showed that polythene sachets containing sworm-lure 2, a pungent mixture of 11 chemicals, attracted flies (not *C. bezziana*) for at least 2 weeks and was as efficient as jar bait. This result needs confirming in a screwworm-endemic country.

WOHLFAHRTIOSIS (FLESH FLY, *WOHLFAHRTIA MAGNIFICA*)

Cutaneous infestation by larvae of the sarcophagid fly, *Wohlfahrtia magnifica*, has become a major disease of domestic livestock, including birds managed extensively (e.g., geese) in the Mediterranean basin, eastern Europe, and western regions of China. The disease is particularly significant for sheep in these regions, where it is more prevalent than strike by the calliphorid fly, *L. sericata*.

Other species of this genus are known from North America, but they do not infest domestic species. They are predominantly reported in very young rodents and birds, although there are occasional reports in infants.[1] Mortality of infested hosts tends to be very high.

LIFE CYCLE AND EPIDEMIOLOGY

Larvae of this species are obligatory parasites developing only in the living flesh of warm-blooded vertebrates. They are not host specific. Adults are typical for this group of flies, being dark gray in color with three distinct black stripes on the thorax where the wings are attached.

Female flesh flies, which are active during the warm parts of the day, deposit first instars on the host, usually in small groups of 15 to 20. Each female may produce up to 170 larvae. Completion of the three larval stages takes from 5 to 7 days, after which the mature third instars leave the lesion and fall to the ground, where they pupate. Development of the fly within the pupa is regulated by temperature and may require between 7 and 21 days.

Larvae are usually deposited near small wounds (bites of blood-feeding arthropods are sufficient to attract the larvae), but the favored sites appear to be the genitalia.[2] Irritation of the vulva associated with the use of vaginal sponges for estrus synchronization may be a predisposing factor in sheep.

Flies are active between April and October, with several generations being produced. Little information is available on overwintering. Wildlife are suspected as being reservoir hosts, but little information is available on which are the most important.

PATHOGENESIS

Larvae have well-developed mouthhooks that are used to abrade the skin surface, and with the aid of a wide variety of salivary enzymes, they quickly produce a dramatic lesion. Lesions increase in size as the larvae grow and require additional fresh tissue. Each animal may have one or more focal lesions, each packed with larvae. In severe cases several lesions may coalesce into one larger site.

Animals are often struck multiple times during a season, suggesting the absence of protective immunity. This adds to the impact of this disease because animals must be constantly monitored.

CLINICAL PATHOLOGY AND NECROPSY FINDINGS

A clinical examination is all that is necessary to make the diagnosis. Larvae can be distinguished from those of the screwworm or strike flies by the presence of a large posterior cavity surrounded by a number

of prominent tubercles. However, specific identification should be done by a specialist. Larvae should be preserved in 70% ethanol.

Affected animals are clearly stressed, showing restlessness and anorexia. Lesions formed at the vulva or prepuce are the most significant, causing great discomfort and dysfunction. Lightly infested animals shown no impairment of productivity.[2] Infested animals develop strong antibody responses to salivary secretions, particularly of the third instars.[3]

TREATMENT

There are currently no products specifically registered for management of this disease. Evaluations of several drugs and treatment approaches have been made. Of particular interest is the equivocal results of trials with macrocyclic lactones. In sheep, ivermectin and moxidectin had no effect on existing infestations and no prophylactic effect or only short protection against early instars. In contrast, doramectin provided complete prophylactic protection for 21 days and significant reductions for 40 days.

The insect growth regulator dicyclanil has also been evaluated and shown to reduce prevalence of infestation in sheep. The reduction not only occurred in treated animals, but was seen in untreated herdmates, possibly as a result of the overall reduction in fly numbers.

RECOMMENDATION

Animals likely to be attractive to these flies should be checked weekly, and appropriate treatment should be applied as soon as fly larvae are detected.

Mite Infestations

HARVEST MITES (CHIGGER MITES)

Infestations with trombidiform mites cause dermatitis in all species. Except for *Psorergates ovis*, *P. bos*, and *Demodex* spp., they are referred to as harvest or grain mites. These mites are primarily predatory on other arthropods associated with harvested grain and infesting animals only secondarily and usually transiently. It is usually the larval stages that are found feeding on animals, whereas the nymphs and adults are free-living. Hair loss and patchiness in cattle that are extremely well bedded often results from these mites but can be confused with louse infestations.

The larvae of *Pyemotes ventricosus*, *Neotrombicula autumnalis*, *Neotrombicula heptneri*, *Eutrombicula alfreddugesi*, *Eutrombicula splendens*, *Eutrombicula batatas*, *Trombicula* spp., and some species of *Leptotrombidium* and *Schoengastia* are parasitic on humans and most animals, causing dermatitis and, in humans, transmitting rickettsial diseases. Nymphs and adults are free-living predators feeding mainly on arthropods in grain and hay. The larvae are most active in the autumn at harvest time and may cause dermatitis in animals grazing at pasture or those confined in barns and being fed newly harvested grain.

Horses, cattle, and goats[1] are usually affected on the face and lips, which, in white-faced horses, may suggest a diagnosis of photosensitization, and around the feet and lower limbs, especially in the flexures. Affected areas are itchy and scaly, but with rubbing, small fragile scabs and absence of hair may become apparent. Infestation of horses with *Trombicula sarcina* causes a severe pruritus, and yearlings show irritation by lip-biting their legs and rubbing against stable walls. Stamping is uncommon and usually occurs when yearlings are stabled on fresh, contaminated bedding. Sheep, when first affected, stamp their feet repeatedly and bite their legs. The skin at the heels, coronet, and pasterns, and sometimes the shank, becomes erythematous and weeps fluid. The mites detach after 3 to 5 days and leave a small ulcerated area. In light infestations the mites may be confined to the area between the accessory digits, but in heavy infestations the skin over the whole of the lower limbs may be swollen and thickened. The infestation is self-limiting, and treatment is not usually necessary.

Infestation with *Tyroglyphus* spp. in pigs appears to be manifested by itchiness and the development of fragile scabs about 3 cm in diameter scattered over the body. Unlike the thick scabs of sarcoptic mange, the skin beneath appears normal. The infestations occur in pigs eating dry ground grain from automatic feeders, with lesions appearing several weeks after the dry feeding is begun and disappearing spontaneously about 3 weeks later. No treatment is necessary. Affected pigs show no ill-effects, but the lesions may be mistaken for those of swinepox or sarcoptic mange. The ingestion of large numbers of mites appears to have no ill-effects.

Recent work on the role of *N. autumnalis* has suggested that these mites are capable of acting as reservoirs of *Borrelia burgdorferi*,[2] but this remains to be established.

RECOMMENDATIONS

No treatment is usually recommended, but a macrocyclic lactone will be effective if a treatment is required.

ITCHMITES (*PSORERGATES OVIS, PSORERGATES BOS*)

The "itchmite," *Psorergates ovis*, has been recorded as a parasite of sheep in Australia, New Zealand, South Africa, the United States, Argentina, and Chile. *Psorergates bos* has also been recorded in cattle in the United Kingdom.

