VETERINARY MEDICINE: A TEXTBOOK OF THE DISEASES OF CATTLE, HORSES, SHEEP, PIGS, AND GOATS, ELEVENTH EDITION

Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Dr. Otto M. Radostits, August 31, 1934-December 15, 2006, Senior Author, Fifth to Seventh Editions; Lead Author, Eighth to Tenth Editions

Otto Martin Radostits was a veterinary educator, clinician, and researcher who had a profound influence on students and practicing veterinarians throughout the world through his writings, not the least this text. Otto was closely involved with writing and editing the Fifth to Tenth Editions of *Veterinary Medicine*.

Otto, the eldest son of Austrian immigrants, was raised on a small mixed farm in Alberta, Canada. His early farm experiences and those obtained from working with a local veterinarian while attending high school sparked an interest in pursuing a career in veterinary science and were the beginning of his lifelong passion for large-animal veterinary medicine. He was admitted to the Ontario Veterinary College in 1954, at that time the only English-speaking veterinary school in Canada. During his undergraduate years, his clinical interests and potential were recognized such that following graduation, he was invited to join the faculty as a member of the ambulatory clinic practice of the college—at that time a vigorous practice in a rural area. Otto spent the next 5 years teaching in this position, with the exception of a year spent at the veterinary school at Purdue University in West Lafayette, Indiana.

The Western College of Veterinary Medicine in Saskatchewan, Canada, was established under the leadership of Professor D. L. T. Smith in the mid-1960s, and Otto was one of the founding faculty members. He established the ambulatory practice and helped design the college clinical buildings and finalize the curriculum. He remained a faculty member at the Western College of Veterinary Medicine until he retired in June 2002 and was awarded the title Emeritus Professor. Here he matured as a clinical teacher to influence students and veterinarians locally and internationally through his writings and presentations at veterinary meetings.

Otto's international recognition in large-animal veterinary medicine rests mainly on the strength of his writing and authorship of veterinary texts. These span the spectrum of large-animal veterinary medicine, from the clinical examination of the individual animal to the epidemiology, diagnosis, treatment, and control of livestock diseases, to herd health and preventive medicine.

The most notable are his contributions to this textbook, which has been used by veterinary students and practicing veterinarians around the world for over 50 years and through 11 editions, for 6 of which Otto was a senior or lead author. Otto joined the original authors, Doug Blood and Jim Henderson, for the Fifth Edition of this text in 1979 and, in 1994, became the senior author for the Eighth, Ninth, and Tenth Editions. During his sojourn as senior author, the text continued its original design as a student textbook with many student-friendly features. It also continued its importance as a reference book including the available information on all of the diseases of large animals, a truly formidable task. Otto did a large part of the work and would surely have been very proud of this new Eleventh Edition.

In the writing of these and his other texts, Otto read the veterinary literature and was a firm believer in evidenced-based medicine. He insisted that all statements in these texts were supported by references in the literature, and he maintained the format of a very large bibliography at the end of each disease description. He believed that other veterinary educators should also be current with the veterinary literature and had little regard for those who were not. He could be a forceful presence in discussions, but Otto was also one of the quickest to recognize new information that negated previous theories concerning a disease, and he was always responsive to reasoned argument.

Otto taught that making a correct diagnosis was the crux to the solution of a disease problem, and he had a passion for the art and science of clinical examination. Many of his students affectionately remember his admonition, "We make more mistakes by not looking than by not knowing." Otto's insistence on the need for accurate diagnosis did not preclude this realization that what the practicing veterinarian needed as the final message from his books was the best current information on what to do to cure or prevent the disease in question.

Otto has authored other texts. In the late 1990s he became concerned that the traditional skills of physical clinical examination were being supplanted by laboratory and instrumental analysis. As a consequence, he consulted with veterinary clinicians around the world and in 2000 was a senior author of the text *Veterinary clinical examination and diagnosis*. From his work on farms, Otto recognized that disease in farm animals commonly was a population concern, and he recognized the limitations of "fire brigade" medicine. He authored the first major text in herd health and preventive medicine with its first edition in 1985. Otto published many other works of significance to global veterinary medical education and presented more than 250 invited lectures and seminars in veterinary medicine in countries around the world.

Dr. Radostits's contributions have been recognized by many awards. For him, probably the most important were the award of Master Teacher from his university and, nationally, the Order of Canada.

Dr. Clive Collins Gay

Dr. Clive Collins Gay, DVM (Guelph, 1960), MVSc (Guelph, 1962), MVSc (*Ad Uendem Statum*, Melbourne, 1970), FACVSc (1977), Diplomate of the American College of Veterinary Internal Medicine (honorary, 2008), and Doctor of Veterinary Science (*Honoris Causa*, Melbourne, 2008) has a distinguished career as an agricultural animal veterinarian, scientist, author, and educator spanning five decades.

After graduating from Guelph in 1960, he was appointed as an assistant lecturer in the Department of Veterinary Medicine at the University of Glasgow from 1962 to 1964. In 1964, he was a George Aitken Pastoral Research Fellow (Sheep) and worked at the Veterinary Investigation Centre, Edinburgh University (Scotland); the Veterinary Investigation Centre, Ministry of Agriculture, Penrith (England); and the Nuffield Institute for Medical Research, Oxford University.

In 1965, Dr. Gay was recruited by his mentor Professor Douglas Blood to the newly reestablished veterinary school at the University of Melbourne as a senior lecturer in agricultural animal medicine. Ken Hinchcliff was one of Dr. Gay's students at the University of Melbourne. Dr. Gay was a genuinely gifted clinician, with an enthusiasm for veterinary science that inspired generations of undergraduate and postgraduate students and staff alike. His teaching attributes were recognized by various student accolades over the years, both in Australia and North America, and by the Washington State University (WSU) Faculty Award in 2000 from the Washington State Veterinary Medical Association (WSVMA).

In 1979, Dr. Gay became a professor of food animal medicine at WSU, where he concentrated on agricultural animals, establishing the Field Disease Investigation Unit in 1982 and leading the unit until his retirement in 2005. The approach used by the Field Disease Investigation Unit was groundbreaking at the time it was implemented in that it applied a multidisciplinary approach including university and private veterinarians, animal scientists, extension agents, and producers to tackle economically important livestock diseases. Dr. Gay was also one of the earliest proponents of evidenced-based medicine. He served on several committees of the U.S. Department of Agriculture (USDA). In recognition of his extensive contribution in this area, he received the prestigious Calvin W. Schwabe Award for lifetime achievement in veterinary epidemiology and preventive medicine from the American Association of Veterinary Epidemiology and Preventive Medicine in 2007. Dr. Gay became Professor Emeritus at WSU in 2005. His extensive contribution to veterinary medicine was recognized with a Distinguished Achievement Award from the Washington State Veterinary Medical Association in 2006, and he was made an Honorary Diplomat of the American College of Veterinary Internal Medicine in 2008.

Dr. Gay's research activities covered the breadth of veterinary science in regard to both species and systems, including topics as diverse as colic in horses, cardiology in dogs, diarrhea in pigs, colostral immunity in calves, and trace-element deficiency in ruminants. He supervised 13 PhD students and 14 master's degree students. This work resulted in more than 90 articles in journals, more than 100 proceedings and abstracts, and the delivery of more than 150 invited presentations to scientific groups, veterinary conferences, and agricultural groups. The latter reflected his commitment to "knowledge transfer" (extension work), which was a cornerstone of his approach to epidemiological studies and preventive medicine.

Reflecting his international standing, Dr. Gay had been a Visiting Research Fellow in the following areas: the Department of Veterinary Microbiology, University of Guelph, in 1971; the Department of Veterinary Clinical Studies, University of Cambridge, in 1972; the Department of Veterinary Clinical Sciences, Massey University, in 1993; the Central Veterinary Laboratory, Ministry of Agriculture Fisheries and Food, Pirbright, in 1994; and the Department of Geospatial Science, RMIT University (Melbourne), in 2001.

Over the years, Dr. Gay contributed actively to national and state veterinary associations, serving as a committee member of the Victorian Division of the Australian Veterinary Association (1968–1971); and editor of the *Victorian Veterinary Proceedings* (1968–1971); and an executive committee member of the Washington State Veterinary Medical Association (1999–2005), where he held the positions of vice president (2000), and president (2003–2004).

Dr. Gay was a contributing author of *Veterinary Medicine*, edited by Blood, Henderson, and Radostits in 1979, 1983, and 1989, and an author and editor for the Eighth (1994), Ninth (2000), and Tenth (2007) Editions. His most important contributions to those editions included diseases of the newborn, infectious diseases of sheep and goats, prion diseases, practical antimicrobial therapy, and selected metabolic and protozoan diseases, emphasizing the important roles that environment, management, host factors, and pathogen virulence factors play in disease occurrence and severity. Dr. Gay was largely responsible for bringing the Tenth Edition to print when Dr. Radostits, the lead author and editor, became ill during the final stages of preparation of the text.

Dr. Clive Gay and Professor Doug Blood, Veterinary Clinical Centre, University of Melbourne, 1978. (Courtesy of D. Blood's family.)

Professor Douglas Blood

1920–2013

Professor Douglas Blood came to Australia in 1926 from East Ham, London. His family settled in Richmond, New South Wales, and toughed out the Great Depression. Through a scholarship, he attended Hurlstone Agricultural High School, where he enjoyed studying animals, especially cows and dogs. Following high school, Doug entered the Bachelor of Veterinary Science program at the University of Sydney. During World War II, he and a group of colleagues convinced the university to allow them to complete an accelerated course so that they could graduate in 1942 and then enlist in the armed services. Doug became a captain in a surveillance unit called Curtin's Cowboys in the Northern Territory. He returned to teach at the University of Sydney Veterinary School for 12 years. Then, from 1957 to 1962, Doug taught large-animal medicine at the Ontario Veterinary College at Guelph. It was during this time that he taught and mentored Otto Radostits and Clive Gay, both of whom were subsequently to become authors, along with Doug, of this text.

In 1962, Doug was appointed Professor of Veterinary Medicine and Founding Dean of Veterinary Science at the University of Melbourne. Doug passed on the deanship in 1968, but he continued to teach, retiring in 1985 after 23 years of service. During his time at the University of Melbourne, Doug recruited Clive Gay to a faculty (academic) position in the School of Veterinary Science and taught both Ken Hinchcliff and Peter Constable, both of whom followed him as authors of this text and deans of veterinary faculties—Hinchcliff at the University of Melbourne and Constable at the University of Illinois.

In recognition of his service to veterinary science, Doug was the recipient of many awards and honorary degrees, including the Schofield Medal from the University of Guelph, the Gilruth Prize for Meritorious Service to Veterinary Science from the Australian Veterinary Association, and an Order of the British Empire. He was involved in the formation of the Australian and New Zealand College of Veterinary Scientists. He also served as a committee member of the Victorian Division of the Australian Veterinary Association and as a board member of the Veterinary Surgeons Registration Board of Victoria.

In the early years, Doug Blood revolutionized the teaching of clinical veterinary medicine. For those of us privileged to have been taught by him at this time, he was a superlative teacher. Doug was one of the first teachers in clinical veterinary medicine to recognize that pathophysiology was the basis for teaching the disease processes in large animals. He also concentrated on the principles of pathophysiology in his explanations of disease syndromes and in teaching clinical examination and diagnosis. This was an approach that he developed from the teaching of his mentor, Oxford veterinary scientist H. B. Parry, to whom the first edition of this text was dedicated. This approach to clinical teaching was in marked contrast to the rote learning that was common in many of the disciplines taught at that time and in stark contrast to the teaching method in clinical examination and diagnosis, which primarily relied on pattern recognition.

Doug Blood also taught that the method of clinical examination should be system based, that it should be conducted in a systematic manner, and that it should be conducted using all available senses and techniques. He further taught that the intellectual diagnostic rule-out process should also incorporate a consideration of the presenting epidemiology of the disease problem, an examination of the environment, and an estimation of the probability of disease occurrence, summarized with his often repeated adage "common diseases occur commonly." Although these approaches might seem obvious to recent graduates, in the 1950s and early 1960s, they were revolutionary. In fact, they set the foundation for current teaching principles in large-animal clinical veterinary medicine. Students of that older vintage recall with great appreciation the understanding of clinical veterinary medicine imparted by Doug Blood and his particular contribution to their education. Throughout subsequent years in his teaching career, Doug had the ability to inspire students and is viewed with respect, admiration, and even veneration by the generations of students he has taught.

Professors Ken Hinchcliff, Peter Constable, and Doug Blood (Werribee, Australia, 2008). (Source: Hinchcliff K.)

The First Edition of this text was published in 1960 and authored by D. C. Blood and J. A. Henderson. It was entitled *Veterinary Medicine: A Textbook of the Diseases of Cattle, Horses, Sheep, Pigs and Goats* and was based on Doug Blood's and Jim Henderson's lectures and Doug's teaching and philosophical approach. At that time, there were few textbooks in the disciplines of veterinary science and up-to-date texts published in English that were primarily concerned with clinical veterinary medicine and diseases in agricultural animal species were not available. The original text was divided into two major sections. One section, "General Medicine," covered system dysfunction, and the other, "Special Medicine," covered the specific diseases of the large-animal species. This format was followed until the Eleventh Edition. The Second Edition was published in 1963 and had an additional two chapters covering parasitic diseases. Subsequently, new editions have been published approximately every 5 years, with major or minor changes in format in most editions, such as the addition of chapters dealing with new subjects or the addition of material in specific subheadings to highlight, for example, the epidemiology or zoonotic implications of disease. However, always, with each edition, there was an extensive revision of disease descriptions based on current literature. Professor Henderson's involvement with the text ceased with the Fifth Edition, and that edition recruited Professor O. M. Radostits as senior author and others as contributing authors. Blood coauthored nine editions over a span of 45 years, with coauthors including Radostits, Gay, Hinchcliff, and Constable.

In the preface to the First Edition, it was stated that the book was directed primarily to students of veterinary medicine, although it was expected that the book would be of value to practicing veterinarians and field workers. The latter expectation has certainly proved true, and the book has come to be extensively used as a reference by veterinarians in large- and mixed-animal practice around the English-speaking world. Editions of the text have also been translated into French, Italian, Spanish, Portuguese, Japanese, Chinese, and Russian.

In addition to his passion for the method and accuracy of diagnosis of disease in individual animals and herds, Doug Blood also had a passion for preventive medicine and was a firm proponent of the thesis that subclinical disease is economically more important than clinical disease in agricultural animal populations. With other

colleagues at the University of Melbourne, he developed health programs for dairy cattle, beef cattle, and sheep and conducted practical trials of these programs in private herds and flocks. These programs were based on a whole-farm approach and centered on the concept that performance targets could be tracked through computer-based productivity monitoring to detect deviation from target performance. Doug Blood was a very early proponent of the use of computers to manage and analyze data in clinical diagnosis and herd health management. These herd health programs have been successfully commercially adopted in several countries.

Doug had a formidable intellect combined with an inexhaustible work ethic. He was a generous family man who had a zest for life and dry wit and who was so proud of his family and their achievements. He loved his morning runs/walks with his beloved Border Collies, music, and literature, and Doug had a passion for baking bread, brewing beer, photographing birds, and wearing bow ties.

Preface to the Eleventh Edition

We are delighted to present the Eleventh Edition of *Veterinary Medicine*, 56 years since the first "Blood and Henderson" *Veterinary Medicine* was published in 1960 and 9 years since the Tenth Edition was published in 2007. *Veterinary Medicine* focuses on diseases of ruminants, horses, and swine, and it is the most extensively cited textbook in veterinary medicine, with a recent total of 4,267 citations (Google Scholar, May 2016). Because the demand for this book remains strong, we assume that we have developed a philosophy, format, and price that are attractive and meet the demands of undergraduate veterinary students and graduate veterinarians working in the field of large-animal medicine.

Substantial changes were made to the format of the book for the Eleventh Edition to keep current with the continuing expansion of knowledge about the diseases of large animals. The book has been extensively revised and reorganized based on the major organ system affected. The **organ systems approach** reflects the profound impact that Dr. D. C. Blood had on the practice of large-animal medicine worldwide (see Foreword); he emphasized that the clinical examination procedure should be a systems-based method. We have extended the systems approach implemented in the First Edition through the assignment of diseases to the primary organ system affected or the most obvious clinical sign referable to an organ system. As a result, the Eleventh Edition contains 21 chapters, compared with 36 chapters in the Tenth Edition. Thirteen chapters deal with specific organ systems, including the alimentary tract of ruminants and nonruminants; the liver and pancreas; and the cardiovascular, hemolymphatic/immune, respiratory, urinary, nervous, musculoskeletal, and reproductive systems; in addition to metabolic/endocrine abnormalities, diseases of the mammary gland, and, finally, diseases of the skin, eye, and ear. Each of these chapters is organized in the following manner: general diseases; infectious diseases, listed in order of cause (bacterial, viral, prion, protozoal, fungal, metazoan) and species affected (all large animals, ruminants, horses, pigs); metabolic diseases; nutritional diseases; toxicologic diseases and environmental agents; neoplastic diseases; congenital and inherited diseases; and, finally, diseases of unknown etiology. The remaining eight chapters deal with specific medicine topics, as follows: clinical examination and making a diagnosis; examination of the population; biosecurity and infection control; general systemic states; disturbances of free water, electrolytes, acid-base balance, and oncotic pressure; practical antimicrobial therapeutics; perinatal diseases, and systemic and multi-organ diseases. A comprehensive index permits the reader to easily access relevant information in different chapters of the book.

We have attempted to ensure that the book continues to have an **international scope** by including clinically important diseases occurring in large animals **worldwide**. The book notes the eradication of Rinderpest in 2011 and includes new or extensively revised sections on a variety of topics, such as biosecurity and infection control; the Schmallenberg and bluetongue viral epidemics of ruminants in Europe; Wesselsbron disease in cattle and hypokalemia in adult cattle; equine multinodular pulmonary fibrosis; Hendra virus infection; multisystemic, eosinophilic, epitheliotropic disease of horses; hypoglycin A intoxication and equine metabolic syndrome; porcine reproductive and respiratory syndrome; porcine epidemic diarrhea and circovirus, and malignant catarrh in pigs; Torque teno, Menangle, and Japanese B viruses in pigs; and numerous recently identified congenital and inherited disorders of large animals.

Reflecting the international scope of the book, the four authors and nine coauthors were educated or have practiced veterinary medicine in 12 countries covering five continents, including Australia, Austria, Canada, Germany, Japan, the Netherlands, Nigeria, Turkey, Switzerland, the United Kingdom, the United States, and Zambia.

We continue to emphasize the **epidemiology** and **pathophysiology** of each disease, which are important in understanding the rationale for the **diagnosis**, **treatment,** and **control**. This means that we strive to maintain an optimum balance between published research and what field veterinarians find useful in their daily work. To make it easier for the reader to find particular pieces of information, long passages of prose have been divided into smaller sections using **headings** and **subheadings.** Key words, terms, and phrases have been emboldened for emphasis and to make it easier for the reader to identify important points. We also continue to include the **zoonotic** and **bioterrorism implications** of many diseases and how the large-animal veterinarian is becoming more involved in the control of diseases transmissible to humans. The use of individual diagnostic tests, described under *Clinical Pathology* for each disease, continues to be a challenge for all of us, especially with the increased availability of genomic or genetic testing and point-of-care testing. We have continued to concentrate on those tests that are accepted through common use, to discuss their limitations if they are known, and to provide a reference to newer tests that have future promise in diagnosis. A common limitation of publications describing new diagnostic tests is the absence of, or inadequate, information on the characteristics (sensitivity, specificity, accuracy) of the test in the population of animals in which it will be used.

Consistent with our deep commitment to practicing **evidenced-based veterinary medicine**, relevant references from 2006 onward have been cited, and important review and scientific papers, including Internet sites, are identified as Further Reading. We refer readers to previous editions of the book for references to earlier works.

When permitted by the quality and number of peer-reviewed publications, we have applied the Grading of Recommendations Assessment, Development and Evaluation (**GRADE)** process (see Foreword) to provide a summary of treatment and control recommendations in a box at the end of the section. This process distills information down to one of four recommendations that reflect "a judgment that most well-informed people would make": R1, "do it"; R2, "probably do it"; R3, "probably don't do it"; and R4, "don't do it." We believe that the GRADE approach will prove helpful to large-animal veterinarians, and we look forward to expanding this approach in future editions of this book.

Constraining the size of the book has been a constant preoccupation and a difficult task with the ever-increasing volume of published information and the constantly growing list of diseases. Our intention has always been to provide information on all recorded diseases. Despite of reductions in reference lists and extensive editing to minimize repetition, the book is still large, necessitating a move to two volumes. More than 150 new figures have been added to the book to assist in presenting information.

We continue to subscribe to the practice and philosophy of earlier editions of this book in having a small number of authors contribute the majority of the text, with contributions from content specialists for particular topics. We believe that analysis and review of the relevant literature by a small number of authors with a broad knowledge and global perspective of large animal medicine assures a consistency of approach to each topic. Our authors are based in the United States, Australia, Europe, the United Kingdom, and Canada and have extensive experience in international veterinary medicine.

Dr. Peter Constable, Dean of the College of Veterinary Medicine, University of Illinois, USA, has assumed the responsibilities of senior author. He revised a number of sections related to specific ruminant diseases, in addition to major sections of the chapters on general systemic states and diseases of the ruminant alimentary tract, cardiovascular system, urinary system, musculoskeletal system, nervous system, and mammary gland. Dr. Constable also revised the chapters

on examination of the population and disturbances of free water, electrolytes, and acid-base balance.

Dr. Kenneth Hinchcliff, CEO of Trinity College, University of Melbourne, and former Dean of the Faculty of Veterinary and Agricultural Sciences, University of Melbourne, Australia, revised all the equine diseases and major sections of the chapters on diseases of the respiratory system, nonruminant alimentary tract, hemolymphatic and immune systems, endocrine abnormalities, and diseases of the neonate. Dr. Hinchcliff also revised the chapter on clinical examination and making a diagnosis and the Foreword of the book. Dr. Hinchcliff acknowledges the support of St. John's College, Cambridge, in appointing him as Overseas Visiting Scholar in 2013 during preparation of parts of this text. Drs. Constable and Hinchcliff are responsible for the revised format of the book.

Dr. Stanley Done, recently retired from the Animal Health and Veterinary Laboratories Agency, Thirsk, United Kingdom, joined our book as a coauthor and revised all the sections on diseases of pigs. This was a major task given the very large literature base on infectious diseases of pigs on a worldwide basis.

Dr. Walter Grünberg, Farm Animal Internal Medicine Specialist, Tieräerztliche Hochschule, University of Veterinary Medicine, Hannover, Germany, is also a new coauthor. He revised a number of sections related to specific ruminant diseases and extensive sections of the chapters on diseases of the liver and pancreas and the skin, eye, conjunctiva, and ear.

The legacies of **Drs. D. C. Blood, C. C. Gay, J. A. Henderson,** and **O. M. Radostits** continue in this edition of *Veterinary Medicine*. **Dr. Doug Colwell**, Principal Research Scientist at Agriculture and Agri-Food Canada, once again revised the sections on diseases caused by arthropod ectoparasites. **Dr. Sara Connelly**, Clinical Assistant Professor of Clinical Pathology, College of Veterinary Medicine, University of Illinois, USA, revised the appendices dealing with conversion tables and reference laboratory values. **Dr. Levent Dirikolu**, Professor of Pharmacology, School of Veterinary Medicine, Louisiana State University, USA joined our book as a contributor by revising the chapter on practical antimicrobial therapeutics. **Dr. Robin Gasser**, Professor of Veterinary Parasitology, Faculty of Veterinary and Agricultural Sciences, University of Melbourne, Australia, is a new contributor who revised the coverage of protozoal diseases. **Dr. Lynn Hovda**, Director of Veterinary Services, PLLC and Pet Poison Helpline, Minnesota, USA also joined our book by revising the sections related to diseases caused by toxins in plants, fungi, cyanophytes, clavibacteria, and venoms in ticks and vertebrate animals. **Dr. Basil O. Ikede**, recently retired from the Atlantic Veterinary College in Prince Edward Island, Canada, once again revised the sections on the major exotic viral and protozoan diseases. **Dr. John Larsen**, Director of the Mackinnon Project, Faculty of Veterinary and Agricultural Sciences, University of Melbourne, Australia, is a new contributing author and revised many chapters related to diseases of sheep and goats. **Dr. William Witola**, Assistant Professor of Parasitology, College of Veterinary Medicine, University of Illinois, USA, is also a new contributor to the book, revising chapters related to nematode, trematode, and tapeworm parasitic infection. **Dr. Amelia Woolums**, Professor of Pathobiology and Population Medicine, College of Veterinary Medicine, Mississippi State University, USA, joined the Eleventh Edition by authoring a new chapter on biosecurity.

We believe that we have completed another authoritative and comprehensive review of the peer-reviewed literature of large-animal medicine, at a standard at least equal to that of the previous 10 editions. We hope that the Eleventh Edition of *Veterinary Medicine* provides the information necessary to meet the needs of veterinary students and large animal clinicians for the next 5 to 8 years.

P. D. Constable
K. W. Hinchcliff
S. H. Done
W. Grünberg

Introduction

The first edition of this book established its role as a textbook of the diseases of traditional farm animals in the Western world, those being cattle, horses, sheep, pigs, and goats. The primary objective of this book was to **offer** the veterinary student and the practitioner the knowledge and information necessary to provide animal health management for farm animals. Although this intent has not changed, the context of veterinary medicine and large-animal practice has changed markedly in the 56 years since publication of the first edition.

VETERINARY MEDICINE IN THE ANTHROPOCENE

Anthropocene is the proposed name for a new, and the current, geological epoch following on from the Holocene and demarcated as the time when human activities began to have a substantial global effect on the Earth's systems.[1,2] Although not universally accepted, the proposal recognizes that human activity has become the primary determinant of Earth's biophysical conditions, influencing global systems and having profound effects on local and regional environments. The Anthropocene is also associated with marked political and economic changes, including regional instability and reductions in political or economic barriers to trade. All of these factors have influenced, and will continue to influence, veterinary practice and the management of the health, well-being, and productivity of animals used for production of fiber and human food.[3]

The concept of the Anthropocene allows veterinarians to consider how the veterinary profession will adapt to our changing environment and associated social, political, environmental, and economic challenges to animal and human health. The challenges include, but are not limited to the following:[4]

- A changing climate with flow-on effects on the geographic distribution of diseases, emergence or reemergence of infectious and noninfectious diseases, and extension of diseases into species not historically affected
- Altered farming patterns, and hence use of animals, as climatic changes force farmers to abandon decades or centuries old land and animal management practices
- Increasing internationalization of trade and freedom of movement of people, animals, and potential fomite, with important implications for the biosecurity of countries, regions, and industries
- Political instability, with subsequent loss of animal health monitoring and disease control
- Economic pressures to produce more and safer food with no increase in water or land use
- Societal expectations for increased animal welfare and the associated mandated changes in farm animal management practices, for example, housing of dairy cattle or mulesing of lambs

As noted by the "Safeguarding Human Health in the Anthropocene Epoch: Report of the Rockefeller Foundation-Lancet Commission on Planetary Health,"[2] the scale of human impact on the planet is immense and includes the following changes:

- About a third of the ice-free and desert-free land surface of the planet has been converted to cropland or pasture.
- Annually, roughly half of all accessible freshwater is appropriated for human use.
- More than 2.3 million km^2 of primary forest has been cleared since 2000.
- More than 60% of the world's rivers are dammed, affecting in excess of 0.5 million km of river.
- Extinction rate of species is more than 100 times that observed in the fossil record, and many remaining species are decreasing in number.
- Concentrations of major greenhouse gases—carbon dioxide, methane, and nitrous oxide—are at their highest levels for at least the past 800,000 years.
- The global temperature continues to rise above long-term historic levels, driving changes in climate and weather patterns.

These changes have a profound impact on human and animal health, as evidenced by altered geographic distributions of diseases, emergence of new diseases, and reemergence of previously controlled or repressed diseases. Anthropogenic changes in the environment influence animal health by affecting the productivity of agricultural and animal production systems and increasing the likelihood of spread of diseases from animals to humans. One-half of the global emerging infectious disease events of zoonotic origin between 1940 and 2005 are estimated to be the result of changes in land use, agricultural practices, and food production practices.[5] There is evidence of an increased risk of zoonotic disease transmission in disturbed and degraded habitats, as exemplified by the emergence of two diseases caused by henipaviruses in animals and humans. Both Nipah and Hendra henipaviruses "spill over" from bats to pigs and horses, respectively, and subsequently infect humans. In both instances, disease is associated with altered habitats, including land clearing that creates a pathway for the repeated transmission of virus from fruit bat reservoirs, emphasizing the role of intact ecosystems and the suitability of climatic conditions in regulating the transmission of diseases.[6-8]

Change in weather systems and climate can profoundly influence the distribution of vectors for important pathogens. Climate is a major factor in determining the geographic and temporal distribution of arthropods, characteristics of arthropod life cycles, dispersal patterns of associated arboviruses, the evolution of arboviruses, and the efficiency with which arboviruses are transmitted from arthropods to vertebrate hosts.[9] For example, emergence of bluetongue virus infection and disease in Europe has been attributed to climate change–induced alterations in distribution of hematophagous midges that transmit the virus, although this concept is disputed, and the importance of other anthropogenic, vector, or virus factors in the spread of the disease is unclear.[10-13]

There is concern that changes in land-use patterns and climate might provide for the spread of Rift Valley fever into new locations, including more frequent or deeper incursions into the Arabian Peninsula.[14] The emergence of Schmallenberg virus, an orthobunyavirus, as a cause of disease in ruminants in Germany and the Netherlands in late 2011, and its subsequent rapid spread across Europe, highlights the potential for emergence of new diseases. The virus is apparently spread by culicoides midges, but its origin remains unknown. Its roughly concurrent occurrence with new strains of bluetongue virus (e.g., BTV-6) in the same region might be more than a coincidence.[15]

International transport of animals and animal products has the proven potential to introduce disease into areas in which it was not present. Introduction of African horse sickness into regions with populations of susceptible horses and competent midge (*Culicoides* spp.) vectors can result in spread of the disease, as occurred in the Iberian Peninsula in 1987.[16-18] Equine influenza virus was inadvertently introduced into Australia in August 2007 by importation of infected horses from Japan, with spread occurring because of apparently inadequate quarantine procedures.[19] Incursion of the virus, which was subsequently eliminated from the continent, had an adverse economic impact.[20]

Similarly, political instability and conflict, which might or might not be associated with climate change but in either case is clearly human-related, results in altered patterns of human movement, loss of control and eradication programs, and absence of surveillance, with

resultant resurgence of previously repressed diseases. Examples include the incursion of rinderpest into Turkey from Iraq in the aftermath of the first Gulf War in the early 1990s, and spread of bovine contagious pleuropneumonia in Angola and the Horn of Africa as a result of civil wars.[21]

It is not just in infectious diseases that we will see changes in the Anthropocene. Increasing global temperatures and altered rainfall conditions will increase the potential for heat- and drought-associated illnesses in farm animals and for disruption to social systems by altered rainfall patterns causing flooding, droughts, and an increase in extreme weather events.[4] For instance, heat stress profoundly influences milk production, weight gain, and fertility of cattle, with these effects extending beyond the period of actual exposure to heat.[4] Heat stress is a concern for dairy, feedlot, and range cattle in temperate and tropical regions of much of the world and has led to the introduction of management systems to accommodate the changes in weather.[3,22,23] Increases in mean global temperature will increase the number of days annually, in some instances by over 100%, on which cattle are exposed to conditions that will cause heat stress.[4]

Veterinary input to animal productions systems will need to reflect these complex and changing climatic, political, social, and economic environments that represent the nature of contemporary livestock production of fiber and food for human consumption.

CONTEMPORARY LIVESTOCK PRODUCTION

Although traditional farms incorporating multiple livestock systems still exist, much more important economically and in terms of the numbers of animals involved are farms that concentrate on one or two livestock systems or species. For example, witness the almost absence in developed countries of farms on which pigs are run in extensive systems on pastures or fields shared with cattle, horses, or sheep. Much more common, and economically important, are the large piggeries that house hundreds to thousands of pigs, often with farms focusing on breeding pigs that are then transferred to other farms or facilities for finishing. Or consider the ascension of feedlots in which sometimes massive numbers of cattle are aggregated from the many individual farms on which they were bred, or the change in dairies from small (50–100 cows) farms to large operations with thousands of cows. The disease issues confronting managers and their veterinary advisors in these facilities are much different from those encountered by a veterinarian responding to a call for a sick cow in a small dairy herd on a family-run farm that also produces sheep, pigs, and poultry. This edition of *Veterinary Medicine* reflects these changing circumstances, which are discussed in more detail in this Introduction.

Another important change confronting veterinarians is the increasing value of some individual animals, particularly horses. The manner in which this book deals with medicine of horses is discussed in detail during the planning of each edition. Increasing value of individual horses and desire by owners to protect the health or performance of these animals have driven the veterinary profession to develop sophisticated, and expensive, diagnostic and therapeutic modalities and interventions directed toward care of individuals. However, this is offset by the recognition that preservation of the health of bands of horses on studs or in stables, or in whole populations in a country, is economically important and based on a thorough understanding of epidemiology and biosecurity—just as for food- and fiber-producing animals. For this latter reason, equine medicine in this book is dealt with as much from a population perspective as it is from the perspective of diagnosis and treatment of an individual horse.

It is stating the obvious that veterinary medicine has advanced in ways that were unimaginable 56 years ago. For example, our understanding of the genetic, and increasingly the genomic, basis of production and susceptibility to disease is something that is now included in discussions of almost every disease, and not just those diseases with a clear monogenetic basis. Associated with this is the incalculable value of use of diagnostic tests based on detection of all or part of the genome of a pathogen. Polymerase chain reaction tests now allow detection of infinitesimally small quantities of DNA or RNA with great rapidity and absolute specificity, often permitting detection of the presence of pathogen genetic material on the same working day as the samples were collected. Additionally, analysis of part (such as single-nucleotide polymorphisms, or SNIPs) or all of the genome of an animal or pathogen provides information critical to understanding the pathogenesis, pathogenicity, or epidemiology of the organism. The utility of this type of information is evident in discussion of many of the diseases—from detection of mutations in the genome of animals that cause them to display particular diseases, for example, bovine leucocyte adhesion deficiency, or, conversely, decrease their susceptibility to infectious diseases, such as occurs with scrapie in some breeds of sheep; to understanding of the pathogenicity of microbes, such as equine herpesvirus 1 neuropathic and less neuropathic strains, or their epidemiology, such as in strain typing of equine influenza H3N8 viruses.

VETERINARY CLINICAL EPIDEMIOLOGY

Important to our understanding of the basis of disease has been the emergence of clinical epidemiology as a means of interrogating the patterns of disease and disease spread and identifying risk factors for development of disease. Understanding patterns of disease spread is fundamental to developing and implementing sensible and effective biosecurity and control measures. Similarly, knowing the risk factors for development of disease and quantifying the relative importance of each ("relative risk" or "odds ratio," depending on the context) are key to determining which of these factors can be modified to reduce risk of the disease and whether it is economical to do so.

The importance of use of applied and analytical epidemiology in large-animal practice and veterinary medicine is clear. The tools of epidemiology are now readily available to allow the veterinarian to identify and quantify the risk factors associated with the disease, to provide a more accurate prognosis, to accurately assess treatment responses and not depend on clinical impressions, to scientifically evaluate control procedures, and to conduct response trials. There is a large and challenging opportunity for veterinarians to become involved in clinical research in the field where the problems are occurring. It will require that they become knowledgeable about the use of computerized databases. These now provide an unlimited opportunity to capture and analyze data and generate useful information, which heretofore was not considered possible. The technique of decision analysis is also a powerful tool for the veterinarian who is faced with making major decisions about treatment and control procedures.

VETERINARY SCIENTIFIC LITERATURE AND HOW TO USE IT

Perhaps the single greatest advance in veterinary medicine has been the collective increase in knowledge. The large increase in knowledge of animal diseases and animal health, including information about efficacy of diagnostic and therapeutic techniques and interventions, coupled with the ease of access of this information through online databases and web-based search engines, presents challenges in assessing the quality of information and in collating the information into a useable form.

Development of formal methods for assessing information and providing a recommendation have led to the term *evidence-based veterinary medicine*.[24-26] Evidence-based veterinary medicine is defined as the use of best relevant evidence in conjunction with clinical expertise to make the best possible decision about a veterinary patient, taking into account the circumstances of each patient and the circumstances and values of the owner/carer.[27] The questions related to use of an evidence-based approach can be summarized as follows:

- Why do we need evidence of effectiveness of our clinical actions (assessment of clinical signs, diagnostic tests, interventions, prognostication)?

- What are the levels of evidence, and how good are they?
- How does one translate evidence into a recommendation or decision?
- What factors contribute to the weighting of evidence?
- Does weak evidence allow us to make a strong recommendation?
- Does strong evidence not always allow us to make a strong recommendation?
- How do I use this in practice?

There are five steps to evidence-based veterinary medicine:[27]

1. Ask the pertinent question and thereby define what it is that needs to be known to allow for the most appropriate action.
2. Acquire the evidence, usually by a review of the available literature or, less commonly, performing a new research study.
3. Appraise the quality of evidence and its external validity (evidentiary value for the question being asked).
4. Apply the evidence to practice, where appropriate. See comments that follow about the GRADE process.
5. Audit—Assess whether the application of the new evidence has affected the outcome of interest.

Quality of Evidence

The confidence we have in our evidence-based approach to veterinary practice depends on our assessment of the quality of the evidence available to us.[28] Not all evidence is of equal merit or utility, and although there are slight differences in the ratings of quality of evidence from different sources, an approximate hierarchy of evidence from lowest to highest in terms of value of evidence for practical use is as follows:

- Expert opinion/editorials/nonstructured consensus statements or opinion pieces
- Case reports and case series
- In vitro studies with an appropriate control group
- Animal models of the disease of interest (induced disease in species other than the species in which the disease occurs naturally, e.g., mouse model of a disease in horses)
- Case-control or cross-sectional studies
- Nonrandomized trials, cohort studies, or models of induced disease in the species of interest (target species, e.g., induction of viral diarrhea in calves)
- Randomized controlled trials under field conditions
- Systematic review of randomized controlled trials
- Systematic review, including meta-analysis

The higher the quality of evidence, the greater is our confidence in making decisions based on this evidence. The highest-quality evidence is provided by systematic reviews, which might include a meta-analysis. Systematic reviews differ from narrative reviews, which have much lower evidentiary value, in that systematic reviews are approached in a manner and with methodology designed to ensure the validity of the conclusions.[29] Systematic reviews should be based on a clearly defined question and prespecified criteria for inclusion and evaluation of the literature, among other factors. Criteria and methodology for performing systematic reviews are available.[30-32]

Assessment of the quality of evidence provided by scientific articles is dependent on the authors of the article reporting exactly what they did and how they did it. It is clear from studies in human medicine and small animals that poorer reporting of methodology in articles is associated with a greater proportion of positive outcomes, leading one to suspect that reports that are less well documented are more likely to provide unreliable evidence of efficacy.[33] There are increasing numbers of guidelines that provide advice for authors on how to adequately report on trials, and these guidelines are also useful as checklists for readers of articles. Available guidelines are CONSORT, REFLECT, STARD, STROBE, and others, which are available through the EQUATOR website (http://www.equator-network.org/reporting-guidelines/).[34]

From Evidence to Recommendation

The approach of using evidence to guide clinical decision making has been formalized in the last two decades in human medicine and is gaining traction in veterinary practice. As veterinary clinicians, we have ethical and legal obligations to use methods and practices that are most likely to provide the "best" outcomes for the animals we treat and their owners. A traditional approach to deciding on the "best" treatments, diagnostic tests or methods, and preventative measures has been to identify the highest-quality evidence of effectiveness and to adopt the approach with the strongest evidence of efficacy. The Cochrane Collaboration and the Cochrane Reviews exemplify and lead this approach in human medicine (http://www.cochrane.org/cochrane-reviews).

This "evidence-based" approach has the implicit assumption that one should rely on the highest-quality evidence and that high-quality evidence of efficacy necessarily leads to the adoption of that treatment, diagnostic test, or prophylaxis. However, this approach falls short when formulating recommendations for use in clinical practice. What practitioners need is recommendations that are based on the available evidence but that also take into account the other factors that must be considered when advising an owner or trainer on the "best" approach to dealing with their animal's (and their) problem. This methodology has been developed in human medicine as the GRADE (Grading of Recommendations Assessment, Development, and Evaluation) process.[35] GRADE fundamentally works by providing a framework to determine a final recommendation on an intervention through use of the following:

1. The quality of evidence (Cochrane and similar evaluations of quality of evidence stop here),
2. Seriousness of the outcome,
3. Magnitude of the treatment effect,
4. Precision of the treatment effect,
5. Risk of the target event (how frequent),
6. Risk of adverse events associated with the intervention,
7. Cost of the intervention, and
8. The values and preferences of the end users (patients).

All of these criteria have at least some applicability in veterinary medicine. Briefly, judgments about the quality of recommendations require consideration of the following factors:

- **The quality of evidence on which the recommendation is based**. The quality of evidence is assessed on the type of study (with systematic reviews being designated *a priori* as the highest level of evidence and observational studies providing a lower quality of evidence), imprecision of the results over a number of studies, inconsistency of the studies, indirectness, reporting bias, magnitude of the effect, biological plausibility, and strength of association.[36-40]
- **The balance between benefits and harms**. Will the intervention do more good than harm? What is the extent of the benefit and of the potential harm?
- **Feasibility of translating the evidence into the circumstance in which the intervention will be made**. Can I apply this in my practice? Is it affordable?
- **Certainty of the baseline risk**. How important is the problem?
- **Cost.** Both monetary costs and expenditures in terms of resources must be considered.

The balance between benefit and harm (the trade-off) can be categorized as follows:

- Net benefits = the intervention clearly does more good than harm.
- Trade-off = there are important trade-offs between the benefits and harms.
- Uncertain trade-offs = it is unclear whether the intervention does more good than harm.
- No net benefits = the intervention clearly does more harm than benefit.

The quality of evidence informing the recommendation can be categorized as follows:

- **High:** We are very confident that the true effect lies close to that of the estimate of the effect. In other words, we can be very confident that both the direction of the effect and its magnitude are known with reasonable certainty and that the magnitude of the effect is clinically relevant.
- **Moderate:** We are moderately confident in the effect estimate. The true effect is likely to be close to the estimate of the effect, but there is a possibility that it is substantially different. In other words, the direction of the effect is likely known, although the magnitude might change with further research. The magnitude of the effect is likely clinically significant.
- **Low:** Our confidence in the effect estimate is limited. The true effect could be substantially different from the estimate of the effect. In other words, both the direction of the effect and its magnitude are very likely to change with further research.
- **Very low:** Any estimate of the effect is very uncertain, and the direction and magnitude of the real effect of the intervention are unknown.

Finally, all of the considerations just described can be distilled down to the following recommendations being "a judgement that most well-informed people would make":[41]

- "Do it"—there is high-quality evidence of net benefits within appropriate resource constraints (costs) for a problem that has significant importance (a judgment that most well-informed people would make).
- "Probably do it" = when the strength of evidence is moderate or when the benefit : harm trade-off is unclear or marginal.
- "Probably don't do it" = when the strength of evidence is low or very low, when the benefit : harm trade-off is unclear or marginal, or when the baseline risk is low.
- "Don't do it" = there is high-quality evidence of harm clearly exceeding benefits, the cost is too great compared with benefits, or the baseline risk is very low (i.e., the problem is not important).

The GRADE guidelines, although not well established for veterinary medicine, have been used and provide the opportunity to make evidence-based recommendations to practitioners.[42]

FOOD- AND FIBER-PRODUCING ANIMALS

Veterinary practice with food-producing animals provides service primarily to the owners of the meat-, milk-, and fiber-producing animals such as dairy and beef cattle, pigs, sheep, and goats. Veterinarians also provide service to owners of captive ungulates, such as red deer, elk, and bison, which are being raised under farm conditions for the production of meat and byproducts such as hides. Although some commercially processed horsemeat is consumed by humans, the market is small compared with that for beef and pork, and horses are not usually included in discussions about food-producing animal veterinary practice. Poultry, fish, and rabbits are also important sources of human food but are not the subject of this book.

For the past several decades, the major activity in food-producing-animal practice, and a major source of income for veterinarians, was the provision of **emergency veterinary service** to the owners of herds or flocks in which a single animal was affected with one of the common diseases. Occasionally, outbreaks of disease affecting several animals occurred. In addition, routine elective veterinary services, such as castration, vaccination, dehorning, and deworming; the testing for diseases, such as brucellosis and tuberculosis; and the dispensing of veterinary drugs, pharmaceuticals, and biologicals accounted for a significant source of revenue for the veterinarian. Since about the early 1970s, there has been a shift from emphasis and dependence on emergency veterinary medicine and routine procedures to more attention being paid by the veterinarian and the producer to **planned animal health and production management** using the whole-farm approach. Livestock producers are now much more knowledgeable about animal agriculture and are concerned about the cost-effectiveness and the scientific basis of the recommendations made by veterinarians and agricultural advisors. More and more producers are doing the routine elective procedures themselves. From firsthand experience and extension courses provided for them, they have also learned how to diagnose and treat many of the common diseases of farm livestock. Many veterinary pharmaceuticals antimicrobials and biologicals can now be purchased by producers from either veterinary or nonveterinary sources.

INDUSTRIALIZED ANIMAL AGRICULTURE

The intensification of animal agriculture has created complex animal health and production problems for which there are no simple and reliable therapeutic and preventive procedures, and this has made the task of the veterinarian much more challenging. For example, acute undifferentiated respiratory disease is a common disease of feedlot cattle that is difficult to treat and control effectively because the etiology and epidemiology are complex. Acute diarrhea of calves under 30 days of age may be caused by several different enteropathogens, but a knowledge of the risk factors or epidemiologic determinants, such as colostral immunity and population density, is probably more important for effective clinical management and control of the disease. The rearing of pigs intensively and in complete confinement has exaggerated a number of disease problems, many exacerbated by inadequacies of the environment.

Suboptimal reproductive performance resulting from a variety of management and environmental factors is common, and pneumonia in growing and finishing pigs may be almost impossible to eradicate unless the herd is depopulated and repopulated with minimal-disease breeding stock. Infectious diseases such as porcine reproductive and respiratory syndrome are difficult to control. The solutions to these complex problems are not always readily apparent, in part because of insufficient research on etiology and epidemiology and different control strategies in the herds where the problems are occurring. The veterinarian must be knowledgeable and skillful in the principles of epidemiology, applied nutrition, and animal housing; the education and training of animal attendants; and the analysis of production indices, including profit and loss, which includes the use of computers, in addition to being skilled in the traditional veterinary disciplines of medicine, reproduction, pharmacology, and pathology. Thus, the food-producing-animal practitioner must become more skilled in the simultaneous management of animal health and production; the modern livestock producer is cost-conscious, and anything veterinarians do or recommend must be cost-effective.

COMPANION-ANIMAL PRACTICE

In contrast, developments in companion-animal medicine (small animals) have followed in the footsteps of human medicine, with an ever-increasing emphasis and reliance on extensive use of clinical pathology for the in-depth evaluation of the hematology, clinical chemistry, enzymology, immune status, and many other body functions of the individual animal.

Diagnostic techniques such as ultrasonography, endoscopy, nuclear imaging, and computed tomography are being used both in veterinary teaching hospitals and in referral veterinary practices. These in-depth "diagnostic workups" presumably lead to a greater understanding of the etiology and pathophysiology of disease, with the ultimate aim of a more accurate and early diagnosis that allows much more effective medical and surgical therapy than is economically possible or necessary in food-producing animals. There is not the same emphasis on the efficiency of production, epidemiology, and cost-effectiveness that constantly faces the food-producing-animal practitioner. More and more companion-animal owners, because of the sentimental value of their animals and the growing importance of the human–companion animal bond, are willing to pay for the costs associated with extensive laboratory and sophisticated diagnostic tests and intensive and prolonged veterinary hospital care. Palliative care for dogs and cats affected with diseases that may not be curable over the long term is now a recognized fact in small-animal practice.

EQUINE PRACTICE

Equine practice has evolved along similar lines to small-animal practice. Some aspects of it, such as reproduction, intensive clinical care of the newborn foal, and the treatment of medical and surgical diseases of valuable athletic and competitive horses, have advanced a great deal. The great strides that have been made in our understanding of the diagnosis, prognosis, and medical and surgical therapy of colic in the horse are a result of the in-depth diagnostic laboratory work and the medical and surgical expertise that have been used. Our improved understanding of the prognosis of equine colic is in part attributable to prospective studies of the clinical and laboratory findings in horses with colic. However, the large advances in improvement in survival made in the early years of surgical and intensive medical treatment of colic have not continued, and there is an urgent need for appropriately designed prospective clinical trials to determine optimal treatment regimes in these horses. The same is true for intensive treatment of sick foals. In addition to the advanced diagnostic and therapeutic procedures being done on valuable horses at veterinary teaching hospitals, there are now many privately owned equine veterinary centers that provide the same service. Undoubtedly the high financial value of some horses has provided the impetus for the development of these services.

Although the increasingly sophisticated diagnostic and therapeutic techniques used in equine practice are readily noted, advances in the understanding of infectious and contagious diseases of horses have also increased markedly. This is particularly true for economically important diseases that have the potential to affect large numbers of horses, consequently causing disruption to important athletic events and the sale and shipment of horses. These diseases are typically the infectious respiratory diseases and those diseases, such as African horse sickness, that are exotic to most of the horse population worldwide. The economic incentive to control these diseases has resulted in considerable increases in knowledge of their etiology (and consequently vaccinology), epidemiology, immunology, diagnosis, and prevention. Few advances have been made in treatment of what are, for the most part, self-limiting diseases with low case-fatality rates.

CONTRASTING OBJECTIVES

It is clear that there are major differences between the objectives and principles of companion-animal practice and those of food-producing-animal practice. In companion-animal practice, the objective is the restoration of the clinically ill animal to a normal state, if possible, or in some cases a less-than-normal state is acceptable provided it is a quality life, using all the readily available diagnostic and therapeutic techniques that can be afforded by the client. In sharp contrast, in food-producing-animal practice, the objective is to improve the efficiency of animal production using the most economical methods of diagnosis, treatment, and control, including the disposal by culling or slaughter of animals that are difficult to treat and are economic losses.

This growing dichotomy in the delivery of veterinary services to the food-producing-animal owner and to the companion-animal owner prompted us to present a short introductory commentary on the objectives and principles of food-producing-animal practice.

The Objectives of Food-Producing-Animal Practice

EFFICIENCY OF LIVESTOCK PRODUCTION

The most important objective in food-producing-animal practice is the continuous improvement of the efficiency of livestock production by the management of animal health. This involves several different but related activities and responsibilities, which include the following:

- **Providing the most economical method of diagnosis and treatment** of sick and injured animals and returning them to an economically productive status, or to a point where slaughter for salvage is possible, in the shortest possible time. The financially conscious producer wants to know the probability of success following treatment of a disease in an animal and to minimize the costs of prolonged convalescence and repetitive surgery.
- **Monitoring animal health and production** of the herd on a regular basis so that actual performance can be compared with targets and the reasons for the shortfalls in production or increases in the incidence of disease can be identified as soon as possible, so that appropriate and cost-effective action can be taken. The routine monitoring of production records and the regular monitoring of bulk-tank milk somatic cell counts in dairy herds are examples.
- **Recommending specific disease control and prevention programs,** such as herd biosecurity, vaccination of cattle against several important infectious diseases that occur under a variety of conditions, and the strategic use of anthelmintics in cattle and sheep.
- **Organizing planned herd and flock health programs** for the individual farms with the objective of maintaining optimum productivity through animal health management.
- **Advising on nutrition, breeding, and general management practices**. Food-producing-animal practitioners must be interested in these matters when they affect animal health. It is a large part of production-oriented health management, and it is now common for veterinarians to expand their health-oriented animal husbandry advisory service to include an animal-production advisory service. To do so is a matter of individual preference, an option that some veterinarians take up and others do not. Some veterinarians will rely on consultation with agricultural scientists. However, veterinarians still require a working knowledge of the relevant subjects, at least enough to know when to call in the collaborating advisor for advice. Members of both groups should be aware of the extensive list of subjects and species-oriented textbooks on these subjects, which should be used to support this kind of service.

ANIMAL WELFARE

Encouraging livestock producers to maintain standards of animal welfare that comply with the views of the community is emerging as a major responsibility of the veterinarian. The production of food-producing animals is an animal welfare concern that practitioners face and an area in which they must become proactive.[43,44] Increasing public concern for the welfare of animals, including those that produce food and fiber for human consumption, must be addressed using high-quality scientific evidence and a sound understanding of the arguments of individuals and groups opposed to such use of animals.

ZOONOSES AND FOOD SAFETY

Promoting management practices that ensure that meat and milk are free of biological and chemical agents capable of causing disease in humans must also become a preoccupation for food-producing-animal veterinarians. This is because the general public is concerned about the safety of the meat and milk products it consumes, and the most effective way to minimize hazards presented by certain infectious agents and chemical residues in meat and milk is to control these agents at their point of entry into the food chain, namely, during the production phase on the farm. Veterinarians will undoubtedly become involved in the surveillance of the use of antimicrobial compounds and other chemicals that are added to feed supplies to promote growth or prevent infections, and they will be expected to minimize the risk

of the occurrence of zoonotic disease agents in farm-animal populations.

Principles of Food-Producing Animal Practice

REGULAR FARM VISITS

A unique feature of a food-producing animal veterinary practice is that most of the service is provided by the veterinarian who makes emergency or planned visits to the farm. In some areas of the world, where veterinarians had to travel long distances to farms, large-animal clinics were established, and producers brought animals that needed veterinary attention to the clinic. For the past 25 years these clinics have provided excellent facilities in which, for example, surgical procedures such as cesarean sections could be done and intensive fluid therapy for dehydrated diarrheic calves could be administered much more effectively and at a higher standard than on the farm. However, much less veterinary service is being provided in these clinics now because of the high operating costs of providing hospital care and the limited economic returns that are possible for the treatment of food-producing animals, which have a fixed economic value. Producers have also become less enthusiastic about transporting animals to and from a veterinary clinic because of the time and expertise involved, and because of increasing concern about biosecurity and the potential impact of pathogen introduction on the health and productivity of their animals.

CLINICAL EXAMINATION AND DIAGNOSIS

The diagnosis, treatment, and control of diseases of food-producing animals are heavily dependent on the results of the clinical examination of animals on the farm and the careful examination of the environment and management techniques. This means that the veterinarian must become highly skilled in obtaining an accurate and useful history on the first visit to an animal or group of animals and in conducting an adequate clinical examination to make the best diagnosis possible, and economically, so that the treatment and control measures can be instituted as soon as possible. On the farm, during the day or in the middle of the night, the veterinarian will not have ready access to a diagnostic laboratory for the rapid determination of a cow's serum calcium level if milk fever is suspected. The practitioner must become an **astute diagnostician** and a skillful user of the physical diagnostic skills of visual observation, auscultation, palpation, percussion, succussion, ballottement, and olfactory perception. On the farm, the clinical findings, including the events of the recent disease history of an animal, are often much more powerful, diagnostically, than laboratory data. It therefore becomes increasingly important that the clinical examination should be carefully and thoughtfully carried out so that all clinically significant abnormalities have been detected.

An outline of the clinical examinations of an animal and the different methods for making a diagnosis are presented in Chapter 1. Becoming efficient in clinical examination requires the diligent application of a systematic approach to the task and, most importantly, evaluation of the outcome. A most rewarding method of becoming a skillful diagnostician is to retrospectively correlate the clinical findings with the pathology of those cases that die and are submitted for necropsy. The correlation of the clinical findings with the clinical pathology date, if available, is also an excellent method of evaluation but is not routinely available in most private practices. The food-producing-animal practitioner must also be a **competent field pathologist** and be able to do a useful necropsy in the field, usually under less-than-desirable conditions, and to make a tentative etiologic diagnosis so that additional cases in the herd can be properly handled or prevented. Doing necropsies on the farm or having them done by a local diagnostic laboratory can be a major activity in a specialty pig or beef feedlot practice, where clinical examination of individual animals is done only occasionally, compared with dairy practice.

EXAMINATION OF THE HERD

The clinical examination of the herd in which many animals may be affected with one or a number of clinical or subclinical diseases, or in which the owner's complaint is that performance is suboptimal but the animals appear normal, has become a major and challenging task. This is particularly true in large dairy herds, large pig herds, beef feedlots, lamb feedlots, and sheep flocks where the emphasis is on health management of the herd. Intensified animal agriculture may result in an increased frequency of herd **epidemics** or **outbreaks** of diseases such as bovine respiratory disease syndrome, bloat, and acute diarrhea in beef calves and peracute coliform mastitis in dairy cattle. Such well-known diseases are usually recognizable, and a definitive etiologic diagnosis can usually be made, and in some cases the disease can be controlled by vaccination. However, in some cases of herd epidemics of respiratory disease, salmonellosis, or Johne's disease, for example, the veterinarian may have to make repeated visits to the herd to develop effective treatment and control procedures. The steps involved in the examination of the herd affected by a clinical disease or suboptimal performance are presented in Chapter 1.