LIFE CYCLE AND EPIDEMIOLOGY

The entire life cycle of this mite—egg, larvae, two nymphal stages, and adult—takes place entirely on the host. In sheep the cycle takes 4 to 5 weeks. All stages occur in the superficial layers of the skin. The adults are extremely small and can be seen only with the aid of a microscope. Only the adults are mobile on the skin surface, and they spread infection by direct contact. In sheep this often occurs between recently shorn animals when contact is close and prolonged, such as when shorn sheep are packed in yards after shearing, or from ewe to lamb while suckling. Mite feeding activity, in addition to excreta, causes skin irritation, leading to rubbing and biting of the affected parts (principally the sides, flanks, and thighs) and raggedness, and sometimes shedding, of the fleece. Wool over these areas becomes thready and tufted and contains dry scales.

PATHOGENESIS

The skin shows no gross abnormality other than an increase in scurf. Histologically there is hyperkeratosis, desquamation, and increased numbers of mast cells. Irritation appears to be caused by hypersensitivity and results in biting and chewing of the fleece on the flanks and rump behind a line approximately from the elbow to the hips. In the individual sheep and in flocks, the disease spreads slowly, and thus it may be several years before clinical cases are observed and appreciable numbers are visibly affected. The incidence of clinical cases in a neglected flock may be as high as 15%. Sheep on poor nutrition have significantly higher mite populations, more scurf, and greater fleece derangement. Affected sheep may become tolerant after 1 to 2 years and show no signs, even though they remain infested.

Among sheep, Merinos are most commonly affected. The highest incidence is observed in this breed, particularly in areas where the winter is cold and wet. There is a marked seasonal fluctuation in the numbers of mites; the numbers are very low in summer, begin to rise in the autumn, and peak numbers are found in the spring. Spring or summer shearing exacerbates the decline in numbers. Clinically, the disease resembles louse infestation, but may be distinguished by the smaller proportion of the flock affected (10% to 15%), the less severe irritation, and the tendency of the sheep to bite those areas they can reach. Hence lesions are confined to

parts of the flank and the hindquarters, and the wool tufts have a chewed appearance.

CLINICAL FINDINGS

Diagnosis depends on finding the mites in a skin scraping. The selection of sheep with excess scurf and fleece derangement increases the chance of finding mites, and in the absence of lice, ked, and grass seed infestation, about 75% of such sheep prove positive for *P. ovis.* The wool should be clipped as close as possible, the skin smeared lightly with oil, and then scraped over an area of about 25 cm^2. The mites have a seasonal incidence and may be very difficult to find in summer and autumn. For best results the scraping should be made on the ribs or shoulder in winter or spring. Scrapings are usually teased out in oil and examined microscopically without digestion. A number of scrapings may be needed from each sheep before mites can be demonstrated. Because of the difficulty of finding mites in summer and autumn, sheep dipped at that time cannot be said to be free of infestation until they prove negative on skin scraping in the following spring, when mite numbers should be at the highest levels.

TREATMENT AND CONTROL

There is no compound available that will eradicate itchmite after a single treatment. Arsenic, lime sulfur, and finely divided sulfur have been used and markedly reduce the number of mites. Because the mites are slow to build up, dipping every second year will mask the signs of infestation. However, arsenic is no longer used in most countries. Finely divided rotenone by itself or mixed with the synergist piperonyl butoxide reduces the mite population. It is usually combined with an organophosphate to include lice and ked control in the one product. Phoxim, an organophosphorous compound, has good activity, but two dippings 1 month apart are necessary to eradicate infestations. Amitraz causes a marked reduction in mites that will be maintained for some months.

A single subcutaneous injection of 0.2 mg/kg ivermectin freed sheep of mites for up to 56 days posttreatment. However, these sheep would have to be examined over a longer period to ensure eradication. Other macrocyclic lactone products, in various formulations, have been shown to have good efficacy. The absence of reports of itchmites over the last 15 years would suggest that the widespread use of macrocyclic lactone products has decreased the prevalence of infection.

DEMODECTIC MANGE (FOLLICULAR MANGE)

Mites of *Demodex* spp. infest hair follicles of all species of domestic animals. The disease causes little concern, but in cattle and goats there may be significant damage to the hide, and, rarely, death may result from a secondary bacterial invasion.

ETIOLOGY

Mites infesting the different host species are considered to be specific and are designated as *Demodex bovis* for cattle, *Demodex ovis* for sheep, *Demodex caprae* for goats, *Demodex equi* for horses, and *Demodex phylloides* for pigs.

Demodicosis may occur in farm animals of any age, especially those in poor condition, but most cases in cattle occur in adult dairy cattle in late winter and early spring. This differs from the well-known condition in the dog, which occurs in young, immunodeficient animals.

LIFE CYCLE AND EPIDEMIOLOGY

The entire life cycle is spent on the host. Adult mites invade the hair follicles and sebaceous glands, which become distended with mites and inflammatory material. The life cycle passes through the egg, larval, and two nymphal stages. The disease spreads slowly, and transfer of mites is thought to take place by contact, probably early in life. Calves can acquire mites from an infected dam in half a day. However, in horses, grooming instruments and rugs may transmit infection.

PATHOGENESIS

Invasion of hair follicles and sebaceous glands leads to chronic inflammation, loss of the hair fiber, and, in many instances, the development of secondary staphylococcal pustules or small abscesses. It is these foci of infection that cause the small pinholes in the hide that interfere with its industrial processing and limit its use. In most farm animals, the lesions are difficult to see externally, and only the advanced ones will be diagnosed.

CLINICAL FINDINGS

The important sign is the appearance of small (3-mm-diameter) nodules and pustules, which may develop into larger abscesses, especially in pigs and goats. The small lesions can be seen quite readily in short-coated animals and on palpation feel like particles of bird-shot in the hide. In severe cases there may be a general hair loss and thickening of the skin in the area, but usually there is no pruritus, and hair loss is insufficient to attract attention. The contents of the pustules are usually white in color and cheesy in consistency. In large abscesses the pus is more fluid. In cattle and goats the lesions occur most commonly on the brisket, lower neck, forearm, and shoulder, but also occur on the dorsal half of the body, particularly behind the withers. Larger lesions are easily visible, but very small lesions may only be detected by rolling a fold of skin through the fingers. In horses the face and around the eyes are predilection areas. Demodicosis in pigs usually commences on the face and spreads down the ventral surface of the neck and chest to the belly. There is little irritation, and the disease is observed mainly when the skin is scraped at slaughter. The disease may be especially severe in goats, spreading extensively before it is suspected and in some instances causing death. Severe cases in goats commonly involve several skin diseases, such as mycotic dermatitis, ringworm, besnoitiosis, and myiasis. Demodicosis is rare in sheep. In this species pustules and scabs appear on the coronets, nose, and tips of the ears, and around the eyes, but clinical signs are not usually seen, and mites may be found in scrapings from areas of the body not showing lesions.