COLLECTION AND ANALYSIS OF ANIMAL HEALTH DATA

With the shift in emphasis to the problems of the herd, the collection, analysis, and interpretation of animal health and production data will be a major veterinary activity. Livestock producers must keep and use good records if the veterinarian is to make informed decisions about animal health and production. The once tedious and unpopular work of recording and analyzing animal health and production data is now done by the computer. Veterinarians will have to move in the direction of developing a computer-based animal health and production profile of each herd for which they are providing a service. Veterinary colleges will also have to provide leadership and provide undergraduate and graduate student education in the collection, analysis, and interpretation of animal health data. This activity will include methods of informing the producer of the results and the action necessary to correct the herd problem and to improve production.

PUBLIC HEALTH AND FOOD SAFETY

Veterinarians have a major responsibility to ensure that the meat and milk produced by the animals under their care are free from pathogens, chemicals, antimicrobials, and other drugs that may be harmful to humans. The prudent use of antimicrobials, including adherence to withdrawal times for meat and milk, are becoming major concerns of the veterinary associations, such as the American Association of Bovine Practitioners, the American Association of Small Ruminant Practitioners, and the American Associate of Swine Practitioners. Traditionally, veterinary public health was not a career option considered by new or recent graduates. However, because of the recent concern about the contamination of meat supplies by pathogens and **xenobiotics** (any substance foreign to an animal's biological system), and the potentially serious economic effects of such contamination on the export markets of a country, it is now clear that veterinarians, using a variety of testing techniques, will become increasingly involved in monitoring the use of veterinary drugs so that treated animals are not placed in the food chain until the drugs have been excreted. The same principles apply to the contamination of milk supplies with antimicrobials, prevention of which is a major responsibility of the veterinarian.

ECONOMICS OF VETERINARY PRACTICE

The successful delivery of food-producing-animal practice will depend on the ability of the veterinarian to provide those services that

the producer needs and wants at a price that is profitable to both the producer and veterinarian. Several constraints interfere with this successful delivery. Maximizing net profit is not a high priority for many farmers. Being independent and making a living on the farm are commonly ranked higher. Consequently, when veterinarians make recommendations to control a disease, their subsequent enthusiasm for giving advice may be dampened if farmers do not adopt the control procedures even though the advice is based on good information about expected economic returns.

The frustrations that many veterinarians experience in attempting to get dairy producers to adopt the principles of an effective and economical mastitis control program are well known. In some cases, producers do not use modern methods of production and disease control because they are unaware of their importance. The variable financial returns that farmers receive for their commodities, particularly the low prices received during times of oversupply of meat and milk, may also influence whether they purchase professional veterinary service or attempt to do the work themselves.

VETERINARY EDUCATION

We have described our views on the state of food-producing-animal medicine and what it requires of veterinarians who practice it. Traditionally, veterinary colleges have provided undergraduate students with the knowledge and clinical skills necessary to enter veterinary practice and begin to engage in food-producing-animal practice. Field-service units and large-animal in-clinics devoted to clinical teaching have been an integral part of most veterinary colleges. The clinical caseload is for the students, clinicians, and those in the paraclinical sciences such as microbiology, toxicology, clinical pathology, and pathology. However, recently, it seems that veterinary colleges have not maintained their farm-animal teaching clinics, and in fact, some of these teaching clinics have ceased to exist. The demise of in-house food-producing-animal practice in veterinary teaching hospitals, as opposed to the care of agricultural animals from hobby farms, is contributed to by the increasing use of stringent biosecurity measures on medium- and large-scale operations. Animals brought to veterinary teaching hospitals for diagnosis and possible treatment cannot be returned to the farm because of the fear of introducing infectious disease. Regardless, the demise of in-house food-producing-animal practice in some universities should be of major concern to the veterinary profession because universities have an obligation to serve the veterinary needs of animal agriculture. Some veterinary colleges have developed extensive programs in which undergraduate students spend time in private veterinary practice to gain clinical experience. However, the failure to maintain and support viable farm-animal teaching clinics will diminish the clinical experience of clinicians and those in the paraclinical sciences who have a primary responsibility for teaching. In addition, the lack of clinical cases will adversely affect the clinical research activities of clinicians. Clinicians must experience a critical number of clinical cases to maintain credibility as a veterinary scholar.

> *To study the phenomena of disease without books is to sail an unchartered sea, while to study books without patients is not to go to sea at all.*
> ***Sir William Osler (Books and Men,* Boston Surgical Journal*, 1901*)**

The practicing veterinarian must become knowledgeable about various aspects of **farm animal management**, especially those that cause or contribute to clinical or subclinical disease and impaired animal production. Such veterinarians will become **species-industry specialists** who can provide totally integrated animal health and production management advice to those managing a dairy herd, a beef cow-calf herd, a beef feedlot, a pig herd, or a sheep flock. To be able to do this, veterinarians will need to undertake a postgraduate clinical residency program or develop the expertise on their own by diligent self-education in a veterinary practice that is committed to the concept of a total animal health management and allows the veterinarian the time and the resources to develop the specialty.

OPTIMAL UTILIZATION OF THE FOOD-PRODUCING-ANIMAL PRACTITIONER

All that we have said in this Introduction is related to enhancing and improving the performance of the professional food-producing-animal veterinarian. In developed countries, this could mean greater utilization of each veterinarian by farmers and improved financial viability of their farming enterprises. In developing countries, it could mean a greater volume of production at a time when malnutrition appears to be the fate of so many groups of the world community. These could be the outcomes if the world's agricultural situation was a stable one. As it is, there is currently a great upheaval in agriculture; developed countries are heavily overproduced, and there is a sharp decline in farming as an industry and way of life. In developing countries, the decisions governing the health and welfare of animals and the people that depend on them often seem to depend more on political expediency than on the basic needs of humans and their animals. In these circumstances we do not feel sufficiently courageous and farsighted to predict our individual futures, but with the hindsight of how far the human population and the attendant agricultural and veterinary professions have come in the past 56 years, we are confident that you will have an opportunity to properly pursue the objectives and principles that we have described.

Clinical Examination and Making a Diagnosis

1

Introduction

Illness is the situation of being unhealthy or having poor health and is caused by disease. One must recognize illness and then determine the disease causing poor health. The focal point of any investigation of animal disease is the making of a diagnosis, and the critical part in making that decision is the clinical examination of the individual animal or group of animals. Similar to human medicine,[1] the diagnostic act is actually a process to categorize the animal's illness. It is an attempt to recognize the group or class of the animal's illness so that one can, based on prior individual or collective experience, determine the likely disease and what further acts or interventions are required to resolve or mitigate the effects of the illness. Collective experience refers to information about diseases assembled in scholarly articles, accumulated in texts, and generally available to the relevant professional. The diagnostic act not only provides information about the identity of the illness, but also its severity and, with repeated examinations, progression of the disease. This information can then be used to determine a prognosis and for monitoring efficacy of interventions, if any.

Disease can be defined as the "inability to perform physiologic functions at normal levels even though nutrition and other environmental requirements are provided at adequate levels."[2] Traditionally, a disease was defined by a specific combination of clinical signs and pathologic and clinicopathologic abnormalities; for example, pneumonia was defined by a combination of fever, cough, increased respiratory rate, abnormal lung sounds, presence of inflammatory exudate in tracheal mucus, radiographic evidence of abnormalities in the lungs, an inflammatory leukogram, and distinctive lesions in lungs at postmortem examination. The definition has been widened to include those animals or herds that are not clinically ill but do not perform as expected, for example, suboptimal growth rates in piglets, failure to perform to expectation for an athletic horse, or lower than anticipated reproductive rates. Veterinarians working with food-producing animals and horses are required to recognize individual animals that are affected with a particular, recognizable pathologic lesion, or biochemical or metabolic deficit, or nutritional deficiency, which results in recognizable clinical signs such as fever, dyspnea, convulsions, or lameness. This is traditional veterinary medicine based on a transposition of attitudes and behavior from human medicine. However, it is also necessary to investigate disease that the owner recognizes simply as failure to perform or to reach predetermined objectives. This is not necessarily subclinical disease: it is recognizable clinically but perhaps only as poor performance, such as unthriftiness, without any specific system-oriented clinical signs. In other situations, the owner might not recognize any abnormality unless productivity is measured, e.g., milk production or growth rate per day.

There has been considerable emphasis on the clinical and laboratory examination of individual animals affected with clinical disease or that have not performed normally, and the large body of information now available in laboratory medicine testifies to this preoccupation. Its greatest importance is in animals, such as companion and racing animals, which are kept as singles and, unless the diagnosis is simple and readily obvious, if a laboratory is available there can be a tendency to make one or more laboratory examinations. The more valuable the animal, the greater is the tendency toward some laboratory work. Many biochemical, hematologic, and biophysical examinations of each body system can yield valuable clues about system or organ function, which usually lead to more accurate and detailed examination of that system or organ. In animals kept in herds or flocks, these laboratory tests are also important but are equaled in importance overall by epidemiologic investigations.

Epidemiologic information deals with the distribution and determinants of health and disease in groups,[1] and by extrapolation it provides diagnostically, therapeutically, and prognostically useful information for individual animals. Clinical epidemiology uses data regarding causes of disease, efficacy (sensitivity, specificity, etc.) of diagnostic acts and therapeutic interventions, and prognosis in the management of disease in individuals, herds, or flocks.

With a herd of animals affected with clinical disease or failing to achieve expected objectives, an epidemiologic investigation, in addition to the clinical examination of individual animals, can make a valuable contribution to the diagnostic process. Epidemiologic investigations in these situations imply or involve the collection of data related to risk factors for disease, quantitative evidence of production shortfalls, clinicopathologic data from a large number of animals, and quantitative assessment of the outcomes of the disease. This is not to suggest that clinical and laboratory examinations are deemphasized in the examination of herd problems. In some instances, the clinical and laboratory examinations assume major importance to ensure that animals in a herd that is not performing normally are not clinically ill. When the presenting complaint is poor performance, it is necessary to collect all the pertinent epidemiologic data, including accurate production measurements, and to decide whether or not an abnormality is present and, if so, its magnitude. It is at this point that veterinarians become the arbiters of what is *health* and what is *illness*. In herd health programs this is a continuing and positive service provided by veterinarians to farmer clients.

In this chapter the standard procedure for the clinical examination of an individual animal followed by some guidelines for the examination of the herd are described. The level of the examination is sufficient to enable the clinician to determine the nature of the abnormality and the system involved. For more detailed examination it is recommended that subsequent chapters, which deal with individual systems, be consulted. Each of them describes a method for a special examination of the particular system.

Making a Diagnosis

The practice of clinical veterinary medicine consists of two major facets: the making of a diagnosis and the provision of treatment and control measures. For treatment and control to be of optimum value the diagnosis must be as accurate as possible; thus, the diagnosis is the crux of all medical problems.

A diagnosis is the identification of the disease affecting the animal, and to be complete should include three parts:

1. Identification of the clinical manifestation of that abnormality produced by the causative agent–classification of the animal's illness
2. Abnormality of structure or function (the disease) produced by the causative agent
3. The above two then usually allow identification of the specific cause of the illness

The illness should be classified as precisely as possible and should, ideally, include the animal species (and if possible more detail), the causative agent, and the predominant body system affected, for example, equine *Rhodococcus equi* pneumonia and lung abscess or bovine neonatal colibacillosis. Many diagnoses fall short of this objective because of a lack of confirmatory laboratory assistance and are assigned a classification (diagnosis) based on clinical signs, such as bovine chronic diarrhea or necropsy lesions (such as bovine polioencephalomalacia).

DIAGNOSTIC METHODS

At least five distinctly recognizable methods are used and are presented here in order of increasing complexity.[1] Generally, the experienced clinician uses more of the simpler strategies, and the novice clinician uses more of the complex ones. This occurs because the simple method omits several steps in the clinical reasoning process or the appropriate and safe *cutting of corners* that it is possible to perform with confidence only after gaining wide experience and after paying a good deal of attention to assessing one's own personal competence as a clinician, especially as a diagnostician.

METHOD 1: THE SYNDROME OR PATTERN RECOGNITION

Sometimes referred to as the *Aunt Minnie* or gestalt diagnostic technique, this method involves the rapid, almost instantaneous, arrival at a diagnosis.[1] It is gestalt because it involves the recognition of a pattern among apparently chaotic or confused information and Aunt Minnie because one instantly recognizes a close acquaintance without the need to thoughtfully identify and assimilate their distinctive attributes. The diagnosis is made instantaneously and intuitively in the first few moments of viewing the animal, e.g., the behavior of a horse with abdominal pain or the skin lesions of ecthyma in a sheep or papillomatosis in a cow. The same experience can occur while taking the history—in fact most diagnoses in human medicine are made during collection of the history—in which the description of the clinical situation and signs are pathognomonic or highly suggestive of a disease. This recognition is based on the comparison of the subject case and previous cases in the clinician's memory or training, and one is recognized as a replica of the other. There is no need to seek further supporting advice, and the definitive diagnosis is made then and there. In the hands of experienced or well-trained clinicians this method is quick and accurate.

METHOD 2: HYPOTHETICO-DEDUCTIVE REASONING

As soon as the client begins to relate the presenting signs, usually commencing with the key clinical sign, the clinician begins to draw up a short list (usually three or four) of diagnostic possibilities. This is the process of generating multiple plausible **hypotheses** from initial cues. The clinician then begins to ask questions and conduct clinical examinations that test the hypotheses. The questions and examinations should be directed at supporting or discounting the tentative diagnoses (the confirm/exclude technique) but can lead to the addition of more hypotheses and the deletion of some others. (The questions used here are search ones, aimed at supporting a hypothesis, and are distinctly different from scanning questions, which are *fishing* expeditions looking for more key signs about which search questions to ask.) This process of hypothesis and deduction is continued until one diagnosis is preferred over the others. The original list of hypotheses can be expanded but not usually to more than seven, and in the final stages it is usually reduced to two or three. These are then arranged in order of preference and become the list of **diagnostic possibilities**.

In farm animal medicine there is usually a general absence of both hard primary data and ancillary data, such as clinical pathology; thus the clinician might be in the position of having to provide treatment for two or three possible illnesses. An example is the parturition syndrome of recently calved dairy cows in which the treatment of subacute mastitis, metritis, and acetonemia is standard procedure because the clinician is uncertain about which disease is most accountable for the illness. In the more resource-rich arena of a veterinary hospital it might still be necessary to proceed in this way in the first instance but then to narrow down the list of hypotheses when additional information is received from the laboratory. This *polypharmacy* approach is inefficient and has a number of disadvantages, among which are the additional expense and the increased possibility of contamination of food products of animal origin by medications, especially antibiotics.

One of the important characteristics of this strategy is the dependence on the selection of a critical or key clinical sign or cue on which to base the original hypotheses. The selection of the key sign and additional supporting clinical findings is done instinctively by experienced clinicians on the basis of prior experience in similar situations. For novice clinicians it might be necessary to examine two or more key signs.

METHOD 3: THE ARBORIZATION OR ALGORITHM METHOD

This is really an extension of Method 2, but the hypothetico-deductive reasoning method is formalized and performed according to a preplanned program. This reasoning method depends on the clinician remembering and being aware of an all-inclusive list of diagnostic possibilities in the case under consideration. Because memory is unreliable and impressionistic, the hypothetico-deductive method is subject to error by omission. The arborization or algorithmic method similarly approaches a listed series of diagnoses and examines each one in turn with supporting or disproving questions; if they pass the proving test they stay in, if they fail the test then they are deleted. For example, a key sign of red urine in a cow promotes the question: Has the cow had access to plant substances that color the urine red? If the answer is no, the next question is: Is the red color caused by hemoglobinuria or hematuria? If the answer is hemoglobinuria, all the diagnoses on the hematuria branch of the algorithm are deleted and the questioner proceeds to the next question, which will attempt to determine whether the cow has postparturient hemoglobinuria or any of the diseases characterized by intravascular hemolysis.

This method works well provided the list of possible diagnoses is complete, is frequently updated as new diagnoses become available, and, just as importantly, new ways of supporting or discounting each hypothesis are added as soon as they are published. These algorithms are eminently suited to computerization and use of *apps* on smart phones or personal digital devices. The number of apps for personal digital devices is increasing almost daily, and readers are urged to consider these tools after appropriately considering their efficacy and accuracy.

The arborization method is well suited to the clinician who has not had the necessary experience memorizing long lists of potential diagnoses and the critical tests that confirm or exclude each of them. Because the algorithms are likely to include **all** the recorded diagnoses that have that particular key sign, error by omission is not a risk. Thus they are also valuable to the specialist, who is less able to afford an omission than the general practitioner and certainly cannot

really afford to miss even the most obscure and unlikely diagnosis. Another major advantage is that they provide a system of tests that should be performed and clinical findings that should be searched for, which is really a form of clinical protocol, acting as a reminder of the sequential diagnostic steps to be taken. The arrangement of the algorithm represents the clinical reasoning of the person who designed it and it should have considerable merit, assuming that the designer was an expert. This characteristic does arouse the comment that the method does away with the need for clinicians to do their own clinical reasoning. That might be so, but the interests of optimum clinical care of animals are probably better served by having inexperienced clinicians apply the clinical reasoning of a specialist and, consequently, achieve better results.

METHOD 4: THE KEY ABNORMALITY METHOD

This is a more time-consuming method than the previous ones that requires clinicians to rely on their knowledge of normal structure and function to select the key abnormality or clinical cue. This method consists of five steps and is summarized in Fig. 1-1.

Determination of the Abnormality of Function Present

Disease is an abnormality of function that is harmful to the animal. The first step is to decide what abnormality of function is present. In pursuing a diagnosis using this technique one should be aware of the parsimony principle, sometimes referred to as Occam's razor, which is the principle that the simplest of several hypotheses is always the best when accounting for unexplained facts, i.e., always try first to explain the animal's clinical signs as being caused by the fewest number of diseases. However, one should also be aware of Hickam's dictum: "that patients (animals) can have as many diseases as they damn well please." The practice attempts to explain the animal's illness with as few diseases as possible while not definitively excluding any plausible explanations. Finally, there can be more than one abnormality detected, but some will be clinically unimportant, e.g., a physiologic cardiac murmur in a newborn foal.

Definition of the abnormality is usually in general terms, such as paralysis, diarrhea, bloat, edema, and so on. These terms are largely clinical, referring to abnormalities of normal physiologic function, and their use requires a foreknowledge of normal physiology. It is at this point that the preclinical study of physiology merges with the clinical study of medicine.

The necessary familiarity with the normal, combined with observation of the case at hand, makes it possible to determine the physiologic abnormality, e.g., hypoxia. The next step is to determine the body system or body as a whole or organ involved in the production of the hypoxia.

Determination of the System or Body as a Whole or Organ Affected

Having made a careful physical examination and noted any abnormalities, it is then possible to consider which body system or organ is the cause of the abnormality. In some cases the body as a whole can be involved. This

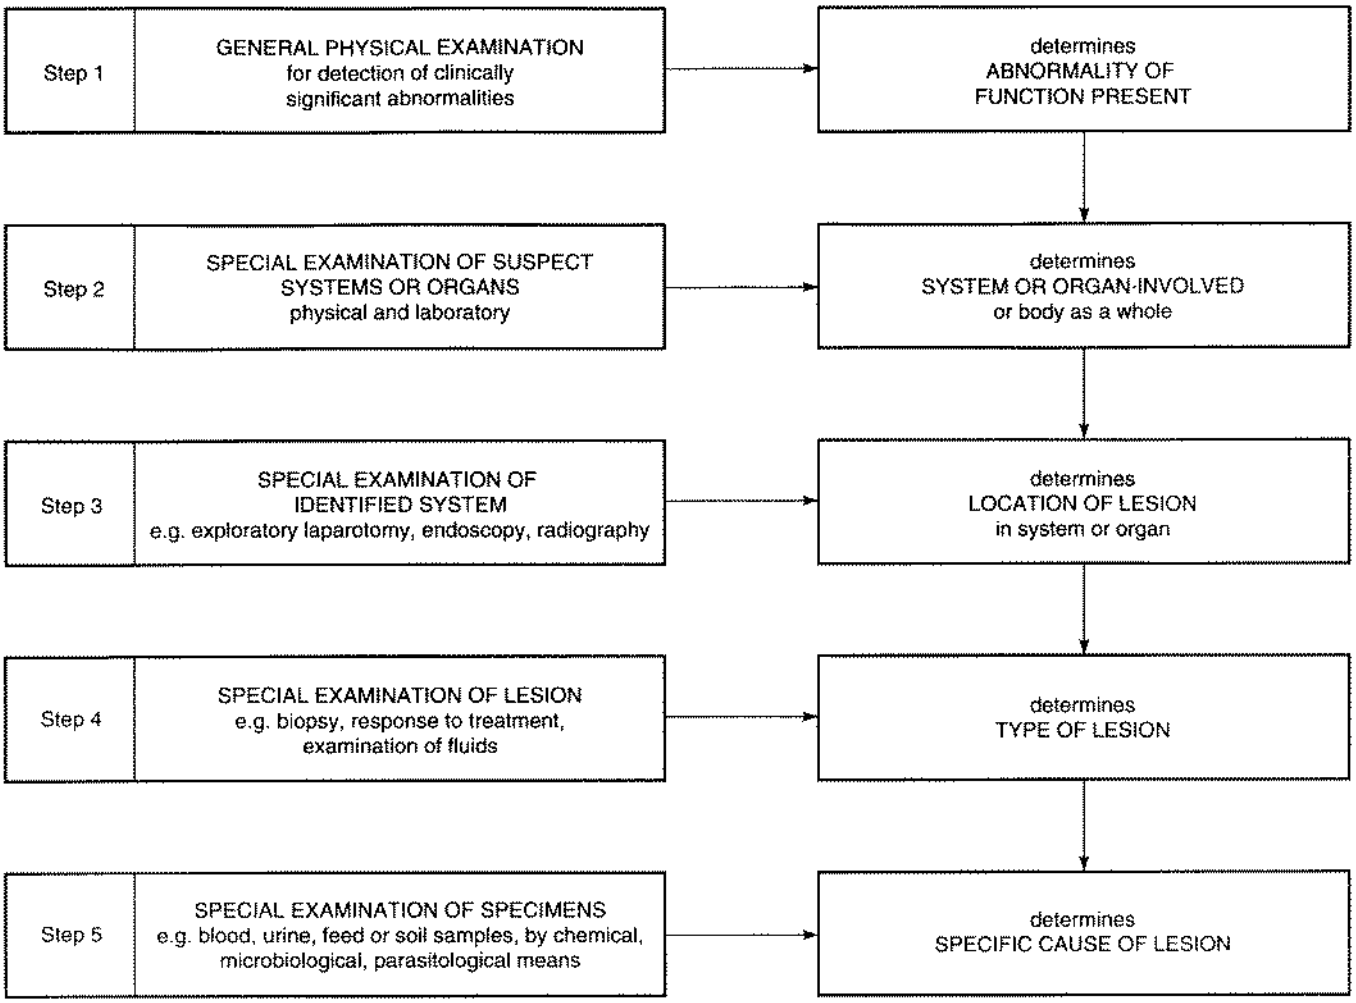

Fig. 1-1 Making a diagnosis.

might not be difficult with some systems; for example, hypoxia can be caused by failure of the respiratory or circulatory systems, and examination of these is not difficult. However, special problems arise when attempting to examine the nervous system, the liver, kidney, endocrine glands, spleen, and hemopoietic systems. Here, routine physical examination by palpation, auscultation, and percussion is not very rewarding: special ancillary examination techniques with the aid of a laboratory are usually necessary. These are described in the special examination methods done for the various systems. As a guiding principle, all functions of the organ under examination should be observed and any abnormalities noted. For example, if the integrity of the central nervous system is to be examined, the clinician would look for abnormalities of mental state, gait, posture, muscle and sphincter tone and involuntary movements, abnormal posture, and paralysis. Knowing the normal physiologic functions of systems, during examination one looks for aberrations.

When only a simple physical examination is available, it can be difficult to choose between two or more systems as the possible location of the abnormality. For example, when an animal is unable to rise from the recumbent position it can be difficult to decide whether the nervous system or the musculoskeletal system or generalized weakness from a systemic illness is the origin of the clinical recumbency. If special diagnostic techniques and laboratory evaluations are inconclusive or not available, it can be necessary to resort to probability as a guide. For example, paresis caused by diseases of the muscles is most common in young calves, lambs, and foals and generally uncommon in mature farm animals, with the exception of the myopathy associated with the downer cow syndrome in dairy cattle. However, paresis is common in mature cows affected with parturient hypocalcemia, peracute coliform mastitis, and acute diffuse peritonitis.

Determination of the Location of the Lesion Within the System or Organ Affected

The location of the lesion within the body system involved is not always obvious and might require special physical and laboratory examination techniques. For example, a detailed neurologic examination will be necessary to localize the lesion in an animal with manifestation of disease of the nervous system. This might be combined with radiographic techniques such as myelography. An exploratory laparotomy with or without biopsy techniques might be necessary to determine the location of an intestinal lesion thought to be the cause of chronic diarrhea. Endoscopy is standard practice for the localization of lesions of the respiratory tract of the horse. Radiography is often necessary to localize lesions of the musculoskeletal system and diseases of the feet of horses and cattle.

Determination of the Type of Lesion

The abnormality observed may be produced by lesions of different types. Generally, lesions can be divided into anatomic or physical lesions and functional disturbances. The physical lesions can be further subdivided into inflammatory, degenerative, or space occupying. These classifications are not mutually exclusive because a lesion may be both inflammatory and space occupying, for example abscesses in the spinal cord or lung. In these circumstances it is necessary to modify the diagnosis and say that such and such a lesion is space occupying and may or may not be inflammatory.

The differentiation between functional disturbances and physical lesions is often extremely difficult because the abnormalities produced may be identical. For example, in a case of hypomagnesemia in a cow there is no physical lesion but differentiation from the encephalitis of furious rabies may be impossible. As a rule, functional disturbances are transient, often recurrent or fluctuating, and are readily reversible by treatment, whereas structural lesions cause changes that are relatively static or at least change slowly and are affected only gradually by treatment. This is by no means a regular rule: the acute abdominal pain of intestinal obstruction usually fluctuates but the lesion is a physical one, whereas the paralysis of parturient paresis in cattle is static but the disturbance is functional.

Differentiation among inflammatory, degenerative, and space-occupying lesions is usually simpler. Space-occupying lesions produce signs characteristic of pressure on surrounding organs and can often be detected by physical means. Inflammatory lesions are characterized by heat, pain, swelling, and a local or general leukocytosis and, in severe cases, a systemic toxemia. A total white blood cell count and differential is a **sensitive** but **nonspecific** test for the presence of an infection. A leukopenia, neutropenia, and a degenerative left shift suggest a severe infection. A neutrophilia and regenerative shift suggest an active chronic infection. The most common infections of cattle, which are often not readily obvious, are in the thoracic and abdominal cavities (pleuritis, pulmonary abscesses, pericarditis, and peritonitis). Degenerative lesions produce the same loss or abnormality of function as lesions of the other types but are not usually accompanied by evidence of inflammation unless they are extensive. If the lesion is accessible, biopsy should be considered as a means of determining its nature.

Determination of the Specific Cause of the Lesion

If the nature of the abnormality and the type of lesion can be satisfactorily determined, then the specific causative agent remains to be found. If, for example, it could be said that a particular case of paralysis in a calf was caused by a degenerative lesion of the musculature, only a few specific etiologic agents would have to be considered to make a final diagnosis. In many cases it is impossible to go beyond this stage without additional techniques of examination, particularly laboratory examinations, and it is general practice to make a diagnosis without this confirmatory evidence because of limitations of time, finances, or facilities.

It is at this stage that a careful history taking and examination of the environment show their real value. It is only by a detailed knowledge of specific disease entities, the conditions under which they occur, the epidemiology, and the clinical characteristics of each disease that an informed judgment can be made with any degree of accuracy. If the diagnostic possibilities can be reduced to a small number, confirmation of the diagnosis by laboratory methods becomes so much easier because there are fewer examinations to be made and confirmation by response to treatment is easier to assess. If it is necessary to treat with many drugs serially or in combination to achieve a cure, the expense is greater and the satisfaction of both the client and the veterinarian is diluted in proportion to the range of treatments. Accuracy in diagnosis means increased efficiency, and this is the final criterion of veterinary practice.

METHOD 5: THE DATABASE METHOD

The basis of this method (also called the **Weed** or **problem-oriented method**) is to conduct a complete clinical and clinicopathologic examination of the animal to acquire a comprehensive animal database. The problems (key signs) in this database are then matched with the diagnostic database, in which collections of signs or syndromes are labeled with diagnoses, to select the best fit with the animal's data.

This method also uses the **problem-oriented veterinary medical record system**, which is an excellent system for the daily recording of clinical and laboratory data in an orderly, systematic, and consistent manner that can be easily followed by clinicians and their colleagues. This system is now used widely by veterinary teaching hospitals. It has four components based on the four phases of veterinary medical action:

- Database
- Problem list
- Initial plans
- Progress notes

The progress notes are created daily and divided into four parts known collectively by the acronym SOAP to designate the following:

- **S**ubjective information
- **O**bjective data
- **A**ssessment of problem

- **P**lans, which may include diagnostic, therapeutic, or client education

The method requires clinicians to be very painstaking in their examination and recording. It places great demands on the time spent by clinicians and clinical pathologists, on laboratory resources, and on clinical record storage. Much of the data have no diagnostic importance because the diagnostic decisions are made largely on the presence or absence of relatively few key signs. It also has the disadvantage that there is a tendency to make the animal fit a category. It is the opposite of the **key abnormality** method, in which only the signs and other indicants relevant to the proposed diagnosis are sought and recorded. Because of its requirement of time and data recording and storage this method is not suitable for use in food animal medicine, in which speed is a vital component of the diagnostic process. As mentioned in the next section, it is an excellent system for the teaching clinical veterinary medicine (i.e., taught how to do it, but then taught never to do it).

The method is really an expanded version of the hypothetico-deductive method, in which the hypotheses are made sequentially as further information becomes available. In the database method all the hypotheses are pursued in parallel because all the possible data have been put into the animal's database. The source of error in the method is the possibility of undue importance being attached to a chance abnormality in, say, the clinical biochemistry. If the abnormality cannot be matched to a clinical sign, it should be weighted downward in value or marked for comment only. The same error can result from inclusion of a sign that is important, e.g., diarrhea, but that happens to be present at low intensity.

Clinical Examination of the Individual Animal

A clinical examination has three parts:

- History
- Animal
- Environment

The usual admonition is that one should collect a comprehensive history and perform a complete physical examination (a diagnosis by exhaustion[1]) when investigating disease in an individual animal. This approach, in which one gathers all pertinent or potentially pertinent information before attempting to arrive at a diagnosis, is often taught to veterinary students as well as medical colleagues, but does not represent the behavior of experienced clinicians. One authority in human medicine states that all medical students should be taught how to do a complete historical and physical examination, but once they have mastered its components they should be taught never to do use this exhaustive methodology.[1]

Inadequate examination of any of these can lead to error. The examination of the affected animal represents only a part of the complete investigation. Careful questioning of the owner or attendant can yield information about the diet or the prior diet, about recent vaccinations or surgery, or about the introduction of animals into the group, which will provide the clues for a successful diagnosis. However, the most detailed examination of the animal and the most careful questioning of the owner might fail to elicit the evidence necessary for a correct diagnosis, for example, in lead poisoning of cattle. Only a careful physical search of the environment for a source of lead can provide this information. Thus neglect of one aspect of the clinical examination can render valueless a great deal of work on the other aspects and lead to an error in diagnosis.

HISTORY TAKING

In veterinary medicine, history taking is often the most important of the three aspects of a clinical examination. The importance of the results obtained by examination of the animal and the environment is liable to be modified by a number of factors. Animals are unable to describe their clinical symptoms (they have clinical signs, which are noticeable to an observer, but it can only be assumed that animals have symptoms or the subjective sensation of illness); they vary widely in their reaction to handling and examination, and a wide range of normality must be permitted in the criteria used in a physical examination. These variations are much greater in some species than in others. Dairy cattle, horses, sheep, and goats are usually easy to examine, whereas beef cattle and pigs can be difficult to examine adequately under some conditions. A satisfactory examination of the environment can prove difficult because of lack of knowledge of the factors concerned or because of the examiner's inability to assess their significance. Problems such as the measurement of the relative humidity of a barn and its importance as a predisposing factor in an outbreak of pneumonia or the determination of pH of the soil with reference to the spread of leptospirosis can present virtually insuperable difficulties to the veterinarian in the field. On the other hand, a search for a specific factor (a known poison), such as a pasture walk to detect toxic yew (*Taxus* spp.) offcuts in a field, can be relatively simple.

Nevertheless, history taking is an important key to accurate diagnosis in veterinary medicine, and to be worthwhile it must be accurate and purposeful. A fit for purpose history requires the focused collection of data that progressively increase or decrease the likelihood of a diagnosis. Collection of information that does not address a clinically relevant question (hypothesis) is a waste of time and resources. Admittedly, human fallibility must be taken into consideration: there might be insufficient time, the importance of particular factors might not be appreciated, and there could be misunderstanding. Although these are excusable up to a point, failure to recognize the importance of the history can lead only to error. To avoid being misled, it is essential that the veterinarian assesses the accuracy of the history by careful examination of what the owner relates about his or her animals.

The history should suggest not only the diagnostic possibilities but also the probabilities: a 1-year-old heifer is unlikely to have clinical Johne's disease, and an adult cow is more likely to have parturient paresis than a first-calf heifer, which in turn is more likely to have maternal obstetric paralysis than is the adult cow. The history can often indicate that special attention should be paid to the examination of a particular system in the animal or a particular factor in the environment. For example, in hypovitaminosis A in beef calves from 6 to 10 months of age, the animals might be seen when they are clinically normal, and the only means of reaching a diagnosis might be a consideration of the history of the clinical findings and the nutritional status.

HISTORY-TAKING METHOD

Good communication skills are an essential component of successful history taking and are increasingly taught as part of a veterinary curriculum.[3] Some suggestions are presented here as guidelines that might prove useful to the clinician.

The veterinarian should establish the context for the consultation and ensure that the environment in which it occurs is safe, professional, and allows for effective interaction with the client and examination of the animal.[3] This includes an introduction so that both parties are aware of the other's roles and responsibilities. For example, the veterinarian might be consulting with the sole owner, one of several owners, the farm manager or animal trainer, or a stable hand or farm worker. Each of these might have different levels of authority (the sole owner presumably has the most authority) or knowledge (a stable hand might have better insight into the horse's condition than a geographically distant part-time owner).

The next step is to establish rapport with the client. How can I help you today? is an effective opening question that provides the owner the opportunity to relate his or her concerns about the animals. Importantly, this allows the client to identify the reasons for the consultation. Recall that the role of a veterinarian in clinical practice is, in most instances, to solve the owner's problems or address his or her concerns. A focus solely on the animal will not necessarily result in a good outcome for the owner.

The owner or attendant must be handled with diplomacy and tact. The use of nontechnical terms is usually essential, because livestock owners can be confused by technical expressions or reluctant to express themselves when confronted with terms they do not understand. The veterinarian must be aware of the vernacular associated with particular breeds or uses of animals and should be able to communicate in these terms. Statements, particularly those concerned with time, should be tested for accuracy and precision. Such terms as *not long ago* or *a little while ago* should be used to ascertain the number of hours, days, or weeks involved. One person's perception of *recently* might be considerably different to another person. Owners, and more especially herdsmen and agents, can attempt to disguise their neglect by condensing time or varying the chronology of events. If a detailed cross-examination of the owner seems likely to arouse some antagonism, it is advisable for the veterinarian to forego further questioning and be content with his or her own estimate of the dependability of the history. The clinician must try to separate owners' observations from their interpretations. A statement that the horse had a bout of bladder trouble may, on closer examination, mean that the horse had an attack of abdominal pain in which it assumed a posture usually associated with urination. Often, however, it is impossible to avoid the use of leading questions—Did the pigs scour?, Was there any vomiting?—but it is necessary to weigh the answers in accordance with the general veracity of the owner.

Absence of a sign can only be determined by inquiring whether or not it occurred. Simply asking for a complete history of what has happened almost invariably results in an incomplete history. The clinician must know the right questions to ask; this knowledge comes with experience and familiarity with disease. Owners seldom describe clinical signs in their correct time sequence, and part of the clinician's task is to establish the chronology of events.

For completeness and accuracy in history taking the clinician should conform to a set routine. The system outlined next includes animal data, disease history, and management history. The order in which these parts of the history are taken will vary. Generally it is best to take the disease history first. The psychological effect is good: the owner appreciates the desire to get down to the facts about his or her animal's illness.

ANIMAL DATA

If records are to be kept at all, even if only for financial purposes, accurate identification of the animal is essential. An animal's previous history can be referred to, the disease status of a herd can be examined, and specimens for laboratory examination can be dispatched with the knowledge that the results can be related to the correct animal. Accurate records are also necessary for the submission of accounts for veterinary services rendered, and the details of the owner's address and of the animals examined and treated must be accurate. These points might have no importance in establishing the diagnosis, but they are of primary importance in the maintenance of a successful practice.

The relevant data include the following:

- Owner's name and initials
- Postal address and telephone number
- Species, type, and breed (or estimate of parentage in a crossbreed)
- Sex, age, name or number, and body weight
- If necessary, a description, including color markings, polledness, and other identifying marks, of the animal

Such a list can appear formidable but many of the points, such as age, sex, breed, and type (use made of animal, e.g., beef, dairy, mutton, wool), are often important to the diagnosis. A case history of a particular animal might suggest that further treatment is likely to be uneconomic because of age, or that a particular disease is assuming sufficient importance in a herd for different control measures to be warranted.

Computers are routinely veterinary practices for recording the details of farm calls, the animals examined and treated, the amounts charged for travel and professional services, the costs of laboratory services, the drugs used and dispensed, and the diseases that occur on a particular farm on an ongoing basis. It is now possible for veterinary practices to provide regular and annual health reports to herd owners so that planned health management programs can be assessed and evaluated. The ability to retrieve and summarize this information on an individual farm basis is a major step forward in providing optimal veterinary service to livestock herds, regardless of their size and complexity.

DISEASE HISTORY

History taking will vary considerably depending on whether one animal or a group of animals is involved in the disease problem under examination. Generally, in large animal work, all disease states should be considered as herd problems until proved to be otherwise. It is often rewarding to examine the remainder of a group and find animals that are in the early stages of the disease.

Present Disease

Attempts should be made to elicit the details of the clinical abnormalities observed by the owner in the sequence in which they occurred. If more than one animal is affected, a typical case should be chosen and the variations in history in other cases should then be noted. Variations from the normal in the physiologic functions, such as intake of food or drink, milk production, growth, respiration, defecation, urination, sweating, activity, gait, posture, voice, and odor, should be noted in all cases. There are many specific questions that need to be asked in each case, and for the most part they are variations on the questions already suggested.

If a number of animals are affected, information could be available from clinical pathologic examinations performed on living animals or necropsy examinations on fatal cases. The behavior of animals before death and the period of time elapsing between the first observable signs and death or recovery are important items of information. Prior surgical or medical procedures, such as castration, docking, shearing, or vaccination, may be important factors in the production of disease.

Morbidity, Case Fatality, and Population Mortality Rates

The morbidity rate is usually expressed as the percentage of animals that are clinically affected compared with the total number of animals exposed to the same risks. The case fatality rate is the percentage of affected animals that die. The population cause-specific mortality rate is the percentage of all exposed animals that die of the disease of interest. The population mortality rate is the proportion of animals in the population of interest that die of any cause during the specified period (a rate always includes a time element in the denominator). The estimates can be important in diagnosis because of the wide variations in morbidity, case fatality, and cause-specific mortality rates that occur in different diseases. An equally important figure is the proportion of animals at risk that are clinically normal but show abnormality on the basis of laboratory or other tests (so-called *subclinical disease*).

Prior Treatment

It is important to determine whether the animal has had any previous treatment for this condition administered by the owner or another veterinarian. Exact details of the preparations used and doses given can be of value in eliminating some diagnostic possibilities. They could be of importance when assessing the probable efficiency of the treatment and the significance of clinical pathologic tests, and in prescribing additional treatment. Drug withdrawal regulations now require that treated animals or their products, such as milk, be withheld from slaughter or market for varying lengths of time to allow drug residues to reach tolerable limits. This necessitates that owners reveal information about recent treatments.

Prophylactic and Control Measures

It should be ascertained whether preventive or control procedures have already been attempted. There could have been clinical pathologic tests; the introduction of artificial

insemination to control venereal disease; vaccination; or changes in nutrition, management, or hygiene. For example, in an outbreak of bovine mastitis careful questioning should be pursued regarding the method of disinfecting the cows' teats after each milking, with particular reference to the type and concentration of the disinfectant used and whether or not back-flushing of teat cups is practiced. Spread of the disease can result from failure of the hygiene barrier at any one of a number of such points. When written reports are available they are more reliable than memory.

Previous Exposure

The history of the group relative to additions is of particular importance in establishing the animal's exposure to the following risk factors:

- Is the affected animal an established member of the group, or has it been introduced, and if so how long ago?
- If the affected animal has been in the group for some time, have there been recent additions?
- Is the herd a *closed herd* or are animals introduced at frequent intervals?

Not all herd additions are potential carriers of disease: they might have come from herds in which control measures are adequate, they could have been tested before or after sale or kept in quarantine for an adequate period after arrival, or they could have received suitable biological or antibiotic prophylaxis. Herd additions might have come from areas in which a particular disease does not occur, although a negative history of this type is less reliable than a positive history of derivation from an area in which a particular disease is enzootic.

A reverse situation may occur in which imported animals have no resistance to endemic infection in the home herd or have not become adapted to environmental stressors, such as high altitudes, high environmental temperatures, and particular feeding methods, or are not accustomed to poisonous plants occurring in the environment.

Transit

The possibility of infection during transit is always a potential risk, and presale certificates of health may be of little value if an animal has passed through a sale barn, a show, or communal trucking yards while in transit. Highly infectious diseases may be transmitted via trucks, railroad cars, or other accommodation contaminated by previous inhabitants. Transient introductions, including animals brought in for work purposes, for mating, or on temporary grazing, are often overlooked as possible vectors of disease. Other sources of infection are wild fauna that graze over the same area as domestic livestock and inanimate objects such as human footwear, car tires, and feeding utensils.

Culling Rate

There may be considerable diagnostic importance in the reasons for culling and the number of animals disposed of for health reasons. Failure to grow well, poor productivity, and short productive life suggest the possible occurrence of a number of chronic diseases, including some associated with infectious agents, caused by nutritional deficiencies, or caused by poisons.

Previous Disease

Information elicited by questioning on previous history of illness can be helpful. If there is a history of previous illness, inquiries should be made along the usual lines, including clinical observations, necropsy findings, morbidity, case fatality rates, the treatments and control measures used, and the results obtained. If necessary, inquiries should be made about herds from which introduced animals have originated and also about herds to which other animals from the same source have been sent.

MANAGEMENT HISTORY

The management history includes nutrition, breeding policy and practice, housing, transport, and general handling. It is most important to learn whether or not there has been any change in the prevailing practice before the appearance of disease. Because a disease has occurred when the affected animals have been receiving the same ration, deriving from the same source over a long period, suggests that the diet is not at fault, although errors in preparation of concentrate mixtures, particularly with the present-day practice of introducing additives to feeds, can cause variations that are not immediately apparent.

Nutrition

The major objective in the examination of the nutritional history is to determine how the quantity and quality of the diet the animals have been receiving compares with the nutrient requirements recommended for a similar class of animal. Attention should be paid to both the macronutrients (protein, roughage, carbohydrate, and fat) and micronutrients (minerals and trace elements). Malnutrition can involve underfeeding (starvation), overfeeding (obesity), or deficiency or excess of micronutrients. In some situations it will be necessary to submit feed and water samples for analyses to assess quality and adequacy of feed.

Livestock at Pasture

Pastured livestock present a problem different from those being stall fed because they receive a diet that is less controlled and thus more difficult to assess. The risk of parasitic infestation and, in some cases, infectious disease is much greater in grazing animals. Inquiries should be made about the composition of the pasture, its probable nutritive value with particular reference to recent changes brought about by rain or drought, whether rotational grazing is practiced, the fertilizer program, and whether or not minerals and trace elements are provided by top-dressing or mineral mixtures. The origin of mineral supplements, particularly phosphates, which can contain excess fluorine, and homemade mixtures, which can contain excessive quantities of other ingredients, should receive attention. Actual examination of the pasture area is usually more rewarding than a description of it.

Hand-Fed/Stall-Fed Animals

Hand-fed or stall-fed animals are subjected to a controlled feed supply but, because of human error, they are frequently exposed to dietary mistakes. Types and amounts of feeds should be determined. Examples of disease caused by inadequate hand-fed diets include osteodystrophia fibrosa in horses on diets containing excess grain, azoturia in the same species when heavy-carbohydrate diets are fed during periods of rest, and lactic acid indigestion in cattle introduced to high-level grain diets too rapidly. The sources of the dietary ingredients can also be important. Grains from some areas are often much heavier and contain a much greater proportion of starch to husk than grains from other areas; thus when feed is measured, rather than weighed, overfeeding or underfeeding can occur.

Because the digestive enzyme capacity of newborn farm animals is most efficient in the digestion of whole milk, the use of nonmilk sources of carbohydrates and proteins in the formulation of milk replacers can result in indigestion and nutritional diarrhea.

Exotic diseases can be imported in feed materials; anthrax, foot-and-mouth disease, and hog cholera are well-described examples.

Variations in the preparation of ingredients of rations can produce variable diets. Overheating, as in pelleting or the cooking of feeds, can reduce their vitamin content; contamination with lubricating oil can result in poisoning by chlorinated naphthalene compounds; and pressure extraction of linseed can leave considerable residues of hydrocyanic acid in the residual oil cake.

Feeding practices may contribute to the production of disease. Pigs fed in large numbers with inadequate trough space or calves fed from communal troughs are likely to be affected by overeating or inanition, depending on their size and vigor. High-level feeding and consequent rapid growth may create deficiency states by increasing the requirement for specific nutrients.

In both hand-fed and grazing animals changes in diet should be carefully noted. Movement of animals from one field to another, from pasture to cereal grazing, and from unimproved to improved pasture may

all precipitate the appearance of disease. Periods of sudden dietary deficiency can occur as a result of bad weather or transportation or a change to unfamiliar feeds. Rapid changes are more important than gradual alterations, particularly in pregnant and lactating ruminants when metabolic diseases, including those caused by hypocalcemia, hypoglycemia, and hypomagnesemia, are likely to occur.

The availability of **drinking water** must be determined and is ideally done by direct examination of the watering facilities.

Reproductive Management and Performance

In the examination of a single animal the breeding and parturition history might suggest or eliminate some diagnostic possibilities. For example, pregnancy toxemia occurs in sheep in late pregnancy, whereas ketosis in dairy cows occurs primarily 2 to 6 weeks after parturition. Acute septic metritis is a possibility within a few days after parturition in any species but unlikely several weeks later.

Breeding History

The breeding history can be important regarding inherited disease. The existence of a relationship between sires and dams should be noted. Hybrid vigor in crossbred animals should be considered when there is apparent variation in resistance to disease between groups maintained under similar environmental conditions. A general relationship between selection for high productivity and susceptibility to certain diseases is apparent in many breeds of animal and even in certain families. The possibility of genetotrophic disease, i.e., the inheritance of a greater than normal requirement for a specific nutrient, should be considered.

Reproductive History

The examination of the herd reproductive history involves comparing past and present reproductive performances with certain optimum objectives. The mean length of the interval between parturition and conception, the mean number of services per conception, and the percentage of young animals weaned relative to the number of females that were originally exposed for breeding (calf or lamb crop and pigs weaned) are general measures of reproductive performance and efficiency.

Using cattle as an example, certain observations can assist in determining the cause of failure to reach reproductive performance objectives. These include the following:

- Percentage of abortions
- Length of breeding season
- Percentage of females pregnant at specified times after the onset of the breeding period
- Bull/cow ratio
- Size and topography of breeding pastures
- Fertility status of the females and males at breeding time

The percentage of females that need assistance at parturition and the percentage of calves that die at birth are also indices of reproductive performance indicative of the level of reproductive management provided.

Climate

Many diseases are influenced by climate. Foot rot in cattle and sheep reaches its peak incidence in warm, wet summers and is relatively rare in dry seasons. Diseases spread by insects are encouraged when climatic conditions favor the proliferation of the vector. Internal parasites are similarly influenced by climate. Cool, wet seasons favor the development of hypomagnesemia in pastured cattle. Anhidrosis in horses is specifically a disease of hot, humid countries. The direction of prevailing winds is important in many disease outbreaks, particularly in relation to the contamination of pasture and drinking water by fumes from factories and mines and the spread of diseases carried by insects.

General Management

There are so many items in the proper management of livestock that, if neglected, can lead to the occurrence of disease that they cannot be related here; animal management in the prevention of disease is a subject in its own right and is dealt with in all parts of this book. Some of the more important factors include the following:

- Hygiene, particularly in milking parlors and in parturition and rearing stalls
- Adequacy of housing in terms of space, ventilation, draining, and situation and suitability of troughs
- Opportunity for exercise
- Proper management of milking machines to avoid udder injury

The class of livestock under consideration is also important; for example, enterotoxemia is most common in finishing lambs and pigs, parturient paresis in milking cows, obstructive urolithiasis in lambs and steers in feedlots, and pregnancy toxemia in ewes used for fat lamb production.

EXAMINATION OF THE ENVIRONMENT

An examination of the environment is a necessary part of any clinical investigation because of the possible relationship between environmental factors and the incidence of disease. A satisfactory examination of the environment necessitates an adequate knowledge of animal husbandry and, with the development of species specialization, it will be desirable for the veterinarian to understand the environmental needs of a particular species or class of farm animal.

Depending on the region, some animals are kept outside year round, some are housed for part of the year during the winter months, and some are kept under total confinement. For animals raised on pasture, the effects of topography, plants, soil type, ground surface, and protection from extremes of weather assume major importance. For animals housed indoors, hygiene, ventilation, and avoiding overcrowding are of major concern. Some of these items will be briefly presented here as guidelines. Each observation should be recorded in detail for preparation of reports for submission to the owners. Detailed records and even photographs of environmental characteristics assume major importance when poisonings are suspected and where litigation proceedings appear possible.

OUTDOOR ENVIRONMENT

Topography and Soil Type

The topography of grasslands, pastures, and wooded areas can contribute to disease or inefficient production and reproduction. Flat, treeless plains offering no protection from wind predispose cattle to lactation tetany in inclement weather. Low, marshy areas facilitate the spread of insect-borne diseases and soil-borne infections requiring damp conditions, such as leptospirosis; Johne's disease and diseases associated with liver fluke infestation and lungworm pneumonia are more prevalent in such areas. Rough grasslands with extensive wooded areas can have an adverse effect on reproductive performance in beef herds because of the difficulty the bulls have in getting to the females during peak periods of estrus activity.

The soil type of a district may provide important clues to the detection of nutritional deficiencies; copper and cobalt deficiencies are most common on littoral sands, and the copper deficiency/molybdenum excess complex usually occurs on peat soils. The surface of the ground and its drainage characteristics are important in highly intensive beef feedlots and in large dairy herds where fattening cattle and dairy cows are kept and fed under total confinement. Ground surfaces that are relatively impermeable and/or not adequately sloped for drainage can become a sea of mud following a heavy rainfall or snowstorm. Constant wetting of the feet and udders commonly results in outbreaks of foot rot and mastitis. Dirty udders increase the time required for udder washing before milking and can seriously affect a mastitis control program.

In some regions of the world, beef cows are calved in outdoor paddocks in the spring when it is wet and cold with an excess of surface water; this increases the spread of infectious disease and results in a marked increase in neonatal mortality. A lack of sufficient protection from the prevailing winds, rain, snow, or the heat of the sun can seriously affect production and can exacerbate an existing disease condition or precipitate an outbreak. Dusty feedlots during the hot

summer months may contribute to an increase in the incidence of respiratory disease or delay the response to treatment of disease such as pneumonia.

Stocking Rate (Population Density)

Overcrowding is a common predisposing cause of disease. There may be an excessive buildup of feces and urine, which increases the level of infection. The relative humidity is usually increased and more difficult to control. Fighting and cannibalism are also more common in overcrowded pens than when there is adequate space for animals to move around comfortably. The detection and identification of animals for whatever reason (illness and estrus) can be difficult and inaccurate under crowded conditions.

Feed and Water Supplies

Pasture and Feed

In pastures the predominant plant types, both natural and introduced, should be observed because they are often associated with certain soil types and may be the cause of actual disease; the high estrogen content of some clovers, the occurrence of functional nervous diseases in pastures dominated by *Phalaris aquatica* (syn. *P. tuberosa*) and perennial rye grass, and the presence of selective absorbing *converter* plants on copper-rich and selenium-rich soils are all examples of the importance of the dominant vegetation. The presence of specific poisonous plants, evidence of overgrazing, and the existence of a bone-chewing or bark-chewing habit can be determined by an examination of the environment.

Vital clues in the investigation of possible poisoning in a herd may be the existence of a garbage dump or ergotized grass or rye in the pasture, or the chewing of lead-based painted walls in the barn, or careless handling of poisons in the feed area. The possibility that the forage has been contaminated by environmental pollution from nearby factories or highways should be examined. In some cases the physical nature of the pasture plants may be important; mature, bleached grass pasture can be seriously deficient in carotene, whereas lush young pasture can have rachitogenic potency because of its high carotene content or it may be capable of causing hypomagnesemia if it is dominated by grasses. Lush legume pasture or heavy concentrate feeding with insufficient roughage can cause a serious bloat problem.

The feed supplies for animals raised in confinement outdoors must be examined for evidence of moldy feed, contamination with feces and urine, and excessive moisture caused by lack of protection from rain and snow. Empty feed troughs may confirm a suspicion that the feeding system is faulty.

Water

The drinking water supply and its origin may be important in the production of disease. Water in ponds can be covered with algae containing neurotoxins or hepatotoxic agents, and flowing streams might carry effluent from nearby industrial plants. In a feedlot, water can suddenly become unavailable because of frozen water lines or faulty water tank valves. This should not go unnoticed if one recognizes the anxiety of a group of cattle trying to obtain water from a dry tank.

Waste Disposal

The disposal of feces and urine has become a major problem for large intensified livestock operations. Slurry is now spread on pastures and may be important in the spread of infectious disease. Lagoons can provide ideal conditions for the breeding of flies, which can be troublesome to a nearby livestock operation. The inadequate disposal of dead animals also can be an important factor in the spread of certain diseases.

INDOOR ENVIRONMENT

There are few aspects of livestock production that have aroused more interest, development, and controversy in the last few years than the housing and environmental needs of farm animals. Several textbooks on the subject have been written, and only some of the important items will be mentioned here, with the aid of some examples. The effects of housing on animal health have not received the consideration they deserve, partly because of insufficient knowledge of animals' environmental needs and partly because there has been a failure to apply what is already known.

Generally, it can be said that inadequate housing and ventilation, overcrowding, and uncomfortable conditions are considered to have detrimental effects on housed animals that make them not only more susceptible to infectious disease but also less productive. Moreover, this reduction in productive efficiency may be a greater cause of economic loss than losses caused by infectious disease. For this reason, the veterinarian must learn to examine and assess all aspects of an indoor environment, which may be the primary cause of, or a predisposing factor to, disease. For example, the major causes of preweaning mortality of piglets are chilling and crushing of piglets in the first few days of life and not infectious disease. These physical causes are commonly related to a combination of poorly designed farrowing crates, slippery floors, inadequate heating, and perhaps overcrowding of the farrowing facilities.

Hygiene

One of the first things to observe is the level of sanitation and hygiene, which is usually a reliable indicator of the level of management; poor hygiene is often associated with a high level of infectious disease. For example, the incidence of diarrhea in piglets may be high because the farrowing crates are not suitably cleaned and disinfected before the pregnant sows are placed in them. A similar situation applies for lambing sheds, calving pens, and foaling boxes. An excessive buildup of feces and urine with insufficient clean bedding will result in a high level of neonatal mortality. The methods used for cleaning and disinfection should be examined carefully. The removal of dried feces from animal pens that have been occupied for several months is a difficult and laborious task and often not done well. Undue reliance may be placed on the use of chemical disinfectants.

The total length of time that animals have occupied a pen without cleaning and disinfection (occupation time) should be noted. As the occupation time increases, there is a marked increase in the infection rate and the morbidity and mortality from infectious disease often increase.