CLINICAL PATHOLOGY

The characteristically elongated mites are usually easy to find in large numbers in the waxy material that can be expressed from the pustular lesions. They are much more difficult to isolate from squamous lesions. Lesions in hides can be detected as dark spots when a fresh hide is viewed against a strong light source. However, lesions may not be readily seen until the hair has been removed and the skin has been soaking for some time.

DIFFERENTIAL DIAGNOSIS

- The commonest error is to diagnose the disease as a nonspecific staphylococcal infection.
- In cattle and goats the disease often passes unnoticed unless the nodules are palpated.
- Deep-seated ringworm in horses has much in common with demodicosis.
- A satisfactory diagnosis can only be made by demonstration of the mite.

TREATMENT AND CONTROL

Repeated dipping or spraying with the acaricides recommended for other manges is usually carried out but is more to prevent spread than to cure existing lesions. Ivermectin, which does not eradicate the infection in dogs, possibly because of the difficulty in getting the acaricide to the mite, has been reported to cure 98% of beef bulls when used at 0.3 mg/kg. Recent developments in the development of diagnostics may allow newer techniques that will effectively detect infestations.[1]

SARCOPTIC MANGE (BARN ITCH)

Sarcoptic mange occurs in a wide variety of host species and causes a severe pruritic dermatitis. Although in most countries it has been a major problem and was a reportable

disease, the advent of macrocyclic lactone endectocides has reduced the incidence of disease dramatically.

ETIOLOGY

The causative mite, *Sarcoptes scabiei*, is usually considered to have a number of varieties, each generally specific to a particular host species. Morphologic, immunologic, and molecular research confirms the close relationship among the varieties, but it does not explain the biological differences, particularly with respect to host specificity. Because host specificity is not strict and transference from one host species to another can occur, there is some concern when attempting to control the disease.

Animals in poor condition appear to be most susceptible, but conditions, especially overcrowding, in which sarcoptic mange occurs often go hand in hand with poor feeding and general poor husbandry. The disease is most active in cold, wet weather and spreads slowly during the summer months.

LIFE CYCLE AND EPIDEMIOLOGY

Female mites form shallow burrows in the lower stratum corneum of the skin, in which they deposit eggs. Development for both sexes includes a larval stage and two nymphal stages before molting to the adult. All life-cycle stages, except the eggs, can be found moving on the skin surface and are thus easily transferred to other hosts. The normal exfoliation of the skin eventually exposes the tunnels, exposing eggs as well. The life cycle, from egg to adult, takes 10 to 13 days.

Although direct contact between hosts is the most effective method of transmission, inert materials such as bedding, blankets, grooming tools, and clothing may act as carriers. Adult mites do not usually survive for more than a few days away from the host, but in optimum laboratory conditions they may remain alive for up to 3 weeks. In pigs, adult sows are often the source of infestation for young pigs even though they show no signs of the disease. Large numbers of mites can often be found in the ears of normal sows, and the mites are transmitted soon after farrowing. Significant scratching does not occur until a hypersensitivity develops some 8 to 10 weeks later and may continue until slaughter. A small proportion of young pigs do not develop a hypersensitivity, and these become chronically affected.

Among domestic species, pigs are most commonly affected, but it is an important disease in cattle and camels and occurs in sheep. It has been a notifiable disease in most countries, because of its severity, but a decline in prevalence accompanying the advent of new therapeutics has resulted in the removal of this requirement in some countries. People handling infested animals may become infected, but lesions will disappear if further contact is prevented.

Infested animals develop protective immunity and are able to clear challenge infestations rapidly. A proportion of infested hosts do, however, remain chronically infested, and mite populations may show a postpartum recrudescence, thereby facilitating transfer to the susceptible offspring.

PATHOGENESIS

Young animals, in particular piglets, become infected in the first few weeks of life and develop a hypersensitivity within 8 to 10 weeks. This allergic phase lasts for 8 to 9 months, and during this time affected animals are constantly itchy. The disease, if untreated, progresses to a localized crust formation characteristic of a chronic hyperkeratotic state.

Many infestations in pigs have little or no effect on weight gain, although there is some controversy, and treatments improve productivity (see following discussion). There are suggestions in other hosts of reduced feed efficiency. In some pigs, the loss of condition, production, and vitality may be severe, and the appearance of affected animals is esthetically displeasing. Erythema, papules, and intense pruritus may be seen. Few mites may be necessary to cause a reaction in a previously sensitized animal. A chronic condition is uncommon but is seen in pigs with an immunodeficiency.

In cattle and camels, severe hypersensitivity lesions occur and often lead to death. Sheep initially show an intense pruritus and rub the affected part against fences or bite at the skin. Later papules and vesicles occur and the skin becomes thickened, covered with pale scabs, and the hair is lost.

CLINICAL FINDINGS

Early lesions are characterized by the presence of small red papules and general erythema of the skin. The affected area is intensely itchy and frequently excoriated by scratching and biting. Loss of hair, thick brown scabs overlying a raw surface, and thickening and wrinkling of surrounding skin soon follow. In pigs the lesions commence on the trunk; in sheep and goats on the face; in cattle on the inner surface of the thighs, the underside of the neck and brisket, and around the root of the tail; and in horses and camels on the head and neck. Except in sheep, where the lesions do not spread to the woolled skin, lesions become widespread if neglected, and such animals may show systemic effects, including emaciation, anorexia, and weakness. In neglected cases, death may occur.

The course of sarcoptic mange is rather more acute than in the other forms of mange and may involve the entire body surface of cattle in a period as short as 6 weeks.

CLINICAL PATHOLOGY

Necropsy examinations are not usually undertaken. Deep scrapings that draw blood are required for accurate diagnosis and must be taken from the edges of any evident lesions (scrapings taken from the central portions of lesions are very often negative). Examination of scrapings either directly or after digestion in 10% potassium hydroxide will reveal mites and/or eggs. When practical, multiple scrapings from affected animals should be taken. Examination of the ear wax of pigs often shows mites when none can be seen in scrapings.

Change in behavior, a result of the intense pruritus, have been used in swine as an initial diagnostic tool. An increase in the rubbing index is indicative of infestation, but other clinical confirmation is required.

An ELISA for detection of antibodies to *Sarcoptes scabiei* has been developed. The test has high specificity and moderate sensitivity, being more sensitive in young animals undergoing their first infestation. It has been shown to work well in herd-level eradication programs and functions afterward as an effective surveillance tool.

Recent description of the genome of a canine variety has elucidated several aspects of the host response and biology of the mite.[1]

DIFFERENTIAL DIAGNOSIS

- Sarcoptic mange is the only mange that occurs in pigs. It can be confused with infestation with *Tyroglyphus* spp. mites or lice, or with swinepox, parakeratosis, infectious dermatitis, pityriasis rosea, and ringworm. In most of these diseases there are clinical features that are characteristic, and final diagnosis can be made on the presence or absence of the mite.
- The same comments apply to the differentiation in cattle of sarcoptic mange from chorioptic and psoroptic mange and from chlorinated naphthalene poisoning and ringworm.
- Horses may be affected by psoroptic or chorioptic mange, but the lesions are most common at the base of the mane and tail and at the back of the pastern, respectively.
- Infestation with the trombidiform mites and photosensitization may resemble sarcoptic mange.
- The disease is uncommon in sheep.

TREATMENT AND CONTROL

Macrocyclic lactone endectocides (including ivermectin, eprinomectin, moxidectin, and doramectin) are the preferred products for treatment of sarcoptic mange. Use of these products in pour-on or injectable formulations is highly efficacious when used at the label-recommended dose. Because of the residual activity of these compounds, retreatment is not usually necessary, although moxidectin given subcutaneously at 0.2 mg/kg to infested sheep resulted in a rapid clinical improvement but did not eliminate the mites. Two doses 10 days apart resulted in negative skin scrapings by 14 days

posttreatment. A single injection to cattle eliminated the mites by day 14. The resolution of the lesions may take considerable time, but should not be misconstrued as product failure.

Prefarrowing treatment of sows with ivermectin to prevent transmission to the newborn piglets improves weight gain and early feed conversion.

If other treatments are used, they must be thoroughly applied so that all parts of the skin, especially under the tail, in the ears, and between the legs, are wetted by the acaricide. Although buildings, bedding, and other inert materials do not support the mite for more than a few days, they should also be treated unless they can be left in a dry state for 3 weeks.

RECOMMENDATION

Always treat affected animals. To control spread, animals should be isolated or quarantined.

PSOROPTIC MANGE (SHEEP SCAB, BODY MANGE, EAR MANGE)

Psoroptic mange is of greatest importance in sheep, in which it causes sheep scab, but it is also responsible for body mange in cattle and horses and ear mange in horses, sheep, goats, and rabbits. The disease is a major animal welfare concern.

ETIOLOGY

The various species of *Psoroptes* have now been reduced to two or three species. Based on molecular evidence, *Psoroptes ovis*, *Psoroptes cunilculi* and *Psoroptes cervinus* are identical despite differences in morphology and biology. It is clear that *P. ovis* from cattle and sheep are identical, although cross-transmission is not always successful. *P. equi* occurs on horses, donkeys, and mules in Great Britain and *P. natalensis* on cattle and the water buffalo. The ear mites are all *P. cuniculi*, and recent work has suggested this is a variant of *P. ovis* adapted to the aural environment. *P. cervinus* assumes a dual role, being an ear mite of the American bighorn and a body mite of the wapiti.

LIFE CYCLE AND EPIDEMIOLOGY

Psoroptic mange is a major disease in sheep that was once virtually eliminated in most progressive countries where wool production is an important industry. With the cessation of organophosphate dips in the United Kingdom there has been a resurgence of the problem. The disease in cattle was widespread in the United States but has now largely been brought under control. It can spread rapidly and cause serious losses in cattle if neglected, as shown by the serious losses that can occur in feedlots. The ear manges cause irritation and, in horses, a touchiness around the head.

Psoroptic mites abrade the surface and feed on lipid exudate, bacteria, and skin debris. Erythrocytes are not normally a constituent of the diet and may be accidentally ingested when host scratching results in skin breakage. They cause the formation of scabs, under which they live. The eggs are laid on the skin at the edge of a scab and hatch in 1 to 3 days, although this is prolonged if eggs are not in contact with the skin. There are the usual larval and nymphal stages, and the whole life cycle is complete in 10 to 11 days. All stages are capable of survival away from the host for up to 10 days, and under optimum conditions adult females may survive for 3 weeks.

Optimum conditions for development include high humidity and cool temperatures. Thus the disease is most active in autumn and winter months. This is a result of not only the increased activity of the mites but also the more rapid development in housed animals and the tendency for the disease to be most severe in animals in poor condition. When conditions are adverse, as in summer, mites survive in sheep in protected parts in the perineum, in the inguinal and interdigital regions, in the infraorbital fossae, and inside the ear and the scrotum. Spread occurs from sheep to sheep, but transmission from infected premises and by passive spread of pieces of wool also occurs.

The life cycle of the other species is thought to be similar. Spread of ear mite in horses can occur by grooming or by the use of infected harness.

PATHOGENESIS

The mite migrates to all parts of the skin and prefers areas covered with hair or wool. Salivary secretions and mite excreta contain proteinases that result in a severe allergic pruritus. The exudation of serum accumulates to form a crust. In cattle the mites are most active at the edge of the crust, and the lesion spreads peripherally. Infested calves have lower weight gains, lower feed conversion, and lower energy retention than noninfested calves. In sheep the mites are more generally distributed, and bacterial invasions of the skin are more common.

CLINICAL FINDINGS

Sheep

Cutaneous lesions may occur on any part of the body, but characteristically in badly affected sheep they are most obvious on the sides.[1] Very early lesions are small (6-mm-diameter) papules that ooze serum. Attention may be attracted to the area by raggedness of the wool caused by biting and scratching. In older lesions thin yellow crusts are present, and the wool commences to shed. The wool may contain large masses of scab material that binds the fibers together in a mat. Under suitable conditions the infestation spreads rapidly, and in 6 to 8 weeks three-quarters of the body may be affected.

In a typical outbreak of sheep scab many animals are affected and show itchiness and shedding of the fleece. Some become markedly emaciated and weak, and deaths may occur. However, it is possible to have the disease in a flock at a very low level of incidence and with minimal lesions. This usually occurs when the sheep are highly resistant because of good nutrition, climatic conditions are adverse for mite development, or treatment has been carried out but has been incomplete. In such cases there may be little or no clinical evidence of the disease, and a careful search for latent cases may be necessary. This is facilitated by packing the animals into a confined space, so that the mites become active, and watching for signs of itchiness.

Behavioral changes in infested sheep are dramatic, with sheep biting at the affected areas and rubbing or scratching. In addition, infested sheep exhibit stereotypic behaviors typical of animals under stress. These changes combine to reduce productivity. Animals exhibiting these changes should be carefully examined by palpating the surface of the skin in search of papules and scabs. Special attention should be paid to the ears, the base of the horns, the infraorbital fossa, and the perineal and scrotal areas in rams.

Goats

Lesions can vary from a dry crusty scab on the external ear canal with no clinical signs to severe lesions covering much of the body and causing death. However, it is commonly an ear mite, feeding on whole blood and causing the production of scabs that vary from a single layer lining the large sulcus at the base of the concha to abundant laminated scab formation occluding the meatus. In severe cases the poll may be affected, and scabs may also be found on the pasterns. Female goats serve as the source of infection for the kid; mites may be found by 5 days, and clinical signs are seen by the 3rd week of life. *Raillietia* may also be found in the ear of goats, but *Raillietia caprae* is easily differentiated microscopically because all legs are on the anterior part of the body.

Horses

P. equi causes the production of large, thick crusts on those parts of the body carrying long hair, such as the base of the mane and the root of the tail, and hairless areas such as the udder, prepuce, and axilla. Affected parts are itchy, the hair is lost, and with constant rubbing the surrounding skin becomes thickened. *P. cuniculi* infestations in horses cause severe irritation in the ear accompanied by discharge, shaking of the head, rubbing of the head, and tenderness of the poll.