Ventilation

Inadequate ventilation is considered to be a major risk factor contributing to the severity of swine enzootic pneumonia in finishing pigs. The primary infection has a minimal effect on the well-housed pig, but inadequate ventilation results in overheating of the barn in the summer months and chilling and dampness during the winter months. This commonly results in subclinical and clinical pneumonia, which severely affects productive efficiency. Similarly, in young calves, which are raised indoors in most of the temperate zones of the world, protection from the cold during the winter is necessary. The effects of enzootic pneumonia of housed calves are much more severe when ventilation is inadequate than when the calves are comfortable and have clean, fresh air.

Evaluating the adequacy of the ventilation of a farm animal barn filled to economic capacity with animals is a difficult task and a major subject. Ventilation is assessed by a determination of the number of air changes per unit of time, the relative humidity during the day and night, the presence or absence of condensation on the hair coats of the animals or on the walls and ceilings, the presence of drafts, the building and insulation materials used, the positions and capacities of the fans, and the size and location of the air inlets. The measurement of the concentration of noxious gases in animal barns, such as ammonia and hydrogen sulfide, may be a valuable aid in assessing the effectiveness of a ventilation system.

Animals raised indoors are frequently overcrowded, which may predispose them to disease, and measurements of population density and observations of animal behavior in such conditions assume major importance. When pigs are raised indoors in crowded conditions with inadequate ventilation, their social habits may change drastically and they begin to defecate and urinate on the clean floor and on their penmates rather than over the slatted floor over the

gutter. This can result in outbreaks of diseases that are transmitted by the fecal–oral route.

Flooring

The quality of the floor is often responsible for diseases of the musculoskeletal system and skin. Poorly finished concrete floors with an exposed aggregate can cause severe foot lesions and lameness in adult swine. Recently calved dairy cows are very susceptible to slipping on poor floors in dairy barns, which is a common cause of downer cow syndrome. Loose-housing systems, particularly those with slatted floors, have resulted in a new spectrum of diseases of the feet of cattle because of the sharp edges of some of the slats. The quality and quantity of bedding used should be noted. Bedding is now rarely used in intensified swine operations. The use of sawdust or shavings in loose-housing systems for dairy cattle may be associated with outbreaks of coliform mastitis. Wet bedding, particularly during the winter months, is commonly associated with endemic pneumonia in calves.

Floor Plan

The floor plan and general layout of an animal house must be examined for evidence that the routine movements of animal attendants, the movements of animals, and feeding facilities may actually be spreading disease. Communal gutters running through adjacent pens may promote the spread of disease through fecal or urinary contamination. The nature of the partitions between pens, whether a solid or open-grid type, may assist the control or spread of infectious disease. The building materials used will influence the ease with which pens, such as farrowing crates and calf pens, can be cleaned and disinfected for a new batch of piglets or calves.

Lighting

The amount of light available in a barn should be noted. With insufficient light it may be difficult to maintain a sufficient level of sanitation and hygiene, sick animals may not be recognized early enough, and errors in management are likely to occur.

When investigating a herd problem of mastitis in dairy cattle the veterinarian should visit the farm at milking time and observe how the cows are prepared for milking, examine the teats and udders before and after they are washed, observe the use of the milking machine, and rate the level of sanitation and hygiene practiced. Several successive visits may be necessary to reveal possible weaknesses in a mastitis control program.

EXAMINATION OF THE ANIMAL

Clinical examination is a key component in any diagnostic process. More is missed by not looking than by not knowing, and care should be taken to ensure that clinical examinations are appropriate for the task at hand. Clinical examinations aid in the identification of abnormalities in form and function of the animal, provide invaluable information regarding the cause of the disease, help to define the severity of the disease, and aid in monitoring the progression of the disease. Increasingly the utility of abnormalities detected on clinical examination is improving. For instance, determining the severity of the clinical abnormality and not just its presence or absence is useful in establishing a prognosis. A simplistic example of this is equine colic, in which the heart rate of affected horses is directly correlated with the likelihood of death. More sophisticated examples include objective assessment of the severity of the neurologic grade made with knowledge of the interobserver agreement about severity and use of the FAMACHA (FAffa MAlan CHArt) scoring system for anemia in small ruminants. To be useful, these signs of clinical abnormality have to be repeatable both within and between observers and must have a demonstrated relationship with either the likelihood of diagnosis or outcome of the disease.

A complete clinical examination of an animal includes, in addition to history taking and examination of the environment, physical and laboratory examinations. A complete clinical examination of every animal is unnecessary because of the simplicity of some diseases and, as with history taking, a more targeted approach is favored by experienced clinicians. However, a general clinical examination of every animal is necessary, and the inexperienced clinician should spend as much time and effort as is practicable and economical in carrying it out. This will help to avoid the sort of embarrassing error in which a calf is operated on for umbilical hernia when it also has a congenital cardiac defect.

As **learned** experience develops, the clinician will know the extent to which a clinical examination is necessary. All the laboratory tests that are likely to be informative and that are practical and economical should be used. Because of the cost of laboratory tests, the clinician must be selective in the tests used. The most economical method is to examine the animal and then select those laboratory tests that will support or refute the tentative clinical diagnosis. In this section a system for the examination of an animal is outlined in a general way. There is a great deal of difference between species in the ease with which this examination is done and the amount of information that can be collected. Additional detailed examination techniques are described under the individual body systems.

The examination of an animal consists of a **general inspection** done from a distance (the **distant examination**, and the particular **distant examination of body regions**) followed by a **close physical examination** of all body regions and systems. Only the major body systems that are routinely examined are presented here as part of the general examination.

GENERAL INSPECTION (DISTANT EXAMINATION)

The importance of a distant examination of the animal cannot be overemphasized, and yet it is often overlooked. Apart from the general impression gained from observation at a distance, there are some signs that can best be assessed before the animal is disturbed. The proximity of the examiner is particularly disturbing to animals unaccustomed to frequent handling.

Behavior and General Appearance

The general impression of the health of an animal obtained by an examination from a distance should be assessed according to the following sections.

Behavior

Separation of an animal from its group is often an indication of illness. The behavior is also a reflection of the animal's health. If it responds normally to external stimuli, such as sound and movement, it is classified as **bright**. If the reactions are sluggish and the animal exhibits relative indifference to normal stimuli, it is said to be **dull** or **apathetic**. Cattle with carbohydrate engorgement are commonly reluctant to move unless coaxed. A pronounced state of indifference in which the animal remains standing and is able to move but does not respond at all to external stimuli is the **dummy syndrome**. This occurs in subacute lead poisoning, listeriosis, and some cases of acetonemia in cattle, and in encephalomyelitis and hepatic cirrhosis in horses. The terminal stage of apathy or depression is **coma**, in which the animal is unconscious and cannot be roused.

Excitation States

Excitation states vary in severity. A state of anxiety or apprehension is the mildest form: here the animal is alert and looks about constantly but is normal in its movements. Such behavior is usually expressive of moderate constant pain or other abnormal sensation, as in early parturient paresis or in recent blindness. A more severe manifestation is restlessness, in which the animal moves about a good deal, lies down and gets up, and may go through other abnormal movements such as looking at its flanks, kicking at its belly, and rolling and bellowing. Again, this demeanor is usually indicative of pain.

More extreme degrees of excited demeanor include **mania** and **frenzy**. In mania, the animal performs abnormal movements with vigor: violently licking at its own body, licking or chewing inanimate objects, and pressing forward with the head

are typical examples. In frenzy the actions are so wild and uncontrolled that the animals are a danger to anyone approaching them. In both mania and frenzy there is usually excitation of the brain, as in rabies, acute lead poisoning, and some cases of nervous acetonemia.

Voice

Abnormality of the voice should be noted. It may be hoarse in rabies or weak in gut edema; there may be continuous lowing in nervous acetonemia or persistent bellowing indicative of acute pain. Soundless bellowing and **yawning** are commonly seen in rabid cattle, and yawning is a common sign in animals affected with hepatic insufficiency.

Eating

The appetite of the animal can be assessed by observing its reaction to the offering of feed or by the amount of feed available that has not been eaten. It is important to determine the total amount of feed that the animal is eating per day. In an animal that has retained its appetite, there may be abnormality of **prehension**, **mastication**, or **swallowing** and, in ruminants, of belching and regurgitation.

Prehension may be interfered with by inability to approach feed, paralysis of the tongue in cattle, in cerebellar ataxia, and osteomyelitis of cervical vertebrae and other painful conditions of the neck. When there is pain in the mouth prehension may be abnormal, and affected animals may be able to take only certain types of feed. Mastication may be slow, one-sided, or incomplete when mouth structures, particularly teeth, are affected. Periodic cessation of chewing when feed is still in the mouth is common in the dummy syndrome, when there are space-occupying lesions of the cranium, or an encephalomyelitis exists.

Swallowing can be painful because of inflammation of the pharynx or esophagus, as is found in strangles in the horse, in calf diphtheria, and where improper use of bailing and drenching guns or bottles has caused laceration of the pharyngeal mucosa. Attempts at swallowing followed by coughing up of feed or regurgitation through the nostrils can also be the result of painful conditions but are most likely caused by physical obstructions such as esophageal diverticula or stenosis, a foreign body in the pharynx, or paralysis of the pharynx. It is important to differentiate between material that has reached the stomach and ingesta regurgitated from an esophageal site. Partial esophageal obstruction resulting in difficult swallowing is usually manifested by repeated swallowing movements often with associated flexion of the neck and grunting.

In ruminants there may be abnormalities of **rumination** and **eructation**. Absence of cudding occurs in many diseases of cattle and sheep; violent efforts at regurgitation with grunting suggests esophageal or cardiac obstruction. There may be inability to control the cud (cud-dropping) caused by pharyngeal paralysis or painful conditions of the mouth. Failure to eructate is usually manifested by the appearance of bloat.

Defecation

In constipation and rectal paralysis or stenosis, the act of defecation may be difficult and be accompanied by straining or tenesmus. When there is abdominal pain or laceration of the mucocutaneous junction at the anus, defecation may cause obvious pain. Involuntary defecation occurs in severe diarrhea and when there is paralysis of the anal sphincter. Consideration of frequency, volume, and character of feces is given later. Constipation must not be mistaken for scant feces, particularly in mature cattle with diseases of the forestomachs and failure of movement of ingesta in a caudad direction.

Urination

This may be difficult when there is partial obstruction of the urinary tract and painful when there is inflammation of the bladder or urethra. In cystitis and urethritis there is increased frequency with the passage of small amounts of fluid, and the animal remains in the urination posture for some time after the flow ceases. Incontinence, with constant dribbling of urine, is usually caused by partial obstruction of the urethra or paralysis of its sphincter. If the animal urinates during the visual inspection, a sample of urine should be obtained, examined grossly, and submitted for urinalysis.

Posture

Abnormal posture is not necessarily indicative of disease, but when associated with other signs it may indicate the site and severity of a disease process. One of the simplest examples is resting of a limb in painful conditions of the extremities; if a horse continually shifts its weight from limb to limb it may indicate the presence of laminitis or early osteodystrophia fibrosa. Arching of the back with the limbs tucked under the body usually indicates mild abdominal pain; downward arching of the back and *saw horse* straddling of the legs is characteristic of severe abdominal pain, usually spasmodic in occurrence; and a *dog-sitting* posture in the horse associated with rolling and kicking at the belly is usually associated with abdominal pain and pressure on the diaphragm, such as occurs in acute gastric dilatation after engorgement on grain. This posture is commonly adopted by normal cattle but will occur in painful conditions of the pelvic limbs such as degenerative osteoarthritis in young cattle. Abduction of the elbows is usually synonymous with chest pain or difficulty in breathing. Elevation and rigidity of the tail and rigidity of the ears and limbs are good indications of tetanus in animals. The carriage of the tail in pigs is a useful barometer of their state of health. Sheep that are blind, as in early pregnancy toxemia, are immobile but stand with the head up and have an expression of extreme alertness.

When the animal is recumbent there also may be abnormalities of posture. In cattle affected by dislocation of the hip or by sciatic nerve paralysis, the affected limb is not held flexed next to the abdomen but sticks straight out in an awkward position; unilateral pain in the chest may cause an animal to lie habitually on the other side; and a weak hindleg may be kept under the animal. The head may be carried around toward the flank in parturient paresis in cows and in horses with colic. Sheep affected with hypocalcemia and cattle with bilateral hip dislocation often lie in sternal recumbency with the hindlegs extended behind in a froglike attitude. Inability or lack of desire to rise are usually indicative of muscle weakness or of pain in the extremities such as in enzootic muscular dystrophy or laminitis.

Gait

Movements of the limbs can be expressed in terms of rate, range, force, and direction of movement. Abnormalities may occur in one or more of these categories. For example, in true cerebellar ataxia all qualities of limb movement are affected. In louping-ill in sheep it is the range and force of movement that are excessive, resulting in a high-stepping gait and a bounding form of progression; in arthritis, because of pain in the joints, or in laminitis, because of pain in the feet, the range is diminished and the animal has a shuffling, stumbling walk. The direction of progress may be affected. Walking in circles is a common abnormality and is usually associated with rotation or deviation of the head; it may be a permanent state as in listeriosis or occur spasmodically as in acetonemia and pregnancy toxemia. Compulsive walking or walking directly ahead regardless of obstructions is part of the dummy syndrome mentioned earlier and is characteristic of encephalomyelitis and hepatic insufficiency in the horse.

Body Condition

The animal may be in normal bodily condition, or obese, thin, or emaciated. The difference between thinness and emaciation is one of degree: the latter is more severe but there are additional signs that are usually taken into consideration. In an emaciated (cachectic) animal the coat is poor, the skin is dry and leathery, and work performance is reduced. Thin animals, on the other hand, are physiologically normal. The difference between fatness and obesity is of the same order. Most beef cattle prepared for the show ring are obese. To inject some degree of numerical assessment it is now customary in all farm animal species and in horses to use body condition on a scale of 1 to 5 or preferably 1 to 10.

Body Conformation

The assessment of conformation or shape is based on the symmetry and the shape and size of the different body regions relative to other regions. An abdomen that is very large relative to the chest and hindquarters can be classified as an abnormality of conformation. To avoid repetition, points of conformation are included in the description of body regions.

Skin

Skin abnormalities can usually be seen at a distance. They include changes in the hair or wool, abnormal sweating, the presence of discrete or diffuse lesions, and evidence of soiling by discharges and of itching. The normal luster of the coat may be absent. It may be dry as in most chronic debilitating diseases or excessively greasy as in seborrheic dermatitis. In debilitated animals the long winter coat may be retained past the normal time. Alopecia may be evident: in hyperkeratosis it is diffuse, and in ringworm it may be diffuse but more commonly occurs in discrete areas. Sweating may be diminished, as in anhidrosis of horses; patchy as in peripheral nerve lesions; or excessive as in acute abdominal pain. Hypertrophy and folding of the skin may be evident, and hyperkeratosis is the typical example. Discrete skin lesions range in type from urticarial plaques to the circumscribed scabs of ringworm, pox, and impetigo. Diffuse lesions include the obvious enlargements caused by subcutaneous edema, hemorrhage, and emphysema. Enlargements of lymph nodes and lymphatics are also evident when examining an animal from a distance.

INSPECTION OF BODY REGIONS (PARTICULAR DISTANT EXAMINATION)

As a general rule, as much of a clinical examination as possible should be performed before the animal is handled. This is partly to avoid unnecessary excitement of the animal but also because some abnormalities are better seen at a distance and in some cases cannot be discerned at close range. The general appearance of the animal should be noted and its behavior assessed. Some time should also be devoted to an inspection of the various body regions, which is a particular distant examination.

Head

The facial expression may be abnormal. The rigidity of tetanus, the cunning leer or maniacal expression of rabies, and acute lead poisoning are cases in point. The symmetry and configuration of the bony structure should be examined. Doming of the forehead occurs in some cases of congenital hydrocephalus and in chondrodysplastic dwarfs, and in the latter there may be bilateral enlargement of the maxillae. Swelling of the maxillae and mandibles occurs in osteodystrophia fibrosa; in horses swelling of the facial bones is usually caused by frontal sinusitis; in cattle enlargement of the maxilla or mandible is common in actinomycosis. Asymmetry of the soft structures may be evident and is most obvious in the carriage of the ears, degree of closure of the eyelids, and situation of the muzzle and lower lip. Slackness of one side and drawing to the other are constant features in facial paralysis. Tetanus is accompanied by rigidity of the ears, prolapse of the third eyelid, and dilatation of the nostrils.

The carriage of the head is most important. Rotation is usually associated with defects of the vestibular apparatus on one side and deviation with unilateral involvement of the medulla and cervical cord. Opisthotonus is an excitation phenomenon associated with tetanus, strychnine poisoning, acute lead poisoning, hypomagnesemic tetany, polioencephalomalacia, and encephalitis.

The eyes merit attention. Visible discharge should be noted. Protrusion of the eyeball, as occurs in orbital lymphomatosis, and retraction of the bulb, as occurs commonly in dehydration, are important findings; spasm of the eyelids and excessive blinking usually indicate pain or peripheral nerve involvement; and prolapse of the nictitating membrane usually characterizes central nervous system derangement, generally tetanus.

Dilatation of the nostrils and nasal discharge suggest the advisability of closer examination of the nasal cavities at a later stage. Excessive salivation or frothing at the mouth denotes painful conditions of the mouth or pharynx or is associated with tremor of the jaw muscles caused by nervous involvement. Swellings below the jaw may be inflammatory, as in actinobacillosis and strangles, or edematous, as in acute hypoproteinemia, protein starvation, or congestive heart failure. Unilateral or bilateral swelling of the cheeks in calves usually indicates necrotic stomatitis.

Neck

If there is enlargement of the throat this region should be more closely examined later to determine whether the cause is inflammatory and whether lymph nodes, salivary glands (or guttural pouches in the horse), or other soft tissues are involved. Goiter leads to local enlargement located further down the neck. A jugular pulse, jugular vein engorgement, and edema should be looked for, and local enlargement caused by esophageal distension should be noted.

Thorax

Respiration should be examined from a distance, preferably with the animal in a standing position, because recumbency is likely to modify it considerably. Allowance should be made for the effects of exercise, excitement, high environmental temperatures, and fatness of the subject: obese cattle may have respiratory rates two to three times that of normal animals. The rate, rhythm, depth, and type of respiration should be noted.

Respiratory Rate

In normal animals under average conditions the rate should fall within the following limits:

- Horses, 8 to 16 per minute
- Cattle, 10 to 30 per minute
- Sheep and pigs, 10 to 20 per minute
- Goats, 25 to 35 per minute

An increased respiratory rate is designated as polypnea, decreased rate as oligopnea, and complete cessation as apnea. The rate may be counted by observation of rib or nostril movements, by feeling the nasal air movements, or by auscultation of the thorax or trachea. A significant rise in environmental temperature or humidity may double the normal respiratory rate. Animals acclimatized to cold outdoor temperatures are susceptible to heat stress when exposed suddenly to warmer temperatures. When brought indoors the respiratory rate may increase to six or eight times the normal, and panting open-mouth breathing may be evident within 2 hours.

Respiratory Rhythm

The normal respiratory cycle consists of three phases of equal length: inspiration, expiration, and pause. Variation in the length of one or all phases constitutes an abnormality of rhythm. The breathing pattern of the neonatal foal is markedly different from that of the adult horse and similar to that of other neonates. It has a higher respiratory rate, a higher airflow rate, and a higher minute ventilation on a body weight basis. In addition, in the standing neonatal foal, both the inspiratory and expiratory airflow patterns are essentially monophasic, whereas the adult horse typically has a biphasic inspiratory and expiratory airflow pattern. The transition from monophasic to biphasic flow patterns occurs within the first year of life.

Prolongation of Phases

Prolongation of inspiration is usually caused by obstruction of the upper respiratory tract; prolongation of expiration is often caused by failure of normal lung collapse, as in emphysema. In most diseases of the lungs there is no pause and the rhythm consists of two beats instead of three. There may be variation between cycles: Cheyne–Stokes respiration is a gradual increase and then a gradual decrease in the depth of respiration, and Biot's breathing, which occurs in meningitis affecting the medullary region, is characterized by alternating periods of hyperpnea and apnea, and the periods often are of unequal length. Periodic breathing also occurs commonly in animals with electrolyte and acid-base imbalances. There are periods of apnea followed by short bursts of hyperventilation.

Respiratory Depth

The amplitude or depth of respiratory movements may be reduced in painful conditions of the chest or diaphragm and increased in any form of anoxia. Moderate increase in depth is referred to as hyperpnea and labored breathing as dyspnea. In dyspnea, the accessory respiratory movements become more prominent. There is extension of the head and neck, dilatation of the nostrils, abduction of the elbows, and breathing through the mouth plus increased movement of the thoracic and abdominal walls. Loud respiratory sounds, especially grunting, may also be heard.

Type of Respiration

In normal respiration there is movement of the thorax and abdomen. In painful conditions of the thorax, e.g., acute pleurisy, and in paralysis of the intercostal muscles, there is relative fixation of the thoracic wall and a marked increase in the movements of the abdominal wall. There also may be an associated pleuritic ridge caused by thoracic immobility with the thorax expanded. This syndrome is usually referred to as an abdominal-type respiration. The reverse situation is thoracic-type respiration, in which the movements are largely confined to the thoracic wall, as in peritonitis, particularly when there is diaphragmatic involvement.

Thorax Symmetry

This can also be evaluated by inspection. Collapse or consolidation of one lung may lead to restriction of movements of the thoracic wall on the affected side. The *rachitic rosary* of enlarged costochondral junctions is typical of rickets.

Respiratory Noises or Stridors

These include the following:

- Coughing caused by irritation of the pharynx, trachea, and bronchi
- Sneezing caused by nasal irritation
- Wheezing caused by stenosis of the nasal passages
- Snoring when there is pharyngeal obstruction, as in tuberculous adenitis of the pharyngeal lymph nodes
- Roaring in paralysis of the vocal cords
- Grunting is a forced expiration against a closed glottis, which happens in many types of painful and labored breathing

An important part of the clinical examination of a horse that produces an externally audible noise, usually a grunt, while working is to determine when the noise occurs in the respiratory cycle. This can be related to limb movement, such as expiration occurring as the leading foot hits the ground at the canter or gallop. Flexion of the head by the rider will exacerbate the noise.

Abdomen

Variations in abdominal size are usually appreciated during the general inspection of the animal. An increase in size may be caused by the presence of excessive feed, fluid, feces, flatus, or fat and the presence of a fetus or a neoplasm. Further differentiation is usually possible only on close examination. In advanced pregnancy, fetal movements may be visible over the right flank of cattle. In severe distension of the intestines with gas, the loops of intestine may be visible in the flank, especially in calves. Intestinal tympany usually results in uniform distension of the abdomen, whereas fluid tends to result in increased distension ventrally.

The term *gaunt* is used to describe an obvious decrease in the size of the abdomen. It occurs most commonly in starvation, in severe diarrhea, and in many chronic diseases in which appetite is reduced. An umbilical hernia, omphalophlebitis, or dribbling of urine from a previous urachus may be apparent on visual inspection of the ventral abdominal wall. Ventral edema is commonly associated with approaching parturition, gangrenous mastitis, congestive heart failure, infectious equine anemia, and rupture of the urethra caused by obstructive urolithiasis. A grossly enlarged asymmetric swelling of the flank may suggest herniation of the abdominal wall. Ruminal movements can be seen in the left paralumbar fossa and flank of cattle, but a complete examination of the rumen requires auscultation, palpation, and percussion, which are described later.

External Genitalia

Gross enlargements of the preputial sheath or scrotum are usually inflammatory in origin, but varicocele or tumors can also be responsible. Degenerative changes in the testicles may result in a small scrotum. Discharges of pus and blood from the vagina indicate infection of the genitourinary tract.

Mammary Glands

A disproportionate size of the udder suggests acute inflammation, atrophy, or hypertrophy of the gland. These conditions can be differentiated only by further palpation and examination of the milk or secretions.

Limbs

General abnormalities of posture and gait have been described. Symmetry is important, and comparison of the various aspects of pairs of limbs should be used when there is doubt about the significance of an apparent abnormality. Enlargement or distortion of bones, joints, tendons, sheaths, and bursae should be noted as well as any enlargement of peripheral lymph nodes and lymphatic vessels.

CLOSE PHYSICAL EXAMINATION

Some of the techniques used in making a close physical examination are set out in the following sections.

Palpation

Direct palpation with the fingers or indirect palpation with a probe is aimed at determining the size, consistency, temperature, and sensitivity of a lesion or organ. Terms used to describe palpation findings include the following:

- Doughy: When the structure pits on pressure, as in edema
- Firm: When the structure has the consistency of normal liver
- Hard: When the consistency is bonelike
- Fluctuating: When the structure is soft, elastic, and undulates on pressure but does not retain the imprint of the fingers
- Tense: When the structure feels like a viscus distended with gas or fluid under some considerable pressure
- Emphysematous: When the structure is puffy and swollen and moves and crackles under pressure because of the presence of gas in the tissue

Percussion

In percussion, the body surface is struck to set deep parts in vibration and cause them to emit audible sounds. The sounds vary with the density of the parts set in vibration and may be classified as follows:

- Resonant: The sound emitted by organs containing air, e.g., normal lung
- Tympanitic: A drumlike note emitted by an organ containing gas under pressure such as a tympanitic rumen or cecum
- Dull: The sound emitted by solid organs such as heart and liver

Percussion can be performed with the fingers using one hand as a plexor and one as a pleximeter. In large animals a pleximeter hammer on a pleximeter disk is recommended for consistency.

The quality of the sound elicited is governed by a number of factors. The strength of the percussion blow must be kept constant because the sound volume increases with stronger percussion. Allowances must be made for the thickness and consistency of overlying tissues; for example, the thinner the thoracic wall, the more resonant is the lung. Percussion on a rib must not be compared with percussion on an intercostal space. The size and body condition score of the animal are also important considerations. The technique may be relatively ineffective in a fat animal. Pigs and sheep are of a suitable size, but the fatness of the pig and the wool coat of the sheep plus the uncooperative nature of both species make percussion impracticable. In mature cattle and horses the abdominal organs are too large and the overlying tissue too thick for satisfactory outlining of organs or abnormal areas, unless the observer is highly skilled. The lungs of cattle and horses can be satisfactorily examined by percussion, but this requires practice and experience to become skillful and accurate.

Percussion is a valuable aid in the diagnosis of diseases of the lungs and abdominal viscera of all large animals. Increased dullness over the thorax indicates consolidation of the lung, a pleural effusion, or space-occupying lesion such as tumor or abscess. Increased resonance over the thorax suggests emphysema or pneumothorax.

Ballottement

Ballottement is a technique used to detect floating viscera or masses in the abdominal cavity. Using the extended fingers or the clenched fist the abdominal wall is palpated vigorously with a firm push to move the organ or mass away and then allow it to rebound on to the fingertips. Ballottement of a fetus is a typical example; the fetal prominences can be easily felt by pushing the gravid uterus through the abdominal wall over the right flank in pregnant cattle. Impaction of the abomasum, large tumors, and abscesses of the abdominal cavity may also be detected by ballottement. Ballottement and auscultation of the flanks of cattle is also useful to detect fluid-splashing sounds. Their presence on the left side suggests carbohydrate engorgement and excessive quantities of fluid in the rumen or left-side displacement of the abomasum. Over the right flank, fluid-splashing sounds may indicate intestinal obstruction, abomasal volvulus, cecal dilatation and torsion, and paralytic ileus.

Ballottement and auscultation of the abdomen of the horse with colic may elicit fluid-splashing sounds indicative of intestines filled with fluid, as in intestinal obstruction or paralytic ileus. A modification of the method is tactile percussion, when a cavity containing fluid is percussed sharply on one side and the fluid wave thus set up is palpated on the other. The sensation created by the fluid wave is called a fluid thrill. It is felt most acutely by the palm of the hand at the base of the fingers. Diseases that cause ascites and accumulation of fluid in the peritoneal cavity are examples in which this technique is useful.

Auscultation

Direct listening to the sounds produced by organ movement is performed by placing the ear to the body surface over the organ. Indirect auscultation by a stethoscope is the preferred technique. A considerable amount of work has been done to determine the most effective stethoscopic equipment, including investigation of such things as the shape and proportions of bell chest pieces, the thickness of rubber tubes, and the diameter and depth of phonendoscope chest pieces. A comparatively expensive unit from a reputable instrument firm is a wise investment. For large animal work, a stethoscope with interchangeable 5-cm diameter phonendoscope and rubber (to reduce hair friction sounds) bell chest pieces is all that is required. The details of the sounds heard on auscultations of the various organs are described in their respective sections. Auscultation is used routinely to assess heart, lung, and gastrointestinal sounds.

Percussion and Simultaneous Auscultation of the Abdomen

Percussion and simultaneous auscultation of the left and right sides of the abdomen is a useful technique for examination of the abdomen of large animals. The stethoscope is placed over the area to be examined, and the areas around the stethoscope and radiating out from it are percussed. This is a valuable diagnostic aid for the detection and localization of a gas-filled viscus in the abdomen of cattle with left-side displacement of the abomasum, right-side dilatation and volvulus of the abomasum, cecal dilatation and torsion, intestinal tympany associated with acute obstruction or paralytic ileus, or pneumoperitoneum.

Simultaneous percussion and auscultation of the abdomen of the horse with colic is useful to detect pings indicative of intestinal tympany associated with intestinal obstruction or paralytic ileus. In diaphragmatic hernia the presence of gas-filled intestines in the thorax may be determined by this method. To elicit the diagnostic ping, it is necessary to percuss and auscultate side by side and to percuss with a quick, sharp, light, and localized force. The obvious method is a quick tap with a percussion hammer or similar object. Another favored method is a *flick* with the back of a forefinger suddenly released from behind the thumb. A gas-filled viscus gives a characteristic clear, sharp, high-pitched ping, which is distinctly different from the full, low-pitched note of solid or fluid-filled viscera. The difference between the two is so dramatic that it is comparatively easy to define the borders of the gas-filled viscus.

The factors that determine whether a ping will be audible are the force of the percussion and the size of the gas-filled viscus and its proximity to the abdominal wall. The musical quality of the ping is dependent on the thickness of the wall of the viscus (e.g., rumen, abomasum, small or large intestines) and the amount and nature of the fluid and gas in the intestines or viscus.

Succussion

This technique, which involves moving the body from side to side to detect the presence of fluid, is an adaptation of the previously mentioned method. By careful auscultation while the body is moved, free fluid in the intestines or stomach will result in fluid-splashing or tinkling sounds.

Other Techniques

Special physical techniques including biopsy and paracentesis are described under special examination of the various systems to which they apply. With suitable equipment and technique, one of the most valuable adjuncts to a physical examination is a radiographic examination. The size, location, and shape of soft tissue organs are often demonstrable in animals of up to moderate size. Radiology, other than of limbs and neonates, is not commonly practiced in larger animals. Ultrasound appears to have much more general application but is beyond the scope of this book.

SEQUENCE USED IN THE CLOSE PHYSICAL EXAMINATION

The close physical examination should be performed as quietly and gently as possible to avoid disturbing the animal and increasing the resting heart and respiratory rates. At a later stage it may be necessary to examine certain body systems after exercise, but resting measurements should be performed first. If possible the animal should be standing, as recumbency is likely to cause variation in heart and pulse rates, respiration, and other functions.

The sequence used in the close physical examination will vary with the species being examined, the results of the distant examinations, the history obtained, and the diagnostic hypotheses that the clinician has generated. The various parts of the close physical examination that are described here can be modified according to individual circumstances, but it is important to do a thorough clinical examination based on the circumstances.

Following the distant examination, and the particular distant examination, it is recommended that the vital signs are determined before the animal is handled for examination of body regions such as the oral cavity.

Generally, an appropriate sequence for the close physical examination would be as follows:

- Vital signs: Temperature, heart and pulse rates, respirations, and state of hydration
- Thorax: Heart sounds (rate, rhythm, and intensity) and lung sounds
- Abdomen: Nasogastric intubation
- Head and neck: Including eyes, oral cavity, facial structures, and the jugular veins
- Rectal examination
- Urinary tract
- Reproductive tract
- Mammary gland
- Musculoskeletal system
- Nervous system
- Skin: Including ears, hooves, and horns

The important principle is to determine the vital signs before handling and examining other body systems, which may distort the vital signs. The sequence that follows taking the vital signs can vary, based on individual circumstances; the urgency of the case, if any; and the ease of doing the particular examinations. For example, it may be very

Table 1-1 Normal average temperatures with critical points

Species	Normal temperature	Critical point
Horse	38.0°C (100.5°F)	39.0°C (102.0°F)
Cattle	38.5°C (101.5°F)	39.5°C (103.0°F)
Pig	39.0°C (102.0°F)	40.0°C (103.5°F)
Sheep	39.0°C (102.0°F)	40.0°C (104.0°F)
Goat	39.5°C (103.0°F)	40.5°C (105.0°F)

Temperature conversions are approximate.

important to pass a nasogastric tube as one of the first diagnostic techniques in a horse with severe colic associated with gastric distension. When presented with a lactating dairy cow with peracute mastitis, the sequence will be recording the temperature, heart rate and sounds, respirations and status of the lungs, and status of the rumen, followed by careful examination of the mammary gland. The close physical examination of each body region or body systems is outlined in the following sections.

Vital Signs

Temperature

Normally the temperature is taken per rectum. When this is impossible the thermometer should be inserted into the vagina. Ensure that the mercury column is shaken down, moisten the bulb to facilitate entry and, if the anus is flaccid or the rectum full of hard feces, insert a finger also to ensure that the thermometer bulb is held against the mucosa. When the temperature is read immediately after defecation, or if the thermometer is stuck into a ball of feces or is left in the rectum for insufficient time, a false, low reading will result.

As a general rule the thermometer should be left in place for 2 minutes. If there is doubt as to the accuracy of the reading, the temperature should be taken again. The normal average temperature range for the various species at average environmental temperature is shown in Table 1-1.

The reference values in Table 1-1 indicate the average resting temperature for the species and the critical temperature above which hyperthermia can be said to be present. Normal physiologic variations occur in body temperature and are not an indication of disease: a diurnal variation of up to 1°C (2°F) may occur, with the low point in the morning and the peak in the late afternoon. There may be a mild rise of about 0.6°C (1°F) in late pregnancy, but a precipitate, although insignificant, decline just before calving is not uncommon in cows and ewes and lower temperatures than normal occur just before estrus and at ovulation. The degree of change [about 0.3°C (0.6°F)] is unlikely to attract clinical attention.

In sows the body temperature is subnormal before farrowing, and there is a significant rise in body temperature coinciding with parturition. This rise is commonly high enough to exceed the critical temperature of 40°C and may be considered erroneously as evidence of disease. The elevation of temperature that occurs in sows at the time of parturition, of the order of 1°C, is maintained through lactation and disappears at weaning.

High environmental humidity and temperature and exercise will cause elevation of the temperature. The deviation may be as much as 1.6°C (3.0°F) in the case of high environmental temperatures and as much as 2.5 to 3°C (4.5°F) after severe exercise. In horses, after racing, 2 hours may be required before the temperature returns to normal.

If animals that have been acclimatized to cold outside temperatures are brought indoors to a warmer temperature their body temperatures may exceed the critical temperature within 2 to 4 hours. Marked temperature variations are an indication of a pathologic process:

- **Hyperthermia** is the simple elevation of the temperature past the critical point, as in heat stroke
- **Fever** or **pyrexia** is the state in which hyperthermia is combined with toxemia, as in most infectious diseases
- **Hypothermia**, a subnormal body temperature, occurs in shock, circulatory collapse (as in parturient paresis and acute rumen impaction of cattle), hypothyroidism, and just before death in most diseases.

Pulse

The pulse should be taken at the middle coccygeal or facial arteries in cattle, the facial artery in the horse, and the femoral artery in sheep and goats. With careful palpation a number of characters may be determined, including rate, rhythm, amplitude, tone, maximum and minimum pulse pressures, and the form of the arterial pulse. Some of these characters are more properly included in special examination of the circulatory system and are dealt with under that heading.

Rate

The pulse rate is dependent on the heart alone and is not directly affected by changes in the peripheral vascular system. The pulse rate may or may not represent the heart rate; in cases with a pulse deficit, in which some heartbeats do not produce a pulse wave, the rates will differ. Normal resting rates (per minute) for the various species are shown in Table 1-2.

Although there are significant differences in rates between breeds of dairy cow and between high- and low-producing cows, the differences would not be noticeable to a clinician performing a routine examination. In newborn thoroughbred foals the pulse rate is

Table 1-2 Resting pulse rates

Species	Pulse rate per minute
Adult horses	30–40
Foals up to 1 year	70–80
Adult cattle	60–80
Young calves	100–120
Sheep and goats	70–90

30 to 90 beats per minute in the first 5 minutes, then 60 to 200 during the first hour, and then 70 to 130 during the first 48 hours after birth. Draught horses have heart rates slightly higher than those quoted, which are based on a light horse population. The pulse is not readily palpable in the pig but the comparable heart rate is 60 to 100 per minute. The same techniques are used in intensive clinical examinations for horses afflicted with poor performance syndrome.

Bradycardia, or marked slowing of the heartbeat, is unusual unless there is partial or complete heart block, but it does occur in cases of space-occupying lesions of the cranium, in cases of diaphragmatic adhesions after traumatic reticulitis in cattle, or when the rumen is much emptier than normal.

Tachycardia, or increased pulse rate, is common and occurs in most cases of septicemia, toxemia, circulatory failure, and in animals affected by pain and excitement. Counting should be performed over a period of at least 30 seconds.

Rhythm

The rhythm may be regular or irregular. All irregularities must be considered as abnormal except sinus arrhythmia, the phasic irregularity coinciding with the respiratory cycle. There are two components of the rhythm, the time between peaks of pulse waves and the amplitude of the waves. These are usually both irregular at one time with variations in diastolic filling of the heart causing variation in the subsequent stroke volume. Regular irregularities occur with constant periodicity and are usually associated with partial heart block. Irregular irregularities are caused by ventricular extrasystoles or atrial fibrillation. Most of these irregularities, except that caused by atrial fibrillation, disappear with exercise. Their significance lies chiefly in indicating the presence of myocardial disease.

Amplitude

The amplitude of the pulse is determined by the amount of digital pressure required to obliterate the pulse wave. It is largely a measure of cardiac stroke volume and may be considerably increased, as in the *water hammer* pulse of aortic semilunar valve incompetence, or decreased, as in most cases of myocardial weakness.

State of Hydration

The state of hydration is assessed by inspection of the eyes for evidence of dehydration and evaluating the elasticity of the skin. Dehydration is characterized by sunken eyes of varying degrees, and the skin will *tent* when lifted with the fingers and remain tented for varying lengths of time.

EXAMINATION OF BODY REGIONS

After the examination of the temperature, pulse, and respirations the physical examination proceeds with an examination of the various body regions.

Thorax

Examination of the thorax includes palpation, auscultation, and percussion of the cardiac area (precordium) and the lung area. The wide variations between species in the thickness of the thoracic wall, the size of the animal, and the respiratory rate require careful and methodical examination. For example, in the adult horse the thick thoracic wall and the normally slow respiratory rate contribute to an almost soundless respiration on auscultation of the thorax. There is also the need to detect minor pulmonary lesions, which may reduce the work performance of the horse only slightly but, because of the importance of perfect fitness in a racing animal, may have major significance. Another important factor that emphasizes the care that must be taken with the examination of the respiratory system of the horse is the ability of racing animals to compensate for even major pulmonary lesions from their immense functional reserve. Because of this, one is likely to encounter horses with massive pulmonary involvement with little obvious impairment of respiratory function.

Cardiac Area

Auscultation of the heart is aimed at determining the character of normal heart sounds and detecting the presence of abnormal sounds. Optimum auscultation sites are the fourth and fifth intercostal spaces and, because of the heavy shoulder muscles that cover the anterior border of the heart, the use of a flat phonendoscope chest piece pushed under the triceps muscles is necessary. Extension of the forelimb may facilitate auscultation if the animal is quiet. Areas in which the various sounds are heard with maximum intensity are not directly over the anatomic sites of the cardiac orifices, because conduction of the sound through the fluid in the chamber gives optimum auscultation at the point where the fluid is closest to the chest wall.

The first (systolic) sound is heard best over the cardiac apex, and the tricuspid closure is most audible over the right apex and mitral closure over the left apex. The second (diastolic) sound is heard best over the base of the heart, the aortic semilunar closure posteriorly, and the pulmonary semilunar anteriorly, both on the left side.

In auscultation of the heart, the points to be noted are the rate, rhythm, intensity, and quality of sounds and whether abnormal sounds are present. Comparison of the heart and pulse rates will determine whether there is a pulse deficit caused by weak heart contractions failing to cause palpable pulse waves; this is most likely to occur in irregular hearts. Normally the rhythm is in three time and can be described as

LUBB – DUPP – pause,

with the first sound being dull, deep, long, and loud and the second sound sharper and shorter. As the heart rate increases the cycle becomes shortened, mainly at the expense of diastole, and the rhythm assumes a two-time quality. More than two sounds per cycle is classified as a *gallop* rhythm and may be caused by reduplication of either the first or second sounds. Reduplication of the first sound is common in normal cattle, and its significance in other species is discussed in Chapter 10.

The rhythm between successive cycles should be regular except in the normal sinus arrhythmia associated with respiration. With irregularity, there is usually variation in the time intervals between cycles and in the intensity of the sounds—louder sounds coming directly after prolonged pauses and being softer than normal sounds after shortened intervals, as in extrasystolic contractions. The intensity of the heart sounds may vary in two ways, absolutely or relatively: absolutely when the two sounds are louder than normal, and relatively when one sound is increased compared with the other in the cycle. For example, there is increased absolute intensity in anemia and in cardiac hypertrophy.

The intensity of the first sound depends on the force of ventricular contraction and is thus increased in ventricular hypertrophy and decreased in myocardial asthenia. The intensity of the second sound depends on the semilunar closure, i.e., on the arterial blood pressure, and is therefore increased when the blood pressure is high and decreased when the pressure is low.

Abnormal sounds may replace one or both of the normal sounds or may accompany them. The heart sounds are muffled when the pericardial sac is distended with fluid. Sounds that are related to events in the cardiac cycle are murmurs or bruits and are caused mainly by endocardial lesions such as valvular vegetations or adhesions and by insufficiency of closure of valves and by abnormal orifices such as a patent interventricular septum or ductus arteriosus. Interference with normal blood flow causes the development of turbulence with resultant eddying and the creation of murmurs. When attempting to determine the site and type of the lesion it is necessary to identify its time of occurrence in the cardiac cycle: it may be presystolic, systolic, or diastolic, and it is usually necessary to palpate the arterial pulse and auscultate the heart simultaneously to determine accurately the time of occurrence. The site of maximum audibility may indicate the probable site of the lesion, but other observations, including abnormalities of the arterial pulse wave, should be taken into account. In many cases of advanced debility, anemia, and toxemia, soft murmurs can be heard that wax and wane with respiration (hemic murmurs) and are probably caused by myocardial asthenia. In cases of local pressure on the heart by other organs, for example, in diaphragmatic hernia in cattle, loud systolic murmurs may be heard and are probably caused by distortion of the valvular orifices.

Abnormal sounds not related to the cardiac cycle include pericardial friction rubs, which occur with each heart cycle but are not specifically related to either systolic or diastolic sounds. They are more superficial, more distinctly heard than murmurs, and have a to-and-fro character. Local pleuritic friction rubs may be confused with pericardial sounds, especially if respiratory and cardiac rates are equal.

Palpation of the heart beat has real value: the size of the cardiac impulses can be assessed and palpable thrills may on occasion be of more value than auscultation of murmurs. It is best performed with the palm of the hand and should be performed on both sides. An increased cardiac impulse, the movements of the heart against the chest wall during systole, may be easily seen on close inspection of the left precordium and can be felt on both sides. It may be caused by cardiac hypertrophy or dilatation associated with cardiac insufficiency or anemia or to distension of the pericardial sac with edema or inflammatory fluid. Care should be taken not to confuse a readily palpable cardiac impulse caused by cardiac enlargement with one caused by contraction of lung tissue and increased exposure of the heart to the chest wall.

Normally, the heart movements can be felt as distinct systolic and diastolic thumps. These thumps are replaced by thrills when valvular insufficiencies or stenoses or congenital defects are present. When the defects are large the murmur heard on auscultation may not be very loud, but the thrill is readily palpable. Early pericarditis may also produce a friction thrill. The cardiac impulse should be much stronger on the left than the right side and reversal of this situation indicates displacement of the heart to the right side. Caudal or anterior displacement can also occur.

Percussion to determine the boundaries of the heart is of little value in large animal work because of the relatively large size of the heart and lungs and the depth of tissue involved. The area of cardiac dullness is increased in cardiac hypertrophy and

dilatation and decreased when the heart is covered by more than the usual amount of lung, as in pulmonary emphysema. More detailed examination of the heart by electrocardiography, radiographic examination, test puncture, and blood pressure are described under diseases of the heart in Chapter 10.

Lung Area

Auscultation, percussion, and **palpation** are the major methods used for examination of the lungs.

The lung area available for satisfactory auscultation is slightly larger than that available for percussion. The normal breath sounds are heard over most of the lungs, particularly in the middle third anteriorly over the base of the lung, and consist of a soft, sipping VEE–EFF, the latter, softer sound occurring at expiration. The sounds are heard with variable ease depending on the thickness of the chest wall and the amplitude of the respiratory excursion. In well-fleshed horses and fat beef cattle the sounds may not be discernible at rest. The amplitude or loudness of the breath sounds is increased in dyspnea and in early pulmonary congestion and inflammation. The amplitude of the breath sounds is decreased or totally inaudible when there is pleural effusion and in space-occupying lesions in the lung or pleural cavity. Abnormal lung sounds include crackles, wheezes, and pleuritic friction rubs. They are the result of interference with the free movement of air in and out of the lungs, and of the presence of lesions that interfere with the normal movement of the lung creating additional respiratory sounds, which are an indication of disease. The descriptions and interpretations of the normal and abnormal lung sounds, and other respiratory noises, are described in Chapter 12.

The intensity of abnormal lung sounds may be increased and their clarity improved by measuring the rate and depth of respirations with forced mild exercise such as walking for a few minutes followed by immediate auscultation. If exercise is undesirable the occlusion of both nostrils for 30 to 45 seconds will be followed by some deep inspirations and accentuation of abnormal lungs. An alternative maneuver, which is effective in both horses and cattle, is to pull a plastic bag over the muzzle and lower face. When respiratory movements become exaggerated the bag is removed and the lungs auscultated immediately.

Sounds of peristalsis are normally heard over the lung area on the left side in cattle and in horses. In cattle, these sounds are caused by reticular movement and in horses caused by movements of the colon. Their presence is not of much significance in these species unless there are other signs. Also in cattle the sounds of swallowing, eructation, and regurgitation may be confused with peristaltic sounds; ruminal movements and the esophagus should be observed for the passage of gas or a bolus to identify these sounds. Other techniques for examination of the thorax are described in Chapter 12.

Palpation of the thoracic wall may reveal the presence of a pleuritic thrill, bulging of the intercostal spaces when fluid is present in the thoracic cavity, or narrowed intercostal spaces and decreased rib movement over areas of collapsed lung.

Percussion may be done by the usual direct means or indirectly by tracheal percussion when the trachea is tapped gently and the sound is listened for over the lung area. By direct percussion within the intercostal spaces the area of normal lung resonance can be defined and abnormal dullness or resonance detected. Increased dullness may indicate the presence of a space-occupying mass, consolidated lung, edematous lung, or an accumulation of fluid. In a pleural effusion the upper limit of the area of dullness can be determined by percussion and the **fluid line** can be delineated and identified and used to assess the progress of therapy.

An overloud normal percussion note is obtained over tissue containing more air than usual, e.g., emphysematous lung. A definite tympanitic note can be elicited over pneumothorax or a gas-filled viscus penetrating through a diaphragmatic hernia. For percussion to be a satisfactory diagnostic aid, affected areas need to be large with maximum abnormality, and the chest wall must be thin.

Abdomen

Clinical examination of the abdomen includes the following:

- **Visual inspection** of the abdominal contour for evidence of distension or gauntness
- **Auscultation** of the gastrointestinal sounds
- **Palpation** and **percussion** through the abdominal wall
- **Rectal palpation**
- **Passage of the nasogastric tube**
- **Paracentesis** of the abdomen

Auscultation

Auscultation of the abdomen is an essential part of the clinical examination of cattle, horses, and sheep. It is of limited value in pigs. The intestinal or stomach sounds will indicate the nature of the intraluminal contents and the frequency and amplitude of gastrointestinal movements, which are valuable aids in clinical diagnosis. The intensity, duration, and frequency of the sounds should be noted. All these characteristics will be increased in animals that have just eaten or immediately following excitement.

Auscultation of the Rumen of Cattle and Sheep

This is a very useful part of the clinical examination. In normal animals there are one to two primary contractions per minute involving the reticulum and the dorsal and ventral sacs of the rumen; the frequency depends on the amount of time that has elapsed since feeding and the type of food consumed. Secondary contractions of the dorsal and ventral sacs of the rumen occur at about 1 per minute and are commonly associated with eructation. The examination is made in the left paralumbar fossa and a normal sequence of sounds consists of a lift of the flank with a fluid gurgling sound, followed by a second more pronounced lift accompanied by a booming, gassy sound. Auscultation over the lower left ribs will reveal the fainter fluid sounds of reticular contractions just before the contractions of the dorsal and ventral ruminal sacs described earlier. The reticular and ruminal sounds are the predominant abdominal sounds in the normal ruminant.

A grunt, detectable by auscultation over the trachea, may occur during the reticular contraction phase of a primary contraction in cattle with traumatic reticuloperitonitis. The factors that result in a decrease in the intensity and frequency of ruminal sounds are discussed in detail in Chapter 8.

The intestinal sounds that are audible on auscultation of the right flank of cattle and sheep consist of frequent faint gurgling sounds, which are usually difficult to interpret. Contraction of the abomasum and the intestines results in a mixture of sounds that are difficult to distinguish.

Intestinal Sounds of the Horse

These sounds are clearly audible and their assessment is one of the most vital parts of the clinical examination and surveillance of the horse with suspected abdominal disease. Over the right and ventral abdomen there are the loud, booming sounds (borborygmi) of the colon and cecum, which are at peak intensity about every 15 to 20 seconds. Over the left abdomen there are the much fainter rushing fluid sounds of the small intestines. An increase in the intensity and frequency of sounds with a distinct fluid quality are heard in enteritis and loud, almost crackling, sounds in spasmodic colic. In impaction of the large intestine there is a decrease in the intensity and frequency of the borborygmi, and in thromboembolic colic caused by verminous aneurysm and infarction of the colon there may be complete absence of sounds. In intestinal obstruction the intestinal sounds caused by peristalsis are markedly decreased and usually absent, and fluid tinkling sounds occur infrequently. In intestinal stasis in the horse, auscultation in the right flank often detects the tinkling sound of fluid dropping from the ileocecal valve through gas into the dorsal sac of the cecum.

Palpation and Percussion Through the Abdominal Wall

Because of the thickness and weight of the abdominal wall in mature cattle and horses, deep palpation of viscera and organs through the abdominal wall has limited value in these

species compared with its usefulness in small animals. No viscera or organ, with the exception of the fetus, can be palpated with certainty through the abdominal wall in the horse. In cattle, the rumen and its contents can usually be palpated in the left paralumbar fossa. Ruminal distension is usually obvious, whereas an inability to palpate the rumen may be caused by a small, relatively empty rumen or to medial displacement, as in left-side displacement of the abomasum.

Percussion and Simultaneous Auscultation

In left-side displacement of the abomasum, percussion and simultaneous auscultation over the upper third of the costal arch between the 9th and 12th ribs of the left side will elicit the typical high-pitched musical-quality sounds or ping. These may be mistaken for similar sounds present in ruminal atony. A markedly enlarged liver in a cow may be palpable by ballottement immediately behind the right costal arch. Using a combination of palpation, percussion, and simultaneous auscultation over the right paralumbar fossa and caudal to the entire length of the right costal arch, it may be possible to detect any of the following in cattle:

- Dilatation and torsion of the abomasum
- Cecal dilatation and torsion
- Impaction of the abomasum and omasum
- Intestinal obstructions, including torsion of the coiled colon

Percussion and auscultation over viscera that are distended with fluid and gas may be undertaken, and the size and location of the tympanitic area will provide some indication of the viscera likely to be involved.

Tactile Percussion of the Abdomen

This technique aids detection of an excessive quantity of fluid in the peritoneal cavity: ascites caused by a ruptured bladder, transudate in congestive heart failure, and exudate in diffuse peritonitis. A sharp blow is struck on one side of the abdomen and a fluid wave, a *blip* or undulation of the abdominal wall, can be seen and felt on the opposite side of the abdomen. The peritoneal cavity must be about one-third full of fluid before a fluid wave can be elicited.

Abdominal Pain

The location of abdominal pain may be located by deep external palpation of the abdominal wall in cattle. Deep palpation with a firm uniform lift of the closed hand or with the aid of a horizontal bar held by two people under the animal immediately caudal to the xiphoid sternum is a useful aid for the detection of a grunt associated with traumatic reticuloperitonitis in cattle. Superficial pain may be elicited by a firm poke of the hand or extended finger in cattle or horses. In cattle, pain may be elicited over the right costal arch when there are liver lesions or generally over the abdomen in diffuse peritonitis.

The response to palpation of a focus of abdominal pain in cattle is a grunt, which may be clearly audible without the aid of a stethoscope. However, if there is doubt about the audibility of the grunt, the simultaneous auscultation of the trachea will detect a perceptible grunt when the affected area is reached. In calves with abomasal ulceration, a focus of abdominal pain may be present on deep palpation over the area of the abomasum.

In cases of severe abdominal distension (ruminal tympany in cattle and torsion of the large intestine) it is usually impossible to determine, by palpation and percussion, the viscera that are distended. Pneumoperitoneum is rare; thus gross distension of the abdomen is usually caused by distension of viscera with gas, fluid, or ingesta. A combination of rectal examination, passage of a stomach tube, paracentesis, and exploratory laparotomy may be necessary to determine the cause.

The abdomen of pigs is difficult to examine by palpation because pigs are seldom sufficiently quiet or relaxed and the thickness of the abdominal wall limits the extent of deep palpation. In late pregnancy in sows the gravid uterus may be ballotted but it is usually not possible to palpate fetal prominences.

In sheep, the rumen, impacted abomasum, and the gravid uterus are usually palpable through the abdominal wall. Positioning the sheep on its hindquarters will shift the viscera to a more easily palpable position.

Nasogastric Intubation

An important part of the examination of the abdomen and gastrointestinal tract of large animals, especially cattle and horses, is the passage of the nasogastric tube into the rumen of cattle and into the stomach of horses. Gastric reflux occurs commonly in the horse with colic, and it is important to determine whether the stomach is distended with fluid and to relieve it as necessary. This topic is presented in detail in Chapter 7. In cattle, when disease of the rumen is suspected, the nasogastric tube is passed into the rumen to relieve any distension and to obtain a sample of rumen juice for determination of rumen pH and the presence or absence of rumen protozoa.

Head and Neck

Eyes

Any discharge from the eyes should be noted: it may be watery in obstruction of the lacrimal duct, serous in the early stages of inflammation, and purulent in the later stages. Whether the discharge is unilateral or bilateral is of considerable importance. A unilateral discharge may be caused by local inflammation, and a bilateral discharge may denote a systemic disease. Abnormalities of the eyelids include abnormal movement, position, and thickness. Movement may be excessive in painful eye conditions or in cases of nervous irritability including hypomagnesemia, lead poisoning, and encephalitis. The lids may be kept permanently closed when there is pain in the eye or when the eyelids are swollen, for instance, in local edema caused by photosensitization or allergy. The membrana nictitans may be carried across the eye when there is pain in the orbit or in tetanus or encephalitis. There may be tumors on the eyelids.

Examination of the Conjunctiva

This examination is important because it is a good indicator of the state of the peripheral vascular system. The pallor of anemia and the yellow coloration of jaundice may be visible, although they are more readily observed on the oral or vaginal mucosa. Engorgement of the scleral vessels, petechial hemorrhages, edema of the conjunctiva as in gut edema of pigs or congestive heart failure, and dryness caused by acute pain or high fever are all readily observable abnormalities.

Corneal Abnormalities

These include opacity, varying from the faint cloudiness of early keratitis to the solid white of advanced keratitis, often with associated vascularization, ulceration, and scarring. Increased convexity of the cornea is usually caused by increased pressure within the eyeball and may be caused by glaucoma or hypopyon.

Size of the Eyeball

Eyeball size does not usually vary, but protrusion is relatively common and when unilateral is caused by pressure from behind the orbit in most cases. Periorbital lymphoma in cattle, dislocation of the mandible, and periorbital hemorrhage are common causes. Retraction of the eyeballs is a common manifestation of reduction in volume of periorbital tissues, e.g., in starvation when there is disappearance of fat and in dehydration when there is loss of fluids.

Abnormal Eyeball Movements

Abnormal movements occur in nystagmus caused by anoxia or by lesions of the cerebellum or vestibular tracts. In nystagmus there is periodic, involuntary movement with a slow component in one direction and a quick return to the original position. The movement may be horizontal, vertical, or rotatory. In paralysis of the motor nerves to the orbital muscles there is restriction of movement and abnormal position of the eyeball at rest.