Cattle

Typical lesions appear first on the withers, neck, and around the root of the tail. In severe cases they may spread to the rest of the body. The lesions are intensely itchy. They commence as papules but soon are covered with a scab, which enlarges peripherally and coalesces with other lesions so that very large areas of skin may become involved. The hair is lost and the skin becomes thickened, wrinkled, and covered with scabs. Badly affected animals becomes weak and emaciated and may die.

CLINICAL PATHOLOGY

The mites can be easily demonstrated in scrapings taken from the edges of the lesions. Examination is facilitated by prior digestion of the scraping in warm 10% potassium hydroxide solution.

An ELISA has been developed for diagnosis of Psoroptes infestation in sheep.[2] It has been applied to monitoring of infestations as part of efficient control programs.

DIFFERENTIAL DIAGNOSIS

- Severe cases of psoroptic mange in sheep are similar to mycotic dermatitis except that there is no itching in the latter. Diseases causing itchiness, such as scrapie, ked, and louse infestations and infestations with *Psorergates ovis* and harvest mites, do not have typical cutaneous lesions, and the latter group can usually be detected by examination for the causative parasites.
- In horses, attention is drawn to the condition because of the horse rubbing its head, by swelling around the base of the ear, or by resentment to the bridle passing over the ears. In some horses, the affected ear may droop.

TREATMENT AND CONTROL

Macrocyclic lactone endectocides are used most frequently for control of psoroptic scabies. Cattle treated with ivermectin must be separated from noninfested cattle for between 9 and 14 days; otherwise, spread and reinfection may occur. In sheep two treatments of ivermectin 0.2 mg/kg subcutaneously are necessary to eliminate infestations.

Moxidectin applied as a 0.5% pour-on at 0.5 mg/kg to cattle is effective against *P. ovis* lice, and *Chorioptes bovis*, and it was equally effective against *P. ovis* as 0.2 mg/kg by subcutaneous injection. In sheep, although a single subcutaneous dose of 0.2 mg/kg moxidectin gave a rapid clinical improvement, two doses 7 days apart were necessary to eliminate mites. In large-scale field use, sheep receiving a single injection in the autumn remained free of the infestation throughout the winter, and two injections 10 days apart were effective in treating outbreaks.

Doramectin injectable at 0.2 mg/kg SC was highly effective in eliminating mites in scrapings of infested cattle. The same treatment was found to protect cattle from infestation for up to 3 weeks.

If sheep are to be dipped, it is important to wet the skin thoroughly and pay special attention to severe cases where mites are likely to be present in inaccessible sites on the body. Thus a plunge dip is almost essential, and the sheep must be kept immersed in the dipping fluid for at least 1 minute. Prior shearing may be advisable but may lead to further spread of the infestation. Care must be taken to ensure that the concentration of the acaricide in the dip is maintained, especially when large numbers of sheep are being treated. Badly affected animals should be set aside, and inaccessible sites, including ears, horn bases, and perineum, should be treated manually with the dipping fluid. Dipped sheep should not be returned to their pastures or to the barn unless the latter has been thoroughly cleaned and sprayed with the dipping fluid.

The synthetic pyrethroids are variable in their efficacy. Flumethrin, used as a nonstripping dipping compound, eradicated *P. ovis* from sheep when used at 55 ppm and gave at least 7 weeks of protection.

In horses, affected ears should be cleaned of all wax, and ear preparations containing benzene hexachloride should be used at weekly intervals. Benzyl benzoate is a safe and effective treatment when given every 5 days for three treatments. Ivermectin is highly effective against *P. equi*.

Eradication of sheep scab on an area basis is usually undertaken by quarantine and compulsory treatment of all susceptible animals in the area at the same time. Now that there are effective treatments that do not require dipping, eradication of scab from areas should be more easily accomplished. The necessity to dip all animals in the area during a short period presents difficulties, and the cost of construction of dips and lack of desire to dip in cold climates are other obstructing factors. The use of pour-ons or injections is an attractive alternative to autumn dipping and has the added advantage of providing helminth control in late-season lambs and in ewes.[3] Further, even pregnant animals can be yarded and treated by subcutaneous injection or pour-on as long as care is taken in the yards. Where it is desired to keep the disease at a low level short of eradication, the disease is made notifiable, movement of stock is restricted, and infested farms are quarantined.

RECOMMENDATION

Treatment is absolutely necessary to keep this from becoming an animal welfare issue.

CHORIOPTIC MANGE (TAIL MANGE, LEG MANGE, SCROTAL MANGE)

Chorioptic mange is the commonest form of mange in cattle and horses. Although the primary effect on cattle is esthetic damage, there are production effects in dairy animals. In horses, leg mange is a source of annoyance and inefficiency at work. In sheep, it affects the scrotum and may cause a decrease in fertility.

ETIOLOGY

Chorioptic mites were formerly named according to the host species, but those on cattle, horses, goats, and sheep are now considered to be one species, *Chorioptes bovis*. Another species, *Chorioptes texanus*, has been reported on goats, cattle, and Canadian reindeer.[1] In cattle, the mites are much more active in the latter part of the winter and tend to disappear in cattle at pasture. This diminution in activity is not noted in cattle kept housed in the summer.

LIFE CYCLE AND EPIDEMIOLOGY

C. bovis feed on the skin surface, abrading the upper layers with their mouthparts and contaminating the area with salivary secretions and excreta. Developmental stages are similar to that of *Psoroptes*, and a complete cycle, from egg to adult, requires approximately 3 weeks. The number of parasites is influenced by temperature and humidity, with the mite populations beginning to increase on sheep in early autumn and numbers reaching a peak in late autumn or early winter and declining in spring. In cattle the cycle is longer, with peak numbers occurring in late winter and early spring and declining in summer. Transmission is probably effected by direct contact in most instances, although in animals housed in barns, grooming tools may be an additional method of spreading the disease. Infestation of bedding is not a common method of transmission.

In horses, the parasites occur almost entirely in the long hair on the lower parts of the legs and are rarely found on other parts of the body. In cattle the disease is most evident in the winter, with lesions occurring most commonly on the perineum and back of the udder, extending in severe cases to the backs of the legs and over the rump. In the summer months, the mites persist in the area above the hooves, particularly the pasterns of the hind leg. In sheep, lesions are confined to the wool-less areas, chiefly the lower parts of the hindlegs and scrotum. Rams are more heavily infected than ewes and probably infect ewes while copulating. Lactating ewes probably act as the source of infection for lambs.

PATHOGENESIS

The mites cause an allergic exudative dermatitis; the yellowish serous exudate coagulates

and breaks as the hair grows so that small scabby lesions are seen on the hair. In horses the mites cause severe irritation and itchiness. The initial lesion in cattle is a small nodule that exudes serum, causing matting of the hair. In severe cases these coalesce to form heavy scabs and cause thickening and wrinkling of the skin. Mites can be isolated from many animals that show no clinical evidence of the disease. Although most cases do not cause any symptoms, a rapidly spreading syndrome characterized by coronitis, intense irritation, and a marked fall in milk production has been reported.[2] *C. bovis* is a common parasite of sheep in the United States, New Zealand, and Australia, and causes an allergic exudative dermatitis on the scrotum of rams. This may cause a rise in temperature of the scrotal contents and severe testicular degeneration if the lesion has an area greater than 10 cm^2.

CLINICAL FINDINGS

The first sign in horses is usually violent stamping of the feet and rubbing of the back of the hind pasterns on wire, rails, or stumps. This is most evident during periods of rest and at night. Examination of the area is difficult because of the long hair present, and the horses may resent manipulation. In cases of long duration, the skin is seen to be swollen, scabby, cracked, and usually greasy; small amounts of serous exudate may be attached to most hair in the affected area.

Cattle show little evidence of cutaneous irritation, but the small crusty scabs (3 mm in diameter) on the escutcheon, udder, and thighs are unsightly. Although the mites appear to cause little trouble in the summer, occasional animals are seen that have thick, crusty scabs on the skin, just above the coronets and around the muzzle.

The main lesion in sheep is seen on the scrotum of rams, where an allergic dermatitis results in the production of a yellowish serous exudate over areas from a few millimeters to several centimeters.

CLINICAL PATHOLOGY

Scrapings from the affected areas usually contain large numbers of mites.

DIFFERENTIAL DIAGNOSIS

Greasy heel in horses resembles chorioptic mange except that pain is more evident in the former and itchiness in the latter. It has been suggested that the two diseases are etiologically related.

The lesions in cattle may go unnoticed but are not likely to be mistaken for those of any other disease, with the possible exception of other manges. The presence of chorioptic mites in footrot and mucosal disease lesions may be purely coincidental, but cases of chorioptic mange that have lesions around the coronet and muzzle may be mistaken for one of the erosive diseases.

Sheep with itchy, scabby legs may be infested with other forms of mange or have contagious ecthyma or strawberry footrot.

TREATMENT AND CONTROL

The macrocyclic lactone endectocides have shown efficacy against *Chorioptes* spp., but eradication of the parasites from a herd is difficult. Moxidectin 0.5 mg/kg applied as a pour-on eliminated *C. bovis* as well as sucking lice and *P. ovis*. When given as a single injection of 0.2 mg/kg, there was a marked decline in the number of mites, but few cattle were cleared of infection. Doramectin has high efficacy at the label rate in cattle, but a single treatment did not clear mites from all of the trial animals. Treatment with eprinomectin at recommended rates was completely effective, but mites persisted for at least 14 days.

Amitraz 0.05% removed 98% and phoxim 0.05% and 0.1% used twice at 10-day intervals has also eradicated the infection from cattle. Other compounds if used repeatedly will reduce mite numbers, but recrudescence may occur. Ivermectin 0.2 mg/kg given subcutaneously on two occasions reduced but did not eliminate the infestation on cattle. A single treatment of infested horses with ivermectin paste also did not remove all mites, but when combined with hair removal, washing encrusted areas with oil of salicylic acid, and the later removal of crusts with a stiff brush, eradication was achieved.

Ked and Louse Infestations

Ked and louse infestations cause irritation resulting in skin or wool damage. Blood loss may occur with some species.

SHEEP KED (*MELOPHAGUS OVINUS*)

Keds are flat, brown, wingless flies, about 6 to 7 mm in length, found on sheep throughout the world. Keds are now rarely reported in many countries because of good management and control. For example, it wasn't mentioned in a review of livestock ectoparasites of Europe and the Mediterranean,[1] although anecdotal evidence suggests it may be present in isolated pockets associated with organic production.[2] The ked can transmit *Trypanosoma melophagium* and *Rickettsia melophagi*, harmless blood parasites of sheep. Recent studies suggest that it may have more importance than otherwise indicated.[3] Staining of the wool by the feces of the ked reduces its value and gives it a peculiar musty odor. Heavy infestations cause skin blemishes, which are costly to the leather industry. Sheep in poor condition suffer most from infestations. Goats may also be infested.

LIFE CYCLE

Keds live their entire life cycle on the host. Adults of both sexes are blood feeders, and although the degrees of infestation usually encountered cause only irritation with resulting scratching, biting, and damage to the fleece, very heavy infestations may cause severe anemia. Spread is generally the result of direct contact between hosts. A recent review[2] suggests that this exchange is primarily between dams and their offspring and that it is predominantly the newly emerged adults that migrate to new hosts. Larvae develop within the female one at a time and are deposited on the host as mature third instars that pupate within a few hours. The female ked lives for 4 to 5 months and may lay up to 10 to 15 larvae, so buildup of infection is slow. The larvae are attached to the wool fiber some distance above the skin, and many larvae and pupae are removed at shearing. The young ked usually emerges in 20 to 22 days, but this period may be prolonged for up to 35 days in winter. The complete life cycle takes 5 to 6 weeks under optimal conditions. Heavy infestations usually occur in winter months, and they decline in the summer. The parasite is mainly seen in colder, wetter areas, and infestations may disappear when sheep are moved to hot, dry districts. Resistance is acquired in time, and resistant sheep grow better and produce more wool.

A seasonal pattern of infestation occurs. Keds are sensitive to hot, dry weather and numbers decrease markedly over the summer. Populations increase slowly over the autumn and winter. Although keds that have been dislodged from the host can live for up to 2 weeks if in mild moist conditions, most die in 3 to 4 days and probably do not play a part in reinfesting sheep.

Keds have recently been implicated in the transmission of *Anaplasma ovis* from infected sheep.[3] This potentially zoonotic disease can infect people, with important implications.

CONTROL

At shearing a large proportion of adults and pupae will be removed. This can provide effective control on adult sheep, particularly where a combination of hot conditions and a short fleece will kill most of the remaining keds. However, some may remain alive in protected places such as the ventral neck and breech regions and on younger stock. If treatment is carried out within the next 2 to 4 weeks, eradication will be achieved as long as all sheep are included and the insecticide

used has a residual protection longer than the time taken for the last pupae to hatch.

Ivermectin and its analogs given at the standard anthelmintic dose will act to eliminate the ked populations. Closantel is also effective against keds.

LOUSE INFESTATIONS (PEDICULOSIS)

Louse infestations are common throughout the world. The species are host specific and are divided into biting and sucking lice.

SYNOPSIS

Etiology Species-specific sucking and chewing lice affecting all animals.

Epidemiology Transmission from host to host. Lice show a marked seasonal periodicity, rising from low numbers after summer to a peak in the following late spring. Foot lice infested from pasture.

Clinical signs Irritation that causes rubbing, damage to the fleece or skin, and loss of milk production. Some species cause anemia. Foot lice cause stamping.

Clinical pathology Hair loss may result from hypersensitivity.

Lesions Skin lesions as a result of rubbing; fleeces have tufts protruding and lose their brightness.

Diagnostic confirmation Lice can be seen on careful inspection. Preferred site varies with host and species of louse.

Differential diagnosis In sheep, must be differentiated from *Psorergates*, ked, and *Psoroptes* infections. In other animals, separate from allergic dermatitis.