Examination of the Deep Structures

Assessment of the deep structures of the eye necessitates an ophthalmoscope but gross abnormalities may be observed by direct vision. Pus in the anterior chamber,

hypopyon, is usually manifested by yellow to white opacity often with a horizontal upper border obscuring the iris. The pupil may be of abnormal shape or abnormal in position caused by adhesions to the cornea or other structures. An abnormal degree of dilatation is an important sign, and unilateral abnormality usually suggests a lesion of the orbit.

Bilateral excessive dilatation (mydriasis) occurs in local lesions of the central nervous system affecting the oculomotor nucleus, or in diffuse lesions including encephalopathies, or in functional disorders such as botulism and anoxia. Peripheral blindness caused by bilateral lesions of the orbits may have a similar effect. Excessive constriction of the pupils (miosis) is unusual unless there has been overdose with organic phosphatic insecticides or parasympathomimetic drugs. Opacity of the lens is readily visible, especially in advanced cases.

Vision Tests

Several tests of vision and of ocular reflexes are easily performed, and when warranted should be done at this stage of the examination. Tests for blindness include the menace reflex and an obstacle test. In the former a blow at the eye is simulated with care being taken not to cause an air current. The objective is to elicit the eye preservation reflex manifested by reflex closure of the eyelids. This does not occur in peripheral or central blindness, and in facial nerve paralysis there may be withdrawal of the head but no eyelid closure. An obstacle test in unfamiliar surroundings should be arranged and the animal's ability to avoid obstacles assessed. The results are often difficult to interpret if the animal is nervous. A similar test for night-blindness (nyctalopia) should be arranged in subdued light, either at dusk or on a moonlit night. Nyctalopia is one of the earliest indications of avitaminosis-A. Total blindness is called amaurosis, and partial blindness is called amblyopia. The pupillary light reflex—closure and dilatation of the iris in response to lightness and darkness—is best tested with a strong flashlight.

Nostrils

Particular attention should be paid to the odor of the nasal breath. There may be a sweet sickly smell of ketosis in cattle or a fetid odor, which may originate from any of a number of sources including gangrenous pneumonia, necrosis in the nasal cavities, or the accumulation of nasal exudate. Odors originating in the respiratory tract are usually constant with each breath and may be unilateral. The sour smell of alimentary tract disturbance is detectable only periodically, coinciding with eructation. Odors originating in the mouth from bad teeth or from necrotic ulcers associated with *Fusobacterium necrophorum* in calves may be smelled on the nasal breath but are stronger on the oral breath.

In certain circumstances it may be important to note the volume of the breath expelled through the nostrils: it may be the only way of determining whether the animal is breathing and, in some cases, of counting the respiratory rate. Variation in volume between nostrils, as felt on the hands, may indicate obstruction or stenosis of one nasal cavity. This can be examined further by closing off the nostrils one at a time; if obstruction is present in one nostril, closure of the other causes severe respiratory embarrassment.

Any nasal discharge should receive special attention and its examination should be performed at the same time as an inspection of the nasal mucosa. Discharges may be restricted to one nostril in a local infection or be bilateral in systemic infection. The color and consistency of the exudate will indicate its source. In the early stages of inflammation the discharge will be a clear, colorless fluid, which later turns to a white to yellow exudate as leukocytes accumulate in it. In Channel Island cattle the color may be a deep orange, especially in allergic rhinitis. A rust or prune juice color indicates blood originating from the lower respiratory tract, as in pneumonia and in equine infectious anemia in the horse. Blood clots derived from the upper respiratory tract or pharynx may be present in large quantities or appear as small flecks. Generally, blood from the upper respiratory tract is unevenly mixed with any discharge, whereas that from the lower tract comes through as an even color.

The consistency of the nasal discharge will vary from watery in the early stages of inflammation, through thick, to cheesy in longstanding cases. Bubbles or foam may be present. When the bubbles are coarse it signifies that the discharge originates in the pharynx or nasal cavities; fine bubbles originate in the lower respiratory tract. In all species, vomiting or regurgitation caused by pharyngitis or esophageal obstruction may be accompanied by the discharge of food material from the nose or the presence of food particles in the nostrils. In some cases the volume of nasal discharge varies from time to time, often increasing when the animal is feeding from the ground, leading to infection of the cranial sinuses.

Inflammation of the nasal mucosa varies from simple hyperemia, as in allergic rhinitis, to diffuse necrosis, as in bovine malignant catarrh and mucosal disease, to deep ulceration as in glanders. In hemorrhagic diseases variations in mucosal color can be observed and petechial hemorrhages may be present.

Mouth

Excessive salivation with ropes of saliva hanging from the mouth and usually accompanied by chewing movements occurs when a foreign body is present in the mouth and also in many forms of inflammation of the oral mucosa or of the tongue. Actinobacillosis of the tongue, foot-and-mouth disease, and mucosal disease are typical examples. Excessive salivation may also occur in diseases of the central nervous system, as in acute lead poisoning in young cattle. Hypersalivation is a characteristic sign in epidemic hyperthermia associated with the mycotoxins of *Acremonium coenophialum* and *Claviceps purpurea* and by the fungus *Rhizoctonia leguminicola* sometimes found on red clover. Dryness of the mouth occurs in dehydration and poisoning with belladonna alkaloids, or when fed high levels of urea.

Abnormalities of the buccal mucosa include local lesions, hemorrhages in purpuric diseases, the discolorations of jaundice and cyanosis, and the pallor of anemia. Care must be taken to define the exact nature of lesions in the mouth, especially in cattle; differentiation between vesicles and erosive and ulcerative lesions is of diagnostic significance in the mucosal diseases of this species.

Teeth

Examination of the teeth for individual defects is a surgical subject, but a general examination of the dentition can yield useful medical information. Delayed eruption and uneven wear may signify mineral deficiency, especially calcium deficiency, in sheep; excessive wear with mottling and pitting of the enamel is suggestive of chronic fluorosis.

Tongue

The tongue may be swollen by local edema or by inflammation as in actinobacillosis of cattle or shrunken and atrophied in postinflammatory or nervous atrophy. Lesions of the lingual mucosa are part of the general buccal mucosal response to injury.

Pharynx

Examination of the pharyngeal region in large animals requires some dexterity and the use of a speculum of appropriate size. The oral cavity and pharynx of calves, lambs, and goat kids is examined by holding the mouth open; depressing the base of the tongue with the fingers or a tongue depressor; and viewing the pharynx, the glottis, and the proximal part of the larynx and arytenoid cartilages. In adult cattle, a metal or Plexiglas cylindrical speculum, 45cm in length and 4cm in diameter, placed in the oral cavity and over the base of the tongue will allow viewing of the pharynx and the larynx. Foreign bodies, diffuse cellulitis, and pharyngeal lymph node enlargement can also be detected this way. The use of a speculum wedged between the upper and lower molar teeth in cattle allows manual exploration and evaluation of lesions of the pharynx and proximal part of the larynx. In the horse, the pharynx cannot be viewed from the oral cavity and manual exploration of the pharynx requires general anesthesia. Endoscopy is a useful method of

examination in this species, and the modern fiberscope has made it possible to visualize lesions in the posterior nares and pharynx–esophagus and larynx–trachea in the standing, conscious horse or ox.

Submaxillary Region

Abnormalities of the submaxillary region that should be noted include enlargement of lymph nodes caused by local foci of infection, subcutaneous edema as part of a general edema, local cellulitis with swelling and pain, and enlargement of salivary glands or guttural pouch distension in the horse. Thyroid gland enlargement is often missed or mistaken for other lesions, but its site, pulsation, and surrounding edema are characteristic.

Neck

The most important part of the examination of the neck of cattle and horses is to determine the state of the jugular veins. Bilateral engorgement of the jugular veins may be caused by obstruction of the veins by compression or constriction or by right-sided congestive heart failure. A jugular pulse of small magnitude moving up the jugular vein about one third of the way up the neck is normal in most animals but it must be differentiated from a transmitted carotid pulse, which is not obliterated by compression of the jugular vein at a lower level. Variations in size of the vein may occur synchronously with deep respiratory movements but bear no relation to the cardiac cycles. When the jugular pulse is associated with each cardiac movement it should be determined whether it is physiologic or pathologic. The physiologic pulse is presystolic and caused by atrial systole and is normal. The pathologic pulse is systolic and occurs simultaneously with the arterial pulse and the first heart sound; it is characteristic of an insufficient tricuspid valve.

Local or general enlargement of the esophagus associated with vomiting or dysphagia occurs in esophageal diverticulum, stenosis and paralysis, and in cardiac obstructions. Passage of a stomach tube or probang can assist in the examination of esophageal abnormalities.

Tracheal auscultation is a useful diagnostic aid. Normally, the sounds that are audible are louder and more distinct than breath sounds audible over the lung. In upper respiratory tract disease, such as laryngitis and tracheitis, the sounds are louder and harsher and may be whistling in the presence of stenosis. Very loud stenotic tracheal sounds are characteristic of calves with tracheal collapse. Abnormal tracheal sounds, regardless of their cause, are usually transferred down the major bronchi and are audible on auscultation over the thorax, primarily during inspiration. They are commonly confused with abnormal lung sounds caused by pneumonia, but in pneumonia the abnormal sounds are usually present both on inspiration and on expiration.

Rectal Examination

Rectal exploration of the abdomen is a vital part of the complete examination of the abdomen of large animals, especially cattle and horses. Abnormalities that are completely unexpected can be present and may be the cause of illness in animals in which no other significant clinical abnormalities were detected on clinical examination. Special care is necessary to avoid injuring the animal and causing it to strain. Suitable lubrication and avoidance of force are the two most important factors. Rectal examination enables observations to be made on the alimentary, urinary, and genital tracts and on the vessels and peritoneum and pelvic structures. The amount and nature of the feces in the rectum should be determined.

Palpable abnormalities of the digestive tract include paralysis and ballooning of the rectum, distension of the loops of the intestine with fluid or gas, the presence of hard masses of ingesta such as in cecal and colonic impactions in the horse, and intestinal obstruction caused by volvulus, intussusception, or strangulation. The detection of tight bands of mesentery leading to displacement segments may be a valuable guide. In cattle, the caudal sacs of the rumen are readily palpable. When the rumen is distended as in bloat or vagus indigestion they may push well into the pelvis or be only just within reach when the rumen is empty. A distended abomasum may be felt in the right half of the abdomen in cases of abomasal torsion and occasionally in vagus indigestion. In healthy animals there is little to feel because of the space occupied by normal intestines. Palpable objects should be carefully examined.

The left kidney in the cow can be felt in the midline and distinct lobulations are evident. In the horse, the caudal pole of the left kidney is easily palpable, but the right kidney is not. There may be abnormalities of size and pain on pressure caused by pyelonephritis, and abnormalities of size caused by hydronephrosis and amyloidosis. The ureters and empty bladder are not normally palpable. A distended bladder or chronic cystitis with thickening of the wall can be felt in the midline at the anterior end of the pelvic cavity. Abnormalities of the bladder and ureters in cattle are also palpable through the ventral aspects of the vagina. Large calculi have a stonelike hardness and are occasionally observed in horses in the same position. Pain with spasmodic jerking of the penis on palpation of the urethra occurs in urinary obstruction caused by small calculi, cystitis, and urethritis. Enlarged, thickened ureters such as occur in pyelonephritis can be felt between the kidney and the bladder.

On the peritoneum and mesentery one may feel the small, grapelike lesions of tuberculosis; the large, irregular, hard masses of fat necrosis; and the enlarged lymph nodes of lymphomatosis. The abdominal aorta is palpable, and in horses the anterior mesenteric artery and some of its branches can be felt. This may be an important examination if a verminous aneurysm is suspected, in which case the vessels are thickened but still pulsate and have an uneven rough surface and may be painful. In horses the caudal edge of the spleen is usually palpable in the left abdomen. During a rectal examination in a horse it is advantageous in some cases to palpate the inguinal ring from inside the abdomen and, by pushing the other hand between the horse's thighs, to palpate the external ring simultaneously. It is then easier to decide whether any abnormal structures are passing through the ring.

Feces and Defecation

Examination of the feces may provide valuable information on the digestive and motor functions of the tract. They should be examined for volume, consistency, form, color, covering, odor, and composition. A note should be made of the frequency and the time taken for material to pass through the tract. Laboratory examinations may be advisable to detect the presence of helminth eggs, occult blood, bile pigments, pathogenic bacteria, or protozoa.

The volume of feces is usually described as scant, normal, or copious but, in certain circumstances, it may be advisable to weigh or measure the daily output. The normal output for each species is as follows:

- Horses: 15 to 20 kg/day
- Cattle: 25 to 45 kg/day
- Pigs: 1 to 2.5 kg/day
- Sheep and goats: 0.5 to 1 kg/day

There is an increased bulk when fed too much fiber or during attacks of diarrhea. The consistency and form of the feces vary with each species and vary widely within a normal range, depending particularly on the nature of the food. Variations in consistency not explainable by changes in the character of the feed may indicate abnormalities of any of the functions of the tract. The consistency is more fluid in diarrhea and less fluid than normal in constipation. The consistency and form of the feces may provide some indication of the location of the dysfunction of the gastrointestinal tract. Generally, large quantities of liquid feces suggest a dysfunction of the small intestine where normally most of the fluid is absorbed. Feces that contain large quantities of undigested feed could suggest overfeeding, incomplete mastication, a digestive enzyme deficiency, or an acute disorder of the small intestine or stomachs. Large quantities of soft feces that contain well-digested ingesta suggest a dysfunction of the large intestine. However, these are only guidelines and are subject to error.

Color of the Feces. This also varies widely with the color of the food, but feces of a

lighter color than normal may be caused by an insufficient secretion of bile or by simple dilution of the pigments, as occurs in diarrhea. The effect of blood on the appearance of feces has already been described. Discoloration by drugs should be considered when the animal is undergoing treatment.

Fecal Odor. This depends largely on the nature of the food eaten, but in severe enteritis the odor is characteristically one of putrefaction.

Composition. The composition of the feces should be noted. In herbivorous animals there is always a proportion of undigested fiber, but excessive amounts suggest incomplete digestion caused by, for example, bad teeth and faulty mastication. Excessively pasty feces are usually associated with a prolonged sojourn in the tract such as occurs in vagal indigestion or abomasal displacement in cattle. Foreign material of diagnostic significance includes sand or gravel, wool, and shreds of mucosa. Mucus is a normal constituent but, in excessive amounts, indicates either chronic inflammation, when it is associated with fluid, copious feces, or constipation when the feces are small in volume and hard. Mucosal shreds or casts always indicate inflammation.

Frequency of Defecation. Frequency and the length of sojourn in the gastrointestinal tract are usually closely allied, and increased frequency and decreased sojourn occur in diarrhea and the reverse in constipation. Most animals defecate eight to 12 times a day but the sojourn varies widely with the species. Omnivores and carnivores with simple stomachs have an alimentary sojourn of 12 to 35 hours, in ruminants it is 2 to 4 days, and in it is horses 1 to 4 days, depending on the type of feed.

Other Observations

Observation of other acts associated with the functions of the alimentary tract may provide information of diagnostic value. Prehension, mastication, swallowing, vomiting, and defecation should be observed and an attempt made to analyze the behavior of the animal when there is evidence of abdominal pain.

Paracentesis of the Abdomen

Paracentesis of the abdomen includes obtaining a sample of peritoneal fluid when peritonitis or inflammation of the serosae of the intestines or other viscera of the abdomen is suspected. Aspiration of fluid from a distended abdominal viscus is also possible and is often a useful aid in the diagnosis (see Chapter 7).

Urinary System

Examination of the urinary tract consists of observations of the **act of urination**, evidence of **difficult** and **painful urination**, **abnormal urine**, collection of urine and urinalysis, and, depending on the species, **palpation** of the **kidneys, bladder, and urethra**. Details of the examination of the urinary tract are presented in Chapter 13.

Reproductive Tract

Examination of the reproductive tract is usually performed at this stage but is not discussed here because it is beyond the scope of this book. In the immediate postpartum period, the vagina, cervix, and uterus should be examined thoroughly for evidence of gross abnormalities such as metritis, retained placenta, and ruptured uterus, which may be the cause of illness not obvious on examination of other body systems.

Mammary Gland

The mammary gland(s) of all species is examined by inspection and palpation of the udder and teats and gross examination of the milk or abnormal secretions of the glands. Details of this examination are presented in Chapter 20.

Musculoskeletal System and Feet

Examination of the musculoskeletal system and feet is necessary when there is lameness, weakness, or recumbency. Inspection of the gait during the walk and trot is used to determine the origin of the lameness. The muscles, joints, ligaments, tendons, and bones are inspected and palpated to determine abnormalities associated with lameness, weakness, or recumbency. The feet are examined by inspection, palpation, and the trimming of hooves in farm animals to identify lesions associated with lameness. Medical imaging is commonly used to define lesions not readily recognizable by routine clinical examination. Details of examination of the musculoskeletal system and feet are presented in Chapter 15.

Nervous System

In routine veterinary practice, veterinarians will commonly include several components of a neurologic examination in a complete clinical examination. Most often a diagnosis and differential diagnosis can be made from consideration of the history and the clinical findings. However, if the diagnosis is uncertain it may be necessary to conduct a complete neurologic examination, which may uncover additional clinical findings necessary to make a diagnosis and give a prognosis.

A complete neurologic examination includes examination of the mental status, head and posture, cranial nerve function, gait and posture, function of the neck and forelimbs, function of the trunk and hindlimbs, palpation of the bony encasement of the central nervous system, examination of cerebrospinal fluid, and medical imaging of the bony skeleton of the head and vertebral column. The details of the neurologic examination are presented in Chapter 14.

Skin Including Ears, Hooves, and Horns

A systematic method for the examination of the skin is necessary to avoid misinterpretation of the lesions. Inspection of the behavior of the animal and of the skin and hair and palpation and smelling of the skin are the most common physical methods used for clinical examination of the skin. The important prerequisites for an adequate examination of the skin are good lighting such as natural light or day-type lamps, clipping the animal's hair when necessary to adequately visualize lesions, magnification of the lesions with a hand lens to improve visualization of the changes, and adequate restraint and positioning of the animal. Palpation can be used to assess the consistency of lesions, the thickness and elasticity of skin, and to determine the presence of pain associated with diseases of the skin.

Close inspection and palpation of the skin and hair coat are necessary to identify and characterize lesions. Magnifying spectacles or an illuminated magnifying glass may prove useful. The dorsal aspect of the body is inspected by viewing it from the rear, as elevated hairs and patchy alopecia may be more obvious from that angle. All parts of the head including the nose, muzzle, and ears are examined. The lateral trunk and the extremities are then examined. The feet of large animals need to be picked up to examine the interdigital clefts and parts of the coronary bands. The skin of the udder and teats of cattle, sheep, goats, and horses must be observed. The ventral aspect of the body is carefully examined using a source of light to illuminate the underside of adult cattle and horses. The external and internal aspects of the ears and the hooves and horns must be examined by inspection and palpation.

Every centimeter of the skin needs to be examined for the presence of lesions in different stages of development. The **visual**, **tactile,** and **olfactory senses** are used to see, feel, and smell the lesions. The presence or absence of some ectoparasites can be determined by direct inspection. For example, lice and ticks of cattle are usually easily visible. The odor of the skin in some diseases may be abnormal; dermatophilosis in cattle is characterized by a foul and musty odor. Parting the hairs with the fingers or by gently blowing them is necessary to evaluate the length of the hair shafts. Broken hairs, changes in hair color, and the accumulation of exudative material on hair shafts are noted. The texture and elasticity of the skin must be assessed by rolling the skin between the fingers. Careful digital palpation of the hair coat which appears normal on visual inspection may reveal underlying lesions such as pustules, which may be covered by the hair coat. In

some cases, tufts of hairs may be seen protruding through an accumulation of exudate. A combination of visual inspection of the wool coat of sheep is done carefully and systematically by parting the wool coat and evaluating the condition of the wool fibers and the underlying skin. The hair coat should not be clipped, groomed, or washed before the lesions have been identified and characterized.

DIAGNOSTIC IMAGING

Use of advanced diagnostic imaging is increasing in large animal practice. Once the domain of university-associated veterinary teaching hospitals, imaging modalities such as digital radiography, computed tomography, fluoroscopy, and sophisticated ultrasonography are increasingly available in ambulatory practice or hospital-based private practices. Magnetic resonance imaging continues to be limited to veterinary teaching hospitals or major private referral hospitals.

Routine ultrasonography is now an accepted part of most large animal practices and is essentially a continuation of the clinical examination usually performed by clinicians rather than imaging specialists. Ultrasonography has developed into a valuable imaging technique in almost all animal species because of the rapid development of technically improved portable units and their potential for use on farms and stables.

The ultrasonographic examination is unique in its animal application because it is a dynamic examination technique with minimal risk to the animal or the sonographer. Ultrasonography is noninvasive and well tolerated in unsedated animals. It enables serial examinations to monitor the progression of an abnormality or response to treatment. Ultrasonography requires skill and experience to make a diagnosis, but this is readily and rapidly obtained by veterinarians. Continuing education courses and workshops are becoming more common and they provide excellent training and the latest concepts. Ultrasonography can be valuable in examining the contents of cavitary lesions, synovial cavities, cysts, or other fluid-filled lesions for the presence of liquid, semisolid, or solid contents and/or effusion. Centesis of synovial cavities or body cavities and biopsy of organs, such as the liver or kidney, are now frequently done as part of the clinical examination. Ultrasonography enables accurate needle placement following ultrasonographic examination of the designated structure, assisting with the measurement of the distance from the skin surface to the structure when, for example, a freehand biopsy technique is to be performed.

During a routine ultrasound examination, real-time B-mode provides information regarding the physical form and structure of tissues, allows subjective assessment of movement such as peristaltic contractions within the intestine, and provides an overview that guides the application of other ultrasound modes. M-mode is now an integral part of echocardiographic examinations.

The benefits of ultrasound as a veterinary diagnostic imaging procedure are numerous. Routine ultrasound examinations have no harmful biological effects. It is a safe procedure for the animal, the operator, and nearby personnel, which allows it to be done in any location without the need for specific safety precautions.

The ability of ultrasound to distinguish fluid from soft tissue and differentiate between soft tissues on the basis of their composition makes it more suited than radiography for examining soft tissue structures. Ultrasonography can often provide information that was previously only available through exploratory laparotomy. Ultrasound is limited by its inability to penetrate gas-filled or bony structures; therefore *acoustic windows* must be found that avoid the interposition of bone or gas between the transducer and the region of interest, although this can often be achieved by judicious positioning of the animal. Transcutaneous examinations in animals can require removal of the hair overlying the region of interest by clipping, because the beam cannot penetrate the air trapped between the hairs, or application of an acoustic coupling material such as gel or 70% alcohol in short-coated animals (horses, foals, cattle, and calves).

Examples of the use of ultrasonography in bovine practice include the diagnosis of gastrointestinal disease, diseases of the mammary gland, thoracic disease, splenic disease, ruptured gallbladder in cows, and the blood flow patterns in the common carotid artery and external jugular vein for cardiac and blood vessel disease.

The use of ultrasonography as a reproductive management aid in dairy cattle practice represents a major advance in understanding their reproductive biology. The literature on veterinary ultrasound equipment, imaging the bovine ovary (ovarian follicles, corpora lutea, and ovarian cysts), the bovine uterus (early pregnancy diagnosis, early embryonic loss, identification of cows carrying twins, and determination of fetal sex), and the diagnostic limitations of ultrasonic imaging has been reviewed. Because nonpregnancy can be established 7 to 14 days earlier after artificial insemination (AI) using ultrasound compared with rectal palpation, nonpregnant cows can be detected earlier and returned to AI service, improving the pregnancy rate through an increased AI service rate.

The use of ultrasonography to examine various body systems is described in a number of chapters in this textbook. Readers are encouraged to consult textbooks dealing with ultrasonography. Short courses and laboratory workshops are now commonplace and readily available and highly recommended. The development of extension education programs to train bovine practitioners is a critical step toward rapid implementation of this technology into the dairy industry.

INTERPRETATION OF LABORATORY DATA

WHY COLLECT LABORATORY DATA?

Collection of a full history and performance of a purposeful physical examination are the most powerful tools available to the veterinarian in determining the nature of an animal's disease and its likely cause, although as noted previously not all of these should be done for every case. However, laboratory data, including results of clinical, biochemical, hematologic, serologic, radiographic, electrocardiographic, ultrasonographic, and other examinations, are often obtained from individual animals or groups of animals. The reasons for collecting paraclinical or laboratory data are to

- Confirm the presence or cause of a disease
- Rule out the presence of a disease
- Assess the severity of a disease
- Predict the clinical course of a disease or to determine a prognosis
- Estimate the likely response to therapy
- Determine the response to therapy or monitor progression of a disease
- Satisfy regulatory requirements
- Determine the disease or immune status of an animal, herd, or flock

Collection of laboratory data should not be viewed as a fishing expedition performed in the hope that "something will turn up." The decision to collect laboratory data should always be made with one or more of the previously listed aims, with the intention that the data collected will answer a particular, clearly stated question. It is very easy, when faced with a sick animal with clinical signs that are not clearly diagnostic or indicative of the organ system involved, to request a "serum biochemical profile" and complete blood count without having a clear idea of the usefulness of the information provided by the results of these tests. Although the

usefulness of these tests in most cases is very clear, the results of the tests are most informative when used to address a particular question, for instance: Does the animal have evidence of kidney disease?

A test should never be performed unless one can anticipate all the likely results and provide a meaningful interpretation for each. Collecting laboratory data for the sake of running a test or as an act of **diagnostic desperation** is wasteful of resources and will not, in all likelihood, contribute to the management of the animal or group of animals. It is more likely that the results of the test will be uninterpretable and will muddy the diagnostic picture.

PROPERTIES OF DIAGNOSTIC TESTS

Reporting of new diagnostic tests or refinement of current tests should be complete to permit the reader to determine the usefulness of the test. Guidelines for determining whether the utility of a diagnostic test is adequately reported are provided as part of the **standard for the reporting of diagnostic accuracy (STARD)** document.[1] The following properties of a test, and of the population to which it is applied, should be known before it is considered to be reliable.

- The test should be developed and validated in the population of interest. Tests developed in one population might not be valid in an animal from another population. For instance, tests developed for use in one species might not be reliable if used in another species.
- The accuracy of the test should be known in the situation in which its use is intended. The test must be able to distinguish between animals with the disease and those that are disease free. This involves knowledge of the sensitivity, specificity of the test, its receiver operating curve characteristics, and likelihood ratios.[2]
- The specificity of the test, i.e., the ability of a positive result of the test to rule in the disease of interest, should be known. Although this is a property of the test that is usually independent of the prevalence of the disease in the population being tested, this might not always be the case.
- The sensitivity of the test, i.e., the ability of a negative result of the test to rule out the disease of interest, should be known. Although this is a property of the test that is usually independent of the prevalence of the disease in the population being tested, this might not always be the case.
- The pretest likelihood of the disease in the population should be known (i.e., the prevalence of the disease in the population of the animal being tested). This permits calculation of posttest odds of the animal having (positive predictive value) or not having (negative predictive value) the disease for which it is being tested.
- The likelihood ratios of the various test results should be known for the population of animals being tested.
- The reliability of the laboratory performing the test should be known. There should be considerable confidence in the quality control of the laboratory such that test results are repeatable and reliable.
- Are the reference ranges (values in animals without the disease or condition of interest) known and with what certainty are they known? The meaning of an abnormal test result should be clear.
- The test should allow the clinician to rule in or rule out one of the differential diagnoses, or markedly influence the likelihood of the presence or absence of the target disorder, in the instance in which a test is being used for diagnostic, as opposed to monitoring or other purposes.
- All test results should be interpretable. In other words, all results should provide information that will be of use in diagnosis or monitoring.

Utility

To be useful, a diagnostic test must be accurate. An accurate test reliably differentiates between normal and diseased animals, contributing to effective management of the animal or its disease. Inaccurate diagnostic tests provide unreliable data, which in the best scenario are useless and in the worst scenario cause mismanagement of the animal or its disease. The diagnostic accuracy of a test should be known before it is used in clinical practice, and a test of unknown diagnostic accuracy should be assumed to be inaccurate until proven otherwise.

The usefulness of a test to a veterinarian depends on a number of factors. First, the test must be accurate, as discussed earlier. Second, it should be technically feasible and reliable, i.e., the test must be readily performed and its characteristics (listed previously) must be known. A test that cannot be readily performed has minimal usefulness, and unreliable tests are inaccurate. For testing of analytes, such as serum biochemical analysis or serology, it is important that the analysis yields results that are accurate and precise. Laboratory tests that are accurate yield results that are the same or very close to the true value of the variable being measured. Precise tests yield results that have very little variability around the expected value. Note that a test can be precise without being accurate, i.e., it has little variability but yields a value different from the actual value. Tests that are inaccurate or are highly variable (have poor precision) are not useful because the results are unreliable.

Third, the test must have diagnostic utility in that the results of the test should enable the veterinarian to make a decision that will affect the subsequent management of the animal or its disease. If the results of the test will not alter the animal's management or treatment of its disease or improve its production or prognosis, then the test has no diagnostic utility and should not be performed. The diagnostic utility depends on the characteristics of the test in the population of animals being tested. The important characteristics, which should be known before the test is widely used, are the sensitivity and specificity of the test and the likelihood ratios associated with the possible results, in the population in which it will be used. That a test has sensitivity and specificity implies that there is a range of values expected in normal animals—the so-called *reference range*.

Reference Range (Interval)

An important aspect of evaluating laboratory data is to decide whether or not the result of a test is consistent with the animal being healthy or diseased. Healthy animals are assumed to have values within a certain range, whereas diseased animals will have values that differ from that expected in a healthy animal. The range of values in healthy animals is often referred to as in the *normal range*, although, because of the statistical connotation of this term, reference range or reference interval is preferred.

The reference range represents the range of values of a test that are expected in a group of healthy animals. Animals with values outside the reference range are at increased risk of having the disease compared with animals with values within the reference range. The actual increase in risk of being diseased depends on the way in which the reference range was determined, the sensitivity and specificity of the test, and the prevalence of the disease in the population from which the animal was selected. Calculation of likelihood ratios, both positive and negative, is a useful means of quantitatively assessing the results of a test provided that the pretest probability (prevalence) of the disease is known.

The reference range for a particular test is usually developed by collecting values from a large number of healthy or *normal* animals and performing a statistical analysis of the values. For variables that have a range of possible values (e.g., serum urea nitrogen concentration), as opposed to being either present or absent (e.g., seropositive or seronegative for antibodies to a disease), the range of values in normal animals will have a characteristic spread. For the range of values of the variable in normal animals, an upper and a lower value are chosen that represent the upper and lower limits of the reference range. These values are usually chosen to include 95% of the values from normal

animals. This can be calculated on the assumption (or after demonstration) that the distribution of values in a population of healthy animals is Gaussian ("normal" distribution) or when transformations of raw data are used to approximate a Gaussian distribution or when nonparametric statistics are used.

Problems With Reference Ranges

There are problems with using the reference range of normal animals to diagnose diseased animals. First, and depending on the statistical methodology used to determine the reference range, approximately 5% of normal animals will have values for the test that are outside the reference range, and these animals can be incorrectly diagnosed as being diseased (**false positive**). Although a 5% false-positive rate is relatively low, the error is compounded when batteries of tests are run at the same time. This is a potentially serious problem when interpreting data from a serum biochemical profile analysis, in which 20 or more analytes are measured simultaneously from one animal. The risk of the value of any one analyte being outside the normal range is only 5%, but when 20 analytes are measured simultaneously the chance of finding one analyte of the 20 with a value outside the reference range is almost 66% ($100(1 - 0.95^{20})$).

This problem can be mitigated in several ways. First, serum biochemical profiles often contain more than one variable that is indicative of a particular disorder. If disease affecting a particular organ system is present, then there should be appropriate changes in all variables indicative of disease in this system. For instance, most serum biochemical profiles measure both serum creatinine and urea nitrogen concentrations. An elevation in the serum urea nitrogen concentration might be indicative of renal disease, but if the serum creatinine concentration is not also increased, then the likelihood of important renal dysfunction is much less than if both analytes were above the reference range. Second, disease can be associated only with marked increases in value of the variable such that unusually low values could be disregarded. For example, a serum creatinine concentration below the reference range is very unlikely to indicate the presence of renal disease, and a serum creatine kinase activity below the reference range has almost no diagnostic value. Third, the extent to which the variable is outside the reference range should be considered. A small difference from the reference range is much less likely to indicate the presence of disease than is a much larger difference—calculation of likelihood ratios is one way of expressing this effect of variables that are markedly abnormal.

Another problem with using the reference range to detect disease is that not all diseased animals will have a value for the variable of interest that is outside the normal range. Some diseased animals will have values of useful variables that are within the reference range and these animals can be falsely diagnosed as not having the disease (**false negative**). This problem can be mitigated by reducing the size of the reference range, although this will increase the false-positive rate, or by measuring other variables that are also useful in detecting the suspected disease. For instance, an animal with liver disease might have a value of the serum activity of a hepatic enzyme that is within the reference range, suggesting the lack of liver disease (a false-negative result, and not uncommon in animals with chronic liver disease). However, the same animal might have marked increases in serum bilirubin and bile acid concentrations, which are findings strongly suggestive of liver disease.

Sensitivity and Specificity

The **sensitivity** of a test is a measure of the test's ability to detect animals that are diseased, and its numerical value represents the proportion of animals with the disease that are detected by the test (Table 1-3). A test with high sensitivity will detect most diseased animals within a population. The specificity of a test is a measure of the test's ability to detect animals that are not diseased, and its numerical value represents the proportion of normal animals detected by the test. A positive result with a highly specific test will rule in the disease in most diseased animals (a low false-positive rate), and a negative result for a test with high sensitivity effectively rules out the disease being tested for (a low false-negative rate).

Sensitivity and specificity are intrinsic properties of the test, and their values are not markedly influenced by the likelihood before the animal is tested that it has the disease for which it is being tested. The ability of a test to detect whether an animal has a particular disease depends on the likelihood that the animal has the disease at the time it is tested (the prevalence of disease in the population from which the animal being tested is drawn) as well as on the sensitivity and specificity of the test. The sensitivity and specificity can be combined to produce a single number, which is called the likelihood ratio.

Likelihood Ratio

The likelihood ratio is an overall measure of the efficiency of the diagnostic test, combining both sensitivity and specificity (see Table 1-3) and permitting the calculation of posttest odds of the disease from the pretest odds of disease. The likelihood ratio is a quality of the test and is not influenced in most instances by the prevalence of the disease in the population. The likelihood ratio is useful for quantifying the posttest odds of an animal having the disease. For instance, in hospitalized neonatal foals, a positive stall-side test for failure of transfer of passive immunity has a likelihood ratio of 4.86. A foal with a 50% pretest probability of having the disease that has a positive test (i.e., indicative of lack of passive immunity) therefore has a 81% posttest probability of having the disease.

Positive and Negative Predictive Value

The usefulness of the test depends on animal characteristics, the probability that it has the disease (prevalence) and the intrinsic characteristics of the test. The combined effects on the prevalence of the disease and the sensitivity and specificity of the test can be calculated and are called the **positive predictive value** (PPV) and **negative predictive value** (NPV), respectively. These are important values because they determine the usefulness of the test in detecting diseased or normal animals. The PPV is the likelihood that a positive test is from an animal with the disease. The NPV is the likelihood that a negative test is from an animal that does not have the disease.

Both the PPV and NPV are inextricably linked to the prevalence of the disease in the population being tested. Reports of the PPV and NPV are therefore only useful for populations of animals similar to those in which the values of these variables were determined, especially regarding the prevalence of the disease in the population. The prevalence of the disease can also be viewed as the probability that an animal selected at random from the population has the disease—it is the pretest probability of disease in the animal. For a test of given sensitivity and specificity, the likelihood that a positive test correctly

Table 1-3 Method for determining sensitivity, specificity, likelihood ratio for positive and negative tests, positive predictive value, and negative predictive value of a test

True disease status	Disease present	Disease absent
Test positive	True positive (TP)	False positive (FP)
Test negative	False negative (FN)	True negative (TN)

Sensitivity = (TP/[TP + FN]) × 100
Specificity = (TN/[FP + TN]) × 100
Likelihood ratio positive test = Sensitivity/(1 − Specificity)
Likelihood ratio negative test = Specificity/(1 − Sensitivity)
Positive predictive value = TP/(TP + FP)
Negative predictive value = TN/(TN + FN)

predicts the presence of disease (the PPV) increases as the proportion of diseased animals in the population increases (the disease has higher prevalence). Conversely, the NPV increases as the prevalence of the disease decreases.

The effect of changes in prevalence on the PPV and NPV of two tests with differing sensitivities and specificities is illustrated in Table 1-4 and Fig. 1-2. The probability that either test will detect the presence of disease in an animal with a high pretest likelihood of having the disease is very high. Similarly, the probability that a negative result is indicative of the absence of disease in an animal from a population with very low prevalence of disease is also very high. Importantly, the ability of a very good test (sensitivity and specificity both 95%) to correctly predict the presence of disease in an animal with a positive test from a population with a low prevalence (1% of animals affected) of the disease is very poor. Applied to an individual animal, this means that even a very good test is more likely to yield an incorrect result than a correct result in an animal that is unlikely to have the disease.

Conversely, a positive result in an animal with a very high pretest probability of having the disease yields little further information; in other words, the test is inefficient in that it adds little additional information. The test result does not increase the likelihood of the animal having the disease by a clinically useful margin. The diagnostic test has its greatest utility when the pretest probability of disease is approximately 50% and the increase in PPV and NPV is much greater for a test with higher sensitivity and specificity.

The pretest probability of disease, and thus the positive predictive value of the test, can be increased by selecting animals to be tested through careful physical examination and collection of an appropriate history. The PPV of a test in an animal that has signs of the disease it is being tested for is much higher than the PPV of a test in an animal without signs of the disease. Testing clinically normal animals is more likely to yield false-positive than true-positive results, and such indiscriminate testing is not wise.

Table 1-4 Effect of changes in prevalence (pretest probability of disease) on the positive predictive value and negative predictive value of tests with 95% sensitivity and specificity (Test A) and 60% sensitivity and specificity (Test B)

Prevalence or pretest probability of disease (%)	Test A PPV (%)	NPV (%)	Test B PPV (%)	NPV (%)
1	17	99	1	99
10	67	99	14	92
25	85	98	33	82
50	95	96	60	60
75	98	86	83	31
90	99	65	94	12
99	99	19	99	1

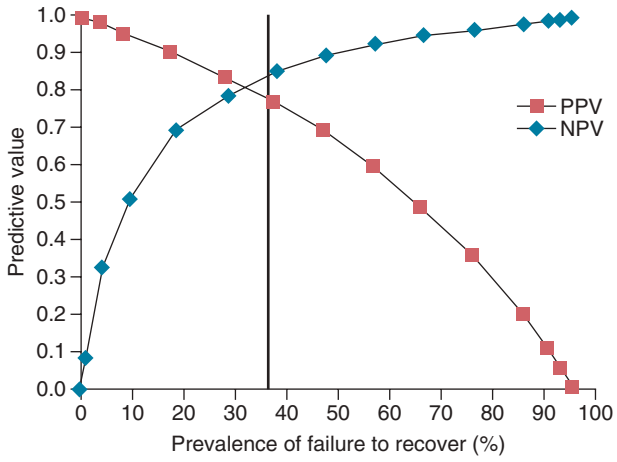

Fig. 1-2 Effect of prevalence on positive and negative predictive values of a test with set sensitivity and specificity. The prevalence in this example is prevalence of failure to recover by recumbent cows (i.e., to stand), and the curves represent the consequent NPV and PPV for a serum aspartate aminotransferase activity of 171 U/L. COMPUTER-ASSISTED DIAGNOSIS

In the 1980s there was considerable interest in computer-assisted diagnosis. The entry of the clinical and laboratory data from an animal into a computer program could yield a differential diagnosis list of diseases in order of highest to lowest probability. However, despite over 30 years of activity and interest in the use of computers for diagnosis, the impact of computer-assisted diagnosis in medical practice has been slight. Computerized programs have been useful in circumscribed areas such as the differential diagnosis of abdominal pain in humans and the diagnosis and treatment of meningitis. However, no program developed for use in a specific localized area of the body has been successfully adapted for generalized use. Theoretically, the computer could be expected to be useful to aid the clinician with the workup to make multiple and complex diagnoses.

Research on clinical decision making has confirmed the importance of creating the list of differential diagnoses or diagnostic hypotheses. A clinician faced with a diagnostic problem must use clinical findings to develop a list of possible diagnoses. With knowledge of the epidemiologic and clinical characteristics of each disease, the veterinarian can confirm or exclude certain diagnostic possibilities. Diagnostic acumen depends on the ability to recognize the most important clinical abnormalities and to generate a list of differential diagnoses—a task that becomes more efficient with experience.

Specialists can generate many differential diagnoses in a narrow area of expertise, but the breadth of knowledge required in general practice makes it difficult for generalists to keep current on rare or unusual conditions. If a disease is not considered by the clinician faced with a presenting problem, it is frequently overlooked as a possibility and may not be "stumbled-on" during the diagnostic process. This problem is complicated in veterinary education by the common practice of

teaching according to disease entity. All the nosology of a disease is presented in a standard format, but the information must then be used in reverse order in clinical practice: the clinician generates a list of diseases based on the history and clinical findings. Textbooks that feature lists of differential diagnoses for animals with similar clinical findings assist in this task, but rapidly become outdated because of the many major and minor clinical findings that can be associated with a disease. The large storage capacity of computer databases and the ease of access to stored data make the computer useful for handling this sort of information.

The success of a computer-assisted diagnosis will depend first on the clinician determining the important finding or **forceful feature** or **pivot** of the case, which can be useful in separating possible look-alike diseases. The second most important requirement is to know the propensity for a certain clinical finding to occur in a disease syndrome. The algorithm is the center of a computer-aided diagnostic system. Statistical algorithms calculate the most likely diagnosis from explicit statistical analysis of disease probabilities and the frequency of clinical findings in a particular disease. A statistical algorithm is based on the Bayes theorem. The posterior probability that an animal has a given disease can be calculated if one has access to the

- Incidence (prior probability) of the disease
- Probability of a given clinical finding if the animal has the disease
- Probability of the same clinical finding occurring if the animal has the disease

After receiving the data, the computer uses this theory to calculate the likelihood of various diseases. However, a major problem of a Bayesian system is the nonavailability of an order of probabilities of the incidence of diseases and clinical findings associated with them. There is a need in veterinary medicine to generate comprehensive databases from which the probabilities of incidence and clinical finding for each disease can be determined from actual clinical practice.

In spite of these limitations, some progress is being made in the development of computer-assisted diagnosis in veterinary medicine. One computer-assisted diagnostic system for veterinary medicine was developed at the College of Veterinary Medicine, Cornell University, Ithaca, New York. The CONSULTANT program designed by M. E. White and J. Lewkowicz is a web-based program facilitating compilation of differential diagnoses based on presenting signs or by disease.[1]

The data bank contains a description of several thousand diseases of dogs, cats, horses, cattle, sheep, pigs, and goats. For each disease there is a short description including information on diagnostic testing, a list of current references, and a list of the clinical findings that might be present in the disease. The clinician enters one or more of the clinical findings present in an animal. The computer supplies a list of the diseases in which that clinical finding or combination of clinical findings are present. The complete description can be retrieved for any disease in the list of differential diagnoses. A major limitation of the program to date is that the list of differential diagnoses is not in order of probability from highest to lowest. This is because the program does not include the probability of incidence and clinical findings for each disease, information that, as mentioned earlier, is not yet available.

Experience with the Cornell CONSULTANT program has shown that computer-assisted diagnosis is not used in day-to-day management of routine cases but is used primarily when faced with an unusual problem, to provide assurance that a diagnosis was not overlooked. Computerized databases also offer a mechanism for the generalist to search through a complete list of differential diagnoses compiled from the recorded experience of many specialists and kept current as new information is published.

Prognosis and Therapeutic Decision Making

SYSTEMATIC REVIEWS

Decision making, whether for diagnostic, therapeutic, or prognostic purposes, should involve consideration of the evidence contributing to the decision. Evidence-based medicine is the name given the process of using the best available evidence to arrive at a decision regarding health care in animals (or humans). In many instances, this involves consideration of evidence from a number of studies, often with conflicting outcomes and recommendations. This process can be challenging for nonexperts not least because of the difficulty in maintaining familiarity with the scientific literature and more so because of the need for expertise in assessing trial design and quality of scientific reporting.

An increasingly important contribution of evidence-based medicine to veterinary and human medicine is the process of developing and publishing **systematic reviews** (see[1-4] for recent examples). These reviews differ from the more historically common narrative review that systematic reviews explicitly define a specific review question, use methods to reduce bias in the selection and inclusion of studies that address the review question (including a systematic and specified search strategy and selection of studies based on explicit eligibility criteria), an assessment of the risk of bias for included studies, and objectively summarizing the results qualitatively or quantitatively such as by meta-analysis.[5] Detailed guidelines are available for preparing such reviews.[5-12] Systematic reviews provide readers with a transparent report and assessment of the scientific literature addressing a particular well-defined clinical question. The number of these reviews is limited and not all provide unequivocal outcomes or recommendations. An extension of the systematic review is the **GRADE** approach in which evidence is then used to make recommendations (systematic reviews typically provide only an assessment of the quality of evidence and not how or whether it should be used).[13,14]

The dilemma of whether or not to administer a certain drug or perform a certain operation in an animal with or without an established diagnosis, or when the outcome is uncertain, is familiar to veterinarians. Owners of animals with a disease, or merely a minor lesion, expect to receive a reasonably accurate prediction of the outcome and the cost of treatment, but often considerable uncertainty exists about the presence or absence of a certain disease, or its severity, because confirmatory diagnostic information is not available.

The information required for a reasonably accurate prognosis includes the following:

- The expected morbidity and case fatality rates for the disease
- The stage of the disease
- Whether or not a specific treatment or surgical operation is available or possible
- The cost of the treatment

If success is dependent on prolonged and intensive therapy, the high cost can be prohibitive to the owner who might then select euthanasia of the animal as the optimal choice. Veterinarians have an obligation to keep their clients informed about all possible outcomes and the treatment that is deemed necessary and should not hesitate to make clear recommendations regarding the options for treatment or disposal of a case. There are also different levels of outcome, which may affect the prognosis and therapeutic decision making. In the case of breeding animals, mere survival from a disease is insufficient and treatment is often not undertaken if it is unlikely that it will result in complete recovery and return to full breeding capacity. Slaughter for salvage may be the most economical choice. In other cases, e.g., a pleasure horse, the return of sufficient health to permit light work might satisfy the owner.

DECISION ANALYSIS

Veterinarians must routinely make decisions that have economic consequences for the client and the veterinarian. Questions, such

as whether to vaccinate or not, whether to treat an animal or recommend slaughter for salvage value, whether or not to perform surgery, or even which surgical procedure to use to correct a case of left-side displacement of the abomasum, are common. Many of these questions are complex, requiring several successive decisions, and each decision may have more than one outcome. Clinical decisions are not only unavoidable but also must be made under conditions of uncertainty. This uncertainty arises from several sources and includes the following:

- Errors in clinical and laboratory data
- Ambiguity of clinical data and variations in interpretations
- Uncertainty about the relationships between clinical information and presence of disease
- Uncertainty about the effects and costs of treatment
- Uncertainty about the efficacy of control procedures such as vaccination or the medication of feed and water supplies in an attempt to control an infectious disease

The process of selecting a management plan from a range of options involves a mental assessment of the available options and their probable outcomes. Decision analysis provides a framework for handling complex decisions so that they can be more objectively evaluated. Decision analysis is a systematic approach to decision making under conditions of uncertainty. Because the technique can be so useful in sorting out complex questions associated with the treatment and control of disease in individual animals and in herds, it is almost certain to become more commonly used by large-animal practitioners.

Decision analysis involves identifying all available choices and the potential outcomes of each and structuring a model of the decision, usually in the form of a decision tree. Such a tree consists figuratively of nodes, which describe choices and chances and outcomes. The tree is used to represent the strategies available to the veterinarian and to calculate the likelihood that each outcome will occur if a particular strategy is used. A probability value must be assigned to each possible outcome, and the sum of the probabilities assigned to the branches must equal 1.0. Objective estimates of these probabilities may be available from research studies or from a veterinarian's own personal records or it may be necessary to use subjective estimates. The monetary value associated with each possible outcome is then assigned, followed by calculation of the expected value at each node in the tree. At each decision node the value of the branch with the best expected value is chosen and that becomes the expected value for that node. The expected value establishes a basis for the decision. An example of a decision tree without probability values assigned is shown in Fig. 1-3.

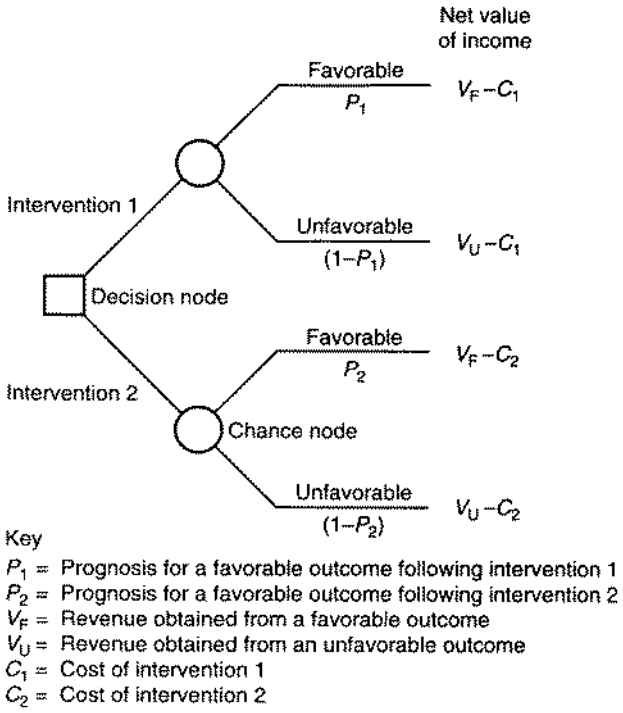

Fig. 1-3 A decision tree for choosing between two interventions. (With permission from Fetrow J et al. *J Am Vet Med Assoc* 1985; 186:792-797.)

In the decision tree, choices such as the decision to use Intervention Number 1 or Intervention Number 2 are represented by squares called **decision nodes**. Chance events, such as favorable or unfavorable outcomes, are represented by circles called **chance nodes**. When several decisions are made in sequence, the decision nodes must be placed from left to right in the same order in which the decisions would have to be made, based on information available at that time. The tree may become very complicated, but the basic units of choice and chance events represented by squares and circles remain the same. Lines, or **branches**, follow each node and lead to the next event. The branches following each decision node must be exhaustive; for example, they must include all possible outcomes, and the outcomes must be mutually exclusive. After each chance node there is a probability that an event occurs. The probabilities following a chance node must add up to 1.0. The probabilities are placed on the tree following the chance node. The expected outcomes (V_F and V_U in Fig. 1-3) are entered at the far right of the tree. The outcomes represent the value that would result if the events preceding them on the tree were to take place and must include the costs of the intervention.

When a complete tree accurately representing the problem has been constructed, the next step is to solve it for the best decision to follow. This is done by starting at the right of the tree, in which outcome values are multiplied by the probabilities of outcome at the preceding chance node. The figures derived from this procedure are added together to obtain the equivalent of a weighted average value at the chance node, known as the **expected value**, which by convention is circled with an oval. This procedure is repeated from right to left on the tree at each chance node. When a decision node is reached when moving from right to left, the most profitable path is chosen and a double bar is drawn across the branches leading to the lesser cost-effective decisions. When the first decision node at the left of the tree is reached, a single path will remain that leads from left to right and has not been blocked by double bars. This path represents the best way to handle the problem according to the available information, including the outcome at the end of that path.

An example of the construction and use of a decision tree to assist in deciding at what day postpartum an ovarian cyst should be treated, as opposed to waiting for spontaneous recovery, is illustrated in Fig. 1-4. In structuring the problem, over time, the clinician knows that the cyst can be treated or left to be treated later. Retreatment is possible if the first treatment is ineffective. The structure must include all alternatives. The other information needed to solve the problem includes the following:

- The incidence or chances of spontaneous recovery
- The response to treatment, both initially and following repeated treatments
- When the response occurs
- The cost of treatment and the cost of the disease

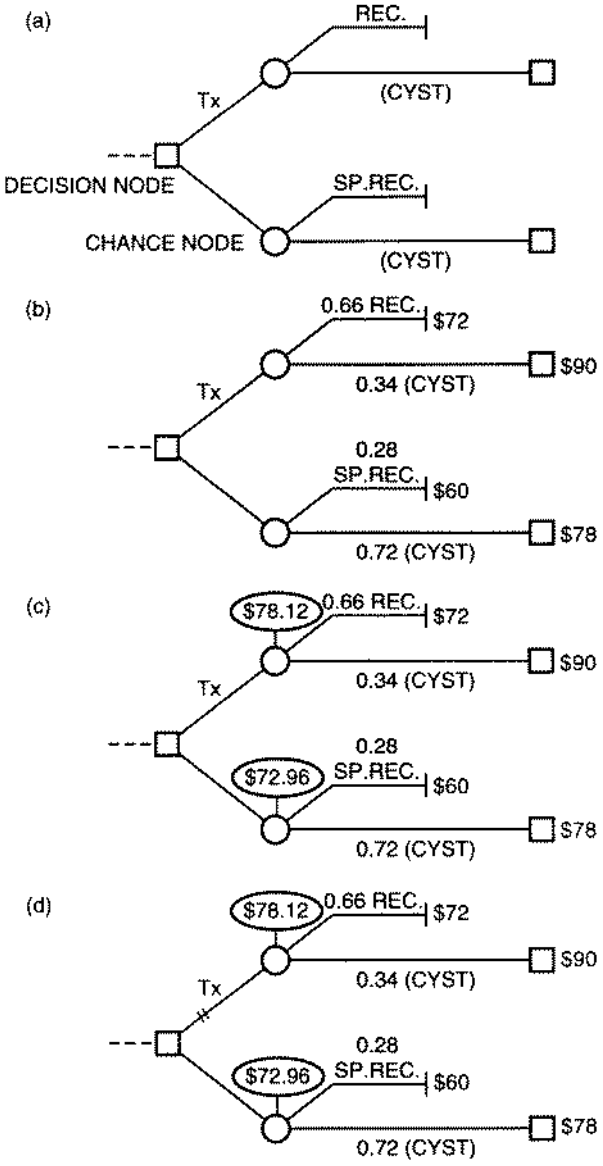

Fig. 1-4 Example of the construction and use of a decision tree. The sources of probabilities and dollar values are discussed in the text. (a) The skeleton of the decision tree with a decision [treat *(Tx)* versus do not treat) and chance outcomes [recovery *(REC)* or spontaneous recovery *(SPREC)* versus continued cyst *(CYST)*]. (b) Probabilities and previously calculated outcome values are placed on the tree. (c) Expected costs of decision alternatives have been calculated and written in balloons above the chance nodes. (d) At this decision node, the correct choice is no treatment because it is cheaper ($72.96 versus $78.12). Double bars mark the pathway that is not chosen (treatment). The value $72.96 is then the outcome cost for this decision node. The value is used in the calculation of the best alternative to the previous decision node, because the process is repeated from right to left (not shown). (With permission from White ME, Erb HN. *Comp Cont Educ Pract Vet* 1982; 4:S426-S430.)

The critical factor in each tree is the probability value for each possible outcome. The monetary value of each outcome can be estimated on a daily basis but, unless the probability of the outcome can be assessed as accurately as possible, the decision analysis will be unreliable. Decision analysis has been used to determine the cost-effectiveness of heat mount detectors, the time at which to treat bovine ovarian cysts, the effectiveness of three alternative approaches to the control of *Haemophilus* meningoencephalitis in feedlot cattle, the economically optimal control strategy among several alternatives for the control of infection with *Brucella ovis* in a sheep flock, and the relative merits of testing or not testing calves entering a feedlot with a metabolic and cellular profile test as predictors of performance in the feedlot. Decision analysis can now be done on a microcomputer, which makes the process highly suitable for assisting the veterinarian in daily decision making.

The details of the steps used in decision analysis of several different problems in food-animal practice have been described, and the reader is referred to the publications for further information. There are some limitations to using decision analysis in animal health programs, and the technique requires time and effort, which practitioners are reluctant to provide unless the benefits are obvious. The estimates of the probabilities associated with the respective branches of the tree are seldom readily available.

A number of techniques that can be used to derive these probabilities and incorporate them in decision making have been recorded. The rapidly developing use of analytical veterinary clinical epidemiology can now provide the tools to generate the numerical data necessary to make reliable decisions. There is a need to apply epidemiologic principles to prospective clinical studies to determine the most effective therapy or the efficacy of control procedures for the commonly occurring economically important diseases of food-producing animals. The inputs and outputs of a given strategy may not have a market value, or the market value may not be an appropriate measure, or they may not be tangible or measurable in the usual monetary units. For example, the market value of a dairy cow may not represent the true or real value of the cow to the farmer. The farmer may consider the value of the cow in relation to cattle replacement determinants such as herd size, the availability of replacements, and the genetic potential of the animal. The final selection of one option or the other is usually a complex process that will also vary from individual to individual depending on the decision criterion used.

In summary, decision analysis provides a systematic framework for making rational decisions about major questions in animal health, and it is hoped that some veterinarians will adopt the technique for field use.

Examination of the Population

2

The examination of the herd or flock assumes importance where there are outbreaks of disease or problems of population productivity caused by subclinical disease. The purpose of a herd examination is to define the exact nature of the problem and to identify those dysfunctions within the herd environment that are associated with its occurrence. The ultimate objective in the examination of a herd is to establish strategies for the treatment, correction, and control of the disease problem at the herd level. This may involve strategies to increase the resistance of the animals or strategies that change adverse factors in the herd environment.

There are a number of ways in which these objectives can be achieved, and they are not mutually exclusive. The methods for examination of the population include the following:

- Initial definition of the problem to be examined
- Clinical examination of individual animals in the population
- Analysis of records of performance and disease
- Examinations of the environment
- Laboratory examination of the animal and nutritional and environmental sampling
- Necropsy examinations of dead or sacrificed animals
- Descriptive and analytical epidemiologic examinations

Methods for correction of the problem include the following:

- Treatment of individual sick animals
- Selective or strategic prophylactic medication of the impacted group (metaphylaxis)
- Immunoprophylaxis
- Alterations to the nutrition, the environment, or the management of the herd or of selected groups within it

One or several of these methodologies may be used in dealing with herd problems depending on the nature of the disease under consideration.

Herd examinations can be expensive, and in clinical settings the depth of investigation must be justified by the degree of economic importance of the problem. Some diseases are well defined, they are easily and definitively recognized by clinical or postmortem examination, their determinants are well established, and there are established effective methods for their control. In these instances a herd examination in a clinical setting would be limited to the initial examinations that establish the diagnosis and to the implementation of corrective strategies.

Other diseases are less well defined. There may be several determinants of their occurrence and, consequently, all facets of the examination methods may be needed to determine the most appropriate method for control. It is for this type of disease that **epidemiologic investigations** are of particular importance and, where there is an economic justification, an in-depth epidemiologic investigation should be considered to determine the appropriate method of intervention.

Approach to Examining the Population

Chapter 1 discussed the approach to clinical examination of the individual animal and the methods for determining the presence of an organ system dysfunction and for reaching a diagnosis as to cause. Basically, these consist of a physical examination to assess the function of each body system coupled with laboratory or other ancillary diagnostic methods and information that can assist in this assessment and in the establishment of cause. In the individual animal, disease is usually diagnosed and classified by the system involved and the inciting agent, for example, pneumonia associated with *Pasteurella multocida* and myopathy caused by a deficiency of selenium. Subsequent treatment is based on this knowledge and usually consists of therapy directed against the cause and therapy aimed at correcting the system dysfunction. The **traditional approach** therefore emphasizes diagnosis and treatment of individual animals, with the **assumption that a healthy individual leads to a healthy herd** because a **herd is composed of individuals**.

The approach to the examination of the herd has a similar logical and systematic approach, but it is obviously expanded beyond the examination of individual animals and involves different systems. It also involves different approaches to the cause of disease. Herd examinations are conducted because there is an outbreak of disease or a problem of production inefficiency. By definition this involves a group or a population of animals. Most outbreaks of this type in groups of animals result from faults or dysfunctions in the complex of interactions that occur within groups of animals and between the groups of animals and their management, environment, and nutrition. Thus the characteristics of the group of animals that are affected become the focus of the examination and the management, environment, and nutrition are the broad systems that are examined in relation to this group of animals. The **integrated animal health and production management program** therefore emphasizes the management system, with the **assumption that an optimized production system leads to a healthy herd**. During the examination of the herd the following questions are asked:

- What is the disease problem present?
- What are the characteristics of the animals involved?
- Why has this group of animals developed the disease?
- Why are they at increased risk in relation to others within the herd?
- What are the factors in their management, nutrition, or other environment that have led to his increased risk?
- What intervention strategies can be used to correct the problem?

A major objective of the examination is to establish a diagnosis of cause. In particular, the objective is to establish a diagnosis of cause that can be altered by an intervention. The diagnosis of cause in a herd disease problem is often different from the diagnosis of cause established in the examination of an individual. Disease occurrence in groups of animals is often multifactorial in cause and the result of the interaction of several risk factors, which may be characteristics of the animals, their environment, or of an inciting agent. In the context of the herd the cause or *etiology* of a disease can be a management fault. In making a diagnosis of cause, the clinician establishes and ranks the major determinants of the problem from among the various risk factors.

EXAMPLES OF MULTIFACTORIAL ETIOLOGY OF A DISEASE

The examination of an individual animal that is representative of a group of young calves with respiratory disease may lead to a diagnosis of pneumonia associated with *P. multocida*. The diagnosis of the cause of the same problem following a herd examination that evaluates the numerous risk factors for pneumonia in calves might include the following:

- Inadequate ventilation in the calf house
- Failure of adequate transfer of colostral immunoglobulins
- Lack of a vaccine program against respiratory pathogens
- Failure to use all in, all out, housing changes
- Presence of a calf that is persistently infected with bovine virus diarrhea
- Most probably, a combination of one or more of these risk factors, plus other additional factors

In making a diagnosis of cause, the clinician establishes and ranks the major determinants of the problem from among the various risk factors. With many diseases one progresses to an examination of cause in the herd using the recognized risk factors for the disease. These risk factors usually have a logical relation to the disease being examined, such as with the previous example of calf pneumonia. With other diseases the logic of these relationships may be less apparent. This occurs particularly with newly developing or recently recognized diseases, in which the pathogenesis of the disease is poorly understood but epidemiologic examinations have established certain relationships that have a causal association. The definition of circumstances of occurrence for a disease can lead to a method of control even though the cause of the disease, in the traditional sense, is not known and the relationship between the inciting or associated circumstance and the disease is obscure. A current example would be the developing recognition of an association between dry cow nutrition in dairy cattle and metabolic and infectious diseases that occur early in lactation.

EXAMPLE OF THE CONTROL OF A DISEASE WITHOUT KNOWLEDGE OF ITS ETIOLOGIC CAUSE

It is now known that facial eczema in sheep is a toxicosis from fungal toxins produced in pastures. However, long before the toxic nature of this disease was fully understood, the epidemiologic circumstances of its occurrence were defined, and it was prevented by removing sheep from pastures at risk for the disease during predicted risk periods.

Problems of disease and production inefficiency encountered in herds can present a considerable challenge in diagnosis and correction. In part this is because disease in groups or herds is commonly multifactorial in cause and, for this reason, when examining the herd all the factors that influence the behavior of a disease in that herd are important. The obvious approach is a quantitative definition of the disease and a quantitative examination of the relative importance of these risk factors. However, this approach can be difficult in practice.

In clinical settings there is usually no difficulty in achieving a quantitative definition of the animals affected and their characteristics. In large, well-recorded herds it is usually possible to conduct a quantitative examination of risk factors if the records contain information that relates to them. In small herds, a quantitative examination of the relative importance of risk factors may be limited by small numbers of animals. Knowledge of risk factors and their relative importance in disease causation is improving with epidemiologic research studies that involve large numbers of animals and several herds. The role of the clinician in the approach to a herd disease problem is to know and to be able to detect these established influences, to be able to quantify them where possible, and to be able to choose which influences are best corrected by intervention from both a practical and an economic standpoint.

Examination Steps

There is no single protocol that can be used for the examination of the herd, because this will depend on the type of disease problem and the type of herd. For example, the methods of examination that would be used in the examination and definition of a problem of ill-thrift in a flock of weaned lambs would be different from those used for a problem of lameness in dairy cattle. Most herd investigations will follow certain broad principles and steps, which are outlined in Fig. 2-1. A given herd examination does not necessarily follow all of these steps and does not necessarily proceed in the exact order given; however, the general principles apply to most investigations.

Step 1: Defining the Abnormality

It is essential first to define the abnormality in either clinical or subclinical terms. This definition must be accurate because this step of the examination determines the focus of the examination and the types of cases that will be included in the examination and analytical procedures. The definition must also address the producer's concerns because they must implement change, and will be reluctant to do so if they feel their concerns have not been addressed. A **case** is defined as an animal or a group of animals that have the characteristics of the disease or a defined deviation from targets of production. With some investigations the problem will have obvious clinical manifestations and the primary definition of cases will be made by clinical examination of affected individuals. With others the primary complaint may be lowered production in the absence of clinical disease. An apparent problem in production efficiency can be found by examining the records. In many herds this will prove to be an immediate major limitation to the investigation because of a lack of sufficient records on reproduction, production, and associated management to define the complaint. In these circumstances the criteria of the production inefficiency considered in the examination will need to be determined and some form of measurement established.

Step 2: Defining the Pattern of Occurrence and Risk Factors

This step of the examination is often conducted in conjunction with Step 1. It defines the characteristics of the animals that are affected in the disease problem and that have been established as cases. It also determines the differences between them, as individuals or as a group, and the nonaffected animals within the herd. These differences may be attributes of the animals themselves or of environmental influences that affect them.

The initial examination is usually directed toward the determination of the characteristics of the animals involved and the **temporal** (when) and **spatial** (where) patterns of the disease. Generally, the information that allows these examinations is collected at the same time and consists of the following factors:

- A listing of the cases that have occurred
- The date when disease was first observed in each case
- The age, breed, and other individual information for each case, which may include information such as source, family association, vaccination history, and previous medication
- Management group membership, which may be pen membership, milking string, pastoral group, and so forth
- Type of ration and nutritional data
- Management and other environmental information relevant to the problem

To compute **risk group analysis** the number of animals present in both sick and well groupings must be recorded as well as any similarities and differences in their management and environment. After the identity of the abnormality has been established, all the available clinical, production, and laboratory data are examined according to the affected subgroups in the herd and according to time occurrence, management differences, nutritional and environmental influences, and factors such as vaccination history.

In most herd examinations the analysis of these data is restricted to a cross-sectional

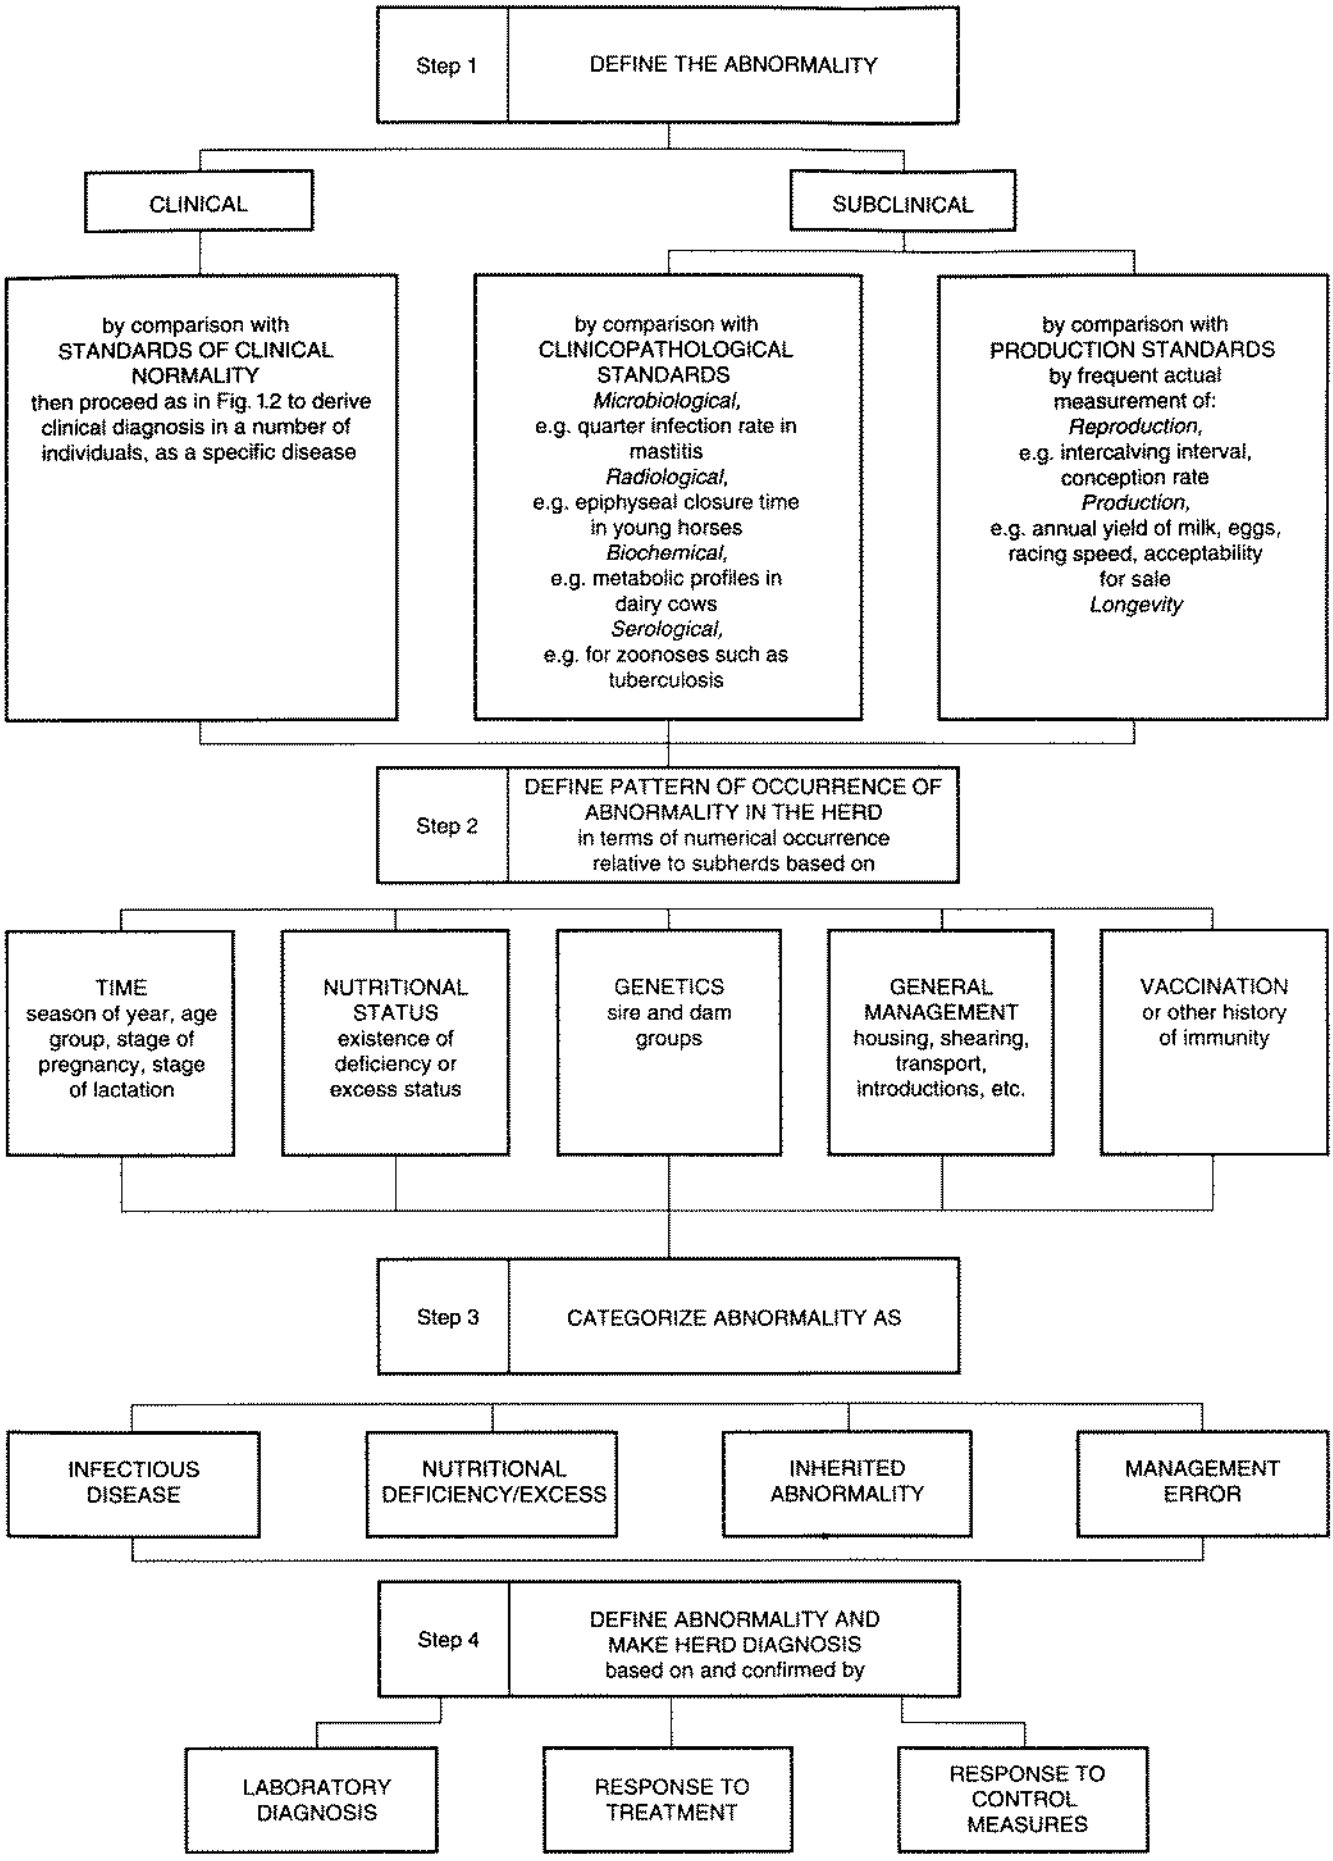

Fig. 2-1 Examination of the herd with the objective of making a diagnosis.

study. Prevalence rates within the various groups are calculated and the population at risk can be determined. Animals or groups can be examined as those with and without disease and those with and without hypothesized risk factors using a 2×2 contingency table generated for each variable. Relative risk, odds ratios, or rate ratios can be calculated as a measure of association of the variable with chi-square and Mantel–Haenszel procedures used for evaluation of the significance of the risk. These procedures attempt to determine whether any associations exist between certain groups of animals and those factors that can influence the behavior of disease.

In some herds, in which there has been extensive historical recording, it may be possible to examine the nature of the problem on the basis of a case-control study. However, in most herds this will not be possible because the factors important for defining the disease problem are less extensively recorded. Because the economic viability of the herd is very important, it may be necessary to establish recording systems that allow a prospective examination of disease problems.

Temporal Pattern

The temporal pattern of distribution of a disease in a population can be important in suggesting the type of disease that is occurring and its possible causes. Temporal recording and graphing of cases is valuable in indicating possible portals of entry of an infectious agent or sources of a toxic influence. For this analysis the temporal occurrence of the disease is determined by the collection and graphing of the time of onset of clinical cases (hours, days, and weeks) and by relating this information to management or environmental changes.

Generally two types of epidemic curves are graphed. A **point source** epidemic curve is characterized by a rapid increase in the number of cases over a short period of time. This type of epidemic curve occurs when all the animals in a population are exposed at one time to a common agent. This may be a toxin or a highly infectious agent, with many animals affected at approximately the same time and, depending on the variation in the incubation period, a sharply rising or a bell-shaped curve of short time duration. The graphing of a sporadic outbreak suggests the occasional introduction of a disease agent into a susceptible population or the sporadic occurrence of factors suitable to the clinical manifestation of an endemic agent, as opposed to the relatively continual occurrence of an endemic disease.

When the infection has to be transferred from animal to animal after undergoing multiplication in each animal, delay results and the epidemic curve develops a flatter bell-shaped occurrence of much longer duration and with varying peaks depending on temporal differences in, and opportunities for, transmission. This is known as a **propagative** epidemic. Although the occurrence and identification of an index case has considerable value in epidemiologic examinations of this nature, it often cannot be identified in veterinary clinical settings.

Spatial Examination

The spatial examination of a disease problem requires gathering information on affected and nonaffected animals relating to housing environment, or pastures, or animal movements. A cluster of cases associated with a specific area may indicate the source of the problem. This is best analyzed by plotting the frequency of cases on maps of the environment that include possible risk factors, such as pen locations within buildings, buildings themselves, water sources, pastures, rubbish dumps, roads, implement storage areas, and so forth. When spatial associations are established, further detailed examination of the location is indicated.

Step 3: Defining the Etiologic Group

Following characterization of the abnormality according to groups within the herd, and having made comparisons of the prevalence rates between groups, it may be possible to discern to which etiologic category the abnormality most logically belongs. In many instances considerable difficulty may be encountered in deciding in which of the general areas of etiology the major determinant is located. In many cases herd problems are not the result of a single error but are multifactorial, with several determinants contributing to a greater or lesser degree, and the problem may fall into several categories.

An example might be a problem of mortality in calves in which examinations have determined that population mortality rates are highest in the winter period, that most mortality occurs between 4 days and 1 month of age, that calves that die early in this period have septicemia or have scours associated with rotavirus and cryptosporidial infections, that the body condition scores of the calves fall during the third and fourth weeks of life, and that calves that die later in the time period appear to die of starvation. Probable causes include improper feeding of colostrum, a poor environment leading to a high infection pressure and possibly also to excess cold exposure, and malnutrition resulting either from the residual effects of enteric disease on intestinal absorption of nutrients or from an inadequate caloric intake or both. This complex could be placed in the categories of infectious disease, nutritional disease, and management error, and further definition is the next step.

The use of **path models** that summarize current knowledge of the causality of the disease under consideration can help in this aspect of the herd examination. Path models specific to the problem at hand can be constructed and can show the interrelationships between various risk factors. These models can give some indication of the dependence of any one factor on the occurrence of another. This information can be used to estimate the relative contributions of the various etiologic categories and to give guidance as to the area where intervention is most likely to be effective.

Step 4: Defining the Specific Etiology

The final step is to select the probable most important determinant or combination of determinants from within one or more of the general areas and to make corrective interventions based on this diagnosis. In many instances the primary cause may be clear, and the correction (alterations in nutrition, alterations in management, vaccination, etc.) can be made at this stage. In other cases further prospective examinations may be conducted for a better definition before an intervention is attempted. In the previous example, failure of transfer of colostral immunoglobulins and inadequate caloric intake would have been suspect or even identified as underlying determinants of the problem. However, with most farm recording systems there is likely to be no available data that would help delineate the specific reasons and the specific management deficiencies that require correction; thus a prospective study to provide these data would need to be established.

It can be very difficult to obtain a clearly defined diagnosis of disease in a herd because of its complexity, but the known important relationships are given for the individual diseases in each chapter. Methods for practical clinical quantitative assessment of the level of management expertise or, more importantly, the intensity with which it is applied, are not available. Consequently, this must be assessed qualitatively for most management practices. Surrogates such as the percentage of cows presented for pregnancy diagnosis but not pregnant, bulk tank somatic count, rates of failure of passive transfer of colostral immunoglobulins, and so forth, can provide some indication.

Techniques in Examination of the Herd or Flock

In the following sections are some of the techniques used in examining a group or herd of animals. Any one or combination of the techniques may be used at the same time, depending on the nature of the problem and the availability of support facilities such as diagnostic laboratories and data analysis laboratories and their cost. Fundamental requirements for success are the veterinarian's communication skills[1] and willingness to collaborate with other animal health professionals,[2] such as agricultural engineers, agricultural economists, nutritionists, crop scientists, and soil scientists.

CLINICAL EXAMINATION

A clinical examination is essential if clinical illness is a feature of the disease, and a representative sample of animals should be examined. The importance of this component of the examination cannot be overemphasized. When there is clinical disease an accurate definition by clinical examination may lead to a diagnosis of a disease with known and specific determinants, and further examination of the herd can focus specifically on these factors. When clinical examination does not lead to a finite definition of the cause of the disease but gives a diagnosis of a disease of multifactorial determinants, the examination will still lead to the identification of risk factors that need to be included in the herd examination.

Recording the findings is important and is greatly assisted by a structured report form so that the same clinical features are recorded for each animal. Often clinically affected animals are enrolled as cases in an investigation on the basis of the presence of certain defined signs or clinical abnormalities, and a recording form aids in this selection. This is especially important when several veterinarians in a practice may be involved in the herd examination over time.

Selection of the animals to be examined is vital. This should not be left to the farmer because that selection may be biased to include the sickest, the thinnest, and the oldest, and not necessarily the animals that are representative of the disease under examination. This is particularly important if a group of animals is to be brought from the farm to a central site for detailed clinical examination as part of the workup of the problem. Strict instructions should be given to the owner to select 10 to 12 animals as a minimum. The groups should include eight sick animals, if possible four advanced and four early cases, and four normal animals as controls. If the situation permits, the inclusion of animals that can be sacrificed for necropsy examination is an advantage. Ideally, unless facilities will not allow it, the clinical examinations should be on the farm and the veterinarian should select the animals for examination.

In outbreaks of disease in which there is mortality, necropsy examination and associated sampling is an extremely valuable investigative and diagnostic tool. Necropsy examination should not be ignored as the primary method of establishing a diagnosis of problems of disease or production inefficiency in larger herds and flocks. With many diseases in swine herds and larger sheep flocks the costs associated with the sacrifice of a few animals for this purpose are far outweighed by the benefits of an early and accurate diagnosis and the ability to intervene quickly with corrective strategies. Even in cattle herds, owners are willing to sacrifice affected cattle if it can facilitate a more accurate definition of their problem. It must also be recognized that some diseases cannot be accurately defined on the basis of their clinical manifestation and epidemiology and a necropsy is required as part of the examination system.

SAMPLING AND LABORATORY TESTING

Laboratory examination is conducted for a number of legitimate reasons. It may be conducted to aid in the establishment of a diagnosis or it may be conducted following the establishment of a diagnosis to aid in the definition of risk factors or in the evaluation or the efficacy of treatment and control strategies.

The validity of laboratory testing in the investigation of disease is only as good as the quality and relevance of the samples submitted. Frequently samples that can be most conveniently obtained are not the best for this purpose, and a **sampling strategy** specifically directed to the question may need to be established.

Laboratory analysis of samples is expensive and should not be undertaken unless there is a specific objective. Before submitting samples for examination the following questions should be asked:

- Is the sampling strategy structured to answer specific questions or is it a random fishing expedition?
- Has a sampling strategy been established that will allow a comparison of animals in the at-risk category with those thought not at risk for the disease or the exposure factor? Is pooling of samples appropriate, and if so, what is the optimal number of samples to be pooled and what impact does pooling have on overall test sensitivity?
- Is there a gold standard for the analysis and its interpretation?
- What information will be gained from the results of the laboratory examination that could not be gained by other examinations or logically inferred without these examinations?
- What are the specific steps to be taken that depend on the results of these examinations, or will the steps be taken regardless of the results?

This type of questioning may limit laboratory examination to situations where it is most cost-effective.

The ideal laboratory test should provide immediate on-farm results and be low cost, widely available, simple to use and interpret, and have appropriate sensitivity and specificity. Six excellent examples of extremely useful laboratory tests are the California Mastitis Test (CMT) for detecting subclinical mastitis on a quarter or cow level, the urine nitroprusside test for detecting subclinical or clinical ketosis, daily milk production on an individual cow and herd level that provides immediate feedback on nutrition and environmental stress, milk fat percentage that provides insight into rumen pH and diet formula, urine pH that provides information on the adequacy of acidogenic diet formulation in the late dry period, and body condition score using morphologic parameters or back-fat thickness determined ultrasonographically. Successful implementation of an integrated animal health and production management program requires more on-farm tests like these, and more validated indices of health based on behavior, such as rumination time per day and activity level based on pedometers.

Laboratory examination of samples taken in association with clinical examination is usually conducted to help establish the presence and severity of organ dysfunction, which generally cannot establish cause. The value and use of laboratory examinations in the assessment of organ function is discussed in the sections in this text that deal with system diseases relevant chapters of this text. Similarly the nature and value of sampling to establish the etiologic association of toxic or infectious agents with disease is discussed under specific disease headings.

Laboratory testing can also be conducted to determine risk and exposure factors. When used for this purpose the sampling strategy must be directed and should be conducted after the preliminary diagnosis has been made. It must be aimed at answering the specific questions listed earlier, otherwise it will be inordinately expensive. An example would be the examination of specific feeds that have been implicated as potential sources for a toxin following the epidemiologic examination and risk factor analysis in a herd in which a specific toxicity was established as the cause of mortality. Without this prior epidemiologic examination a mass sampling of the herd and its environment for the presence of the toxin would be extremely expensive and of limited value.

At the time of the initial farm visit, it is advisable to collect samples that are pertinent to the problem and its differential diagnosis but are not of primary analytical significance in the initial definition of the problem. These can be stored and, depending on the results of initial laboratory examinations, may be discarded or used to further define the problem. Duplicate samples are often desirable so that second thoughts on tests can be accommodated. This is particularly important in serologic work in which hindsight may occur much later and extra samples might be useful when one is attempting a retrospective examination.

In many outbreaks it is usually wise to collect samples from controls that are established specifically to evaluate the problem under investigation. These may be clinically normal animals that have not experienced the suspect exposure factor, animals that are clinically normal but have been exposed and are possibly in an incubation or subclinical stage, and from a third group of clinically affected animals. This system approximates the protocol for the Compton Metabolic

Profile, which is described in detail in Chapter 17.

The other consideration is the number of animals to be included in each sampling group. The sample size required for the detection of an attribute varies with the confidence of detection that is desired and with the size of the population and the prevalence or frequency of the attribute in that population. There can be no set recommendation even for one disease. For example, the sample size required to confirm a diagnosis of copper deficiency in a group of animals with overt clinical deficiency disease will be much smaller than that required to establish a developing deficiency state or the risk for clinical disease in the face of deficient intakes when grazing pasture. Unfortunately, cost severely limits the size of the sample that can be tested in most circumstances, and the small size that is common can place severe restrictions on any meaningful interpretation. The commonly recommended 10 animals or 10% of the group would appear to have little validity in most examinations.

Numerical Assessment of Performance

Productivity indexes can be used as indicators of health; they can also be used to measure response to treatment or control measures. More and more they are used as guides to husbandry and management questions to meet the present-day farmer's concerns with costs and returns. If recording systems are present on the farm they can be invaluable data sources in the investigation of herd problems with disease. Monitors of production efficiency are used extensively in performance or production management veterinary practice and are detailed in texts on that subject in the reference sections.

Intervention Strategies and Response Trials

As the result of a herd examination, a clinician formulates a hypothesis concerning the disease. This may include hypotheses on the population of animals at risk, the determinants of the disease, and the source of the problem and its methods of transmission or propagation. There may be sufficient confidence in these hypotheses that they may result in **intervention strategies** to correct the problem without further analysis. In other outbreaks the hypotheses may be less secure and may require further examination of response trials.

Response trials are often used in an approach to herd disease problems and problems of production inefficiency. They have several purposes: they may be used to establish or confirm a diagnosis, and when used for this purpose it is usually because of the difficulty in confirming the diagnosis by other methods. This may result from the lack of a suitable laboratory test or because the result of the test is supportive for the diagnosis but not confirmatory. Response trials can also be used to determine the degree of intervention that is required and the efficacy of the level of intervention that has been used.

EXAMPLE OF REASON FOR RESPONSE TRIALS

The finding of hypocupremia in a group of poorly growing calves would support a diagnosis of growth retardation caused by copper deficiency but does not confirm it, because calves with normal growth can also be hypocupremic. The only way to confirm the association and the diagnosis is to conduct a response trial with copper treatment as the variable.

AN EXAMPLE OF MONITORING EFFICACY OF INTERVENTIONS

Response trials can be used to determine the degree of intervention required and the efficacy of the level of intervention that has been used. Copper deficiency in grazing calves may occur as a simple deficiency or as a conditioned deficiency. Simple copper deficiency can usually be prevented by a single subcutaneous treatment of copper glycinate and this may protect the calves for several months. On the other hand, a conditioned copper deficiency may require treatment every 4 to 6 weeks.

Some prediction as to the required treatment frequency can be made by pasture element analysis. A response trial with 6-week-interval monitoring of blood copper concentrations and weight gain can monitor the efficacy of the treatment used and allow a corrective intervention, if indicated. In the absence of a treatment response trial, a nonresponse caused by an incorrect decision on treatment frequency could result in discarding the correct diagnosis.

There are many limitations to conducting response trials in clinical situations in private herds, and their structure may not always meet the strict requirements of those conducted in research. It is not always possible to establish a controlled response trial in clinical practice but the efficacy of intervention strategies should still be monitored. The ultimate interest is in whether the disease or production problem is corrected; however, the efficacy of the individual strategies should be specifically monitored where possible. In the earlier example of calf mortality a decision might have been made to change the method of feeding colostrum and to improve the caloric intake of the calves. There can be various ways that either of these changes could be achieved. The overall efficacy of these changes will be determined by improved survival of the calves. However, the efficacy of the colostrum management change in improving passive transfer should be determined specifically by measurements of serum immunoglobulin concentrations in the serum of a proportion of calves and the efficacy of caloric improvement by weight measurements. Should calf mortality drop, these latter measures are of limited value, but if it does not then there are ways to predict whether the failure was caused by misdiagnosis of the problem or poor efficacy of the suggested corrective strategies in correcting their respective target areas.

A diagnosis made on the basis of a response trial is often presumptive, and it has become customary to couch the diagnosis in terms of response to a treatment, for instance, selenium-responsive infertility in sheep. This is not a diagnosis in terms of satisfying the original concepts of Koch's postulates, although it does satisfy the subsequent modifications of these postulates that are now generally accepted and have been based on a broader interpretation of disease causation. In populations of animals, diseases are largely the result of a number of interacting factors of different genres, including management, nutrition, and environmental factors, and interacting with traditional agent-causes of disease, including microbiological and toxic agents. The answer for the practical problem may be most economically derived by finding the cure rather than the cause. This is especially desirable if that course is cost-effective and finding the cause is more expensive than the wastage caused by the disease.

A simple example would be mortality in a group of cattle that followed a change of feed to a more concentrated ration. An epidemiologic examination, including a temporal examination of cause or determinants, might closely link the mortality to the change in ration. This should be sufficient to indicate that the ration should be withdrawn or its method of feeding modified. The alternative approach would be to defer any decision for correction of the problem until the exact problem with the ration was established. This could involve a ration analysis and an examination for unknown toxic components. These examinations would take considerable time, would involve considerable costs, and could give no additional information that would modify the immediate initial intervention strategy.

Role of the Integrated Animal Health and Production Management Program

Properly conducted integrated animal health and production management programs maintain accurate records on all matters of production and health. These are maintained against a background of epidemiologic data, including number of animals in the herd and

numbers of animals in the reproductive cycle segment group or age group that are at risk. In many instances all the data required to effectively diagnose a disease or monitor its prevalence are already in the records of these herds. It does put the veterinarian and the farmer in the position of almost being able to do a herd examination simply by consulting the records. Goal setting and production evaluation are important components of the integrated animal health and production management program and are both highly valued by producers. The approach is detailed in texts on herd health and production medicine, such as those listed in Further Reading.

An important issue yet to be clarified is whether integrated animal health and production programs provide a suitable return on investment for both the producer and veterinarian. Such programs must do more than increase production; they must improve profitability and sustainability of the agricultural enterprise while addressing animal welfare issues. Very few studies have evaluated the economic aspects of integrated animal health and production programs. The first such analysis, conducted by the pioneering preventive medicine program at the University of Melbourne in Australia led by Blood, Morris, and Williamson, concluded that "the dairy health and management program tested in this study represents a highly profitable investment for dairy farmers."[3] Similar detailed studies documenting the return on investment of integrated animal health and production programs in other production systems and countries are scarce. Recent studies from The Netherlands examining dairy farms that participated or did not participate in veterinary herd health management programs failed to identify a beneficial effect of such programs on overall farm efficiency.[4,5]

3 Biosecurity and Infection Control

Definitions and Concepts

Biosecurity has been defined in various ways; one informative definition is "the outcome of all activities undertaken by an entity to preclude the introduction of disease agents into an area that one is trying to protect."[1] Thus biosecurity is the intended result of efforts to protect animals and humans from disease-causing materials of biological origin. Preventing infection of animals by various agents by preventing transmission of infectious agents between animals and the people who contact them is the most common focus of veterinary biosecurity planning. A useful distinction can be made in applying the term biosecurity to efforts intended to prevent introduction of infectious agents onto an operation in which the agents are not present, and the term **biocontainment** to practices intended to minimize transmission of disease-causing agents that are already present. **Biohazard** is a general term for any material of biological origin that may be hazardous to animals or humans that contact the material; biosecurity or biocontainment planning can be aimed at limiting or preventing infection or disease caused by any biohazard. For the sake of brevity, the remainder of this section will focus on biosecurity and biocontainment to prevent infections that cause disease in animals on a single operation (farm, ranch, feedlot, or birthing or rearing facility). The term biosecurity will be used to refer to practices that are relevant to either biosecurity or biocontainment. Readers are referred elsewhere for information on national biosecurity, on biosecurity for veterinary hospitals, and on control of agents that may cause foodborne illness in humans but not animal disease.

Disease caused by infectious agents can have a negative effect on the health, welfare, and productivity of animals; therefore, some degree of attention to biosecurity is likely warranted on any operation in which animals are maintained, either permanently or transiently. However, determination of the exact biosecurity plan that is appropriate for an operation first requires an assessment of the **risks** for infection for animals on the operation in question. In recent years, increased recognition of the possible impact of infectious disease on domestic animal populations has led to the development of risk calculators for certain livestock species or diseases to be used in the assessment of the risk of introduction of specific diseases or infectious diseases in general. Many of these are available online through the World Wide Web. See examples of some websites providing risk calculators in Table 3-1. General information on biosecurity for animal operations can also be found on the World Wide Web, and some examples of sites with useful information are shown in Table 3-2. Like all information accessed via the Web, the qualifications and agenda of the person or group providing biosecurity information should be considered and determined to be trustworthy before the information is used. Generally, information provided by regional or national organizations of animal health experts or animal producers should be reliable.

Determination of the biosecurity plan will require identification of the infectious agents likely to cause important disease in the animals on the operation, and this will depend on the species and geographic

Box 3-1 Diseases or agents that may be appropriate targets for biosecurity planning

Dairy cattle
Bovine herpesvirus-1 (BHV-1)
Bovine leukosis virus (BLV)
Bovine viral diarrhea virus (BVDV)
Brucella abortus (brucellosis)
Leptospirosis
Mastitis: contagious causes
Mycobacterium avium ssp. *paratuberculosis* (Johne's disease)
Mycobacterium bovis (tuberculosis)
Neospora caninum
Salmonella enterica (including numerous serotypes)

Beef cattle
Bovine herpesvirus-1 (BHV-1)
Bovine leukosis virus (BLV)
Bovine viral diarrhea virus (BVDV)
Brucella abortus (brucellosis)
Campylobacter fetus ssp. *venerealis*
Leptospirosis
Mycobacterium bovis (tuberculosis)
Trichomonas foetus

Horses
Equine herpesvirus-1 and -4 (EHV-1 and EHV-4)
Equine infectious anemia virus (EIAV)
Equine influenza virus (EIV)
Salmonella enterica (including numerous serotypes)
Streptococcus equi ssp. *equi* (strangles)

Sheep or goats
Caprine arthritis and encephalitis virus (CAEV)
Corynebacterium pseudotuberculosis (caseous lymphadenitis)
Mycoplasma mycoides ssp. *mycoides* (large colony type)
Ovine progressive pneumonia virus (OPPV)
Scrapie

Swine
Brucella suis
Leptospirosis
Porcine parvovirus
Porcine respiratory and reproductive syndrome virus (PRRSV)
Pseudorabies virus (Aujeszky's disease)
Swine dysentery
Swine influenza virus (SIV)

Some examples of diseases or infectious agents that may be appropriate targets for biosecurity planning, by livestock species. This list is not exhaustive. Other agents or diseases not listed may also be appropriate to target in biosecurity planning.

location of the animals in question as well as the degree to which the operation is *open* (receiving new animals either permanently or transiently from sources outside the operation), because new introductions are an important source of biosecurity risk. Some examples of agents or diseases that may be the focus of animal biosecurity planning are shown in Box 3-1. Development of a biosecurity plan also requires an evaluation of the **cost of biosecurity relative to the cost of the disease** in the absence of biosecurity. Biosecurity measures, particularly when performed properly, cost time and money and can be seen as inconvenient. Time and money are limiting factors on all operations in which animals are maintained, but the degree to which this is true will vary among operations. Lack of information regarding the cost and benefit of biosecurity practices limits the willingness of farmers to undertake biosecurity practices.[2] Thus it is evident that there is no "one size fits all" biosecurity plan that can be applied to all operations; rather, the veterinarian and the owner or manager must work together to define the important infectious disease risks for the operation and then to develop a biosecurity plan that is cost-effective and feasible. On some operations, the manager may elect to undertake efforts to prevent introduction of an infectious agent or to eliminate an agent from the operation; on other operations, the manager may elect to tolerate a level of disease or production loss caused by an agent when exclusion is deemed to be too costly. Although veterinarians must be prepared to defend the welfare of animals by helping producers recognize when a level of disease is inconsistent with animal well-being, they must also recognize that efforts to exclude certain infectious agents may not be financially feasible for some producers. In such cases, biocontainment efforts that minimize disease on the operation, combined with timely identification of affected animals and appropriate treatment, culling, or euthanasia, may be the most appropriate approach to ensuring animal well-being.

A biosecurity plan may be comprehensive, or it may be simple and focused on only a few high-risk areas. To be effective, the biosecurity plan should include a plan for periodic assessment of the efficacy of biosecurity through monitoring and record keeping to identify infection or disease events that should be impacted by the plan. Additionally, communication of the biosecurity plan to all parties involved in animal care, through training and written protocols, is necessary to ensure consistency of biosecurity practices.

Development of a Biosecurity Plan

INITIAL PLANNING

For a given operation, development of a biosecurity plan requires assessment and determination of the following[1]:

WHAT ARE THE INFECTIOUS DISEASE RISKS FOR THE OPERATION?

Are these infectious agents already present on the operation? If so
What are the costs from these agents? Consider treatment expenses, loss associated with animal deaths or early culling, decreased animal value, and decreased animal welfare. For zoonotic agents, costs associated with possible human infection should also be considered.
How or where are these agents transmitted to susceptible animals?
- What measures can be put into place to decrease or stop transmission at these points?
  - What is the likely cost in time and money of implementing these measures?
  - Can these measures be implemented on this operation?
- If introduction of all possible control measures is not feasible, which control measures are likely to have the most impact? Which measures are the most feasible and cost-effective?
  - Can the most impactful and cost-effective subset of control measures be implemented on this operation?

WHAT ARE THE INFECTIOUS DISEASE RISKS FOR THE OPERATION?

For infectious agents *not* currently present on the operation, what is the likelihood of their introduction?
If introduced, what are the likely costs?
How can these infectious agents be introduced to the operation?
- What measures can prevent introduction?
  - What is the likely cost of these measures?
  - Can these measures be implemented on this operation?
- If introduction of all possible control measures is not feasible, which measures are likely to have the most impact? Which measures are the most feasible and cost-effective?
  - Can the most impactful and cost-effective measures be implemented on this operation?

Such an assessment is similar to the Hazard Analysis and Critical Control Point system used to ensure food safety by minimizing the contamination of food by

hazardous materials or agents.[3] Although this list of questions may seem daunting, at least a superficial evaluation of these issues will help to determine whether the cost and inconvenience of biosecurity practices are worthwhile to the producer. The cost of various biosecurity practices have not been thoroughly estimated, and they are likely to vary considerably for different operations based on the local cost and availability of materials and labor and the value of the animals in question. Although some producers may be willing to undertake a thorough economic assessment of the costs and benefits of various biosecurity practices before deciding on a plan, in many cases the assessment will likely depend on rough estimates of the major costs and benefits. The veterinarian and producer should be able to help each other in making these estimates, with each bringing their knowledge and experience to the assessment.

Practices to Aid in Maintaining Biosecurity

TESTING AND/OR ISOLATION OF NEWLY INTRODUCED ANIMALS

Bringing animals from outside sources onto an operation, either permanently or transiently, is an important means by which infectious agents can be introduced into the resident population. Although new introductions may appear healthy at entry, they may manifest signs of disease within days, brought on in part by the stress and exposure to infectious agents that can occur during transport. Animals that have passed through competitions or sales have the added risk of recent exposure to many animals from other sources, amplifying their potential for contact with infectious agents. New introductions may also be chronic shedders of infectious agents, even if they remain persistently healthy in appearance. *Streptococcus equi* ssp. *equi, Mycobacterium avium* ssp. *paratuberculosis,* BVDV, PRRSV, and some serotypes of *Salmonella enterica* are a few examples of transmissible agents that can be shed for weeks to months or years by carrier animals who may appear completely healthy.

It is recognized that isolating new introductions for some time after arrival should help decrease the chance of transmitting infectious agents to the resident population. In spite of this, it has been shown that a minority of cattle and horse producers observe this practice.[4-7] The exact length of time that new introductions should be isolated has not been well defined, and this depends on the agent in question. For diseases with short incubation periods caused by infectious agents that are shed only temporarily, such as many viral respiratory pathogens, a quarantine period of 14 to 28 days is likely adequate to usefully decrease risk of infecting animals in the resident population. For diseases in which agents are shed for several weeks or longer, a quarantine period of a practical length is not likely to be helpful. Ideally, the isolated animals should be housed at a site remote from the resident population; if that is not feasible, then the isolated animals should have no possibility of direct contact with the resident herd, contact with feed or water consumed by the resident animals, or shared airspace. People caring for the newly introduced animals should wear different clothing and footwear than what is worn when caring for the resident herd, and they should clean their hands with antimicrobial soap and water or alcohol-based hand sanitizer after contacting the new introductions or associated materials. Feed troughs, water buckets, tools, and tack used with the new introductions should not be used with animals in the resident population, or they should be cleaned thoroughly and disinfected appropriately before such use.

Testing animals for the presence of infectious agents before introduction, or while they are in isolation after introduction, is one method of decreasing the chance of introducing infectious agents. However, the veterinarian and producer must consider carefully how to use such testing so that it is reliable and cost-effective. It is not likely to be practical or cost-effective to test all new introductions for all infectious agents they could possibly be shedding. Also, the reliability of a test result is related to the sensitivity and specificity of the diagnostic test used as well as the prevalence of disease in the population of animals tested. When testing an individual animal of unknown status to determine whether that individual is infected, the veterinarian is relying on the **positive predictive value** (PPV) and the **negative predictive value** (NPV) of the test being used; that is, the probability that the animal is infected, given a positive test result (PPV), and the probability that the animal is not infected, given a negative test result (NPV). The PPV and NPV of a test are related to the prevalence of disease in the population being tested; when the prevalence of disease is low in a population of animals being tested, the PPV of any test will be lower than the PPV of the same test when it is used to test animals in a population in which the prevalence of disease is high. This is an important point to consider when deciding whether to test new introductions to exclude infectious disease, because a newly introduced animal is usually an animal that has no clinical signs of disease. Such an animal can be thought of as a member of the population of all animals that have no clinical signs of disease, in which the prevalence of any infectious disease is lower than it is in the population of all animals with signs of that disease. (In other words, an animal with no clinical signs of disease is less likely to be infected with an infectious agent than an animal that has signs of disease caused by that agent, generally speaking.) Therefore, the PPV of any diagnostic test run on an animal that appears completely healthy will be lower than the PPV for the same test if it is run on an animal with signs of the disease in question. Thus testing is more likely to give an erroneous result when animals that appear healthy are tested for any infectious disease. However, the degree to which an erroneous result is likely depends on the sensitivity and specificity of the test in question. A highly sensitive test will have a better PPV than a less sensitive test in a population with a low prevalence of disease. Therefore the decision to test new introductions to exclude infectious agents should be based on the reliability of the testing strategy, given the sensitivity and specificity of the test to be used and the likelihood of the disease being present in the animals tested, as well as the cost of testing relative to the cost of introducing the infectious agent in question. Diagnostic specialists at veterinary diagnostic laboratories should be able to give veterinarians information about the sensitivity and specificity of tests they offer to aid them in making such decisions. A helpful review of these points is available for further information.[8]

Another way to help decrease the likelihood of introducing infectious disease with new introductions is to introduce animals only from herds known to be free of disease, if possible. An animal originating from a herd certified to be free of a given infectious disease and transported directly from that herd of origin to the new operation, without contact with any other animals in transit, is less likely to bring that disease onto the new operation than an animal purchased from a herd of unknown status. Although it may not always be possible to obtain accurate and complete information about the presence of infectious diseases on source herds, when that information is available, selecting animals from such herds will help decrease the likelihood of introducing particular diseases. For infections that are not permanent and for which vaccines are available, requiring that animals be vaccinated before introduction should help decrease the chance that they will shed the agent around the time of introduction. For vaccination to be useful in this regard it is important that the animals are vaccinated when they have time to develop protective immunity before shipment. The length of time required varies for different vaccines, but generally the animal should receive an initial vaccine followed by a booster, with the booster occurring no less than 2 weeks before shipment.

CONTROLLING CONTACT BY VISITORS TO THE OPERATION

Visitors to the operation, which includes workers bringing materials (such as feed or fuel) or taking materials to and from the operation (such as manure or carcasses), animal health professionals such as farriers and veterinarians, and those coming to the operation just to observe, can all introduce infectious agents to resident animals. Additionally, employees, family members, and others who are on the operation routinely can introduce infectious agents when they return from visits to outside operations in which animals are maintained. The importance of visitors, vehicles driven by visitors, or visits by workers to outside farms as a source of infectious disease introduction has been shown in multiple research studies.[9-11] Visits by trucks from rendering facilities coming to pick up dead animals are a particularly important risk, because dead animals on these trucks are likely to have been ill and shedding infectious agents before death, leaving their carcasses and the truck transporting them contaminated. Vehicles from outside sites should not be allowed on the operation if possible. In the example of visits by the rendering truck, carcasses should be placed for pick up at a site outside the operation, or at least at a site on the operation that is remote from resident animals. On-site disposal of carcasses is an alternative that removes the need for visits by the rendering truck, but the various methods for carcass disposal also have biosecurity risks that need to be addressed; this has been reviewed in detail.[12]

If visiting vehicles cannot be kept off the operation entirely, they should be directed to drive and park in areas that resident animals are unlikely to contact. If it is not possible to keep visiting vehicles away from resident animals, all parts of the vehicle that contact anything on the operation should be washed and disinfected before entry. However, in one study washing wheels was not protective against introduction of foot-and-mouth disease virus, but parking visitor vehicles away from areas in which animals were housed was protective,[9] suggesting that washing and disinfecting vehicles may not be sufficiently protective. Workers should shower and change their clothes after visiting outside sites and before contacting resident animals. High levels of biosecurity practiced by certain operations mandate that workers or visitors should not come into contact with resident animals for a particular period of time (usually 48 to 72 hours) after visiting other animal operations. Visitor access is best controlled by having all visitors enter the operation through monitored entry points; ideally visitors are met by someone representing the operation to make sure contacts that could introduce infectious disease are prevented or minimized.

CONTROLLING CONTACT BY WILDLIFE, NEIGHBORING LIVESTOCK, AND PETS

Neighboring livestock and wildlife (including birds and rodents) are an important potential source for introducing infectious disease. Multiple research studies have shown that proximity to another farm is an important risk factor for introduction of certain infectious diseases, and this may be caused by direct contact between animals across fences or on shared range; common visits for the delivery or pick up of materials; shared use of equipment; or transmission of infectious agents among farms by wildlife, running water, or wind currents.[10,13,14] Contact with neighboring animals across fence lines or on open range can nullify biosecurity efforts; therefore such contact should be prevented if possible. Pet animals (dogs, cats, or other species) can transmit infectious agents among livestock, so their contact with livestock should be controlled or prevented. Because birds and rodents can shed pathogens such as influenza (birds), *Salmonella,* and *Leptospira* (rodents), access of wild birds, poultry, and rodents to areas in which livestock eat or drink should be prevented. This is done by fencing off areas in which birds may congregate and by undertaking efforts to limit access of wild birds and rodents to feedstuffs and animal-housing areas.

SEPARATING GROUPS OF ANIMALS BASED ON RISK

A useful practice to decrease transmission of infectious agents if they are introduced, or to decrease transmission of agents already present on the operation, is to separate animals into groups based on their likelihood of shedding infectious agents and their susceptibility to infection. For example, sick animals are more likely to be shedding infectious agents than healthy animals, and this is particularly true for sick animals showing signs of acute respiratory disease or acute gastrointestinal disease, especially diarrhea. Therefore sick animals should be housed separately from healthy animals, and designated workers should be assigned to care only for sick animals; or those who care for sick animals should change their clothes and footwear and clean their hands with antimicrobial soap and water afterward. Materials (tools, tack, feed, water, and bedding) from sick animal housing should not be used for healthy animals, unless it is possible to first clean them thoroughly and disinfect them properly.

Neonates and young animals (under 1 year of age) are more likely to be susceptible to infection because of their naive immune status and waning maternal antibody, so these individuals should be separated from sick animals and, ideally, from other older animals who are not sick but who may shed infectious agents inapparently. Pregnant females should not come into contact with juvenile animals (6 months to 2 years of age), because juvenile animals are commonly infected by acute respiratory viruses such as EHV-1 or BHV-1, which can cause disease and possibly induce abortion. Peripartum animals are also at increased risk for shedding infectious agents because the events around parturition can be immunosuppressive; their newborns are also at high risk for infection, especially before they consume colostrum. Thus birthing areas should be separate from areas in which sick animals are kept and separate from juvenile animals that are likely to shed infectious agents. Birthing stalls or pens should also be cleaned and disinfected between uses to minimize the exposure of newborns to infectious agents. Animals that give birth on pasture should not be crowded, and accumulation of mud and manure should be prevented, because these can be sites in which enteric pathogens persist for weeks or months.

It is important not only to prevent direct contact between subpopulations on an operation but also to prevent or limit sharing of airspace, feed, water, and materials between these groups. For example, it has been shown that calves are more likely to develop respiratory disease if they are housed early in life in the same building as adult cows.[15] On dairy farms, feed refused by the lactating cows is sometimes fed to young animals to minimize waste.[16] However, this practice can expose susceptible young animals to infectious agents shed by the lactating cows; therefore, the practice should be avoided, or refused feed should only be fed to older juveniles that will likely have better immunity to any infectious agents in the feed, compared with younger animals. Pasteurization of colostrum and waste milk fed to calves is another practice that can decrease transmission of infectious agents from adult cows to young calves on dairies.

Contact by human caretakers can also be an important means of transmission of infectious agents among subpopulations on an operation. Thus different workers should be assigned to care for different subgroups, if possible. This may be feasible on large operations in which the number of animals justifies the employment of several people. On smaller operations it may instead be necessary to have workers start each day caring for the most susceptible individuals (e.g., young animals and postpartum females) and then moving to the care of more resistant individuals, or those more likely to be shedding infectious agents (e.g., sick animals). This order of care should help decrease the transmission of agents from high-risk animals to animals of high susceptibility. It may be helpful to have coveralls and boots dedicated for wear only in areas in which susceptible and sick animals are housed and to make a hand-cleaning station with water, soap, and

alcohol-based hand sanitizer available. This all makes it easy for workers to minimize the possibility of transmitting infectious agents among subpopulations.

Manure from animals is an important source of many infectious agents, and fecal–oral transmission is a major route of infection. Therefore feed troughs and water tanks should be constructed and situated so they are not inadvertently contaminated with feces from resident animals or wildlife such as birds or rodents. Moreover, equipment used to remove manure and soiled bedding from animal-housing areas should not be also used to transport feed. If the use of shared equipment cannot be avoided, the equipment must be cleaned thoroughly and effectively disinfected before use with feedstuffs.

CLEANING AND DISINFECTION

A helpful review of cleaning and disinfection in the context of animal care is available.[17,18] To summarize briefly, cleaning and disinfection are practices of major importance to biosecurity, but if they are not practiced properly they will not be effective. Protocols for cleaning and disinfection should be established, communicated clearly to people responsible for cleaning and disinfecting, and written and placed where they are easy to reference so people can remind themselves how to complete the protocol correctly. Proper technique for cleaning and disinfection should be made as easy as possible to maximize compliance.