Treatment Macrocyclic lactones and synthetic pyrethroids (where available).

Control Pour-on and injectable treatments control lice on cattle, horses, sheep, and pigs. Good husbandry practices will reduce infestations. Plunge or shower dips used on sheep; all sheep should be treated, and sheep must be thoroughly wetted. Treatment should follow shearing, which removes many lice; sheep in short wool are also easier to wet.

ETIOLOGY

The important species are as follows:

- Cattle:
  Sucking lice—*Linognathus vituli* (long-nosed sucking louse), *Solenopotes capillatus* (small blue sucking louse), *Haematopinus eurysternus* (short-nosed sucking louse), *Haematopinus quadripertusus* (tail louse), *Haematopinus tuberculatus* (buffalo louse)
  Chewing lice—*Damalinia* (= *Bovicola*) *bovis*
- Sheep:
  Sucking lice—*Linognathus ovillus* (sucking face louse), *Linognathus africanus*, *Linognathus stenopsis* (goat sucking louse), *Linognathus pedalis* (sucking foot louse)
  Chewing lice—*Damalinia ovis*
- Goats:
  Sucking lice—*L.* (blue louse), *L. africanus*
  Chewing lice—*Damalinia caprae*, *Damalinia limbata*, *Damalinia crassiceps*
- Pigs:
  Sucking lice—*Haematopinus suis*
- Horses:
  Sucking lice—*Haematopinus asini*
  Chewing lice—*Damalinia equi*
- Donkeys:
  Chewing lice—*Werneckiella* (= *Bovicola*) *ocellatus*

LIFE CYCLE AND EPIDEMIOLOGY

Sucking Lice

All life-cycle stages of sucking lice are found on the host. Both sexes are obligate blood feeders, taking small meals from capillaries in the upper skin.[1] Survival off the host is limited, although some species, such as the foot lice of sheep, may survive away from the host for up to 2 weeks. Females lay 2 to 6 eggs per day, which are attached to individual hair shafts. Eggs complete embryo development and hatch within 5 to 11 days of deposition. Lice have three nymphal stages, which bear a morphologic similarity to the sexually mature adult stage. Each nymphal stage will take 2 to 4 days to complete. Louse development rate, at all stages, is highly temperature dependent and requires a narrow temperature range. Temperatures above 41° C (106 F) and 46° C (115 F) are lethal for eggs and adults, respectively, of *L. vituli.*[2] Optimal development takes place between 33° C and 37° C (91 F and 99 F). Lice therefore show a seasonal periodicity, with very low numbers in the summer when conditions are hot. Populations begin to increase with cooler fall temperatures, reaching maximum levels in late winter.[3]

Chewing Lice

All life-cycle stages of chewing lice are found on the host. Lice feed on dead skin cells, hair, and oil secretions, which they abrade from the surface using their chewing mouthparts. There may be some abrasion of the upper skin layers, and there has been demonstration that sheep develop antibodies to salivary sections of *Damalinia* (= *Bovicola*) *bovis.* Sex ratios are highly female biased, and there are suggestions that parthenogenesis occurs in some species. Females deposit less than 1 egg per day. Embryo development is completed in 7 to 10 days, producing nymphs that molt three times before reaching sexual maturity. As with the sucking lice, there is a strong temperature/development relationship that is highly regulated, with a narrow range for optimal development and survival. Chewing lice can survive off the host for up to 2 weeks.

Transmission of both types of lice occurs by direct contact, but inert objects such as blankets, grooming tools, and harnesses may remain infective for several days. Sheep may become infested with foot lice from the pasture. Young pigs may become infected some 10 hours after birth. Newborn calves rapidly acquire infestations from their dams.

CLINICAL FINDINGS AND DIAGNOSIS

Sucking Lice

All species cause irritation of the skin and stimulate scratching, rubbing, and licking, leading to restlessness, damage to hair coat or fleece and hides, and loss of milk production. These behavioral changes result in reduced efficiency, particularly in feedlot cattle.

Lice appear to be present on a large proportion of cattle, but measurement of their impact on productivity has produced equivocal results. It is often thought that infestation has little or no effect on weight gain and hematological values. However, there appears to be a synergistic effect between louse infestations and the presence of gastrointestinal nematodes that does have an influence on weight gain. Anemia is rare but has been described for heavy infestations of *L. vituli* and *H. eurysternus.* Treatment, however, may be warranted to reduce the damage to hides and prevent damage to fences and other fixtures. Hairballs may occasionally occur in calves as a result of continual licking. Cattle and pig lice have been reported as vectors of several rickettsial diseases, but this remains to be verified.[4]

The pig louse spreads swinepox, and although weight loss may not occur, even with heavy burdens, some pigs develop an allergic dermatitis, and the consequent rubbing leads to skin lesions.

Foot lice of sheep are thought to live on blood. Light infestations may not cause clinical signs, but moderate to severe infestations cause stamping and biting of the affected parts. Lice cause goats to rub or to bite their coats, which become matted and damaged. Angora goats can damage the hair shaft and lose their coats. Signs of infestation are restlessness, hair loss, and decreased milk production. In horses, *H. asini* is the more serious species because it removes blood and may cause some anemia.

Chewing Lice

Chewing lice cause irritation and rubbing. In sheep, the wool loses its brightness and may become matted and more yellow. There is evidence that a pelt defect called cockle is

associated with infestation with body lice. The quantity and quality of the fleece is reduced, and losses up to AUS$3.20 per infested sheep have been measured.

Chewing lice on cattle also cause an increase in rubbing and licking, which contributes to reduction of efficiency and damage to facilities. Hair loss has been attributed to this infestation, but it is a controversial association because many other causes are likely. Lice have been implicated in the transmission of several bacterial pathogens, but this finding requires verification.[5]

Diagnosis of lice on cattle and horses requires close visual inspection, with particular attention being paid to known predilection sites. These include the head, the sides of the neck, the dewlap, the escutcheon, and tail switch. Effective diagnosis requires that hair be parted and skin examined at several locations at each of the predilection sites. Use of a supplementary light source and restraint of the animal are very helpful.

Chewing lice of cattle, sheep, and horses are recognized by their rounded heads and light brown color. These lice are highly mobile and will move away from inspection sites. Their eggs are difficult to see unless on dark-haired cattle or horses. Sucking lice are recognized by their gray or blue–gray color and their pointed heads. They tend to remain fixed to the skin.

Chewing lice may congregate on the dorsal surface and flanks, whereas sucking lice are found on the head and in the long hair of the mane and tail; in heavy winter infestations, however, lice may be found on any part of the body. In sheep with long wool, the greatest numbers of *D. ovis* may be seen on the midside, particularly the shoulders, from where they spread to the back and rump. After shearing, small residual infestations may be found on the ventral neck. Foot lice are usually found in clusters on those parts covered with hair, mainly on the lower limbs, but in heavy infestations they can be found in clusters above the hock, on the scrotum, in the belly wool, and, more rarely, on the face.