There is no single disinfectant that is appropriate for all uses; therefore, the choice of disinfectant to be used will depend on the site that requires disinfection and the type of infectious agents that must be removed. Also, disinfectants vary in their efficacy against different types of agents. In order of increasing resistance, disinfectants may kill or inactivate enveloped viruses, bacteria (nonmycobacterial agents), fungi, nonenveloped viruses, mycobacteria, bacterial spores, and prions. Many disinfectants are effective against enveloped viruses, but fewer are effective against mycobacteria and bacterial spores, and very few inactivate prions. Some chemicals can remove all infectious agents from a surface (sterilize), whereas others decrease the number of infectious agents of one or more types (disinfect), but they do not sterilize. Chemicals that can be sterilizing are also the most toxic and caustic to humans and animals; therefore, on most operations in which animals are maintained, disinfectants that do not actually sterilize will be used, for reasons of safety. Examples of some commonly used classes of disinfectants with some of their benefits and drawbacks are presented in Table 3-3.

Important principles for effective cleaning and disinfecting include the following:

- Surfaces and items to be disinfected must be completely cleaned with detergent and water before disinfection, because organic material such as manure, nasal secretions, or feed on a surface can inactivate some disinfectants and can prevent any disinfectant from contacting the surface to be disinfected.
- After cleaning, detergent should be rinsed completely from the surface with clean water, because detergent residue can inactivate some disinfectants.
- Porous surfaces (such as unpainted wood) are difficult or impossible to disinfect thoroughly, because infectious agents can persist in microscopic crevices on such surfaces. Surfaces and items used around animals should be made only of smooth plastic, metal, concrete, or completely painted wood. If it is not possible for all surfaces to be made of such materials, they should at least be used consistently around animals that are isolated because of recent introduction or illness to allow for effective disinfection of materials contacting high-risk individuals.
- Dirt floors in animal-housing areas cannot be disinfected, although it is possible to decrease pathogen load with thorough cleaning and scraping of dirt floors. Calcium oxide (lime) is often applied to dirt floors for disinfection, and although this may decrease pathogen numbers, evidence also indicates that lime may prolong survival of anthrax spores.[19] This suggests that lime should not be used in areas in which anthrax is a significant risk.
- Disinfectant must be diluted to the appropriate concentration and applied to the surface for the required contact time for effective disinfection. The label on the container of the disinfectant product will indicate the concentration and contact time that must be used.
- After the appropriate contact time, disinfectant should be rinsed off the disinfected surface with clean water, because many disinfectants can be toxic or can leave an unpleasant taste on

Table 3-3 Examples of some classes of disinfectants with some of their benefits and drawbacks[17,18]

Disinfectant class	Benefits	Drawbacks	Notes
Alcohols	Rapid acting, not very toxic, no residue	Inactivated by organic material	Most appropriate for skin prep and for objects that come in direct contact with patient skin
Aldehydes	Very broad spectrum, including sporicidal	Relatively toxic, carcinogenic	
Biguanides (including chlorhexidine)	Not very toxic, broad antibacterial spectrum but less consistent against viruses	Inactivated by organic material	As for alcohols
Halogen chlorine compounds (including bleach)	Effective against many bacteria including mycobacteria, also viruses and fungi Inexpensive	Inactivated by organic material, some soaps, and sunlight Irritating and corrosive	Appropriate for environmental disinfection of clean surfaces
Iodophors	Effective against many bacteria including mycobacteria, also viruses and fungi Rapid acting, not very toxic	Inactivated by organic material, not inexpensive, may stain tissues or materials	Products for skin prep are not appropriate for disinfection of objects or surfaces
Quaternary ammonium compounds	Antimicrobial spectrum of different formulations variable, not effective against nonenveloped viruses	Inactivated by organic material and some soaps	
Phenols	Broad antimicrobial spectrum including many nonenveloped viruses, retain activity in the presence of organic material	Inactivated by some detergents, toxic to some animals	Avoid using on surfaces used to deliver milk, water, or food
Oxidizing agents (hydrogen peroxide based or peroxygen compounds)	Broad antimicrobial spectrum including many nonenveloped viruses and some spores, relatively nontoxic, retain activity in the presence of organic material	Can be corrosive to materials	Some products: good choice for footbaths because of prolonged stability efficacy in the presence of organic matter

items used to deliver water, milk, or food. Disinfectants can also be irritating if they come into contact with human or animal skin, and they can be corrosive to surfaces of buildings and tools.

Note that disinfectants are required to be labeled with detailed information regarding their chemical class, the infectious agents against which the product is effective, and the directions for effective use, including the concentration at which the product must be used and the required contact time for disinfection. People devising cleaning and disinfection protocols should read the label on the disinfectants they use to ensure that the protocol is consistent with the product label and to ensure effective disinfection.

Footbaths containing disinfectant are often used on operations so that caretakers can step into a footbath to disinfect their footwear when moving between areas of animal housing in which transmission of infectious agents is likely. The evidence supporting footbath efficacy is mixed; footbaths have been shown to be associated with decreased risk of introduction of infectious agents in some research studies but not in others. One research study showed that footmats containing phenolic disinfectant did not prevent transmission of *Salmonella* from a large animal clinic to the adjacent small animal clinic presumably on the feet of people walking between these areas.[20] Similarly, disinfection of footwear did not have a consistent impact on floor bacterial counts in another hospital.[21] Various disinfectants can decrease the number of bacteria on the soles of footwear significantly, but they do not sterilize footwear.[22-24] A footbath does not decrease bacterial counts significantly if footwear is contaminated with feces.[23] For a footbath to significantly decrease bacteria on footwear, the soles of the footwear should be scrubbed free of feces and other organic matter in water, or in a primary footbath intended for cleaning footwear, before the wearer then steps into a second disinfecting footbath. People who are expected to use footbaths should be required to wear footwear that is nonporous and impervious to water or they are unlikely to step into the footbath completely, nullifying the value of the footbath. A footbath becomes less effective with repeated use, likely because of contamination of the footbath with organic matter and inactivation of the disinfectant by chemical change occurring over time. Because traces of organic material are likely to persist on footwear even after scrubbing, only disinfectants that retain efficacy in the presence of organic matter should be used for footbaths (see Table 3-3). The length of time a disinfectant is effective at the working concentration should be indicated on the product label, and the disinfectant solution in footbaths should be changed regularly at an interval that ensures the disinfectant retains efficacy.

People may be more likely to step on footmats containing disinfectant, which only contact the soles of footwear. These have been shown to be equally efficacious at decreasing bacterial counts on the footwear soles compared with footbaths.[22] Disposable plastic boots can effectively protect footwear from contamination,[25] but because holes can form in the bottom of such boots when they are worn for long, they should only be used for short episodes. In summary, footbaths and footmats can decrease the number of microorganisms on the soles of footwear, and their use may decrease transmission of infectious agents, but they must be used properly to be effective. Proper use includes scrubbing footwear free of manure and other organic material before use of footbaths or footmats, use of disinfectants that retain efficacy in the presence of organic matter, and regular replacement of used disinfectant solution when it becomes heavily contaminated with organic matter or when the expiration period has been met.

Proper hand hygiene is another important component of biosecurity. Detailed information regarding effective hand hygiene, materials to support worker training regarding hand hygiene, and guidelines for monitoring worker compliance are available.[26] Briefly, hand hygiene should be practiced after any interaction with an animal likely to be shedding infectious agents, or after contacting any object or material that has contacted such an animal. If hands are visibly soiled with dirt, manure, urine, or secretions or excretions, they should be washed thoroughly with antimicrobial soap and water. However, if hands are not visibly soiled, the use of alcohol-based hand sanitizer is more effective than hand washing. Moreover, because effective hand washing takes longer than effective use of hand sanitizer, and repeated hand washing can lead to chapped hands, the availability of hand sanitizer may improve hand hygiene compliance by people working with animals. Disposable examination gloves should be worn when undertaking activities in which hands are likely to become heavily contaminated with infectious agents, but it is important to note that hands must still be cleaned by washing or use of hand sanitizer after gloves are removed, because microscopic holes in gloves can allow hand contamination.

DISEASE MONITORING AND RECORD KEEPING

Regular and consistent disease monitoring and record keeping are necessary for accurate assessment of the biosecurity risks for an operation and for evaluation of the efficacy of biosecurity practices. Caretakers should be trained to identify signs of common diseases, and they should know how sick or injured animals should be handled and treated and who should be informed when sick or injured animals are identified. On large operations written protocols outlining the criteria for identification of some common health problems may be established. Ideally all animals on an operation should be identified by some form of unique permanent identification, which allows accurate identification of diseased animals for monitoring and treatment. Unique animal identification also facilitates accurate record keeping, which is particularly important to ensure that appropriate withdrawal (withholding) times are observed before treated animals or their products are marketed for human consumption.

Records of animal disease and treatment events should be periodically reviewed by the veterinarian who serves the operation, because this will facilitate identification of patterns of disease occurrence that reveal breakdowns in biosecurity or evidence of new biosecurity risks. Periodic assessment of records also provides the opportunity to track improvements in animal health and productivity that should result from effective biosecurity.

COMMUNICATION, TRAINING, AND ASSESSMENT

People caring for animals are more likely to implement biosecurity practices if they think the practices are effective, which is logical. If people working with livestock do not understand or think in the efficacy of biosecurity practices, it follows that efforts to establish a biosecurity plan may be fruitless, because individuals will not be motivated to observe biosecurity protocols consistently and effectively. Therefore veterinarians can help improve biosecurity by explaining the reason for biosecurity practices in clear and simple terms and by helping responsible parties to develop protocols that are accurate and complete, yet easy to understand and follow. It will likely be useful to develop written protocols for at least the most critical biosecurity practices and to have these displayed prominently in areas in which the protocol should be followed. This is because people often forget the steps of a protocol, and a protocol performed incorrectly may be ineffective or may even lead to the harm of animals or people.

Training and periodic review of training should be provided for animal caretakers and their supervisors to make sure that biosecurity protocols are being performed properly. Periodic assessment of protocols is important, because it has been shown that compliance deteriorates over time, even for people who understand why biosecurity is necessary.[27,28] Regular review of animal health records may lead to identification of either biosecurity breakdowns or biosecurity successes, and communicating these results to everyone working with animals may help reinforce the need for biosecurity.

General Systemic States

4

Several systemic states contribute to the effects of many diseases. Because these systemic states are common to many diseases they are considered here as a group to avoid unnecessary repetition. Hyperthermia, fever, septicemia, toxemia, and the acute phase response are closely related in their effects, and an appreciation of them is necessary if they are not to be overlooked in the efforts to eliminate the causative agent. Likewise, hypovolemic, hemorrhagic, maldistributive, and obstructive shock are best examined together. Anaphylactic shock is covered in Chapter 11. This chapter will also briefly introduce pain and stress as it relates to disease. Syndromes of poor performance, decreased appetite, and sudden and unexpected death are also covered.

Hypothermia, Hyperthermia, and Fever

Hypothermia, hyperthermia, and fever—characterized by physiologically significant changes in core body temperature—are presented here together, along with an introduction to thermoregulation mechanisms of the body.

BODY TEMPERATURE

Farm animals maintain a relatively constant body core temperature (**homeothermy**) during extreme ranges of thermal environments. This **homeothermic** state is achieved by physiologic and behavioral mechanisms that modify either rates of heat loss from the body or the rate at which heat is produced by the metabolism of feed or body energy reserves. For the body temperature to remain constant in changing thermal environments, the rate of heat loss must equal the rate of heat gain. The body temperature is a reflection of the balance between **heat gain** from the environment (radiation, conduction, and convection) or caused by metabolic activity (maintenance, exercise, growth, lactation, gestation, and feeding) and **heat loss** to the environment (radiation, conduction, convection, and evaporation) or caused by metabolic activity (milk removal, fecal elimination, and urinary elimination). Absorption of heat from the environment occurs when the external temperature rises above that of the body.

HEAT PRODUCTION

Heat production occurs as a result of metabolic activity and the digestion of feed, muscular movement, and the maintenance of muscle tone. **Shivering thermogenesis** is a response to sudden exposure to cold and is a major contributor to enhanced heat production. **Nonshivering thermogenesis** is also induced by exposure to cold and is the mechanism by which heat is produced by the calorigenic effect of epinephrine and norepinephrine. In the neonate, heat is produced by the metabolism of brown adipose tissue, which is present in newborn farm animals and is a particularly important mechanism of heat production to prevent neonatal hypothermia.

HEAT LOSS

Heat is transferred to or from an animal by the four standard physical phenomena of **convection**, **conduction, radiation,** and **evaporation**. Convection is a transfer of heat between two media at different temperatures such as the coat surface and the air. As such, convective heat transfer depends on the temperature gradient between the coat surface and air, the surface area, and the air speed over the surface. Conduction is the transfer of heat between two media that are in direct contact such as the skin and water. Radiation is the absorption or emission of electromagnetic radiation at the body surface and depends on the skin surface temperature and area. Evaporative heat transfer is a process by which heat is lost by the evaporation of water

and is dependent on the water vapor pressure gradient between the epithelial surface and the environment and the air speed over the surface.

Evaporation occurs by sweating, salivation, and respiration, with the relative importance of each varying between species. Losses by evaporation of moisture vary between species depending on the development of the sweat gland system and are less important in animals than in humans, beginning only at relatively high body temperatures. Horses sweat profusely, but in pigs, sheep, goats, New World camelids, and European cattle sweating cannot be considered to be an effective mechanism of evaporative heat loss. In zebu cattle the increased density of cutaneous sweat glands suggests that sweating may be more important. Profuse salivation and exaggerated respiration, including mouth breathing, are important mechanisms in the dissipation of excess body heat in animals. The tidal volume is decreased and the respiratory rate is increased at high body temperatures so that heat is lost but alkalemia caused by respiratory alkalosis is avoided.

BALANCE BETWEEN HEAT LOSS AND GAIN

The balance between heat gain and heat loss is controlled by the heat-regulating functions of the hypothalamus. The afferent impulses derive from peripheral hot and cold receptors and the temperature of the blood flowing through the hypothalamus. The efferent impulses control respiratory center activity, the caliber of skin blood vessels, sweat gland activity, and muscle tone. Heat storage occurs and the body temperature rises when there is a decrease in rate and depth of respiration, constriction of skin blood vessels, cessation of perspiration, and increased muscle tone. Heat loss occurs when these functions are reversed. These physiologic changes occur in, and are the basis of, the increment and decrement stages of fever.

BREED DIFFERENCES

Differences exist between breeds and races of cattle in coat and skin characters that affect heat absorption from solar radiation and heat loss by evaporative cooling; differences also exist in the metabolic rate, which influences the basic heat load. Interest in this subject has been aroused by the demands for classes of animal capable of high production in the developing countries of the tropical zone. Detailed information on the physiologic effects of, and the mechanisms of adaptation to, high environmental temperatures are therefore available elsewhere but are not dealt with in this book because they appear to be minimally related to the development of clinical illness.

Hypothermia, caused by exposure to low environmental temperatures, and **hyperthermia** (**heat stroke** or **heat exhaustion**), caused by exposure to high environmental temperatures, are the major abnormalities of body temperature associated with extremes of environmental temperatures. **Anhidrosis**, occurring primarily in horses in hot humid climates and associated with the inability to sweat, is described in Chapter 16.

HYPOTHERMIA

Hypothermia is a lower than normal body temperature, which occurs when **excess heat is lost** or **insufficient heat is produced**. Neonatal hypothermia is a major cause of morbidity and mortality in newborn farm animals within the first few days of life. Cold injury and frostbite are presented under that heading in Chapter 4.

ETIOLOGY

Excessive Loss of Heat

Exposure to excessively cold air temperatures causes heat loss if increased metabolic activity, shivering and sustained muscular contraction, and peripheral vasoconstriction are unable to compensate.

Insufficient Heat Production

Insufficient body reserves of energy and insufficient feed intake result in insufficient heat production. Hypothermia also occurs secondary to many diseases in which there may be a decrease in the ability to shiver and skeletal muscle contraction associated with decreased cardiac output, decreased peripheral perfusion, and shock. Examples include parturient paresis, acute ruminal acidosis (grain overload), during anesthesia and sedation, and the reduction of metabolic activity that occurs in the terminal stages of many diseases. A sudden fall in body temperature in a previously febrile animal, the so-called premortal fall, is an unfavorable prognostic sign.

Combination of Excessive Heat Loss and Insufficient Heat Production

A combination of excessive heat loss and insufficient heat production is often the cause of hypothermia. Insufficient energy intake or starvation of newborn farm animals in a cold environment can be a major cause of hypothermia. This may not occur under the same environmental conditions if the animals receive an adequate energy intake. Fatal hypothermia may also occur in other circumstances such as in certain breeds of pig (pot-bellied) following general anesthesia or sedation with higher doses of azaperone. Mature pot-bellied pigs deprived of feed and kept outdoors during cooler months of the year may develop hypothermia, which would not normally occur in these conditions if the pigs were receiving adequate food.

EPIDEMIOLOGY

Neonatal Hypothermia

Newborn farm animals are prone to hypothermia in cool environments, and hypothermia is a major cause of neonatal mortality. Neonates cannot maintain their core body temperatures at normal values during the first few hours after birth under cold environmental conditions. Hypothermia and environmental thermoregulatory interactions are of particular importance in piglets and lambs because of their surface to volume ratio but are also relevant in calves and sick foals.

At birth, the neonatal ruminant moves from a very stable thermal environment, of similar temperature to its core body temperature, to a variable and unstable thermal environment that is 10 to 50°C colder than its core temperature. The coat is wet with placental fluids, and energy loss is increased by evaporation and the low insulative value of a wet coat. The newborn calf becomes hypothermic in the first 6 hours after birth and only limited tissue substrates are available as energy sources. Neonates also are exposed to a variety of environmental pathogens against which they have little specific immunity. Thus the neonatal period is one of the most critical to the survival of an animal, and during this period the morbidity and mortality can be high under adverse environmental conditions.

The continued emphasis in modern agriculture on the production of neonates throughout the year, including times of inclement weather and limited feed (late winter and early spring calving in beef herds in northern climates); the emphasis on short calving seasons; the use of high stocking densities; and the production of animals with high muscle growth potential, which may be associated with an increased incidence of dystocia resulting in decreased vitality of newborn animals at birth; all appear to combine to increase the incidence of mortality caused by hypothermia and related diseases of the neonate.

In lambs, more than 30% of deaths occur in the first few days of life, and mortalities may be greater than 10%, with more than half of the losses caused by hypothermia from either exposure or starvation. In calves, approximately 50% of deaths occur within 48 hours of birth, and most losses are either directly caused by, or follow, dystocial parturitions in which stillbirths and early postnatal mortality rates are about 20% compared with less than 5% in calves born without dystocia (eutocial).

Thermoregulation in Neonatal Farm Animals

Response to Cold Stress

Neonatal ruminants, compared with many **altricial** neonatal mammals, are **precocial** in their development, with well-developed thermoregulatory mechanisms that allow them to maintain homeothermy in many environments. Prolonged exposure to heat or cold induces hormonal and metabolic changes specific to each stress. This involves

secretion of glucocorticoid hormones and increased activity of the sympathetic nervous system augmented by increased secretion of catecholamines. The principal metabolic effect of these increases is greater availability and utilization of substrates (fat, glycogen, and protein) for catabolism, with increased production of heat.

Cold-Induced Thermogenesis

This is achieved by shivering thermogenesis in skeletal muscle tissue and nonshivering thermogenesis in brown adipose tissue. **Shivering thermogenesis** consists of involuntary, periodic contractions of skeletal muscle. Heat is produced during contraction of muscle bundles in skeletal muscle tissue that has increased in tone as well as in skeletal muscle contracting in overt tremors. Increased heat production in neonatal calves in the first several hours after birth can be significant when the animals first stand for 10 minutes; this effect is reproduced later when the calves are stronger and stand for longer periods. The principal site of cold-induced nonshivering thermogenesis in animals is brown adipose tissue, which is present in neonatal lambs, kids, and calves but not in piglets. In neonatal lambs, approximately 40% of the thermogenic response during summit metabolism is attributed to **nonshivering thermogenesis**, with the balance of about 60% attributed to shivering thermogenesis.

Control of Heat Loss

The insulative nature of the external hair coat and cutaneous tissues to resist nonevaporative heat loss during cold exposure is critical in maintaining homeothermy. Total thermal insulation is the sum of tissue insulation and external insulation.

Tissue Insulation. This is the resistance of cutaneous tissue to conductive heat loss from the body core to the skin surface. Tissue insulation is influenced by subcutaneous fat depth, which is minimal in neonates, and by vasoconstriction. Tissue insulation increases with age.

External Insulation. This is the thermal resistance of the hair coat and air interface to radiative, convective, and conductive heat losses from the skin surface to the environment. External insulation is a function of length and type of hair coat and the air interface. When exposed to dry, cold still air environmental conditions, external insulation as a proportion of total thermal insulation in neonatal calves ranges from 65% to 75%. Moisture and mud in the coat decrease the value of external insulation; wind and rain can also decrease external insulation.

The neonate's total thermal resistance to heat loss is a function of the physical properties of the skin and hair coat and the ability to induce vasoconstriction of cutaneous blood vessels and piloerection of the hair coat. Neonatal calves are remarkably cold tolerant in a dry, still air environment. The thermal demand of an outdoor cold environment is a function of **wind** and **precipitation** as well as **ambient temperature**.

Conductive heat loss is controlled by sympathetic regulation of blood vessels that supply cutaneous tissues, especially the ears and lower extremities. In response to cold, vessels constrict, peripheral blood flow diminishes, and heat transfer is limited. Vasoconstriction of cutaneous vessels during cold exposure occurs first in the ears, followed by the lower extremities, and then the skin surrounding the trunk. **Phasic vasodilation** in the skin of the ears and distal extremities at a point near freezing occurs by the sudden opening of arteriovenous anastomoses to permit **intermittent warming** (called the **hunting reaction**). Phasic vasodilation does not occur on the skin of the trunk.

Thermoregulating Mechanisms

Heat exchange between any homeotherm and the environment is the result of the following:

- Heat production by metabolism
- Insensible heat loss by evaporation of moisture from the respiratory tract and skin
- Sensible heat transfer by conduction, convection, and radiation

There is a range in the effective thermal environment, called the **thermoneutral zone**, over which an animal maintains body temperature with minimal metabolic effort. Within this zone, body temperature is maintained primarily by varying blood flow to the body surface, piloerection of the hair coat, and behavioral and postural changes. These responses adjust the physical processes of heat transfer to balance the body's heat production. The lower limit of the thermoneutral zone (the **lower critical temperature)** is the minimum temperature that an animal can tolerate without actually increasing its rate of metabolic heat production to maintain thermal balance (Fig. 4-1). The lower critical temperature of an animal is determined by the animal's ability to resist heat loss (thermal insulation) and the animal's resting, thermoneutral heat production through metabolism. An increase in thermal insulation or an increase in thermoneutral metabolic rate decreases the lower critical temperature, improving cold tolerance.

Estimates of lower critical temperatures of calves during the first day of life are not available, but some estimates for older calves include 13°C for 2-day-old Ayrshire calves and 8 to 10°C for dairy and crossbred calves at 1 to 8 weeks of age. In lambs, estimates are 37 and 32°C for light (2-kg) and heavy (5-kg) birth weights immediately after birth while still wet with amniotic fluid, and 31 and 22°C when these lambs are more than 1 day old.

The thermoneutral zone for lactating dairy cows is 5 to 25°C. Adult cattle are very cold tolerant, with lower critical temperatures of 0°C for 1-month-old calves, −16 to −37°C for lactating dairy cows depending on their level of milk production, and −36°C for finishing feedlot cattle. At the lower border of the cold zone is the **cold lethal limit,** the ambient temperature below which the calf is unable to generate sufficient heat to offset heat losses required to maintain thermal balance, and at which hypothermia begins. Prolonged periods of exposure below the cold lethal limit will result in death. The cold lethal limit also can be defined as the ambient temperature below which heat loss exceeds the animal's summit or maximal metabolism. Because published values for lower critical temperatures assume **still air**, **dry clean coats**, **standard radiation,** and a **standing animal given a maintenance level of feeding**, there continue to be limitations to their use. Insulation of extremities decreases, and heat loss increases, at temperatures below freezing. Thus some lower critical temperatures for cattle are too low, which means that neonates may be affected by cold temperatures not normally considered harmful. External insulation can change because of changes in air velocity and long-wave radiation. Behavioral changes of animals may occur to minimize heat loss. For example, animals may orient toward the wind to decrease their profile, and they may seek shelter, huddle, and change their posture. Solar radiation varies throughout the daylight hours depending on the quantity of cloud. Generally, radiation balance is positive in the day, whereas at night, when the skies are clear, the radiation balance is usually negative. Heat production varies with the time of day and time since the last meal and physical activity. Rain will often depress intake of feed and illness, hypothermia severely depresses feed intake, and cold stimulates intake.

Heat Production

Heat produced by metabolism varies directly with the level of feed intake, particularly in adult ruminants in which the heat increment produced by forestomach fermentation is considerable. The more an animal eats, the greater the heat increment of feeding, and this results in an increase in core temperature of up to 0.3°C in lactating dairy cows, compared with dry cows. Animals subjected to cold environmental temperatures will increase their feed intake if given the opportunity, with proportionate dry matter increases of up to 35% being typical. Heat is also generated from physical activity. When newborn calves stand for the first time and are able to stand for 10 minutes, the energy expenditure is increased proportionately 30 to 100%. As calves become stronger and are able to stand for more than 30 minutes, heat production increases by 40%.

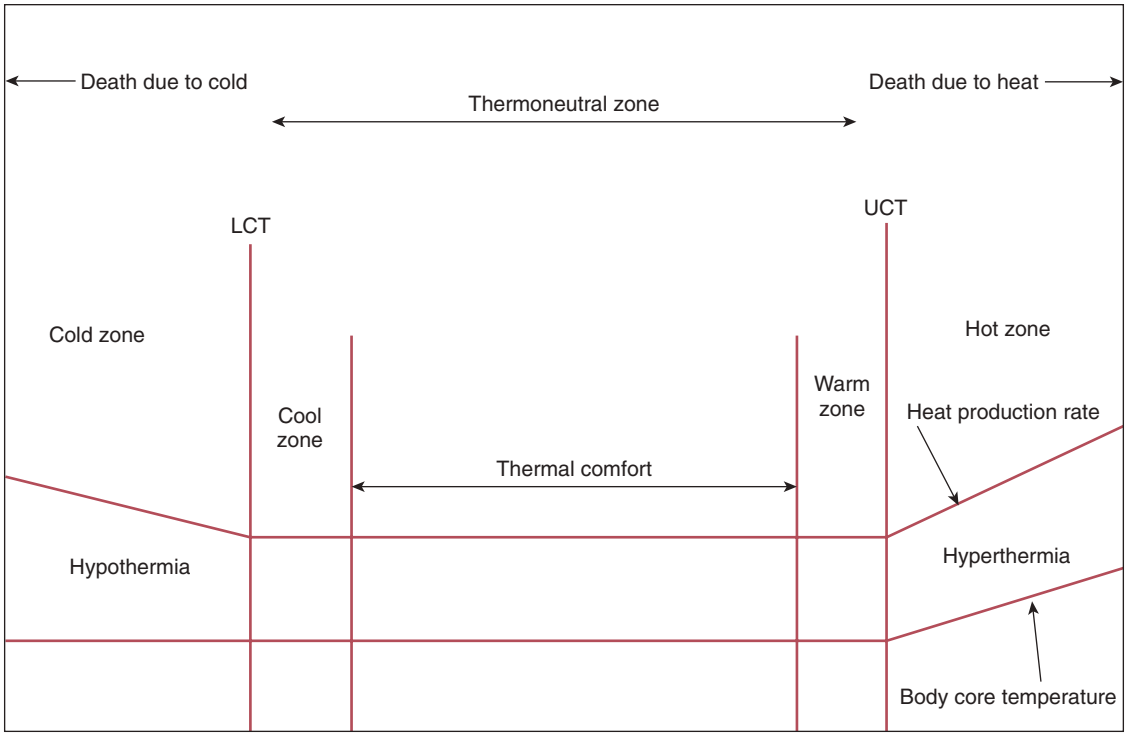

Fig. 4-1 Relationship between environmental temperature, heat production rate, and body core temperature in agricultural animals. *LCT,* lower critical temperature; *UCT,* upper critical temperature. (Adapted from Kadzere et al. *Livestock Prod Sci*, 2002; 77:59-91.)

Cold Thermogenesis

The major source of heat in cold thermogenesis, whether it is induced by either shivering thermogenesis or by nonshivering thermogenesis, is lipid. Glycogen is also important for maximum metabolic rates and for lipid metabolism. For the neonate, in the first 24 hours there is little digestion of colostral proteins and little catabolism of amino acids.

Shivering Thermogenesis. This is the most obvious sign of increased heat production of cold thermogenesis.

Nonshivering Thermogenesis. Functional brown adipose tissue is present in newborn calves, lambs, and kids, and its primary function is to generate heat by nonshivering thermogenesis. The release of norepinephrine during cold exposure in neonatal ruminants stimulates increased blood flow to brown adipose tissue. Thyroid hormones also have an essential role in regulating cold thermogenesis. Glucocorticoids are essential for cold thermogenesis through the mobilization of lipid and glycogen to supply energy substrates. Large deposits of brown adipose tissue are present in the abdominal cavity (perirenal), around large blood vessels, and in the inguinal and prescapular areas. In calves, brown fat may represent 20 g/kg body weight (BW) and in lambs from well-fed ewes, brown fat may represent 6g/kg BW. At parturition, marked changes occur in both the neonate's supply and demand for nutrients. In utero the fetal ruminant is provided with high levels of carbohydrate and low levels of fat, whereas after birth it is provided with colostrum high in fat and low in carbohydrate. Before colostrum is fed, the neonatal ruminant depends on mobilization of tissue glycogen and lipids to provide energy substrates for basal metabolism as well as thermogenesis in shivering muscle tissue and in brown adipose tissue. The major sources of energy substrates for thermogenesis in neonatal ruminants include glycogen and lipid in liver and muscle because protein catabolism is minimal during the early postnatal period.

Summit Metabolism. This is the maximal rate of metabolism that occurs in response to cold without a decline in body temperature. The time for which summit metabolism can be maintained is usually short, e.g., a few minutes in neonatal lambs. Summit metabolism is approximately five times the resting metabolic rate and is associated with increased sympathetic activity, development of metabolic acidosis, and increased plasma concentrations of glucose, glycerol, free fatty acids, and L-lactate. Prepartum hypoxia is likely associated with postpartum depression of sympathetic nervous activity and of thermogenic responses to cold.

Birth Weight and Summit Metabolism. The principal factor that determines an animal's resting, thermoneutral metabolism is body size. In newborn animals, thermoneutral metabolic rates and summit metabolic rates are proportional to their weight (W^1) rather than $W^{0.75}$, which means that summit metabolism per unit of W is similar for all neonates regardless of size, but lightweight animals have more surface area per unit of W than heavyweight neonates. Therefore lightweight neonates have a lower summit metabolic rate per unit of surface area and, consequently, lightweight neonates will be less cold tolerant than heavyweight neonates. Lightweight neonates therefore have a more difficult time maintaining thermal balance during cold stress because of a lower cold-induced thermogenic rate per unit of skin surface area than heavier animals. This, in part, explains the higher incidence of neonatal mortality in smaller piglets and lambs, and in smaller calves born to first-calf heifers, and even to mature cows.

Factors Affecting Cold Thermogenesis

Several factors affect the ability of the newborn calf to avoid hypothermia. Prompt activation of thermogenic mechanisms must occur immediately after birth when the demand for heat production is usually highest. The development of functional brown adipose tissue must occur in fetal life to enable calves to have maximal nonshivering thermogenesis during the early postnatal period. Most of the functional brown adipose tissue is deposited in late gestation in lambs and calves.

Ambient temperature and nutrition during pregnancy can affect cold thermogenesis of lambs. Maternal cold exposure by winter shearing of sheep increases lamb birth weight and the amount of perirenal adipose tissue independent of changes in prepartum feed intake. Thus newborn lambs from cold-exposed ewes are more cold tolerant. Acute cold exposure during late gestation increases glucose supply to the fetus, which stimulates insulin secretion, which in turn promotes fetal growth; recruitment and proliferation of brown adipose tissue occurs to enhance cold tolerance of the newborn lamb. There is some evidence that prepartum exposure of pregnant cows to a cold environment may result in heavier calf weights.

Malnutrition of the Dam During Late Gestation. This can adversely affect neonatal calf survival. Prepartum energy restriction beginning at day 90 of gestation of ewes can also reduce the proportional weight of perirenal adipose tissue and reduce the nonshivering ability of newborn lambs. The influence of prepartum nutritional restriction on cold thermogenesis in newborn calves is unknown, but prepartum protein restriction during the last trimester reduced thermoneutral thermogenic rates by 12% without affecting birth weights, resulting in an estimated increase in the lower critical temperature. Maternal malnutrition also adversely affects the availability of energy substrates required by the neonate for cold thermogenesis. Nutritional restriction of pregnant ewes reduces total body lipid in fetal lambs but not muscle or liver glycogen. Thus nutritional restriction of the fetus impairs cold tolerance of the neonate by reducing body substrate reserves available for cold thermogenesis and reduces nonshivering thermogenic capabilities.

European or British breeds of cattle are also more cold tolerant and more adaptable to temperate climates, whereas zebu cattle are more adaptable to subtropical climates because of greater heat tolerance. The lack of cold tolerance of the newborn *Bos indicus* calf is associated with a higher mortality rate in purebred Brahman herds in the United States. These calves are less cold tolerant and more susceptible to the weak calf syndrome.

Postnatal Changes in Cold Thermogenesis

As calves and lambs grow during the early postnatal period, heat loss per unit of body weight declines because of improved thermal insulation and a decrease in the ratio of skin surface area to body weight. Nonshivering thermogenesis decreases during the first month of age in lambs and calves, which is associated with a decrease in summit metabolism. This coincides with the conversion of brown adipose tissue to white adipose tissue by about 10 days after birth. Postnatal exposure to cold delays the disappearance of brown adipose tissue, which enhances cold tolerance of the lamb and calf by delaying the normal decline in nonshivering thermogenesis.

Risk Factors for Neonatal Hypothermia

Calves

Beef calves born outdoors during cold weather are susceptible to hypothermia. Wind, rain, and snow decrease the level of insulation and increase the lower critical temperature. Dairy calves born indoors are not usually exposed to cold environments that cause hypothermia; however, hypothermia has been recognized in dairy calves reared outdoors in cold climates and in some calves affected with enteritis.

Dystocia can affect cold thermogenesis. During a normal delivery, fetal hypoxemia may occur, causing anaerobic glycolysis, the production of lactic acid, and a mixed respiratory–metabolic acidosis that the calf can usually compensate for within hours after birth. In prolonged dystocia, a metabolic acidosis may occur, which will inhibit nonshivering thermogenesis and impair cold tolerance immediately after birth. Dystocia may result in a weak calf that has weak teat-seeking activity, a poor suck reflex, and a poor appetite for colostrum, resulting in colostrum deprivation and hypogammaglobulinemia.

Colostrum supplies **passive immunity** to the calf and the **nutrients** to meet energy demands during the immediate postpartum period. For the calf to maintain thermal balance during cold exposure, it is critical that the calf ingests colostrum early to provide enough energy reserves to sustain cold thermogenesis. Thus it is vitally important that newborn calves consume adequate colostrum to ensure adequate passive immunity and to aid in the maintenance of thermal stability during the early postnatal period when rates of heat loss are greatest. The limited availability of energy substrates from body reserves also requires that adequate quantities of colostrum are ingested during long periods of cold exposure, especially in neonatal calves at higher risk for developing hypothermia. The thermoneutral maintenance requirements of a 40-kg calf can be met with about 2.4 L of cow colostrum; an additional 125 mL of colostrum is required to supply the energy requirements for every 1°C decrease in effective environmental temperature below the lower critical temperature.

Young calves to be reared for veal are usually transported for 1 to 2 days during the first 2 weeks of life. These calves are prone to cold stress because they are very young and are being fed at a low level directly after transport. Veal calves arriving in a veal calf unit are dependent on body reserves to meet their energy requirement because of limited feed allowances, and ambient temperatures should not be below 14°C immediately after arrival to prevent extra mobilization of energy reserves. The thermal requirements of these calves are higher during standing than during lying, and the provision of bedding that stimulates lying will have a positive effect on thermal requirements.

Lambs

Cold exposure resulting in hypothermia is a primary cause of lamb mortality, as seen when large numbers of lambs die during or soon after periods of a few hours of low temperatures (<5°C) with wind and rain, or after prolonged rain. Deaths in "bad" weather cannot necessarily be attributed with certainty to exposure as a primary cause, because lambs debilitated for other reasons, such as starvation, are highly susceptible to chilling and conditions such as low birth weight, birth injury, and sparse hair coat, which all predispose lambs to cold exposure. Under less harsh conditions such lambs may survive.

Colostrum intake is also critical in lambs. Under field conditions in the United Kingdom it is estimated that lambs require 180 to 210 mL colostrum per kilogram BW in the first 18 hours after birth to provide sufficient energy substrate for heat production. This colostral requirement exceeds that for adequate transfer of colostral immunoglobulins. The thermoneutral and summit metabolic rates are much higher in lambs fed colostrum compared with unfed lambs at 4 to 5 hours of age. The increased metabolic rates are attributed to increased availability of energy substrates from colostrum: plasma concentrations of glucose and nonesterified free fatty acids are doubled from birth to 4 hours of age in colostrum-fed lambs but remain unchanged in colostrum-deprived lambs.

The heaviest losses in Australian sheep flocks, which occur in the form of *outbreaks* when the weather is very bad, are caused by hypothermia. The high mortality rates in newborn lambs caused by the effects of cold exposure and starvation occur because many of these lambs are born during the late winter and early spring, when adverse conditions are most likely to occur. This is also true in the northern United States and Canada. The lambs are often born outdoors in unprotected pens designed to accommodate a large number of ewes. Under these circumstances, the lambs may be severely cold stressed because the ambient air temperatures outside and within the lambing sheds are often 15°C or less, which is considerably lower than the critical temperatures described for heavyweight (32°C) and lightweight (37°C) lambs. Cold-stressed lambs often become hypothermic because of excessive heat loss from exposure to inclement weather and because of heat production caused by severe hypoxia at birth or to starvation. Factors that further increase the susceptibility of lambs to hypothermia include the following:

- Lambs from ewes in poor condition
- Lambs from young or aged ewes
- Lambs from multiple births
- Lambs from dystocias
- Lambs with a low birth weight or born prematurely
- Breed differences in susceptibility to cold, and genetic differences within a breed
- Length of the birth coat
- Wetting of the birth coat
- Exposure to wind

The effects of experimental cold stress (0°C and −10°C) on pregnant ewes during the last weeks of gestation and their lambs of up to 3 days of age have been examined. Generally, ewes were unaffected by treatment. Cold-induced changes in lambs included physical weakness, depression, and poor nursing response. Serum concentrations of glucose and insulin decreased and cortisol increased. The mortality rate was 40% in stressed lambs and 10% in lambs kept at the warmer temperatures. Cold-exposed lambs had reduced amounts of adipose tissue in perirenal areas and extensive subcutaneous hemorrhages and edema in the distal portions of the thoracic and pelvic limbs.

Wetness of the fleece is a major factor in determining whether or not lambs become hypothermic. Wet lambs suffer a reduction in coat insulation, primarily as a result of reduced coat depths, but this effect is small compared with the increase in the evaporative heat loss that occurs as a result of wetting. Lambs exposed to experimental air movement from a fan produce more body heat than those in still air, and differences in resistance to cold stress between single and twin lambs are largely caused by the corresponding differences in body weight and coat depth.

The relative importance of environmental and maternal factors is not easy to determine. Lamb mortality is typically related to birth weight by a U-shaped curve, with an optimal birth weight for survival between 4.5 and 5.5 kg. Inclement weather kills many lambs, probably more than would otherwise die, but principally those that are at risk because of reduced vigor (dependent on poor preceding nutrition) or because of poor mothering (itself as dependent on poor nutrition of the ewe as on her inherited lack of mothering ability). The vigor of the lamb, principally manifested as *sucking drive*, is reduced by lack of reward, so that a vicious cycle is created if the ewe will not stand. Vigor is also greatly reduced by cold discomfort, giving inclement weather two points at which it influences lamb survival rates. The lamb dies of hypothermia and inanition.

Piglets

At birth, the newborn piglet experiences a sudden and dramatic 15 to 20°C decrease in its thermal environment. Because the newborn pig is poorly insulated, maintenance of homeothermia depends almost exclusively on its capacity to produce heat. Unlike most other mammals the newborn pig does not possess brown adipose tissue. Consequently, neonatal pigs are assumed to rely essentially on muscular thermogenesis for thermoregulatory purposes. Newborn pigs shiver vigorously from birth because it is the main heat-producing mechanism and the thermogenic efficiency of shivering increases during the first 5 days of life.

Thermoregulation in the newborn piglet is important in the first 2 days. Metabolic heat production and rectal temperature increase and the development of adequate thermal insulation helps to withstand the effects of a cold environment. Body reserves are important for the piglet to survive in the first few hours, and glycogen and fat reserves are used as major energy substrates for heat production within the first 12 to 24 hours. Thus ingestion of colostrum and a high ambient temperature in the first several days of life are crucial. Application of 0.5 to 1 kg of chopped straw on a daily basis combined with 2 kg for nest building when the sow was about to farrow decreased the percentage of stillbirths by 27% but increased the number of piglets that were crushed.[1] Coldness impairs the development of thermostability and induces hypothermia, which diminishes the vigor of the piglet and reduces colostrum intake and immunoglobulins.

Foals

Newborn foals that are premature, dysmature, or affected with neonatal maladjustment syndrome cannot maintain their rectal temperatures at normal values during the first few hours after birth under the environmental conditions usually encountered within foaling boxes in the United Kingdom. Their overall mean metabolic rate is about 25% below the mean value for recumbent healthy foals.

This difference in resting metabolic rate affects the lower critical temperature or the air temperature below which heat loss exceeds resting heat production. The lower critical temperature for healthy foals is estimated to be about 10°C and for sick foals is about 24°C. When wet with amniotic fluid, the lower critical temperature probably will be much higher. Covering these foals with rugs and providing thermal radiation using radiant heaters would increase the lower critical temperature.

Premature foals are the most compromised compared with dysmature and those with neonatal maladjustment syndrome. They have small body masses, the lowest rates of metabolism, and the lowest rectal temperature. Premature foals are also likely to be deficient in energy reserves and thermal insulation, in addition to immaturity of organ systems, which could limit further energy availability. **Colostrum intake** is also crucial to their survival.

Postshearing Hypothermia in Sheep

Cold, wet, and windy weather can cause high mortality caused by hypothermia in newly shorn sheep; a fall in body weight in the period immediately preceding shearing is a major risk factor for mortality. In outbreaks in Australia in January the mean temperature can be 10°C, with a high rainfall and high wind velocity, accounting for a **wind chill factor** (a function of temperatures, rain, and wind velocity). Other factors that increase heat loss include sunshine versus cloud and the depth of the wool cover. The speed of the wind at the location of the animals varies greatly depending on the presence of protective windbreaks such as trees.

Cold Environments and Animal Production

Farm animals maintain a relatively constant body core temperature during exposure to the extreme range of thermal environments experienced in countries such as Canada. The severity of the winter is particularly challenging. Homeothermy is achieved by physiologic and behavioral mechanisms that modify either rates of heat loss from the body or the rate at which heat is produced by metabolism of feed or body energy reserves. Despite the extremely cold temperatures that occur in most of the agricultural regions of Canada, the effective severity of extremely cold temperatures is reduced because of the dryness of the frozen environment and the effective external insulation of the animal's hair coat. The influence of wind can add to cold stress, and the provision of shelter from wind by natural tree shelter belts or manmade structures such as porosity fences is required.

Prolonged exposure to cold results in subtle adaptation of hormonal and metabolic responses. Acclimatization to cold and winter conditions generally has little long-term effect on energy metabolism but increases thermal insulation and appetite. During prolonged exposure of cattle and sheep to cold environments down to −10 to −20°C there is a reduction in the apparent digestibility of the diet. To offset the lowered digestibility, the animals would accordingly need to consume more feed to achieve a similar digestible energy intake when kept outdoors during winter than if they were kept in a heated barn.

PATHOGENESIS

Sudden exposure of neonatal animals at birth and during the first few days of life to cold ambient temperature results in subnormal body temperature and shivering as well as decreased cardiac output, heart rate, and blood pressure. This results in muscular weakness and mental depression, respiratory failure, recumbency, and a state of collapse and, eventually, coma and death. The entire body, especially the extremities, becomes cold and the rectal temperature is below

37°C and may drop to 30°C or lower in neonates. Cold injury or frostbite of the extremities may occur in extremely cold conditions. Nonshivering-induced thermogenesis may occur, resulting in depletion of brown adipose tissue deposits. The neurologic signs of convulsions seen in some cases of hypothermia have not been adequately explained. The nervous signs observed in piglets with an inadequate intake of milk and exposed to cold environmental temperatures are probably caused by a marked hypoglycemia rather than hypothermia.

In newborn lambs carbohydrate and lipid are the major energy substrates for heat production because protein catabolism is minimal during the first day after birth. Liver glycogen concentrations increase markedly during the last few days before normal parturition. The amount of liver and skeletal muscle glycogen available in the newborn lamb at birth determines how long it can avoid hypoglycemia and hypothermia if not fed. The amount of lipid present in the newborn lamb can also affect the duration of the glycogen reserves. In growth-retarded lambs, lipid availability is decreased and glycogen exhaustion occurs earlier than normal. Such lambs are highly susceptible to hypothermia but this can be minimized by the early ingestion of colostrum, which is rich in lipid and extends the availability of glycogen.

Death results from excessive body cooling caused by low temperature, driving winds, and starvation. Wetness may or may not be involved. The starvation results indirectly from poor mothering by the ewe, either because she is a poor mother, because the weather interferes with mothering, or because the lamb is weak from poor antepartum nutrition. These lambs often walk after birth but at postmortem examination there is little to see. They may have sucked but there is little digestion and the intestine on the recumbent side is flaccid. There are also subcutaneous hemorrhages of the limbs and depletion of brown fat stores.

Hypothermia secondary to other diseases is caused by failure of the thermoregulation mechanism and is usually accompanied by varying degrees of shock and the inability to invoke shivering thermogenesis.

CLINICAL FINDINGS

A decrease in body temperature to below 37°C represents hypothermia for most farm animal species. Weakness, decreased activity, cold extremities, and varying degrees of shock are common. Bradycardia, weak arterial pulse, and collapse of the major veins are characteristic. The mucous membranes of the oral cavity are cool and there is a lack of saliva.

Neonatal Hypothermia

Body temperatures may be as low as 35°C in neonatal calves, piglets, lambs, and foals exposed to a cold environment within hours after birth or following 12 to 24 hours of profuse diarrhea accompanied by marked dehydration and acidemia. However, acute dehydration in a thermoneutral environment is accompanied by a mild increase in rectal temperature. In the early stage of hypothermia, affected animals may be shivering and trembling and the skin of their extremities and ears feels cool to touch. Hypothermic piglets will attempt to huddle together, are lethargic, do not suck, and eventually become recumbent and die. Hypothermic calves exposed to a cold environment will assume sternal recumbency, lie quietly, will have a weak suck reflex, and will die in a few hours. In later stages further weakness leading to coma is common. The mucous membranes of the oral cavity are cool and may be dry. The heart rate is slower than normal and the intensity of the heart sounds decreased. Death is common when the body temperature falls below 35°C, but field observations indicate that the temperature may fall below 30°C and animals still survive if treated intensively.

Shorn Sheep Hypothermia

Sheep with hypothermia associated with recent shearing and inclement weather have a range of body temperatures from 35 to 38°C. They huddle in tight groups and the animals that cannot maintain sufficient heat will become weak, recumbent, and die within a few hours. They may be found in lateral or sternal recumbency with their heads back over their shoulders. Palpebral reflexes are decreased, skin and extremities are cold, mucous membranes are pale to white, and generalized weakness similar to circulatory collapse is common.

Hypothermia Secondary to Other Diseases

Hypothermia secondary to other diseases is usually not marked, and there are clinical findings related to the underlying illness. Hypothermia is common in diseases, such as milk fever in cattle, but returns to normal within a few hours after successful treatment with calcium salts. Successful treatment of the primary disease will usually return the temperature to within the normal range.

CLINICAL PATHOLOGY

Clinical pathologic examinations are usually not done because the diagnosis is frequently obvious and the variability in biochemical changes makes them of limited value in reaching a diagnosis of hypothermia. The serum concentrations of glucose, nonesterified fatty acids, and immunoglobulins are commonly reduced, and hypoglycemia may be profound. However, the glucose concentration depends on the level of starvation that coexisted with the hypothermia. In starvation-induced depletion of body lipid and glycogen reserves, there is a depression in cold thermogenesis and subsequent hypothermia. In neonatal calves and lambs with hypothermia caused by excessive heat loss during short cold exposure, the serum concentrations of glucose, nonesterified fatty acids, and immunoglobulins may be at adequate levels. Hemoconcentration, azotemia, and metabolic acidosis may occur.

Necropsy Findings

Lesions associated with hypothermia depend on the duration and severity of the hypothermia. Fatal hypothermia in lambs and calves is characterized by an absence of lesions. A relative absence of milk in the abomasum is common. Experimental cold stress may result in subcutaneous edema of the ventral body wall and subcutaneous edema and hemorrhages of the extremities. Marked reductions in the amount of perirenal adipose tissue may be obvious. However, intense cold exposure of short duration may cause death of calves with no significant changes in the visual appearance of perirenal and pericardial adipose tissue depots.

TREATMENT

Hypothermic Newborn Lambs

A standardized approach for the detection and treatment of hypothermia in newborn lambs can improve the survival rate. Most lambs become hypothermic within 5 hours or at more than 12 hours after birth. Hypothermia in the first 5 hours of life is most commonly caused by a high rate of heat loss from the wet newborn lamb, whereas a depressed rate of heat production consequent to starvation is the most common cause in the older lamb. Twin and triplet lambs are more susceptible to hypothermia than singles because of lower body energy reserves; the ewe takes longer to lick dry two or three lambs, and the milk requirement of two or three lambs is higher than that of a single lamb and starvation is more likely.

Using an electronic thermometer, the body temperature of any weak or suspect lamb is taken. Lambs of any age with mild hypothermia (37–39°C) are dried off if necessary to reduce heat loss, given ewe or cow colostrum by stomach tube, and placed in a sheltered pen with the ewe. Lambs less than 5 hours of age with severe hypothermia (<37°C) are dried off and given an intraperitoneal injection of 20% glucose at a temperature of 39°C. A large lamb (>4.5 kg) is given 50 mL, a medium lamb (3.0–4.5 kg) 35 mL, and a small lamb (<3.0 kg) 25 mL. Hypothermic lambs are then placed in warming pens, measuring 2 × 2 m and made of horizontally laid straw bales, two bales high. The pen is divided horizontally into two chambers by a sheet of weld mesh upon which the lambs lie. Warm air, at 38 to 40°C, is blown into the lower chamber from a domestic heater, and a sheet of polythene fitted over the entire pen retains the heat. When the lamb's temperature reaches 37°C, it is

removed from the warmer and immediately fed ewe or cow colostrum by stomach tube at a rate of 50 mL/kg BW. Any lamb that is vigorous and able to suck is returned to its ewe in a sheltered pen and monitored over the next several hours. Colostrum can be hand milked from the ewe after administration of oxytocin.

The immersion of hypothermic lambs in water at 38°C can result in the recovery to a euthermic state in about 28 minutes at a reduced expense in metabolic effort by lambs. However, this requires extra labor and lambs must be quickly dried, otherwise the heat loss is exaggerated after removal from water because of the wet fleece.

Hypothermic Newborn Calves

Clinical management of hypothermic newborn calves is similar to that of lambs. Supplemental heat must be provided immediately. Rewarming can be done in small, enclosed boxes bedded with blankets and heat provided by infrared heat lamps. Colostrum or milk should be warmed to 40°C and intubated using an esophageal feeder. Fluids given intravenously must be warmed but their temperature usually decreases to the ambient environmental temperature before entering the jugular vein. Submersion of the intravenous line in a sustained source of hot water and ensuring an appropriate environmental temperature can mitigate the cooling of intravenously administered fluids before they reach the calf. Intravenous dextrose (1 mL of 50% dextrose per kilogram BW) should be routinely administered to all hypothermic calves because most have moderate to severe hypoglycemia. This dosage rate of 50% dextrose will increase the serum glucose concentration of the calf by approximately 100 mg/dL, assuming that the extracellular fluid space is 50% of the calf's body weight. The rectal temperature should be taken every 30 minutes during rewarming to assess progress.

A more aggressive rewarming technique involves the repeated administration of warm (40°C) 0.9% NaCl enemas via a flexible soft tube; a 20 to 30 Fr Foley catheter works well in this regard when it is advanced through the anus and the bulb inflated to maintain the catheter in the rectum. Rectally administered fluid should be aspirated before infusing additional fluid volumes via the Foley catheter to maximize the warming ability of enema fluids. Use of enema fluids as part of the rewarming protocol makes it more difficult to monitor the increase in body temperature. Whether immersion of hypothermic calves in water at 38 to 40°C is beneficial has not been determined, but immersion presents practical difficulties.

Hypothermic Newborn Foals

The clinical management of sick foals that are prone to hypothermia is presented in the section Control.

Hypothermic Newborn Piglets

Hypothermic piglets must be placed in a warming box with a heat lamp and treated with intraperitoneal administration of glucose for the hypoglycemia (see Chapter 19).

CONTROL

Control and prevention of hypothermia is dependent on providing the necessary surveillance at the time of parturition in animals being born in cold environments. Early recognition and treatment of animals with diseases leading to hypothermia is also necessary.

Lambs and Calves

Prevention of hypothermia in calves depends on the planning and implementation of effective management strategies that will limit the risk factors known to predispose newborn calves to hypothermia and starvation. Management strategies to prevent hypothermia from excessive heat loss are most important in the first 24 hours after birth. These include changing the calving season to a warmer time of the year to minimize exposure to severe weather. Measures to minimize excessive heat loss include providing a dry, draft-free environment for calving and lambing. Providing a protective shelter for beef cow/calf pairs for calving and during the first week after birth can reduce mortality from hypothermia. In extensive beef cow/calf herds, calf huts large enough for 8 to 10 calves provide excellent shelter from wind, rain, and snow.

The provision of adequate surveillance and assistance at the time of lambing or calving is necessary to minimize the incidence of dystocia and its consequences for the neonate. The ingestion of adequate quantities of colostrum, beginning as soon after birth as possible, is important to provide immunoglobulin and energy sources for the neonate.

Piglets

The newborn piglet requires an adequate intake of colostrum within a few hours after birth, continued intake of milk after the colostral period, a warm external environment of 30 to 34°C for at least the first 3 days of life (with heat lamps), and protection from traumatic injuries such as crushing by the sow. Sows do not instinctively remove the amniotic fluid from the surface of piglets; it is removed by contact with other surfaces or by evaporation. Smaller than normal piglets and weak piglets should be dried manually after birth to minimize excessive heat loss. Cross-fostering is used when gilts or sows have large litters that they cannot nurse adequately.

Sick Foals

Sick foals are prone to hypothermia, but cold stress can be reduced by good management procedures, including the following:

- The foal should be housed in an environment with minimal drafts, in which the air temperature is controlled at a steady value and set according to the foal's needs. Air temperature should be at, or a few degrees above, the lower critical temperature. This temperature may exceed 24°C for a sick, uncovered recumbent foal. Radiant heaters are useful but should not be placed too close to the foal.
- Excessive moisture should be removed from the foal's hair coat immediately after birth. A sick foal that cannot increase its metabolic rate is particularly susceptible to cold stress when wet with amniotic fluid.
- Additional insulation with foal rugs and leg bandages will reduce heat loss from the dry body surface. The dry sick foal needs an additional 10 mm of insulation for each 10°C decline in air temperature below 24°C. Because sick foals are recumbent, they should lie on a heated pad or on thick bedding material to minimize heat loss by conduction to the floor.
- Energy intake should be sufficient to sustain resting metabolism and can be given by the oral or parenteral route.
- Frequent monitoring of both rectal and air temperature, as well as energy intake, will assist in the diagnosis of thermal stress, so that appropriate action can be taken. A lack of shivering does not indicate an absence of cold stress.

COLD INJURY (FROSTBITE AND CHILBLAINS)

SYNOPSIS

Etiology Exposure of extremities to cold temperatures, usually below freezing, without adequate protection.

Epidemiology Cooler seasons of the year, primarily in young animals, especially beef calves, debilitated from other disease. Teats of lactating dairy cows also susceptible.

Clinical findings Lesions can occur on extremities of limbs, especially hindfeet, ears, and tail. Demarcated lesions with initial swelling with edema followed by necrosis and sloughing. Teats and udder of adult cows can be affected.

Clinical pathology None specific.

Necropsy findings Subcutaneous edema and hemorrhage in affected areas.
Diagnostic confirmation Clinical findings and history of exposure to cold.
Treatment Warm, dry environment. Improve peripheral circulation.
Control Remove debilitated calves from cold environments. Adequate and dry bedding.

ETIOLOGY AND EPIDEMIOLOGY

Injury occurs during cold weather in the winter or spring months and is most common in **calves** that are weak or in which the peripheral circulation of the limbs is impaired, usually because of diarrhea and dehydration. In a retrospective study of frostbite in calves, 80% of cases were associated with a concurrent disease such as pneumonia, diarrhea, omphalitis, septicemia, and ocular disease. Hypothermia (<37.5°C) was present in about 50% of the calves. The disease in calves appears more common in beef breeds, possibly because of management risk factors.

In **dairy herds** with loose housing, access to outdoor exercise yards without adequate bedding can be a risk factor. There can be a high incidence of teat lesions in drylot-housed herds in temperate areas when freak cold weather fronts invade the region. Regional differences in teat chapping in winter are associated with regional differences in winter temperature.

PATHOGENESIS

Physiologically, body heat is lost from the skin surface by radiation and convection and by conduction and evaporation when the skin and hair coat are wet. **Newborn calves** are particularly susceptible to cold because of their inadequate insulation and high ratio of body surface area (through which heat is lost) to body volume (in which heat is generated). The core and trunk body temperature is preferentially conserved during cold stress at the expense of the peripheral tissues, which are most susceptible to cold injury.

Peripheral tissues are also most susceptible because of their contact with the ambient temperature and wet environments. When cattle are in sternal recumbency, the uppermost pelvic limb is fully exposed and the distal aspect of the opposite limb from the hoof to above the fetlock joint is exposed to the environment. The distal extremities of the thoracic limbs are usually covered by the thorax. Thus any situation that results in prolonged sternal recumbency will allow the distal extremities of the pelvic limbs to cool excessively, and if there is impairment of circulation because of preexisting dehydration, varying degrees of cold injury can occur. Field observations suggest that if a weak calf does not move from a sternally recumbent position for several hours then the cold injury can progress to the stage of severe irreversible frostbite before the clinical signs are recognized by the owner.

The **teats of dairy cows** are also exposed when standing and lying. Residual teat dip after milking predisposes to cold injury.

Cold injuries of extremities vary from mild to severe. Exposure to cold results in vasoconstriction and coolness of the affected part. Most dry–cold injury is superficial and the skin may become gangrenous resulting in a hard shell or carapace over healthier tissue. Deeper cold injury causes inflammation, redness or cyanosis, local swelling, and pain or loss of sensation.

CLINICAL FINDINGS

Frostbite of the **feet** of calves is not readily obvious, even to the experienced observer. The normal hair covering and pigmentation of the skin often mask the early changes of frostbite. Commonly, cases are identified during the treatment with fluids of scouring, recumbent calves, when further clinical examination reveals that the hindfeet are cool and clammy.

In the **early stages** of frostbite of the distal parts of the limbs, the tissues are swollen, edematous, and may have well-demarcated limits. After several hours of warming indoors, the feet remain cool and close examination reveals some moistness and dark red to bluish coloration of the skin. There may be a line of demarcation between normal and affected tissue at about the level of the fetlock joints. If the injury is not severe, complete recovery can occur in a few days.

In more **severe cases**, within 24 to 48 hours, necrosis and sloughing of the skin occur and the hooves become detached several days later. There is pain on palpation of affected tissues, especially at the line of demarcation.

When there is avascular necrosis of the affected part, the skin will be hard like a shell (known as a carapace) and moderate palpation will elicit pain.

Freezing of the **ears** results in loss of pliability of the ears, gangrene, and loss of the affected parts and curling of the affected skin adjacent to the affected parts. Some sloughing of affected parts will occur, and after several days the ears appear shortened.

Freezing of the **tail** occurs most commonly at the distal end, resulting in stiffness and loss of flexibility because of a carapace. Varying portions of the tail may be affected, but usually 5 to 10 cm of the distal end is involved. The distal parts of the tail of adult cattle may freeze in very cold weather.

In adult cattle, freezing of the **teats** and **base of the udder** can occur in lactating cattle that have inadequate bedding and shelter from wind and snow. Affected teats are swollen and cold and the skin begins to vesiculate and peel. Freezing of the teats of cows may result in permanent injury, chronic thelitis, and the possibility of mastitis with gangrene. Less severe lesions predispose to mastitis.

Freezing of the **scrotum** occurs in yearling beef bulls kept outdoors during the cold winter months, but the lesions are not commonly recognized until the spring of the year.

NECROPSY FINDINGS

Necrosis of the skin of the affected area with severe diffuse hemorrhagic subcutaneous edema is typical of frostbite.

TREATMENT

Affected calves should be moved to a warm, well-bedded **dry environment** and circulation should be improved by providing **fluid therapy** as necessary. In early cases, affected calves will recover in a few days and the swelling and pain will regress. Field observations suggest that superficial freezing of the skin between the fetlock and coronets will heal over a period of several weeks providing the lesion does not extend into the coronary bands and the laminae of the feet, which commonly results in sloughing of the hoof.

In severe cases with extensive necrosis, the skin will begin to slough. Such open wounds should be treated with suitable antibiotic ointments and bandaged for several days. Calves with extensive freezing of the hindlimbs extending from the feet up to hock joints are incurable and should be euthanized.

There is no specific treatment for freezing of the ears and tails of calves or the teats of cows.

CONTROL

The prevention of cold injury in newborn **calves** requires daily surveillance of calves to ensure that any animal that is inactive for any reason is examined for evidence of illness and treated immediately and placed in a protected environment.

When an exceptional cold period is forecast for **dairy cows** at risk, teat dipping should be temporarily suspended during the cold period. Additional bedding should be provided for loose-housed cows, and bedding with some manure can be piled in the center of drylot yards to provide composting heat upon which the cows can bed.

HYPERTHERMIA (HEAT STROKE OR HEAT EXHAUSTION)

Hyperthermia is the elevation of core body temperature caused by excessive heat production or absorption, or to deficient heat loss, when the causes of these abnormalities are purely physical. Heat stroke (heat exhaustion) is the most commonly encountered clinical entity.

ETIOLOGY

The major causes of hyperthermia are the physical ones of high environmental

temperature and prolonged, severe muscular exertion, especially when the humidity is high, the animals are fat, have a heavy hair coat, or are confined with inadequate ventilation such as on board ship or during road transportation. Fat cattle, especially British beef breeds, can be overcome by the heat in feedlots. Brahman cattle in the same pen may be unaffected. Angora goats are much more sensitive to high environmental temperatures than sheep, especially when they are young.

High Environmental Temperature

The upper border of the thermoneutral zone (the **upper critical temperature)** is the effective ambient temperature above which an animal must increase heat loss to maintain thermal balance (see Fig. 4-1). The upper critical limit for dairy cows is 25 to 26°C. The upper critical temperature in sheep with a light wool coat on board ship appears to be 35°C (95°F) at a humidity of 33 to 39 mm Hg (4.4–5.2 kPa) vapor pressure. Differences between breeds of animal in their tolerance to environmental high temperatures, exposure to sunlight, and exercise are important in animal management and production. Holstein cows carrying the *slick hair* gene (phenotypically having a short, sleek and sometimes glossy hair coat) are better able to regulate body temperature during heat stress than wild-type Holsteins, with slick-haired animals having an increased sweating rate.[1] Water buffalo have been shown to be less heat tolerant than Shorthorn steers, which were less tolerant than Javanese Banteng and Brahman crossbreeds (the last two appear to be equally tolerant). The differences appear to be at least partly caused by the capacity to increase cutaneous evaporation under heat stress.

There are similar differences in heat tolerance between lactating and nonlactating cows; lactating animals show significantly greater increases in rectal temperature and heart and respiratory rates when the environmental temperature is raised. This is primarily a result of the greater dry matter intake and heat of fermentation in dairy cattle that must be dissipated. Heat stress is therefore an important production-limiting disease when dairy cattle are kept in conditions of high heat and humidity.

Rested, hydrated horses are well able to maintain homeothermy in the hottest environmental conditions. Their most efficient mechanism in ensuring that body temperature is kept low is their capacity for heavy sweating.

Other Causes of Hyperthermia

- Neurogenic hyperthermia: Damage to hypothalamus, e.g., spontaneous hemorrhage, may cause hyperthermia or poikilothermia
- Dehydration: Caused by insufficient tissue fluids to accommodate heat loss by evaporation
- Excessive muscular activity: For example, strychnine poisoning
- Miscellaneous poisonings, including levamisole and dinitrophenols
- Malignant hyperthermia in the porcine stress syndrome
- Malignant hyperthermia in Quarter Horses[2,3]
- Hyperkalemic periodic paresis in horses
- Fescue toxicity in ruminants and horses
- Cattle with hereditary bovine syndactyly
- Administration of tranquilizing drugs to sheep in hot weather
- Specific mycotoxins, e.g., *Claviceps purpurea* and *Acremonium coenophialum,* are causes of epidemic hyperthermia; bovine idiopathic hyperthermia in cattle in Australia may be caused by *Claviceps purpurea*
- Iodism
- Sylade (possibly) poisoning

PATHOGENESIS

The means by which hyperthermia is induced have already been described. The physiologic effects of hyperthermia are important and are outlined briefly here.

Unless the body temperature reaches a critical point, a short period of hyperthermia is advantageous in an infectious disease because phagocytosis and immune body production are facilitated and the viability of most invading organisms is impaired. These changes provide justification for the use of artificial fever to control bacterial disease. However, the metabolic rate may be increased by as much as 40 to 50%, liver glycogen stores are rapidly depleted, and extra energy is derived from increased endogenous metabolism of protein. Feed intake is decreased and there is a change in postabsorptive carbohydrate metabolism in cattle, characterized by increased plasma insulin concentration and insulin release to a glucose tolerance test. If anorexia occurs because of respiratory embarrassment and dryness of the mouth, there will be considerable loss of body weight and lack of muscle strength accompanied by hypoglycemia and an increase in plasma urea nitrogen concentration caused by the use of skeletal muscle for energy.

There is increased thirst caused in part by dryness of the mouth. An increase in heart rate occurs directly because of the rise in blood temperature and indirectly to the fall in blood pressure resulting from peripheral vasodilatation. An increased respiratory rate cools by increasing salivary secretion and the rate of air flow across respiratory epithelial surfaces, increasing the rate of evaporative cooling. Urine secretion is decreased because of the reduced renal blood flow resulting from peripheral vasodilatation and because of physicochemical changes in body cells that result in retention of water and chloride ions.

When the critical temperature is exceeded, there is depression of nervous system activity and depression of the respiratory center usually causes death by respiratory failure. Circulatory failure also occurs caused by myocardial weakness and the heart rate becoming fast and irregular. If the period of hyperthermia is unduly prolonged, rather than excessive in degree, the deleterious effects are those of increased endogenous metabolism and deficient food intake. There is often an extensive degenerative change in most body tissues, but this is more likely to be caused by metabolic changes than by the direct effects of elevation of the body temperature.

Malignant hyperthermia is an autosomal dominant trait in Quarter Horse lineages caused by a single missense point mutation in the ryanodine receptor 1 (*RyR1*) gene. Dysfunction of the *RyR1* gene leads to excessive release of calcium into the cytosol and a hypermetabolic state of the skeletal muscle cells, which in severe cases can result in rectal temperatures exceeding 43°C. Malignant hyperthermia is potentially fatal in horses carrying the genetic defect, with an estimated mortality rate of 34%.[2,3]

CLINICAL FINDINGS

An elevation of body temperature is the primary requisite for a diagnosis of hyperthermia, and in most species the first observable clinical reaction to hyperthermia occurs when the rectal temperature is increased by 3 to 4°C (4–7°F) above normal. In most instances the temperature exceeds 42°C (107°F) and may reach 43.5°C (110°F). An increase in heart and respiratory rates with a weak pulse of large amplitude, sweating, and salivation occur initially, followed by a marked absence of sweating. The animal may be restless but soon becomes dull, stumbles while walking, and tends to lie down.

In the early stages there is increased thirst and the animal seeks cool places, often lying in water or attempting to splash itself. Additional increases in rectal temperature lead to labored respiration and general distress is evident. Beyond this point the respirations become shallow and irregular, the pulse becomes very rapid and weak, and these signs are usually accompanied by collapse, convulsions, and terminal coma. Death occurs in most species when the core temperature exceeds the normal value by approximately 5 to 7°C (8–10°F). Abortion may occur if the period of hyperthermia is prolonged, and a high incidence of embryonic mortality has been recorded in sheep that were 3 to 6 weeks pregnant. In cattle, breeding efficiency is adversely affected by prolonged heat stress and in intensively housed swine a syndrome known as summer infertility, manifested by a decrease in conception rate and litter size and an increase in anestrus, occurs during and following the hot summer months in most countries. A

case series of 4- to 6-month-old lambs examined in summer with clinical signs of high rectal temperature, tachypnea, and neurologic disease has been reported in Texas.[4] Neurologic signs included postural kyphosis and limb hyperextension to sternal recumbency and was attributed to hyperthermia-induced spinal cord injury.

Respiratory rate at the lower end of the thermoneutral zone is 20 breaths per minute in cattle and 25 to 30 breaths per minute in sheep and goats. An increase in respiratory rate above 40 breaths per minute in adult ruminants represents panting, which has the homeostatic goal of facilitating cooling by respiratory evaporation. The respiratory rate is therefore the most practical indicator of heat stress in adult ruminants, with respiratory rates of 40 to 60, 60 to 80, and 80 to 120 breaths per minute representing low, moderate, and severe heat stress, respectively. It is not uncommon in hot humid climates to see cattle open-mouth breathing with respiratory rates exceeding 80 breaths per minute during periods of heat stress. In summary, the progression of changes in cattle with heat stress is increased respiratory rate, rectal temperature, and heart rate; followed by decreased urine concentration (caused by increased water intake); and finally decreased appetite and milk production.

Heat stress in horses and donkeys is associated with increased respiratory rate and depth, flared nostrils, nodding of the head, and apathy.[5] Hyperthermic horses are fatigued and have profound fluid and electrolyte losses, characterized by hypotonic dehydration caused by excessive sweating. The resultant clinical signs include decreased performance, depression, weakness, increased heart and respiratory rates, and marked increases in rectal temperature (usually exceeding 42°C). Because of the hyponatremia, affected horses may lose the stimulus to drink, exacerbating their dehydration. In advanced cases, the skin is dry and hot because sweating is impaired. Hyperthermic horses that have been participating in an endurance event may have synchronous diaphragmatic flutter as a result of hypocalcemia and metabolic alkalosis. Coma and death can occur in extreme cases of hyperthermia that are not identified and treated until the condition is advanced.

CLINICAL PATHOLOGY

No important clinicopathologic change is observed in simple hyperthermia. However, horses with advanced hyperthermia typically have hyponatremic dehydration and azotemia. Horses with synchronous diaphragmatic flutter are typically hypocalcemic.

Necropsy Findings

At necropsy there are only poorly defined gross changes. Peripheral vasodilatation may be evident, clotting of the blood is slow and incomplete, and rigor mortis and putrefaction occur early. There are no constant or specific histopathologic changes.

TREATMENT

The presence of adequate drinking water is essential and, together with shade and air movement, is of considerable assistance when multiple animals are exposed to high air temperature.

If treatment of individual animals is necessary because of the severity or duration of the hyperthermia, affected animals should be immediately placed in the shade and hosed on the midline of the back with cold water so that their coats are saturated. Fans should be immediately placed in front of the animal to promote evaporative cooling, and cooled water, with and without added electrolytes, should be made available for the animal to drink. In severe cases of hyperthermia in which large volumes of water are not available, very cold water (2–8°C) should be applied and immediately scraped off because the water becomes warm almost immediately. The application of very cold water does not induce a clinically relevant degree of peripheral vasoconstriction and has not been associated with clinically relevant side effects. Water applied by hose does not need to be scraped off because heat is conducted to the applied water stream. Placement of wet sheets or towels over the head or neck is not recommended because they provide unneeded insulation.

The rectal temperature should be monitored frequently during cooling, and water application should be stopped when the rectal temperature has returned to normal. Because affected animals may not be interested in or capable of drinking, the intravenous administration of fluids such as 0.9% NaCl is indicated in animals that are weak, recumbent, or dehydrated. Horses often need 20 to 40 L of intravenous fluids over the first few hours of treatment. Horses with synchronous diaphragmatic flutter should be treated with intravenous calcium after verifying the presence of hypocalcemia.

Fluids can also be administered orally to horses, but care should be taken to ensure that gastrointestinal motility is not impaired. A practical oral electrolyte solution is obtained by dissolving 20 g of table salt (NaCl) and 20 g of Litesalt (NaCl and KCl) in 5 L of water; this provides 107, 28, and 132 mmol/L of sodium, potassium, and chloride, respectively. Five liters of this fluid can be administered to an adult horse each hour by nasogastric tube.

CONTROL

Shade alone is the most important factor in maintaining the comfort of livestock and preventing heat stress. Shade reduces the heat gain from solar radiation and can be provided by trees or artificially by roofs or shades made from cloth or artificial material. Shades should be placed over feed and where the producer wants the animals to spend their time. The efficiency of metal shades can be increased by painting metal shades white on the topside and black on the underside. A north–south orientation will permit drying under the shades as the shaded area moves throughout the day; this may be helpful in decreasing the incidence of coliform mastitis if sprinklers are used under the shades and cattle prefer to lie under the shades than in freestalls.

In dairy and feedlot cattle, the following measures should be taken to manage heat stress:

- Provide cool clean water and plenty of trough space for drinking.
- Use shades and intermittent sprinkler systems (wet time of 1–2 min with an adequate dry off time of 20–30 min); continuous application of water increases the local humidity and decreases the effectiveness of evaporative cooling.
- Enhance airflow by fans or by providing mounds for cattle to stand on.
- Adjust rations and feed a larger percentage of the ration in the evening when it is cooler.
- Minimize handling during periods of greatest heat stress.
- Select cattle based on breed and coat characteristics, and house the most susceptible cattle (heavy, black) on east-sloping lots with the most shade; genetic studies have identified genes associated with resistance to heat stress in dairy cattle.[1,6]

In exercising horses, periodic rests in the shade with fans and water sprinklers and maintaining a normal hydration status can be very helpful in preventing heat stress. Monitoring the heart rate is a useful and practical method of assessing the degree of heat stress in horses, because heart rates remain elevated for a longer period of time in horses undergoing heat stress.

If animals have to be confined under conditions of high temperatures and humidity, the use of tranquilizing drugs has been recommended to reduce unnecessary activity. However, care is needed because blood pressure falls and the animals may have difficulty losing heat if the environment is very hot and in some cases may gain heat. Chlorpromazine, for example, has been shown to increase significantly the survival rate of pigs exposed to heat and humidity stress.

FEVER (PYREXIA)

Fever is an elevation of core body temperature above that normally maintained by an animal and is independent of the effects of ambient conditions on body temperature. It is important to realize that fever is a combination of hyperthermia and infection or inflammation that results from an elevated set point for temperature regulation.

ETIOLOGY

Fevers may be septic, the more common type, or aseptic, depending on whether or not infection is present.

Septic Fevers

These include infection with bacteria, viruses, protozoa, or fungi as

- Localized infection such as abscess, cellulitis, and empyema
- Intermittently systemic, as in bacteremia and endocarditis
- Consistently systemic, as in septicemia

Aseptic Fevers

- Chemical fevers, caused by injection of foreign protein and intake of dinitrophenols
- Surgical fever, caused by breakdown of tissue and blood
- Fever from tissue necrosis, e.g., breakdown of muscle after injection of necrotizing material
- Severe hemolytic crises (hemoglobinemia)
- Extensive infarction
- Extensive necrosis in rapidly growing neoplasms such as multicentric lymphosarcoma in cattle
- Immune reactions such as anaphylaxis and angioneurotic edema

PATHOGENESIS

Most fevers are mediated through the action of endogenous pyrogens produced by granulocytes, monocytes, and macrophages. The most important and best known **endogenous pyrogen** is interleukin-1 (IL-1), produced by monocytes and macrophages. The febrile response is initiated by the introduction of an **exogenous pyrogen** into the body. Exogenous pyrogens include pathogens such as bacteria, viruses, bacterial endotoxins, antigen–antibody complexes, hemoglobinemia in a hemolytic crisis, and many inorganic substances. In hypersensitivity states, soluble antigen–antibody complexes may act as mediators. One of the most potent exogenous pyrogens is the lipopolysaccharide of gram-negative bacteria.

Endogenous Pyrogens

Endogenous pyrogens are proteins released from monocytes and, to a lesser extent, lymphocytes. These proteins were originally designated as **monokines** and **lymphokines,** respectively, but are now more commonly referred to under the more general term of **cytokines**. One of the pyrogenic cytokines is IL-1, formerly known as lymphocyte activating factor. **IL-1** stimulates T-lymphocyte proliferation in the presence of antigen, enhancing the immune response. The mediators between endogenous pyrogen and the hypothalamus appear to be prostaglandins, and the level of calcium in the hypothalamus appears to regulate its activity.

Interleukin-1 initiates fever by inducing an abrupt increase in the synthesis of **prostaglandins**, particularly prostaglandin E_2, in the anterior hypothalamus. The elevated prostaglandin levels in the hypothalamus raise the thermostatic set point and induce the mechanisms of heat conservation (vasoconstriction) and heat production (shivering thermogenesis) until the blood and core temperature are elevated to match the hypothalamic set point.

Prostaglandin precursors are thought to be the chemical mediators of fever according to the following sequence:

1. Endogenous pyrogens cause the release of arachidonic acid, with subsequent synthesis of prostaglandins.
2. Arachidonic acid breakdown products modulate the hypothalamic thermoregulatory mechanism, resulting in an increase in the set point value.
3. Prostaglandin synthetase-inhibitor antipyretics lower fever by blocking the synthesis of prostaglandins or prostaglandin precursors from arachidonic acid.

A cytokine known as **tumor necrosis factor-α (TNF-α)** reproduces many of the physiologic derangements observed in septic shock and mediates many of the deleterious effects of gram-negative bacterial infection, including fever.

In addition to their pyrogenic activity, cytokines mediate the acute phase response, which is a term now being used to describe the reaction of animals to pathogen invasion, tissue injury, immunologic reactions, and inflammatory processes. The physiologic mechanisms involved in the production of fever after stimulation by pyrogens must be matured or sensitized by previous exposure to pyrogen. Injection of pyrogens into newborn lambs does not cause fever but subsequent injections do.

Effect of Pyrogens on the Hypothalamus

The effect of bacterial and tissue pyrogens is exerted on the thermoregulatory center of the hypothalamus so that the thermostatic level of the body is raised. The immediate response on the part of organs involved in heat regulation is the prevention of heat loss and the increased production of heat. This is the period of **increment**, or chill, which is manifested by cutaneous vasoconstriction, resulting coldness and dryness of the skin, and an absence of sweating. Respiration is reduced and muscular shivering occurs, and urine formation is minimal. The extremities are cold to the touch, the rectal temperature is elevated, and the pulse rate increased. When the period of heat increment has raised the body temperature to a new thermostatic level the second period of fever, the **fastigium**, or period of constant temperature, follows. In this stage the mechanisms of heat dissipation and production return to normal. Cutaneous vasodilatation causes flushing of the skin and mucosa, sweating occurs and may be severe, and diuresis develops. During this period there is decreased forestomach motility in ruminants, metabolism is increased considerably to maintain the body temperature, and tissue wasting may occur. There is also an inability to maintain a constant temperature when environmental temperatures vary.

When the effect of the pyrogenic substances is removed, the stage of **decrement**, or fever defervescence, appears and the excess stored heat is dissipated. Vasodilatation, sweating, and muscle flaccidity are marked and the body temperature falls. The fall in body temperature after the initial rise is accompanied by a decline in plasma zinc and plasma total iron concentrations. If the toxemia accompanying the hyperthermia is sufficiently severe, the ability of tissues to respond to heat production or conservation needs may be lost and as death approaches there is a precipitate fall in body temperature.

Febrile Response

The febrile response, and the altered behavior that accompanies it, are thought to be part of a total mechanism generated to conserve the resources of energy and tissue being wasted by the causative infection. The febrile response has major effects on immune mechanisms. Endogenous pyrogens stimulate T-cell proliferation. The increased body temperature causes increases in leukocyte mobility, leukocyte bactericidal and phagocytic activities, and lymphocyte transformation as well as enhances the effects of interferon and IL-1.

Some possible adverse effects of fever include anorexia, which can lead to excessive catabolism if prolonged. Rarely, extremely high fevers can result in disseminated intravascular coagulation and effects on the central nervous system (CNS) that may lead to convulsions.

CLINICAL FINDINGS

The effects of fever are the combined effects of hyperthermia and infection or inflammation. There is elevation of body temperature, an increase in heart rate with a diminution of amplitude and strength of the arterial pulse, hyperpnea, wasting, oliguria often with albuminuria, increased thirst, anorexia, scant feces, depression, and muscle weakness. The temperature elevation is always moderate and rarely goes above 42°C (107°F).

The **form of the fever may vary.** Thus the temperature rise may be

- Transient
- Sustained, without significant diurnal variation
- Remittent, when the diurnal variation is exaggerated
- Intermittent, when fever peaks last for 2 to 3 days and are interspersed with normal periods
- Atypical, when temperature variations are irregular

A biphasic fever, consisting of an initial rise, a fall to normal, and a secondary rise, occurs in some diseases, e.g., in strangles in the horse and in erysipelas in swine. The outstanding example of intermittent fever in animal disease is equine infectious anemia.

In farm-animal practice the most common cause of a fever is the presence of an inflammatory process such as pneumonia, peritonitis, mastitis, encephalitis, septicemia, viremia, etc. The clinical abnormalities that are typical of the particular disease must be detected and differentiated in the process of making a diagnosis. In the absence of physical causes of hyperthermia, the presence of a fever indicates the presence of inflammation, which is not always readily apparent. A **fever of unknown origin** occurs commonly in farm animals and requires repeated clinical and laboratory examinations to elucidate the location and nature of the lesion.

In **horses**, a **fever of unknown origin** is characterized by prolonged, unexplained fever associated with nonspecific findings such as lethargy, inappetence, and weight loss. In a series of horses with fever of unknown origin, the cause was found to be infection in 43%, neoplasia in 22%, immune mediated in 7%, and miscellaneous diseases in 19%. The cause remained undetermined in 10%.

The **magnitude of the fever** will vary with the disease process present, and it is often difficult to decide at what point the elevated temperature is significant and represents the presence of a lesion that requires specific treatment. This is especially true when examining groups of animals with nonspecific clinical findings including an elevated temperature. The typical example is a group of feedlot cattle affected with depression, inappetence, dyspnea, and fever ranging from 39.5 to 40.5°C. The suspected disease may be pneumonic pasteurellosis but it may be impossible to make that diagnosis based on auscultation of the lungs of all the affected animals. Some of the animals may have a fever of unknown origin from which they will recover in a few days and specific therapy is not required. Under these circumstances and based on clinical experience, the tendency is to make a diagnosis of **acute undifferentiated bovine respiratory disease** or **undifferentiated fever** in animals with a temperature ≥40.5°C for 2 days in succession. This emphasizes the need to select an upper threshold value that indicates a clinically and physiologically significant fever. Infrared thermography offers great promise as a noninvasive method of identifying pyrexic individuals in group housing, particularly pigs raised in confinement housing and feedlot cattle.

CLINICAL PATHOLOGY

There are no clinicopathologic findings that are specific for fever. The hemogram will reflect the changes associated with the cause of the fever. Inflammation is characterized by marked changes in the total and differential leukocyte count characteristic for each disease. A wide variety of tests can be performed to identify the location and nature of the lesion causing the fever. The most common tests include the following:

- Microbiologic testing of blood samples
- Analysis of serous fluids from body cavities
- Cerebrospinal fluid analysis
- Milk sample analysis
- Reproductive tract secretion analysis
- Joint fluid analysis
- Biopsies
- Exploratory laparotomy

Medical imaging may be necessary to detect deep abscesses.

Necropsy Findings

The necropsy findings will be characteristic of the individual disease process and are commonly characterized by varying degrees of peracute, acute, and chronic inflammation depending on the severity of the disease, the length of illness, and whether or not treatment had been given. In the case of long-standing fevers, these findings are still characteristic but they may fluctuate in severity daily or over longer periods.

Fever must be differentiated from hyperthermia caused by a physical cause such as **heat stroke** or **exhaustion** or **malignant hyperthermia** of pigs and Quarter Horses. In **fever of unknown origin**, the history, physical examination, laboratory findings, and epidemiologic setting should be reviewed. Localizing clinical findings may provide a clue to the body system or organ involved. Common inflammatory processes include the following:

- Abscesses of the peritoneum, pleura, and lungs
- Septic metritis
- Endocarditis
- Polyarthritis
- Pyelonephritis

Many animals are placed in the category of fever of unknown origin because the veterinarian overlooks, disregards, or rejects an obvious clue. No algorithms or computer-assisted diagnostic programs are likely to solve this diagnostic challenge. To improve the diagnostic accuracy veterinarians will have to work harder. This requires obtaining a detailed history, repeated physical examinations, reconsideration of the epidemiologic characteristics of the affected animal, requesting consultations from colleagues, and the investment of time to consider the diagnosis and the circumstances.

TREATMENT

Antimicrobial Agents

The most important aspects of the clinical management of fever should be directed at its cause. The main objective is to identify and treat the primary disease. Antimicrobial agents are indicated for the treatment of bacterial infections. The selection of antimicrobial, the route of administration, and the duration of treatment depend on the cause of the infection, its severity, and the accessibility of the lesion to the drug. The use of antimicrobial agents to prevent secondary bacterial infections in animals with viral diseases (e.g., viral interstitial pneumonia) is controversial and of doubtful benefit.

In animals with a **fever of unknown origin**, broad-spectrum antimicrobial agents seem rational. However, blind therapy is not recommended because it may lead to drug toxicity, superinfection caused by resistant bacteria, and interference with subsequent accurate diagnosis by cultural methods. In addition, the fall of the temperature following treatment may be interpreted as a response to therapy, with the conclusion that an infectious disease is present. If such a trial is begun the response should be monitored daily to determine effectiveness, and continued efforts should be made to determine the cause of the fever. In some cases it may be necessary to surgically remove by drainage techniques the source of the infection located in abscesses or body cavities such as the pleural cavity.

Antipyretics

Because fever ordinarily does little harm and usually benefits the animal's defense mechanism, antipyretic agents are rarely essential and may actually obscure the effect of a specific therapeutic agent or of the natural

course of the disease. If the fever is high enough to cause discomfort or inappetence, or is so high that death from hyperthermia is possible, then nonsteroidal antiinflammatory drugs (NSAIDs) should be administered. Most NSAIDs, such as flunixin meglumine, are inhibitors of prostaglandin synthesis and act centrally to lower the thermoregulatory set point. Rectal temperatures start to decline within 30 minutes of parenteral NSAID administration but usually do not completely return to within the normal physiologic range.

Acute Phase Response

Acute phase proteins are plasma proteins that change their concentration when animals are subjected to external stressors, such as transportation, or internal stimuli, such as inflammation, bacterial infection, neoplasia, and surgical trauma.[1] Acute phase proteins have been categorized as positive or negative dependent on whether their concentration increases (positive) or decreases (negative) in response to an external or internal stimulus. There has been increased interest in measuring the serum concentration of acute phase reactants to monitor the severity of an infectious disease, assist in making a diagnosis, and to verify that an animal produced for food is healthy and fit for slaughter. During the hepatic acute phase response, the liver increases the synthesis of specific proteins (**positive acute phase proteins**) in response to release of IL-1β, IL-6, and TNF-α (proinflammatory cytokines) from macrophages and monocytes, whereas albumin synthesis is reduced (negative acute phase protein). Interleukin-1β induces type 1 acute phase proteins (serum amyloid A [SAA] and C-reactive protein) within 4 hours. Interleukin-6 induces haptoglobin at a later stage with serum concentrations remaining elevated for up to 2 weeks. A clinically important issue is that IL-1β is the primary initiator of fever as well as an important upstream initiator of the acute phase response; therefore, it remains to be determined whether laboratory measurement of acute phase reactant concentration in plasma provides practical information beyond that provided by rectal temperature alone. It should be recognized that although the liver plays a central role in the acute phase response, extrahepatic tissues, such as the bovine mammary gland, can also synthesize acute phase reactants.

Fibrinogen is the most widely studied positive acute phase protein in large animals. The interpretation of plasma fibrinogen concentration is complicated by its involvement in the clotting cascade (and potentially decreasing in animals with severe coagulopathies such as disseminated intravascular coagulation) and its relatively narrow range of increase (typically no more than a three- to fourfold increase). Moreover, the plasma fibrinogen concentration is slower to increase in inflammatory conditions than other acute phase reactants, typically taking 24 hours to increase with peak values at 2 to 3 days.

The **SAA** is a positive acute phase protein (apolipoprotein) that is rapidly synthesized and released primarily by hepatocytes in response to inflammation or bacterial infection. The specific role of SAA in the inflammatory response is incompletely understood, but amyloid A is thought to have immune-related functions including opsonization of gram-positive and gram-negative bacteria, increased chemotaxis of neutrophils and monocytes, and the clearance of plasma endotoxin and high-density lipoproteins including cholesterol.

Haptoglobin is a positive acute phase protein and is thought to provide an exquisitely sensitive screening test for the release of endogenous glucocorticoids and proinflammatory cytokines. Haptoglobin is the principal scavenger of free hemoglobin in plasma and therefore decreases growth of most bacteria by decreasing the availability of iron. A major confounder for the interpretation of an increased serum haptoglobin concentration is that trauma, and increased plasma cortisol and estradiol concentrations associated with parturition, increase serum haptoglobin concentrations.[2]

Lipopolysaccharide binding protein (LBP) is an antiinflammatory in low concentrations and proinflammatory in high concentrations. It binds to the lipopolysaccharide portion of gram-negative bacteria and the bound complex then attaches to membrane or soluble CD14 receptors, initiating a signaling cascade. **C-reactive protein** and **α1-acid glycoprotein** are also positive acute phase proteins that have been extensively investigated in humans but have not been well investigated in large animals.

Several positive acute phase proteins have been evaluated in horses including SAA, C-reactive protein, haptoglobin, and fibrinogen. The most clinically relevant acute phase reactant in the horse appears to be SAA, because SAA concentrations are extremely low in healthy horses, increase markedly and rapidly during the acute phase of inflammation, and decrease rapidly after recovery because of its short half-life.[1,3,4] The clinical utility of SAA as a marker of infection is decreased in neonatal foals because SAA concentrations increase for up to 7 days in response to inflammation associated with vaginal delivery and absorption of amyloid A present in colostrum.[5]

Serum amyloid A, haptoglobin, and fibrinogen are important positive acute phase proteins in cattle and are produced by the liver in response to endogenous release of glucocorticoids and proinflammatory cytokines. Of these acute phase reactants, SAA is considered to have the most diagnostic utility in cattle. A potential confounder for the interpretation of SAA concentration in cattle is that its concentration normally increases at calving.[6] This means that an increased SAA concentration is not specific for inflammation or bacterial infection in the postparturient dairy cow and may be more associated with the extent of hepatic lipidosis than the presence of an inflammatory process in early lactation.[6,7]

Serum or plasma haptoglobin concentration is increased in cows with hepatic lipidosis, displaced abomasum, traumatic reticuloperitonitis, respiratory disease, mastitis, metritis, pododermatitis, and renal amyloidosis.[6,8-12] More research is needed to increase our understanding of changes in the concentration and kinetics of haptoglobin in cattle. C-reactive protein does not appear to be an acute phase reactant in cattle. The increase in SAA and haptoglobin in cattle appears to be dose dependent; therefore, the magnitude of the increase reflects the severity of the underlying inflammatory process.[13,14]

Important **negative acute phase proteins** in cattle include **albumin**, transferrin, and **paraoxonase**.[8] Albumin does not appear to be as sensitive an acute phase reactant as SAA in cattle. Moreover, serum albumin concentrations are decreased for 2 weeks after calving in lactating dairy cattle, partly as a result of increased plasma volume and decreased albumin synthesis,[6] further decreasing the clinical utility of serum albumin concentration as an acute phase reactant in postparturient cattle. The acute phase response in sheep appears similar to that in cattle.[15]

Plasma or serum iron concentrations decrease as part of the acute phase response; this has been attributed to sequestration of iron stores by the animal to make less iron available for bacterial growth.[16] Inflammation causes the release of IL-6 that stimulates hepatocytes to release the peptide hormone **hepcidin,** which blocks iron efflux from macrophages, directly resulting in hypoferremia.[16] Plasma iron concentration appears to be a better acute phase reactant than fibrinogen concentration in horses.[16]

Sepsis, Septicemia, and Viremia

Sepsis is a suspected or proven bacterial infection in conjunction with the presence of **systemic inflammatory response syndrome (SIRS)**, which is defined as systemic inflammation in response to injury, being caused by infectious agents (e.g., bacteria, viruses, protozoa, fungi) or by noninfectious causes (e.g., trauma, toxins, hyperthermia, burns). Accurate criteria for SIRS have yet to be identified in domestic animals, but the presence of at least two of the following abnormalities is used to identify the presence of SIRS in humans:

- Hyperthermia or hypothermia
- Tachycardia
- Tachypnea or hyperventilation
- Leukopenia, leukocytosis, or >10% band neutrophils

These criteria for SIRS should not be applied when environmental conditions impact the measurement (such as heat stress or environmental cold or the presence of pain).

Severe sepsis is sepsis accompanied by organ dysfunction. **Septic shock** is defined as severe sepsis with hypotension (mean arterial blood pressure <65 mm Hg) despite aggressive intravenous fluid therapy. **Septicemia** is the acute invasion of the systemic circulation by pathogenic bacteria accompanied by septic shock with possible bacterial localization in various body systems or organs. It is a common cause of morbidity and mortality in newborn farm animals that have not received a sufficient quantity of colostrum in the first 24 hours after birth. **Bacteremia** is different from septicemia in that bacteremia is not accompanied by sepsis or septic shock. The difference between septicemia and bacteremia is one of degree. In bacteremia, bacteria are present in the bloodstream for only transitory periods and do not produce clinical signs; for example, a clinically unimportant bacteremia probably occurs frequently after rectal examination or other manipulations in which the mucosa is disturbed. In septicemia, the pathogen is present throughout the course of the disease and is directly responsible for initiation of the disease process. There is a current movement to eliminate the term septicemia from use and use the term **multiple organ dysfunction syndrome**, which indicates dysfunction to two or more organ systems, but the definitions stated earlier are clinically useful.

Viremia is the invasion of the systemic circulation by pathogenic viruses with localization in various body tissues and in which the lesions produced are characteristic of the specific virus. Many infections associated with rickettsias, protozoa, and fungi are also spread hematogenously throughout the body but usually do not initiate a systemic inflammatory response syndrome.

ETIOLOGY: ALL SPECIES

Many different infectious agents can result in septicemia or viremia. Some of the notable examples of septicemias and viremias are outlined next. Anthrax, pasteurellosis, and salmonellosis are found in all species of food animal.

Neonatal Septicemias

Neonatal septicemias are caused most commonly by gram-negative bacteria.

Calves

Bacteremia and septicemia are often associated with *Escherichia coli* and *Salmonella* spp. *E. coli* is most frequently isolated from the blood of calves, but gram-positive infections may be found in 10% of septicemic calves and polymicrobial infections in 28%. Calf septicemia is infrequently caused by bacteria similar to *Actinobacillus suis* bacteria. Thirty percent of severely ill calves with or without diarrhea are bacteremic, and the risk of bacteremia is higher in calves with failure of transfer of colostral immunoglobulins.

Piglets

Septicemia caused by *E. coli* is possible along with septicemia with localization in the joints, endocardium, and meninges associated with *Streptococcus suis* type 1.

Foals

Septicemia with localization associated with *E. coli, A. equuli, Klebsiella pneumoniae,* α-hemolytic *Streptococcus,* and *Salmonella* spp. are seen.

Lambs

Septicemia associated with *E. coli* occurs most frequently.

Cattle

Histophilus somni, Pasteurella multocida, Mannheimia haemolytica, Pasteurella (Yersinia) pseudotuberculosis, acute and chronic infections with bovine virus diarrhea virus, and bovine malignant catarrh are encountered.

Sheep (Young Lambs)

H. somni is the main pathogen.

Pigs

Hog cholera and African swine fever viruses and *Erysipelothrix insidiosa* are encountered.

Horses, Donkeys, and Mules

African horse sickness and *M. haemolytica* infection are implicated.

Secondary Septicemias

The principal cause of death in subacute radiation injury is septicemia resulting from loss of leukocyte production because of injury to bone marrow. Septicemia may also result when there is a congenital defect in the immune system or when immunosuppression occurs in older animals as a result of corticosteroid therapy or toxin such as bracken.

EPIDEMIOLOGY

Systemic infections associated with bacteria, viruses, rickettsia, protozoa, and other pathogens occur in animals of all ages and under many different circumstances. The epidemiologic characteristics for each entity are presented under each disease described in this book. The risk factors for each infectious disease are categorized according to

- Animal risk factors
- Environmental risk factors
- Pathogen risk factors

For example, colostrum-deprived newborn animals are highly susceptible to septicemia. **Failure of transfer of passive immunity** (FTPI) in foals is defined by serum IgG_1 concentrations of ≤400 mg/dL and partial failure of transfer of passive immunity between 400 and 800 mg/dL. Serum IgG concentrations of ≥800 mg/dL are less frequently associated with sepsis in foals, and this is considered the threshold concentration for prophylaxis in foals.

PATHOGENESIS

Two mechanisms operate in septicemia: the **exotoxins** or **endotoxins** produced by the infectious agents initiate a profound toxemia and high fever because of their initiation of the release of host mediators and because of the rapidity with which the agents multiply and spread to all body tissues (see also Toxemia, Endotoxemia, and Septic Shock). The clinical manifestations are the result of the effect of the pathogens on monocytes and lymphocytes, which initiate **SIRS**. TNF-α is associated with clinical septicemia in

newborn foals and calves, and plasma TNF-α concentration is associated with the severity of clinical signs.

Localization of certain pathogens occurs in many organs and may produce severe lesions in animals that survive the toxemia. Direct endothelial damage and hemorrhages may also be caused. The same general principles apply to a viremia, except that toxins are not produced by viruses. It is more likely that the clinical manifestations are the result of direct injury of the cells invaded by the virus. **Transplacental infection** can occur, resulting in fetal **mummification**, **abortion**, or **infection of the fetus that may be carried to term**.

Disseminated Intravascular Coagulation

Progression of SIRS can result in disseminated intravascular coagulation (DIC) caused by intravascular fibrin formation, particularly in severe septicemic diseases. Disseminated intravascular coagulation is initiated by vascular injury with partial disruption of the intima, caused by the circulation of foreign materials such as bacterial cell walls, antigen–antibody complexes, and endotoxin, with subsequent platelet adherence and the formation of platelet thrombi. Severe, uncontrolled hypercoagulation results in a high mortality rate caused by MODS. Once coagulation proceeds, the initial hypercoagulable state changes to hypocoagulation as clotting factors and platelets are consumed. The activation of the fibrinolysis system can be a major cause of the hemorrhagic diathesis present in this syndrome.

CLINICAL FINDINGS

The major clinical findings in septicemia are **fever**, **cardiovascular dysfunction and shock**, and **submucosal and subepidermal hemorrhages** that are usually petechial and occasionally ecchymotic. The hemorrhages are best seen under the conjunctiva and in the mucosae of the mouth and vulva. Tachycardia, tachypnea, and shock-induced organ dysfunction with cardiovascular hypotension, myocardial asthenia, and respiratory distress may occur in severe cases if the pathogen initiates the release of the host mediators, causing **SIRS**. These features are described under Toxemia, Endotoxemia, and Septic Shock.

Specific signs may occur as the result of localization of the infection in joints, heart valves, meninges, eyes, or other organs. The clinical findings characteristic of each disease in which septicemia and viremia occur are presented under each disease heading in this book.

Neonatal Septicemia

Neonatal septicemia is common in all farm animal species from a few hours up to several days of age. The following features are common:

- Recumbency
- Depression
- Absence or marked depression of the suck reflex
- Dehydration
- Fever
- Diarrhea
- Injected or congested mucous membranes
- Weakness
- Rapid death

Colostrum-deprived foals are commonly very ill and become comatose and die within several hours. Localized infections in the joints and lungs are frequent in foals that survive for several days. Septic polyarthritis is common and is characterized by heat, pain, synovial distension, and lameness, and occurs in 14% to 38% of neonatal foals with sepsis. About half the foals with septic arthritis have two or more joints clinically infected, with the femoropatellar and tarsocrural joints being most commonly involved. Pneumonia is often observed and is characterized by dyspnea and abnormal lung sounds. The survival rate of foals with confirmed septicemia in one series was 70%.

In calves under 30 days of age with septicemia clinical findings can include evidence of shock with cold extremities, dehydration, weak pulse, prolonged capillary refill time, weakness, and recumbency. Findings indicative of localization include ophthalmitis, neurologic abnormalities, omphalophlebitis, and polyarthritis.

Clinical Sepsis Score

A **clinical sepsis score** for the early diagnosis of septicemia in newborn foals has been evaluated and validated. It should be recognized that application of such scoring systems is statistically flawed, even if they assign different weights to predictors, because they assign equal weights to the change in severity within a given predictor. Nevertheless, such sepsis scores have been adopted by some and do have the value of facilitating the identification of neonates at risk for being septicemic. A score for predicting bacteremia in neonatal dairy calves from 1 to 14 days of age has also been suggested to predict clinically whether a sick calf has bacteremia. The calves are scored according to degrees of **hydration status**, **fecal appearance**, **general attitude**, **appearance of scleral vessels,** and **umbilical abnormality**. However, the sensitivity, specificity, and positive predictive value are too low to be of diagnostic value.

CLINICAL PATHOLOGY

Blood Culture

Isolation of the causative bacteria from the bloodstream should be attempted by culture. Ideally, blood cultures should be obtained just before the onset of fever and from a major vein or any artery. The standard is three blood cultures or animal inoculation at the height of the fever. A minimum of 10 mL of blood (preferably 30 mL) should be collected anaerobically after aseptic preparation of the venipuncture site by clipping and scrubbing with povidone iodine scrub. Blood samples should be inoculated into a broth medium with the ratio of blood to broth being 1:10 to 1:20, and the culture bottles should be examined for growth daily for up to a week. Growth is manifested as turbidity and possibly by the presence of hemolysis.

Hemogram

The presence of **leukopenia** or **leukocytosis** is an aid in diagnosis and the type and degree of leukocytic response may be of prognostic significance, particularly the presence of band neutrophils, metamyelocytes, or toxic neutrophils.[1]

Plasma fibrinogen concentrations may be increased. Consumption coagulopathy is detected by falling platelet counts, prothrombin and fibrinogen concentrations, and by the presence of fibrin-linked degradation products such as **D-dimer**. In neonatal calves, plasma activated partial thromboplastin time was prolonged in calves suspected to have septic shock.[1]

Immunoglobulin Status

Low concentrations of serum protein and immunoglobulins are associated with failure of transfer of colostral immunoglobulins in newborn farm animals with consequent septicemia caused, most commonly, by gram-negative bacteria.

Biomarkers

Biomarkers of sepsis are becoming increasingly used to guide diagnosis and treatment in humans. The main challenges with the use of biomarkers of sepsis in domestic animals are their availability, cost, and time required to obtain a result. Calves with abnormal coagulation profile results indicating the presence of severe hemostatic dysfunction were much more likely to die despite intensive therapy.[1] Plasma or serum biomarkers that show promise for diagnosing sepsis in foals or adult horses are SAA,[2] a soluble form of the CD14 molecule that binds endotoxin in plasma,[3,4] adrenomedullin,[5] arginine vasopressin,[6] and adrenocorticotropin hormone (ACTH).[6] C-reactive protein[7] and haptoglobin[7] do not currently appear to be useful biomarkers for sepsis in foals.

Serology

Serologic tests are available for most infectious diseases described in this book; however, the rapid onset of septicemia in most instances precludes the use of immunoglobulin tests, with the possible exception of IgM.

Necropsy Findings

The lesions will reflect the specific disease causing the septicemia. Subserous and submucosal hemorrhages may be present, together with embolic foci of infection in

various organs accompanied by the lesions typical of the specific pathogen.

TREATMENT

The principles of treatment are similar to those described for the treatment of toxemia, endotoxemia, fever, and septic shock, and treatment should focus on broad-spectrum antimicrobial agents and general supportive measures. For neonatal septicemia the provision of a source of immunoglobulins by plasma or blood transfusion is thought to be advantageous when there is FTPI. Whether such treatment alters the mortality rate is uncertain. Intensive care of the newborn with septicemia is described in Chapter 19. The frequency of bacteremia (approximately 30%) is sufficiently high in calves with diarrhea that are severely ill (as manifested by reduced suckle reflex, >6% dehydration, weakness, inability to stand, or clinical depression) that affected calves should be routinely treated for bacteremia, with emphasis on treating potential *E. coli* bacteremia. Strict hygienic precautions to avoid spread of infection are also necessary.

Toxemia, Endotoxemia, and Septic Shock

Toxemia is a clinical systemic state caused by widespread activation of host defense mechanisms to the presence of toxins produced by bacteria or injury to tissue cells. Toxemia does not include the diseases caused by toxic substances produced by plants or insects or ingested organic or inorganic poisons. Theoretically, a diagnosis of toxemia can be made only if toxins are demonstrable in the bloodstream. Practically, toxemia is often diagnosed when the endotoxemia is present. In most cases there is contributory evidence of a probable source of toxins, which in many cases are virtually impossible to isolate or identify.

The most common form of toxemia in large animals is **endotoxemia**, caused by the presence of lipopolysaccharide cell-wall components of gram-negative bacteria in the blood and characterized clinically by abnormalities of many body systems. Because of the overwhelming importance of endotoxemia in large animals with gram-negative bacterial infections, the focus of this discussion will be on endotoxemia. The abnormalities of endotoxemia include the following:

- Marked alterations in cardiopulmonary function
- Abnormalities in the leukon (neutropenia and lymphopenia) and thrombocytopenia that may lead to coagulopathies
- Increased vascular permeability
- Decreased organ blood flow and metabolism, leading to heart and renal failure
- Decreased gastrointestinal motility
- Decreased perfusion of peripheral tissues, leading to shock
- The need for intensive and complex therapy
- A high case fatality rate

Current therapeutic regimens are only moderately successful in treating endotoxic large animals with clinical signs of **septic shock** (severe sepsis with hypotension [mean arterial blood pressure <65 mm Hg] despite aggressive intravenous fluid therapy).

Gram-negative bacteria such as *E. coli*, *Salmonella* spp., *Pasteurella* spp., and *H. somni*, as examples, cause many diseases of ruminants in which endotoxemia is common. Varying degrees of severity of toxemia occur in diseases such as mastitis, peritonitis, pneumonia and pleuritis, pericarditis, septic metritis, septicemia of neonates, myositis, meningoencephalitis, and some enteritides. Endotoxemia is also one of the most common causes of death in horses affected with gastrointestinal disease from a physical obstruction causing strangulation and ischemic necrosis.

ETIOLOGY

Toxins can be classified as antigenic or metabolic.

Antigenic Toxins

These are produced by bacteria and to a lesser extent by helminths. Both groups of pathogens act as antigens and stimulate the development of antibodies. Antigenic toxins are divided into exotoxins and endotoxins.

Exotoxins

These are protein substances produced by bacteria that diffuse into the surrounding medium. They are specific in their pharmacologic effects and in the antibodies that they induce. The important bacterial exotoxins are those produced by *Clostridium* spp., for which commercial antitoxins are available. They may be ingested preformed, as in botulism, or produced in large quantities by heavy growth in the intestines, such as in enterotoxemia, or from growth in tissue, as in blackleg and black disease.

Enterotoxins

These are exotoxins that exert their effect principally on the mucosa of the intestine, causing disturbances of fluid and electrolyte balance. The most typical example is the enterotoxin released by enterotoxigenic *E. coli,* which causes a hypersecretory diarrhea in neonatal farm animals.

Endotoxins

The endotoxins of several species of gram-negative bacteria are a major cause of morbidity and mortality in farm animals. The endotoxins are lipopolysaccharides found in the outer wall of the bacteria. Endotoxins are released into the immediate surroundings when the bacteria undergo rapid proliferation with production of unused sections of bacterial cell wall or, most commonly, when the bacterial cell wall breaks. Endotoxin gains access to the blood when there is a severe localized infection, such as a coliform mastitis in dairy cattle, or a disseminated infection, such as coliform septicemia in newborn calves.

Gram-negative bacteria are present in the intestinal tract as part of the normal microflora and endotoxins are also present. The endotoxins are not ordinarily absorbed through the intestinal mucosa unless it is injured, as in enteritis or more particularly in acute intestinal obstruction. Ordinarily, small amounts of endotoxin that are absorbed into the circulation are detoxified in the liver but, if hepatic efficiency is reduced or the amounts of toxin are large, a state of endotoxemia is produced. Endotoxins may also be absorbed in large amounts from sites other than the intestine including the mammary gland, peritoneum, abscesses and other septic foci, or from large areas of injured or traumatized tissue. The best known endotoxins are those of *E. coli,* which have been used extensively as models for experimental endotoxemia, and *Salmonella* spp.

The most common causes of endotoxemia in horses are associated with diseases of the gastrointestinal tract including colitis, intestinal strangulation, or obstruction and ileus. Complications associated with foaling and grain overload are also common causes.

Metabolic Toxins

These may accumulate as a result of incomplete elimination of toxic materials normally produced by body metabolism, or by abnormal metabolism. Normally, toxic products

produced in the alimentary tract or tissues are excreted in the urine and feces or detoxified in the plasma and liver. When these normal mechanisms are disrupted, particularly in hepatic dysfunction, the toxins may accumulate beyond a critical point and the syndrome of toxemia appears. In obstruction of the lower alimentary tract there may be increased absorption of toxic phenols, cresols, and amines that are normally excreted with the feces, resulting in the development of the syndrome of autointoxication. In ordinary circumstances in monogastric animals these products of protein putrefaction are not absorbed by the mucosa of the large intestine but when regurgitation into the small intestine occurs there may be rapid absorption, apparently because of the absence of a protective barrier in the wall of the small intestine.

In liver diseases, many of the normal detoxification mechanisms, including oxidation, reduction, acetylation, and conjugation with such substances as glycine, glucuronic acid, sulfuric acid, and cysteine, are lost and substances that are normally present in insufficient quantity to cause injury accumulate to the point where illness occurs. The production of toxins by abnormal metabolism includes the production of histamine and histamine-like substances in damaged tissues. Ketonemia caused by a disproportionate fat metabolism, and lactic acidemia caused by acute ruminal acidosis (grain overload), are two common examples of toxemia caused by abnormal metabolism.

PATHOGENESIS

The specific effects of the particular bacterial exotoxins and metabolic toxins are presented in the relevant sections of specific bacterial diseases in this book. The principles of the effects of bacterial endotoxemia will be presented here.

The total toxic moiety of the lipopolysaccharide molecule is generally similar regardless of the bacterial source. Endotoxemia results in an extraordinary array of pathophysiologic effects, involving essentially all body systems. Of the endotoxins produced by bacteria, the most is known of those produced by *E. coli*.

Endotoxins are normally present in the intestine and, although the intestinal mucosa provides a highly efficient barrier, limiting transmural movement of endotoxins, small quantities are absorbed into the portal blood. These endotoxins are removed by the liver and do not reach the peripheral blood. In hepatic failure the level of endotoxins in plasma is increased. Significantly greater quantities of endotoxins escape the intestine when the mucosal barrier is disrupted by intestinal ischemia, trauma, ionizing radiation, bacterial overgrowth, reduced luminal pH, or inflammatory intestinal disease. These conditions not only temporarily overwhelm the capacity of the liver to remove endotoxin from the portal circulation but also allow transmural movement of endotoxins into the peritoneal cavity from which they reach the peripheral blood.

Endotoxemia may also occur when gram-negative bacteria gain access to tissues and/or blood. Most of these organisms liberate endotoxin during rapid growth and gain access to the blood from primary foci of systemic or superficial tissue infections. One example is coliform septicemia in newborn farm animals. Once the endotoxins gain access to the blood, they are removed from the circulation by the mononuclear phagocyte system, and the response of these phagocytes to the lipopolysaccharides determines the severity of the clinical illness.

Biochemical Mediators

Endotoxins do not cause their effects via direct toxic effect on host cells; instead they induce the production of soluble and cell-bound mediators from a broad range of host cells, including endothelial and smooth muscle cells, polymorphonuclear granulocytes, platelets, thrombocytes, and cells of the monocyte/macrophage lineage. These cells release a series of phlogistic biochemical mediators, which include cytokines, platelet-activating factor, thromboxane A_2, prostaglandins, leukotrienes, proteinases, toxic oxygen metabolites, and vasoactive amines. Macrophages become highly activated for enhanced secretory, phagocytic, and cidal functions by the lipopolysaccharide. The cytokines derived from the macrophages are responsible for many of the pathophysiologic consequences of endotoxemia. Pulmonary intravascular macrophages are the most important producers of cytokines in large animals.