TREATMENT AND CONTROL

Self-grooming and grooming by herdmates effectively regulates louse populations on most hosts, but the effectiveness is limited when hair coat or fleece become too long for the tongue surface to effectively remove lice and eggs. Similarly, shearing is an important factor in reducing body lice populations on sheep. Between 30% and 50% of the population is removed with the fleece, and those remaining are subjected to a more variable microclimate. Populations are at their lowest 30 to 60 days after shearing. Reversing temperature gradients as sheep move in and out of shade, and very wet conditions, will also reduce lice numbers.

Body lice of sheep are relatively easy to eradicate if a clean muster is achieved, the sheep are thoroughly treated, and reinfestation is avoided. However, in practice, failure to eradicate commonly occurs as a result of the inability to thoroughly wet the fleece because of poor formulation of products or because the lice are resistant to the chemical used. The most difficult problem when attempting to eradicate lice from flocks over a large area is the diagnosis of lice in lightly infested flocks. Methods of detection of louse antibodies in fleece have been developed for use on the farm that give good results. Adoption has been limited, and in many cases the methods have been withdrawn from practice because the delay between testing and results has been too long. Similarly, techniques have been devised to test for lice by digesting the wool and examining the residue for lice, but the delays inherent in such a system often mean that by the time the farmer obtains the results, the optimum time to treat sheep has passed.

Affected sheep can be effectively treated with macrocyclic lactone or chitin synthesis inhibitors. An ivermectin 0.03% jetting fluid was reported to have high efficacy in treating lice in sheep with 3 to 9 months of wool, but failed to eradicate the lice. No treatment is known that can eradicate lice from long-woolled sheep under field conditions. Following treatment of foot lice, sheep should be moved to a paddock that has been free of sheep for a month.

Treatment of goats has not been studied extensively, and the treatments used on sheep and cattle are thought to be effective in goats. Lactating goats should not be treated.

Macrocyclic lactone-based products (ivermectin, moxidectin, doramectin, and eprinomectin) are available as pour-on or injectable formulations for cattle and have shown excellent efficacy against both sucking and chewing lice. Persistence of activity is one of the exceptional benefits of these products.

Essential oil treatments using a variety of products have been evaluated against *W. ocelatus* in donkeys and have been proven an effective alternative to synthetic chemicals.[4]

Sheep lice have been shown to quickly develop insecticide resistance, and strains of *D. ovis* that are resistant to the insecticides are common in the United Kingdom and Australia.[6] Tolerance has been reported in other species as well.[7] Resistance management strategies that use combination treatments are now considered the best approach to management of the problem.

Treatments should be timed to coincide with the beginning of louse population growth (i.e., autumn or early winter). Extremely early treatments often result in spring outbreaks that are caused by very small residual populations on a few animals.[8] Products with persistent activity, in excess of 21 days (e.g., macrocyclic lactones), do not require a second application.

Effective management of lice in a herd requires that new animals be isolated for a period of time sufficient for all lice to be eliminated by treatment. The introduction of one or two infested individuals, such as occurs when strays are allowed into a herd, leads to a slow buildup of infestation. In Australia, modeling approaches have been developed for the treatment of sheep.[9]

RECOMMENDATION

All animals in a herd should be treated for louse control to prevent the buildup of the louse population to a point that is damaging.

Miscellaneous Skin Diseases Caused by Flies, Midges, and Mosquitoes

Although these insects differ quite markedly, they are dealt with together because they exert similar deleterious effects. Their activity causes stress and induces behavioral changes, and in many cases they are important vectors for a variety of parasites and infectious diseases.

STABLE FLIES (*STOMOXYS CALCITRANS*)

ETIOLOGY

The stable fly, *Stomoxys calcitrans*, has a cosmopolitan distribution. Other species, including *Stomoxys nigra*, occur in South Africa. *S. calcitrans* is a moderate-sized, gray to black fly about the size of a housefly. These are the most economically important species of fly affecting confined livestock in North America.

LIFE CYCLE AND EPIDEMIOLOGY

These insects have a typical fly life cycle, with eggs being deposited in high-organic-matter areas with an elevated moisture content, such as spilled feed and the edge of silage pits. The larvae grow in a temperature-dependent manner in the same high-organic-matter area through three larval stages. Pupae form in dry material at the edges of the areas where the larvae develop. Flies rest on fences and structural surfaces in a characteristic head-upward position and can readily be recognized by the prominent, forward-directed, pointed proboscis between short palps.

Stable flies of both sexes are blood feeders, attacking particularly cattle and horses, people, and, to a lesser extent, pigs. Bites are painful and often bleed freely when fresh. The flies are intermittent feeders, spending only short periods on the host; most of their time is spent resting on fences and building sides. Eggs are laid in high-moisture areas of rotting hay or straw, along the edge of silage pits, and on the edges of manure pack of feedlots and compost piles. Mature larvae leave the high-moisture sites to pupate in drier sites nearby. Development times are regulated by temperature, with higher temperatures resulting in more rapid development. A complete life cycle will require 3 to 4 weeks in summer. In temperate climates flies exhibit a distinct seasonality, with peak populations in middle to late summer. Larvae will overwinter in warmer areas of silage piles. The flies are highly mobile, traveling up to 20 km in search of suitable hosts. These flies have now moved onto pasture, where they can affect cattle that are fed from round bales left as a food source.[1]

Feeding activity by the flies results in stress to the animals and reduced efficiency through reductions in feeding time. When large numbers of flies are present, the animals will bunch to reduce biting rates. At high temperatures the bunching may result in cattle overheating.

PATHOGENESIS

S. calcitrans organisms are mechanical vectors for anthrax, infectious equine anemia, bovine virus, diarrhea virus, and surra. They are intermediate hosts for the nematode *Habronema majus*,[3] which is reputed to be a cause of allergic dermatitis in horses in Japan.

CLINICAL FINDINGS

A localized sensitivity of the forelimbs of cattle may develop and result in the formation of intradermal blisters that coalesce to form bleeding sores. With very heavy infestations some deaths may occur. Populations can be assessed by counting the number of flies on the front legs of cattle. When the average number exceeds 2 per leg, significant losses occur, and population management is required.

TREATMENT AND CONTROL

Effective management of stable flies requires removal of high-moisture, rotting organic matter from the environment.[2] Edges of silage pits, manure packs, and compost piles should be kept dry, and manure-contaminated bedding should be removed regularly. Insecticide treatments must be applied to all exterior surfaces (e.g., barn sides, fences, and exterior of feed bunks). Spraying of fixtures and walls, particularly sunlit walls where the flies often remain unnoticed, with long-acting compounds reduces infestations for 2 weeks or longer.

Application of insecticides or repellants directly on animals is generally impractical because of the short duration of efficacy. Low frequency of insecticidal application, when necessary, slows the development of insecticide resistance. Permethrin applied as a microencapsulated formulation gave longer protection than an emulsifiable concentrate. Affected horses can be treated locally with an analgesic cream, and if the irritation is severe they can be tranquilized with acetylpromazine.

RECOMMENDATION

Treatment is absolutely necessary to keep these flies from reaching population levels that are in excess of the economic threshold and from reaching levels where they are an animal welfare issue. Populations are also an issue for humans.