Animals have evolved to recognize and respond to the lipopolysaccharide of gram-negative bacteria. Although lipopolysaccharides may directly injure the host tissue, many of its effects are indirectly mediated through inappropriate activation of host defense mechanisms, culminating in multiple organ dysfunction and failure. Importantly, the response to endotoxin can be attenuated with certain substances. Experimentally, the use of detergents, such as a nonionic surfactant, can attenuate the response of the horse given endotoxin. There is a large individual variability in the response to endotoxin administration. Much of the variability remains unexplained but appears to have a genetic component.[1] Circulating lipopolysaccharide forms complexes in plasma with high-density lipoproteins or a unique plasma protein termed LBP and bound lipopolysaccharide is cleared from plasma within a few minutes by fixed and circulating macrophages in the bovine lung and liver that recognizes the lipopolysaccharide–LBP complex. The lipopolysaccharide–LBP complex binds to a membrane-bound receptor (**mCD14**) on mononuclear cells via a secreted linking protein called MD-2 and then attaches to **toll-like receptor-4** (TLR-4) on the mononuclear cell membrane; the lipopolysaccharide–LBP–mCD14–MD-2 complex is then internalized and lipopolysaccharide is thought to be destroyed in the process. Internalization of lipopolysaccharide activates the intracellular signaling pathway via nuclear factor κB (**NF-κB**), which translocates to the nucleus and causes the transcription of many cytokine genes and release of proinflammatory cytokines, of which **TNF-α**, **IL-1,** and **IL-6** are the most important. Some of the genes activated include those that code for cyclooxygenase 2 (**COX-2**, the inducible form of cyclooxygenase); inducible nitric oxide; **endothelial adhesion molecules**, which promote the adhesion of neutrophils to endothelial surfaces; and chemokines. Some of the membrane-bound receptors (mCD14) are shed from the cell surface into the plasma; in plasma the shed receptors are termed soluble CD14 receptors (sCD14), which play a crucial role in the pathophysiology of endotoxemia. This is because sCD14 receptors can transfer bound lipopolysaccharide directly to mCD14 or the MD-2/TLR-4 complex, activating the intracellular signaling pathway. Increased serum concentrations of sCD14 are associated with the severity of some clinical signs in critically ill horses.[2]

The plasma concentrations of the **arachidonic acid metabolites**, **thromboxane A_2** and **prostacyclin**, increase in several species during endotoxemia, and these eicosanoids are probably responsible for the hemodynamic abnormalities caused by endotoxin. Endotoxin initiates cellular events that activate a cell-membrane enzyme known as phospholipase A_2. Activation of this enzyme leads to the hydrolysis of membrane-bound phospholipids; arachidonic acid is released from the phospholipid portion of damaged mammalian cell membranes. The enzyme cyclooxygenase converts arachidonic acid into intermediate endoperoxides, which are substrates for the formation of prostaglandins, thromboxane, and prostacyclin, by specific synthetases. Platelets are the principal source of thromboxane, which acts as a potent vasoconstrictor and induces platelet aggregation. Most prostacyclins are synthesized in vascular endothelial cells and cause vasodilation and inhibit platelet aggregation. The generalized endotoxin-induced production of cyclooxygenase products may contribute to the multisystemic organ dysfunction, shock, and disseminated coagulopathy that culminates in death.

Tumor necrosis factor-α is released by macrophages and monocytes in a dose-dependent manner early in the course of endotoxemia, and circulating TNF-α activity correlates with the severity and outcome of disease. Infusion of TNF induces an endotoxemic-shock–like syndrome and TNF-α blockade confers marked protection against the effects of gram-negative sepsis and

lipopolysaccharide administration. Experimentally, pretreatment of horses with monoclonal antibody to TNF-α can reduce the hematologic and clinical effects of endotoxin-induced TNF activity and IL-6 activity can be reduced by neutralization of TNF-α. Interleukin-1 release is proinflammatory and leads to pyrexia and the hepatic **acute phase response**. Interleukin-6 contributes to the hepatic acute phase response and promotes B-lymphocyte proliferation. Interleukin-6 may have value as a prognostic indicator, because its plasma concentration appears to be a better predictor of mortality in humans than TNF-α or IL-1.

The systemic effects of endotoxemia can be demonstrated experimentally by parenteral injection of purified endotoxin, TNF-α, or IL-1. In naturally occurring disease, however, the total effect includes those of bacterial toxins plus those of mediators produced by tissues in response to the toxins and the counterbalancing effects of antiinflammatory molecules that are also secreted during sepsis such as IL-4, IL-10, IL-11, and IL-13, and soluble CD14 receptors. The pathophysiologic effects of endotoxemia associated with gram-negative bacteria are summarized here according to their effects on various body systems or functions.

Cardiopulmonary Function

The hemodynamic effects of endotoxemia are manifested in two phases. In the early stages, heart rate and cardiac output commonly increase, although systemic blood pressure remains near or slightly less than normal. This is known as the **hyperdynamic phase** of endotoxemia. Oxygen demands of peripheral tissues are increased during the hyperdynamic phase, resulting in compensatory mechanisms that increase blood flow in an attempt to meet the increased metabolic demands. However, despite the absolute increase in cardiac output and oxygen delivery during this hyperdynamic phase, blood flow still may be inadequate to meet the needs of tissues in a hypermetabolic state. During the hyperdynamic state, affected animals hyperventilate and have decreased capillary refill time and red, congested mucous membranes. Microcirculatory shunting of blood continues in organs such as the gastrointestinal tract and kidney. Ischemia of intestinal mucosa is manifested clinically by ileus and diarrhea may occur. Decreased renal perfusion will result in decreased urine output.

With uncontrolled endotoxemia, the hyperdynamic phase progresses to the **hypodynamic phase** of shock. Changes include decreased cardiac output, systemic hypotension, increased peripheral resistance, and decreased central venous return. Hypothermia, rapid irregular pulses, prolonged capillary refill time, pale to cyanotic mucous membranes, acidemia, and hypoxemia provide clinical evidence of this advanced stage of endotoxemia. The skin and extremities are cool. Severe pulmonary edema and increasing pulmonary hypertension occur. In horses, administration of endotoxin at high dosages can induce circulatory shock with increased heart rate, decreased cardiac output and stroke volume, and concomitant increases in peripheral vascular resistance. The slow intravenous infusion of low doses of endotoxin into conscious horses results in pulmonary hypertension without causing hypotensive hypovolemic shock. Intestinal vasoconstriction occurs as part of the compensatory response to endotoxemia following slow infusion of low dosages of endotoxin.

Infusion of endotoxin into swine induces widespread changes including intense pulmonary vasoconstriction and hypertension, bronchoconstriction, increased vascular permeability, hypovolemia, systemic hypotension, pulmonary edema, hypoxemia, granulocytopenia, and thrombocytopenia. The vascular changes in endotoxemia include increased vascular permeability, changes in vascular tone, and microvascular obstruction. Increased capillary permeability promotes transmural movement of albumin and other colloids that carry water to the interstitial space. The result is hypoalbuminemia, hypoproteinemia, interstitial edema, pulmonary edema, relative hypovolemia, decreased return to the heart, and further decreases in cardiac output. Arterial and arteriolar vasoconstriction develops in the systemic and pulmonary circulations. Prolonged infusion of endotoxin into sheep causes systemic hypotension, pulmonary hypertension, and acute lung injury with progressive respiratory failure.

Activation of the Renin–Angiotensin–Aldosterone System and Dysfunction of the Hypothalamic–Pituitary–Adrenal Axis

The renin–angiotensin–aldosterone system (RAAS) system is activated in critically ill foals, characterized by increased plasma angiotensin-II and aldosterone concentrations. Critically ill foals also have hypothalamic–pituitary–adrenal (HPA) axis dysfunction, which was originally called **relative adrenal insufficiency** (defined as an inappropriately low plasma cortisol concentration or a low ACTH to cortisol ratio).[3] In 2008 a consensus statement developed by human critical care specialists recommended that the preferred term for the HPA axis dysfunction in septic shock is critical illness-related corticosteroid insufficiency, which reflects an inadequate corticosteroid activity for the severity of the patient's illness.

Leukocytes and Platelets

Foals in septic shock most commonly have gram-negative septicemia, but a minority have gram-positive septicemia or mixed bacterial isolates identified on blood culture. The presence of leukopenia or lymphopenia in a foal with presumed sepsis makes it more likely that a gram-negative septicemia is present.[4] Endotoxemia causes an acute and severe neutropenia, which precedes neutrophilia and hemoconcentration. Neutropenia is caused mainly by leukocyte margination and sequestration; persistence of severe neutropenia is a poor prognostic indicator. Hemoconcentration is caused by movement of fluid from the vascular to extravascular spaces. Endotoxin administration causes an immediate accumulation, margination, and activation of leukocytes in the microcirculation, particularly in the alveolar capillaries. This is followed by degranulation and leukocyte migration into the interstitium and endothelial cell damage. Pulmonary sequestration of neutrophils is preceded by endotoxin uptake by pulmonary intravascular macrophages, indicating that the pulmonary macrophage response is pivotal to the subsequent inflammatory response. Leukopenia appears to be an immediate response to endotoxin administration and is observed as early as 5 minutes after infusion. The rebound leukocytosis is caused by humoral effects on the bone marrow; a neutrophil-releasing factor that promotes release of neutrophils from bone marrow; and macrophage colony-stimulating factor, which stimulates granulopoiesis. Colostrum-fed calves have a greater neutrophilia in response to endotoxin than colostrum-deprived calves, possibly because of absorption of a granulopoietic factor from colostrum. Endotoxemia also induces a lymphopenia that is secondary to the release of endogenous corticosteroids and redistribution of lymphocytes from peripheral blood and the spleen to lymphatic tissue.

Thrombocytopenia is consistently observed after endotoxin administration, but occurs later than neutropenia, although it is sustained for a longer period of time. Endotoxin affects platelet function by a number of different mechanisms.

Hemostatic System

Endotoxins cause endothelial injury directly or indirectly, exposing subendothelial collagen and tissue thromboplastin, initiating the intrinsic and extrinsic coagulation cascades, respectively. Endotoxin can initiate the coagulation cascade directly by activation of factor XII or by inducing platelet release of thromboxane and other procoagulant substances. Endotoxin may induce coagulopathy indirectly by endothelial damage with secondary factor XII activation, or through the effects of complement activation. Macrophages and leukocytes have been shown to release a procoagulant substance in response to endotoxin, which functions similarly to factor VII and may also have a role in perpetuating coagulopathy in endotoxemia via the extrinsic pathway.

Disseminated intravascular coagulation is the cause of diffuse microvascular

thrombosis and eventual organ failure subsequent to endotoxemia. The experimental injection of endotoxin can cause diffuse microthrombosis in multiple organ systems. The principal clinical finding of DIC in horses is petechial and/or ecchymotic hemorrhages on mucous membranes and sclerae with a tendency to bleed from venipuncture sites. Spontaneous epistaxis or prolonged hemorrhage after nasogastric intubation may also occur. The result of exaggerated thrombin formation during DIC is widespread fibrin deposition in the microcirculation causing circulatory obstruction and organ hypoperfusion that may lead to ischemic necrosis and failure. The ultimate consequences are multiple organ failure and death.

Thermoregulation

Bacterial endotoxins are potent stimulators of macrophage interleukins, which belong to a family of polypeptides functioning as key mediators of various infectious, inflammatory, and immunologic challenges to the host. Interleukin-1 induces fever, an increase in the number and immaturity of circulating neutrophils, muscle proteolysis through increased prostaglandin E_2 production, hepatic acute phase protein production, and reduced albumin synthesis. Interleukin-1 participates in the acute phase response, which is characterized by fever, hepatic production of acute phase proteins, neutrophilia, and procoagulant activity.

Endotoxins commonly cause a fever followed by hypothermia. Serum IL-6 concentrations are lower in endotoxin-induced colostrum-deprived foals and take longer to reach peak levels compared with colostrum-fed foals. The higher and more rapid concentrations in colostrum-fed foals may be part of a resistance factor in equine neonates. Interleukin-6 plays a key role in host defense, regulating antigen-specific immune responses, hematopoiesis, cellular differentiation, and the acute phase reaction subsequent to an inflammatory insult. Serum TNF-α responds in a similar pattern in colostrum-deprived and colostrum-fed foals given endotoxin, and the mean rectal temperature in colostrum-deprived foals is significantly less than in colostrum-fed foals.

Gastrointestinal Function

Endotoxemia can cause a profound inhibition of gastrointestinal motility, including the stomach and small and large intestines. Postoperative ileus is a frequent and serious complication of equine colic surgery, and there is a good correlation between the incidence of ileus and the presence of ischemic intestine. Low doses of endotoxin infused into ponies produced profound disruption of normal fasting intestinal motility patterns, with an inhibition of gastric contraction amplitude and rate, left dorsal colon contraction product, and small-colon spike rate. In the small intestine, there is an increase in abnormally arranged regular activity and a decrease in irregular activity. Experimental endotoxemia in the horse causes cecal and proximal colonic hypomotility (ileus) by a mechanism involving α-adrenergic receptors, which is reversible by yohimbine. Numerous mediators may interact with the sympathetic nervous system to induce this effect.

The administration of endotoxin to adult dairy cows can reduce the frequency of reticulorumen contractions; this is caused by endotoxin-induced mediators and the effect can be abolished by flunixin meglumine. Endotoxemia also decreases the abomasal emptying rate in cattle and is suspected to play a role in the development of left displaced abomasum.

Carbohydrate Metabolism

The effects on carbohydrate metabolism include a fall in plasma glucose concentration, the rate and degree varying with the severity of endotoxemia; a disappearance of liver glycogen; and a decreased glucose tolerance of tissues so that administered glucose is not used rapidly. Endotoxic shock can result in lactic acidemia and both hyperglycemic and hypoglycemic responses. **Hyperglycemia** occurs early and transiently in endotoxic shock,[5] is accompanied by increased rates of glucose production, and is dependent on mobilization of hepatic glycogen. **Hypoglycemia** is very common in prolonged or severe endotoxemia caused by decreased suckle and septicemia, and hypoglycemia, hypertriglyceridemia, and low plasma insulin concentrations are commonly present in septic foals.[6] Plasma insulin and leptin concentrations may have predictive utility of clinical outcome in critically ill foals.[6] Experimental infusion of endotoxin into sheep results in transient hyperglycemia associated with increased hepatic glucose production followed by hypoglycemia 3 to 8 hours later, when hepatic glucose production decreases. Sympathetic activation occurs early in endotoxemia and is probably responsible for the initial hyperglycemia and glycogenolysis. Blood pyruvate and lactate concentrations increase as a result of poor tissue perfusion and the anaerobic nature of tissue metabolism.

Protein Metabolism

There is an increase in tissue breakdown (catabolism) and a concomitant increase in serum urea nitrogen concentration. The changes observed include alterations in individual plasma amino acid concentrations, increased urinary nitrogen excretion, and increased whole-body protein turnover. The time course changes in the concentrations of plasma amino acids and other metabolites during and after acute endotoxin-induced fever in mature sheep have been described. Rapid and extensive changes occur in the patterns of tissue protein metabolism in the ruminant in response to endotoxin administration, and these changes may contribute to economic losses incurred during infectious disease outbreaks. There is also an alteration in the aminogram (the relative proportions of the amino acids present in blood) and the electrophoretic pattern of plasma proteins. The globulins are increased and albumin decreased as part of the acute phase reaction.

Mineral Metabolism

Negative mineral balances occur. These include hypoferremia and hypozincemia as part of the acute phase reaction as the animal attempts to sequester these microminerals from invading bacteria, but blood copper concentrations are commonly increased concurrently with an increase in blood ceruloplasmin levels.

Reproduction and Lactogenesis

Endotoxemia can cause pregnancy failure in domestic animals, particularly when pregnancy is corpus luteum–dependent. In horses and cattle, experimentally induced endotoxemia causes an immediate and pronounced release of prostaglandin $F_{2\alpha}$. The intravenous administration of endotoxin may influence luteal function by the activation of the arachidonic acid cascade, by a direct effect of prostaglandin $F_{2\alpha}$ on the corpus luteum. The administration of endotoxin to mares pregnant 21 to 35 days results in a decrease in progesterone and fetal death, which can be prevented by daily treatment with a progesterone compound. Similar results have been produced in pregnant dairy cows during the first 150 days of lactation, and coliform mastitis in the first 5 months of lactation is becoming an increasingly important cause of early embryonic death and return to estrus. The uterus of the early postpartum cow is capable of absorbing endotoxin, which may provoke changes in the serum concentrations of prostanoids and is thought to contribute substantially to the systemic signs of toxic metritis in cows. Endotoxin has a negative effect on the genital functions of the ram; the changes in luteinizing hormone and testosterone are similar to those seen after heat-induced stress.

In recently farrowed swine with the mastitis–metritis–agalactia syndrome, it is suggested that the endotoxin from the mammary glands affected with mastitis may be important in the pathogenesis of the agalactia.

Combined Effects on Body Systems

The combined effects of the hypoglycemia, hyper L-lactatemia, and acidemia interfere with tissue enzyme activity and reduce the functional activity of most tissues. Of these factors, acidemia is probably the most important in adult animals; in neonates low plasma glucose concentrations are probably

as important as acidemia because profound hypoglycemia is more commonly encountered in neonatal animals.[5] Experimental endotoxemia in calves at 24 to 36 hours of age causes severe hypoglycemia, lactic acidemia, and hypotension commonly associated with moderate to severe sepsis. The myocardium is weakened, the stroke volume decreases, and the response to cardiac stimulants is diminished. There is dilatation and in some cases damage to capillary walls, so that the effective circulating blood volume is decreased; this decrease, in combination with diminished cardiac output, leads to a fall in blood pressure and the development of circulatory failure. The resulting decline in the perfusion of tissues and oxygen consumption contributes greatly to the animal's decline and to the clinical signs, such as the dark red coloration of the oral mucosa. Respiration is little affected except as it responds to the failing circulation.

There is decreased liver function, and the damage to renal tubules and glomeruli causes a rise in plasma nonprotein nitrogen and the appearance of albuminuria. The functional tone and motility of the alimentary tract is reduced and the appetite fails; digestion is impaired, with constipation usually following. A similar loss of tone occurs in skeletal muscle and is manifested by weakness and terminally by prostration.

Apart from the effects of specific toxins on the nervous system, such as those of *Clostridium tetani* and *C. botulinum,* there is a general depression of function attended by dullness, depression, and finally coma. Because of the suspected role of *E. coli* in the etiology of edema disease of swine, it is noteworthy that some of the characteristic nervous system lesions of that disease are missing from experimentally induced porcine colitoxicosis. Changes in the hemopoietic system include depression of hemopoiesis and an increase in the number of leukocytes—the type of cell that increases often varies with the type and severity of the toxemia. Leukopenia may occur but is usually associated with aplasia of the leukopoietic tissue associated with viruses or specific exogenous substances such as radioactive materials. Most of these pathophysiologic effects of endotoxicosis have been produced experimentally, and it is apparent that very small amounts of endotoxin can contribute greatly to the serious effects of intestinal disease, especially in the horse.

Endotoxin Tolerance

The repeated administration of lipopolysaccharide results in attenuation of the host response, which is known as endotoxin tolerance. This refractoriness to endotoxin-mediated effects comprises two phases. Early phase tolerance is transient, occurs within hours or days, and is not associated with antiendotoxin antibody production. Late phase tolerance requires several days to develop and is long lasting, antigen specific, and the result of antibody production. By this mechanism it is possible for individual animals to survive a dose of endotoxin lethal to the nontolerant individual. Experimentally, horses develop endotoxin tolerance following sequential sublethal infusions of endotoxin.

Hypersensitivity

A secondary effect produced by some toxins is the creation of a state of hypersensitivity at the first infection so that a second infection, or administration of the same antigen, causes anaphylaxis or an allergic phenomenon such as purpura hemorrhagica. Also, a generalized Schwartzman reaction can be induced in pigs by an injection of *E. coli* endotoxin, especially if there are two injections properly spaced (in time). Pigs on a vitamin E–deficient diet are much more severely affected than pigs on a normal diet. Vitamin E is protective, but selenium is not.

Other Infectious Toxins

In mycoplasmosis (*Mycoplasma mycoides* var. *mycoides*), at least part of the toxic effect is attributable to galactans contained in the toxins. These have a noticeably local effect in causing hemorrhages in alveolar ducts and pulmonary vessel walls so that pulmonary arterial blood pressure rises as systemic blood pressure falls. Later lesions are pulmonary edema and capillary thrombosis, which are characteristic of the natural disease of pleuropneumonia. Disseminated intravascular coagulation is also a characteristic of the lesions associated with the toxin of *Pseudomonas* spp.

CLINICAL FINDINGS

Acute Toxemia

The clinical findings of acute toxemia in most nonspecific toxemias are similar. The syndrome varies with the speed and severity of the toxic process but the variations are largely of degree. **Depression**, **anorexia,** and **muscular weakness** are common in acute endotoxemia. **Calves do not suck voluntarily** and may not have a suck reflex. Scant feces are common but a low-volume diarrhea may also occur. The heart rate is increased and initially the intensity of the heart sounds is increased, but later as the toxemia worsens the intensity may decrease. The pulse is weak and rapid but regular. A **fever** is common in the early stages of endotoxemia but later the temperature may be normal or subnormal. In neonatal calves, foals, and lambs a fever may not occur because of failure of thermoregulation or deprivation of colostrum. Terminally, there is muscular weakness to the point of collapse, and death occurs in a coma or with convulsions.

Anterior uveitis, manifested as lacrimation, blepharospasm, photophobia, corneal edema, conjunctival hyperemia, and fibrin in the anterior chamber are commonly present in septicemic foals.[7] Posterior segment lesions, such as multifocal hemorrhages, exudates, and focal retinal detachments may also be visible during ophthalmic examination in foals with minor anterior segment changes. The presence of uveitis is associated with a lower survival rate in foals.[7]

Endotoxemia

When toxin formation or liberation into the circulation is rapid and the toxicity of the toxin high enough, the onset of cardiovascular collapse is rapid enough to cause a state of *toxic* or *septic* shock. The remarkable clinical findings are

- Severe **peripheral vasodilatation** with a consequent fall in blood pressure
- **Pallor of mucosa**
- **Hypothermia**
- **Tachycardia**
- **Pulse of small amplitude**
- **Muscle weakness**

The syndrome is discussed also in the section on Shock, Endotoxemia, and Septic Shock. Endotoxemia is most commonly associated with bacteremia or septicemia caused by infection with gram-negative organisms, especially *E. coli.*

The clinical findings of severe endotoxemia include the following:

- Depression
- Hyperthermia followed by hypothermia
- Tachycardia followed by decreased cardiac output
- Decreased systemic blood pressure
- Cool skin and extremities
- Diarrhea
- Congested mucosae with an increased capillary refill time
- Muscular weakness, leading to recumbency

Renal failure is common and is characterized by anuria. If DIC develops, it is characterized by petechial and ecchymotic hemorrhages on mucous membranes and sclerae with a tendency to bleed from venipuncture sites.

Chronic Toxemia

Lethargy, separation from the group, inappetence, failure to grow or produce, and emaciation are characteristic signs of chronic toxemia.

Localized Infection

With localized infections there are, in addition to the general signs of toxemia, the clinical effects of a space-occupying lesion. These are presented under Localized infections.

CLINICAL PATHOLOGY

Hematology

Changes in total and differential leukocyte numbers occur in endotoxemia. Leukocytosis and neutrophilia occur with mild endotoxemia and leukopenia, neutropenia, and lymphopenia increase in severity and duration with increasing severity of endotoxemia. Endotoxin-induced rebound neutrophilia

may occur and is attributed to an accelerated release of neutrophils from the bone marrow reserve into the circulation through generation of the neutrophil-releasing factor.

In experimental sublethal endotoxemia in foals 3 to 5 days of age, there is leukopenia followed by leukocytosis, hypoglycemia, increased prothrombin time and partial thromboplastin time, and mild hypoxemia.

Coagulopathies are common in critically ill foals, particularly those with sepsis and septic shock.[8,9] Clinical evidence of bleeding is associated with severity of shock in neonatal foals, and is present in 67% of septic shock foals, 39% of septic foals, and 13% of nonseptic foals.[8] Septic foals demonstrate marked activation of the coagulation and fibrinolytic systems, and many meet the criteria for DIC. As a consequence, plasma concentration of D-dimer, a fibrin-linked degradation product from fibrinolysis, is increased in septic foals, with a normal plasma D-dimer concentration having clinical utility as a predictor for the absence of sepsis.[9]

Serum Biochemistry

A low plasma glucose concentration, high serum urea concentration, and a low serum albumin and total protein concentration are usually present in acute endotoxemia. Decreased albumin and total protein concentrations are in response to increased capillary permeability, whereas the azotemia reflects a decreased glomerular filtration rate. Adult herbivores have a mild hypocalcemia, hypomagnesemia and hypokalemia, and hypophosphatemia, which most likely reflects inappetence and decreased gastrointestinal tract motility. Plasma iron concentration is decreased, which reflects redistribution of iron to intracellular storage sites, particularly in the liver. Plasma zinc concentration is decreased via a cytokine-mediated redistribution of zinc to the intracellular compartment, possibly through the zinc transporter Zip14.[10] Hypoferremia and hypozincemia are focused on decreasing the availability of important mineral elements for bacterial replication. High plasma cortisol concentrations are associated with a higher mortality rate in sick neonatal foals.[11]

In more chronic toxemic states, a high serum total protein concentration, with globulins noticeably increased on electrophoretic examination, is more common.

Endotoxin

Endotoxin can be detected in the platelet-rich plasma of critically ill horses and cattle using the chromogenic Limulus amoebocyte lysate (LAL) assay, which is a biologic test using the hemolymph of the horseshoe crab. The results of most studies indicate that higher plasma endotoxin concentrations in critically ill animals are associated with an increased mortality rate.[12] However, the LAL assay is not widely available and is usually run as a research test.

NECROPSY FINDINGS

Gross findings at necropsy are limited to those of the lesion that produces the toxin. Microscopically, there is degeneration of the parenchyma of the liver and the glomeruli and tubules of the kidney and the myocardium. There may also be degeneration or necrosis in the adrenal glands.

TREATMENT

The principles of treatment of endotoxemia or septic shock include (1) removal of the foci of infection; (2) administration of antimicrobial agents with a gram-negative spectrum; (3) aggressive fluid and electrolyte therapy to combat the relative hypovolemia, systemic hypotension, hypoglycemia, and electrolyte and acid-base disturbances; and (4) NSAIDs or glucocorticoids for the inhibition of products of the cyclooxygenase pathway. These four treatments are routinely applied and are called goal-directed therapy. Other treatments that may be applied in selected cases include the administration of inotropic agents or vasopressors, intravenous or intramammary administration of polymyxin B, continuous rate infusion of lidocaine, and intravenous administration of hyperimmune plasma containing antibodies directed against core lipopolysaccharide antigens. Potential therapeutic agents under investigation (such as pentoxifylline, dimethyl sulfoxide,[12a] tyloxapol, and insulin) cannot be currently recommended for treating endotoxemic animals because of the lack of clinical studies in animals with naturally acquired endotoxemia.

Endotoxemic or septic shock occurs when the animal is overwhelmed by an infection or endotoxemia. This is a complex disease that requires a rapid and comprehensive treatment plan, including those interventions in the following sections.

Removal of Foci of Infection

Removal of endotoxin before it can be absorbed is an important cornerstone of treatment in foals and calves with omphalophlebitis, horses with ischemic or necrotic bowel, and lactating dairy cattle with coliform mastitis.

Antimicrobial Agents

Bactericidal gram-negative antimicrobial agents are always indicated whenever there is evidence of septicemia or a localized infection causing endotoxemia. The choice and route of administration will depend on the pathogens suspected of causing the infection and endotoxemia and the site of infection. The speed of kill of gram-negative bacteria may be an important clinical issue, because antimicrobial agents with a rapid kill (such as moxalactam) can produce a bolus release of endotoxin into the bloodstream by punching multiple holes in the bacteria, causing a rapid explosion of the bacteria caused by osmotic fluid shifts and bolus release of endotoxin. Antimicrobial agents that alter the cell wall of gram-negative bacteria can theoretically produce a bolus release of endotoxin when administered to animals with gram-negative septicemia. On this basis, β-lactam antibiotics effective against gram-negative bacteria should theoretically be avoided; however, clinical experience has not indicated deleterious effects following administration of β-lactam antibiotics. Moreover, coadministration of aminoglycosides blocks the potential bolus release of endotoxin by β-lactam antibiotics. However, it is clinically prudent to ensure that whenever antimicrobial treatment is initiated in endotoxemic animals that NSAIDs are administered concurrently. It is also important to adjust dosage rates of water-soluble antibiotics in neonatal animals because some antibiotics, such as gentamicin in foals and ceftiofur in calves, have a larger volume of distribution and slower clearance in neonatal animals.[13]

Aggressive Fluid Therapy

The intravenous infusion of large quantities of fluids and electrolytes is a high priority in the management of endotoxemia. Maintenance of peripheral perfusion is essential to any therapeutic regimen for treatment of endotoxic shock. Large volumes of isotonic fluids have been standard practice. Recent studies have identified concerns with bolus fluid resuscitation in septic patients, such as 20 to 40 mL/kg in the first hour.[14,15] These findings suggest that rapid resuscitation should focus on the use of low-volume hypertonic saline, and that traditional high-volume crystalloid solution resuscitation should not use bolus administration. Instead, traditional high-volume crystalloid fluid resuscitation should focus on slower rates of administration (<20 mL/kg/h); lactated Ringer's solution or other balanced electrolyte solution should therefore be administered over several hours. A beneficial response is noted by the following:

- Correction of peripheral vasoconstriction
- Restoration of an acceptable pulse quality
- Return of urine output
- Increase in the central venous pressure
- Restoration of mean arterial blood pressure to >65 mm Hg
- Restoration of cardiac output
- Restoration of oxygen delivery to acceptable levels

It may be necessary to deliver fluids in amounts equivalent to 0.5 to 1.0 times the estimated blood volume of the animal over a period of several hours.

Hypertonic Solutions

The use of hypertonic saline, 7.5% NaCl, may enhance tissue perfusion and decrease the volume of subsequent fluids required for a beneficial response. Experimentally, the use

of hypertonic saline in sublethal *E. coli* endotoxemia in mature horses was associated with a more effective cardiovascular response than was an equal volume of isotonic saline solution. Cardiac output is increased and peripheral vascular resistance is decreased compared with results for isotonic saline controls. Hypertonic saline rapidly expands the plasma volume and increases preload by acting as an effective osmotic agent in the extravascular compartment, causing a translocation of fluid from the intracellular space and gastrointestinal tract.

Hypertonic sodium bicarbonate is widely used for the initial treatment of metabolic acidosis in endotoxemic adult horses. However, in horses with experimental endotoxemia, hypertonic sodium bicarbonate did not normalize blood pH, and it increased blood L-lactate concentrations and caused hypokalemia, hypernatremia, and hyperosmolality.

Glucose and Insulin Administration

Glucose should always be included in the infusion fluids because hypoglycemia, increased glucose utilization, and inappetence are usually present in endotoxemic animals. The appropriate target range for plasma glucose concentration in septic humans and domestic animals is unknown. Hyperglycemia, hyperinsulinemia, and low leptin concentrations are associated with increased morbidity and mortality in horses, and endotoxemic horses have impaired glucose metabolism and decreased insulin sensitivity.[6,16] Originally, blood glucose concentration was maintained at <180 to 200 mg/dL, but recent approaches have focused on maintaining blood glucose concentrations within the reference range for each species.[17] Coadministration of glucose (37 mg/kg/h, equivalent to 30 kcal/kg/day) and insulin (0.07 U/kg/h) as continuous rate infusions is effective in preventing hypoglycemia in healthy adult horses and adult horses with experimentally induced endotoxemia.[17] Continuous rate infusions of insulin appear to provide better glycemic control than intermittent subcutaneous insulin injections.[17] It should be noted that insulin has an affinity for binding to fluid administration lines.

Inotropic Agents, Vasopressors, and Local Anesthetics

Critically ill neonates and adults may require the administration of positive inotropic agents and vasopressor agents. Inotropic agents increase cardiac contractility, increasing cardiac output and oxygen delivery. Vasopressor agents increase systemic arterial blood pressure. Inotropic and vasopressive agents are usually administered for short periods of time during anesthesia or recovery from anesthesia.

Dobutamine (0.5–1 µg/kg BW/min in adults and 1–3 µg/kg BW/min in neonates) is the inotropic agent of choice in large animals, although human studies prefer dopamine and norepinephrine. Dobutamine should be diluted in 0.9% NaCl, 5% dextrose, or lactated Ringer's solution and the dose carefully titrated by monitoring heart rate and rhythm and blood pressure. **Norepinephrine** (0.01–1 µg/kg BW/min) is the vasopressor agent of choice in hypotensive animals that have not responded to intravenous fluid loading or dobutamine. Norepinephrine should be diluted in 5% dextrose and the dose titrated because there is marked individual variability in the response to norepinephrine administration.

Lidocaine 1.3 mg/kg as bolus intravenous injection followed by a continuous rate infusion of 0.05 mg/kg/minute mitigated some of the effects of endotoxin administration in healthy adult horses, but the effects were not profound and lidocaine was administered 20 minutes after endotoxin administration.[18] Clinical studies of animals with naturally acquired endotoxemia or septic shock are needed before lidocaine administration can be recommended.

Nonsteroidal Antiinflammatory Drugs

The NSAIDs have been in general use for the treatment of endotoxemia because of their analgesic, antiinflammatory, and antipyretic properties. They suppress production of thromboxane and prostaglandins and reduce the acute hemodynamic response to endotoxemia. Although NSAIDs are routinely administered to endotoxemic animals, a large-scale study in humans with severe sepsis failed to demonstrate an effect of ibuprofen on mortality, despite improvement in a number of clinical indices and decreased production of arachidonic acid metabolites.

Flunixin meglumine is the NSAID most commonly used in the treatment of endotoxemia in horses and cattle and remains the NSAID of choice for treating this condition. It is a potent inhibitor of cyclooxygenase and its action on this enzyme to inhibit the synthesis of eicosanoids, such as prostaglandin E_2, may explain the antiinflammatory action of the drug. Flunixin meglumine also modulates the acute hemodynamic changes and hyper L-lactatemia commonly seen during endotoxemia, which may increase survival rate. Endotoxin-stimulated production of thromboxane B_2 (a metabolite of thromboxane) and prostaglandin $F_{1\alpha}$ are blocked by flunixin meglumine at 0.25 and 0.1 mg/kg, respectively, which resulted in a widespread clinical use of an antiendotoxemic dose of 0.25 mg/kg. However, the term *antiendotoxemic effect* should be discouraged because it is misleading, and a dose rate of 1.1 mg/kg BW IV every 12 hours is recommended in horses. Care should be taken to ensure adequate hydration in endotoxemic animals receiving multiple doses of flunixin meglumine. It is usually given intravenously US label is only for IV use in cattle at 1.1 to 2.2 mg/kg BW every 24 hours. The oral administration of flunixin meglumine at 2.2 mg/kg BW before experimentally induced endotoxemia in cattle exerted an effect equal to that after intravenous administration by minimizing the fever and prostaglandin $F_{2\alpha}$ metabolite concentration induced by the endotoxin administration. However, flunixin meglumine did not prevent the decrease in peripheral mononuclear cells and polymorphonuclear leukocytes seen after endotoxin administration. The bioavailability of flunixin meglumine in cattle ranges from 53% to 60% in cattle and 80% to 86% in horses.

Flunixin meglumine was superior to prednisolone and dimethylsulfoxide in providing protection and mitigating the effects of experimental endotoxemia in calves, but it was only partially protective against the hypotension and hyper L-lactatemia and failed to alter the hypoglycemic effect. Although flunixin meglumine is the most widely used NSAID in endotoxemia, there is little experimental evidence demonstrating its efficacy over other NSAIDs. Ketoprofen, flunixin meglumine, ketorolac, and phenylbutazone have been compared for treating experimental endotoxemia in calves. Each drug modified the response to endotoxin but none was clearly superior to the others in modulating the clinical signs. Phenylbutazone given to calves at 5 mg/kg BW/day intravenously for 5 days suppressed the clinical response to experimental endotoxin in neonatal calves with progressively increasing amounts of endotoxin until large amounts were given. There were no significant differences between ketoprofen and flunixin meglumine in in vitro studies of the effects of the drugs on equine peripheral blood monocytes. An interesting finding in adult dairy cows with experimentally induced endotoxemia was that flunixin meglumine and phenylbutazone delayed the plasma clearance of endotoxin by 2 to 3 and 6 to 12 times, respectively, suggesting that both NSAIDs may prolong the clinical signs of endotoxemia in cattle, possibly by interfering with hepatic metabolism. The clinical significance of this finding is unknown. Flunixin meglumine has been associated with impaired healing of the intestinal tract, injury to the gastrointestinal tract and kidneys, and increased intestinal permeability to lipopolysaccharide.[19]

Glucocorticoids

Glucocorticoids (corticosteroids) have been used extensively in the past for the treatment of endotoxemia and shock. The rationale for the use of glucocorticoids includes the following:

- Organelle and cell-membrane stabilization
- Improved cellular metabolism and gluconeogenesis
- Improved microcirculation

- Decreased production of endogenous toxins such as myocardial depressant factor
- Decreased leukocyte activation and degranulation
- Minimal reticuloendothelial depression and histologic organ damage

The corticosteroids most commonly used in endotoxic shock were hydrocortisone, prednisolone, methylprednisolone, and **dexamethasone**. However, these corticosteroids have been most beneficial therapeutically when given as a pretreatment in experimental situations. Published evidence, based on controlled clinical trials, that corticosteroids are efficacious in naturally occurring cases of endotoxemic shock in humans and farm animals is lacking.

Glucocorticoids improve capillary endothelial integrity and tissue perfusion, decrease activation of complement and the clotting cascade, decrease neutrophil aggregation, stabilize lysosomal membranes, protect against hepatic injury, and improve survival rate. However, there are concerns about their use in septicemic animals because they may cause immunosuppression. Large doses are required, which are cost-prohibitive in farm animals when they are used most commonly in acute cases and in doses such as 1 mg/kg BW of dexamethasone intravenously every 24 hours. It is currently thought that glucocorticoids, if they are to be clinically effective, **must be given as early as possible** to endotoxemic animals. Glucocorticoids are less frequently administered to endotoxemic animals as a result of a number of studies supporting the use of NSAIDs.

Polymyxin B

Polymyxin B is a cationic antibiotic that has an appropriate charge distribution to stoichiometrically bind to the lipid A moiety of lipopolysaccharide. Parenteral administration of antimicrobial doses of polymyxin can lead to nephrotoxicity, neurotoxicity, and ototoxicity, but lower, nonnephrotoxic doses are effective in ameliorating the effects of endotoxin in horses. Specific endotoxin binding agents, such as intravenous polymyxin B, are therefore theoretically beneficial and have shown some efficacy in endotoxemic foals and adult horses when administered at a recommended dose of 1 mg (6000 U)/kg BW administered at 8-hour intervals.[20,21] The benefits attributed to polymyxin B administration in endotoxemic animals are not profound, and definitive efficacy studies have not been completed in endotoxemic calves or horses with naturally acquired endotoxemia. In particular, because the efficacy of polymyxin B is focused against circulating lipopolysaccharide before it is bound to LBP, it is currently thought that polymyxin B, like glucocorticoids, must be given as early as possible to endotoxemic animals if it is to be clinically effective. Attractive features of polymyxin B are its shelf-life and ease of storage, ease of administration (intravenous bolus), cost, and 8-hour duration of effect.

Hyperimmune Serum and Plasma Transfusion

Hyperimmune serum is commercially available for the treatment of endotoxemia in the horse. The rationale is that antilipid A antibodies bind circulating lipopolysaccharide, preventing the subsequent inflammatory cascade. On theoretical grounds it is difficult for an antibody to competitively inhibit the strong binding affinity and high specificity between lipopolysaccharide and LBP. There are also difficulties with spatial hindrance between IgG and the R-core subfraction of lipopolysaccharide that contains lipid A. It is therefore difficult to think that antiserum against core lipopolysaccharide antigens will ever be therapeutically successful in animals with naturally acquired endotoxemia, and large-scale studies in septic humans have failed to observe a decrease in mortality following the administration of hyperimmune core-lipopolysaccharide plasma. However, the administration of plasma containing antiserum has many theoretical advantages separate from those of endotoxin neutralization, and it may be that plasma transfusion alone is beneficial.

The use of antiserum to the rough mutant of *E. coli* 0111:B4(J-5) as a treatment of experimental or naturally acquired endotoxemia has been demonstrated in some, but not all, studies in adult horses but not in foals and calves. One study in foals indicated that the administration of hyperimmune serum resulted in a worsening of the clinical signs and augmented release of TNF-α and IL-6. A later study identified a higher survival rate to discharge for septic and critically ill foals receiving hyperimmune plasma rich in anti-endotoxin antibodies; however, survival rate in a subset of the foal population that had gram-negative septicemia was not significantly altered by plasma administration.[22] Antiserum does not appear as rational a treatment for neutralizing circulating lipopolysaccharide as polymyxin B and, for this reason, the administration of hyperimmune plasma or serum should probably be reserved for animals that fail to improve after polymyxin B administration.

Pentoxifylline and Ethyl Pyruvate

Pentoxifylline is a methylxanthine derivative that has been used in foals with septicemia because it has been shown to suppress production of TNF-α in a dose-dependent manner. Oral administration of pentoxifylline at 10 mg/kg BW produces serum concentrations similar to those achieved at therapeutic levels in humans when administered every 12 hours.[23] Clinical trials administering pentoxifylline in large animals with naturally occurring endotoxemia or septic shock have not been performed.

Ethyl pyruvate is a stable derivative of pyruvate that has been shown to diminish the clinical effects of endotoxemia when rapidly administered to horses intravenously at 150 mg/kg BW in lactated Ringer's solution immediately after endotoxin administration.[15,24] The mechanism of action is thought to be via binding to NF-κB and diminished expression of proinflammatory cytokines. There is a potential for synergism between ethyl pyruvate and flunixin meglumine in the treatment of endotoxemia in horses, but clinical trials have not been performed.

Anticoagulants

Disseminated intravascular coagulation (hypercoagulative states) can be treated with heparin in an attempt to impair intravascular coagulation. Much of the knowledge regarding DIC in endotoxemia has been extrapolated from species other than large animals, and there is little objective information available to guide the clinical use of anticoagulants in endotoxemic large animals. Instead, the focus of treatment should be aggressive intravenous fluid administration to maximize microcirculation.

CONTROL OF ENDOTOXEMIA

The hallmarks of a control program are to decrease the risk or prevent neonatal septicemia, institute early and aggressive treatment of gram-negative bacterial infections, and ensure prompt surgical removal of ischemic and damaged intestine. Vaccines based on core lipopolysaccharide antigens are widely used in North America to decrease the incidence and severity of gram-negative mastitis in lactating dairy cows (see Chapter 20) and gram-negative infections in pigs, but similar vaccination protocols have not been developed for horses, small ruminants, and New World camelids, which are also at risk for endotoxemia.

Toxemia in the Recently Calved Cow

A special occurrence of toxemia of major importance in food-animal practice is that caused by several diseases in the period immediately after calving in the dairy cow (and less frequently the beef cow). The syndrome is characterized clinically by lack of appetite, marked reduction in milk yield, reduced ruminal and intestinal activity, dullness, lethargy, and a fever. The term *parturition syndrome* has been used in the past but is no longer recommended, because its general adoption could dissuade clinicians from seeking more accurate identification of the component disease.

The diseases commonly included in the broad category of periparturient toxemia are as follows:

- Acetonemia
- Fat cow syndrome and pregnancy toxemia
- Mastitis
- Peritonitis
- Puerperal metritis

A brief account of puerperal metritis in cattle is provided here because of the common occurrence of puerperal metritis and the profound nature of the systemic signs of illness in affected cattle. All the other diseases are described under their respective headings in this book.

PUERPERAL METRITIS IN CATTLE

Puerperal metritis occurs primarily in dairy cows within the first 7 days after parturition (but up to 21 days after parturition) and is characterized clinically by systemic signs of sickness including fever (≥39.5°C); dullness; inappetence; increased heart rate; low milk production; an enlarged uterus for the number of days postpartum with poor uterine tone; and a copious, foul-smelling red-brown watery uterine discharge, with or without retention of the fetal membranes. Puerperal metritis is one of the most costly diseases of dairy cattle, with an estimated total cost per case of $329 to $386. **Clinical metritis** is defined as the presence of an abnormally enlarged uterus and a purulent uterine discharge detectable in the vagina within 21 days postpartum in an animal that is not systemically ill. This should be compared with **clinical endometritis**, which is characterized by the presence of a purulent (>50% pus) uterine discharge detectable in the vagina 21 days or more after parturition, or the presence of a mucopurulent (approximately 50% pus and 50% mucus) discharge detectable in the vagina 26 days or more after parturition.

ETIOLOGY

The etiology is multifactorial. It is assumed that a combination of impaired neutrophil function; abnormal postpartum uterine involution, often with retained fetal membranes; and infection of the uterus precipitates the disease. A mixed bacterial flora is common, which includes organisms such as *Trueperella* (*Arcanobacterium* or *Actinomyces* or *Corynebacterium) pyogenes, Fusobacterium necrophorum, Prevotella melaninogenica, Bacteroides* spp. *Streptococcus uberis;* these commonly predominate as a mixed flora in cows with retained placenta and postpartum metritis, particularly after 5 to 7 days postpartum. Other observations found that *E. coli* predominates in cows with retained placenta, particularly in the first 5 to 7 days postpartum. *Staphylococcus* spp., *Streptococcus* spp., *Pseudomonas aeruginosa, Proteus* spp., and occasionally *Clostridium* spp. are also present; the last can occasionally result in tetanus if *C. tetani* proliferates. High-throughput automated DNA pyrosequencing of uterine fluid from dairy cows with metritis on postpartum days 1 to 3 and 8 to 10 indicated that *Fusobacterium* and *Bacteroides* accounted for more than 83% of all bacterial DNA.[1] Slow-growing facultative anaerobic gram-positive bacteria (*Helcococcus kunzii* and *H. ovis*) have also been cultured from the uterine fluid in dairy cows with puerperal metritis.[2]

The current view is that *E. coli* colonization within the first 3 days after parturition creates a suitable intrauterine environment that leads to puerperal metritis by facilitating the establishment and persistence of *F. necrophorum* and other gram-negative anaerobic bacteria in the endometrium and uterine lumen. Early intrauterine colonization with *E. coli* strains that carry the virulence factor *fimH* that facilitate adhesion to endometrial epithelial and stromal cells increases the odds of developing metritis by 4.6 to 4.7.[3] Clinical signs of puerperal metritis are most likely caused by intrauterine colonization with the strict anaerobic bacteria *F. necrophorum* and the facultative anaerobe *T. pyogenes,* which are the most likely source for the fetid odor of affected cattle. Another important virulence factor for developing metritis appears to be *lktA* (leukotoxin) of *F. necrophorum.*[3] Together, this sequential colonization pathway suggests that decreasing fecal contamination of the vagina and uterine lumen (and therefore the colonization by *E. coli*) in the immediate postpartum period should decrease the incidence of puerperal metritis in cattle. Interestingly, it appears that uterine colonization by *E. coli* in the early postpartum period increases the risk of puerperal metritis but decreases the risk of clinical endometritis, whereas uterine colonization by *S. uberis* in the early postpartum period increases the risk of clinical endometritis.[4]

EPIDEMIOLOGY

The disease occurs in cows of all ages but is most common in mature dairy cows within 2 to 10 days of parturition. Factors strongly associated with an increased incidence of puerperal metritis include:

- Large herds
- Dystocias
- Retained fetal membranes
- Decreased feed intake in the last 2 weeks before parturition[5]
- Overconditioning or underconditioning of cows

Puerperal metritis is most common in cows with fetal membranes retained for more than 24 hours following parturition. Several cause and effect relationships have been implicated for retained placenta in cattle, with impaired neutrophil function being the most likely underlying cause.

Retention of fetal membranes is associated most commonly with abortion, dystocia, and multiple births. The most commonly used definition is the presence of fetal membranes 12 hours or more following parturition but retention for more than 6 to 8 hours is the time limit set, particularly in older cows. Approximately 10% of dairy cows have retained fetal membranes after parturition. The incidence between herds ranges from 3% to 27%. In single calvings the incidence is about 10% and in twin calvings 46%. Puerperal metritis occurs in about 50% of cows with retained placenta, and puerperal metritis is 25 times more likely to occur with retained placenta than without. Other less common risk factors for retained placenta include the following:

- Old age
- Increased gestation length
- Hormone-induced parturition
- Fetal anasarca
- Uterine prolapse
- Fetotomy

The factors that are associated with retention of the placenta are indirectly associated with the development of puerperal metritis. The forceful removal of retained placenta, particularly in the first 4 days postpartum, is also considered to be a major predisposing factor to puerperal metritis. Recent work indicates that the fundamental cause of retained placenta is impaired neutrophil function, in which the ability of the maternal immune system to recognize the placenta as "foreign" tissue is impaired. Specifically, the separation of a placenta from healthy caruncles in a normal calving depends on incompatibility between maternal and fetal major histocompatibility complex Class I expressed on the epithelium within the fetomaternal unit.[5] In other words, retained placenta is an indication of an impaired immune system, which may be secondary to periparturient deficiency of vitamin E or selenium, or a greater degree of negative energy balance prepartum. Lack of uterine motility is thought to play a minimal to no role in the development of retained placenta and puerperal metritis.

Uncomplicated cases of retained fetal membranes in cattle have no significant effect on subsequent fertility and the calving-to-conception interval. However, it is significantly increased in cows that develop puerperal metritis as a sequel to retained fetal membranes. Vitamin E and selenium deficiency, placentitis, and vitamin A deficiency have also been suggested as factors.

PATHOGENESIS

Failure of normal uterine involution combined with retention of the fetal membranes and infection of the uterus with a mixed bacterial flora results in puerperal metritis and a severe toxemia. There is diffuse necrosis and edema of the mucosa and wall of the uterus. There is marked accumulation of foul-smelling fluid in the uterus and enlargement of the uterus. Absorption of toxins results in severe toxemia, particularly in fat cows, which may develop irreversible fatty degeneration of the liver.

CLINICAL FINDINGS

Affected cows become acutely anorexic and toxemic within 2 to 10 days after parturition. There is a marked drop in milk production. The temperature is usually elevated, in the range of 39.5 to 41.0°C, but may be normal in the presence of severe toxemia. A consensus has not been reached on the threshold rectal temperature cut point for a diagnosis of toxic metritis, because increased ambient temperatures in summer also increase core body temperature, and dystocia-related trauma in primiparous cattle appears to increase rectal temperature. The optimal rectal temperature cut point indicating a cow has puerperal metritis during the first 10 days in milk in dairy cattle is approximately ≥39.5°C (range is >39.2°C to >39.7°C), with the cut point higher for primiparous than multiparous cattle.[6,7] It has become popular on some large dairies to measure the rectal temperature each morning for the first 10 days of lactation, primarily as a screening test for puerperal metritis. One study suggested that rectal temperature measurement from day 5 to 10 of lactation was sufficient, because this protocol did not negatively impact the ability to successfully treat cases of puerperal metritis that are diagnosed before day 5 of lactation.[8] Although an elevated rectal temperature is considered a requirement for a diagnosis of **puerperal metritis**, it is important to recognize that some cows can have systemic signs of illness and a serosanguinous uterine discharge and a normal rectal temperature. An elevated rectal temperature in the 5 to 10 day postpartum period should not be used as the sole criteria for a diagnosis of **clinical metritis**, because this will lead to overtreatment of healthy cows. For example, 14% to 66% of healthy cattle exhibit at least one rectal temperature ≥39.5°C in the first 10 days of lactation, 59% of cows with clinical metritis maintain a rectal temperature <39.5°C, and rectal temperature is impacted by the age of the animal, environmental conditions, and the method used to measure rectal temperature.[9]

The heart rate is usually elevated and may range from 96 to 120 beats/min. The respiratory rate is commonly increased to 60 to 72 breaths/min, and the breath sounds may be louder than normal. Rumen contractions may be markedly depressed or absent. A foul-smelling fluid diarrhea may occur. Mild to moderate dehydration is common because affected cows do not drink normally.

Retention of the fetal membranes is common, and manual examination of the vagina reveals the presence of copious quantities of foul-smelling, dark brown to red fluid containing small pieces of placenta pooled in the vagina. When the fetal membranes are retained and protruding through the cervix, the hand can usually be inserted through the cervix and into the uterus. Manual exploration of the uterine cavity will usually reveal the state of adherence of the fetal membranes. Often the fetal cotyledons are firmly attached to the maternal caruncles, but occasionally they have separated from the caruncles and the placenta can be removed by simple traction.

Rectal examination usually reveals that the uterus is large, flaccid and lacks the longitudinal ridges that indicate normal rate of involution. In large cows the enlarged, flaccid uterus may be situated over the pelvic brim extending into the ventral part of the abdomen and thus may not be easily palpable and examined. This is an important finding because the fetal membranes may be fully retained in the uterus and no evidence of their presence may be detectable on examination of the vagina and the cervix, which may be almost closed, making examination of the uterus impossible.

The presence of viscid, nonodorous mucus in the cervix and anterior part of the vagina usually, but not always, indicates that the fetal membranes have been expelled. When evidence of a retained placenta and puerperal metritis cannot be found on examination of the reproductive tract, either by rectal palpation or vaginal examination, and if the history indicates some uncertainty about the disposition of the placenta, a retained placenta and puerperal metritis should be considered until proven otherwise. Persistent toxemia, tachycardia (100–120 beats/min), anorexia, and rumen stasis that cannot be explained by any other disease should arouse suspicion of septic metritis until proved otherwise.

Tenesmus occurs most commonly when the fetal membranes are retained and this causes irritation in the vagina. Manual examination of the vagina may also stimulate tenesmus.

The course of the disease varies from 2 to 10 days. Those cases with retained fetal membranes may be toxemic and not return to normal appetite until the membranes are fully expelled, which may take up to 10 days. Necrotic pieces of placenta may be passed for 10 to 14 days after treatment is begun.

CLINICAL PATHOLOGY

Hematology

Leukopenia, neutropenia, and a degenerative left shift occur in acute cases and the degree of change parallels the severity of the disease and reflects the absorption of endotoxin from the uterine lumen. Bacteremia caused by *Bacillus* spp. has been identified in 53% (9/17) of cattle with puerperal metritis; however, bacteremia did not reflect the most common isolates from the uterus of affected cattle.[10] The prevalence of bacteremia in healthy dairy cattle at the same stage of lactation (53%, 8/15) was similar to that of cattle with puerperal metritis.

Vaginal/Uterine Fluid

Samples of fluid from the vagina and uterus reveal a mixed bacterial flora including *E. coli, F. necrophorum, T. pyogenes, Proteus* spp., *Staphylococcus* spp. and *Streptococcus* spp., with the predominant bacteria varying mainly with time since parturition. Generally, *E. coli* predominates in the first 5 days after parturition, whereas *F. necrophorum* and *T. pyogenes* predominate after the first 5 days in cattle with retained placenta. Uterine lochia of cattle with retained placenta had a much higher endotoxin concentration in the first 2 days postpartum than did lochia of healthy cattle or cattle that had undergone a dystocia but did not have retained placenta. Endotoxin was not detected in the plasma of cattle with high

lochial endotoxin concentrations, indicating effective systemic clearance.

Other Samples and Tests

Ketonuria may occur in animals that are overconditioned and mobilize excessive quantities of depot fat, resulting in ketosis. **Liver function tests** reveal a decrease in liver function, which may be irreversible in excessively fat cows. A study evaluating the detection of the fetid smell of puerperal metritis indicated considerable subjectivity into the classification of healthy and diseased animals, whereas an instrument that acted as an "electronic nose" was more repeatable but not sufficiently accurate for on-farm use.[11] A subsequent reanalysis focusing on days 2, 5, and 10 using a proprietary algorithm suggested that test performance could be improved.[12]

NECROPSY FINDINGS

The uterus is enlarged, flaccid and may contain several liters of dark brown, foul-smelling fluid with decomposed fetal membranes. The uterine mucosa is necrotic and hemorrhagic and the wall of the uterus is thickened and edematous. In severe cases, fibrin may be present on the serosal surface of the uterus. The liver may be enlarged and fatty and there is usually mild degeneration of the myocardium and kidneys. The presence of perineal, perivulvar, and perivaginal gelatinous or hemorrhagic edema along longitudinal vulvar, vaginal, cervical, and uterine body tears is suggestive of infection with *C. septicum*.[13]

Fat Cow Syndrome

This is characterized by excessive body condition, anorexia to inappetence, ketonuria, a marked loss in milk production, decreased rumen movements, and delayed involution of the uterus. The temperature is usually normal but the heart and respiratory rates may be increased. The prognosis is poor in cows that are totally anorexic; those that are inappetent will usually recover after 5 to 7 days of supportive therapy.

Acute Diffuse Peritonitis

This may occur in cows within a few days postpartum and is characterized by anorexia, toxemia, a spontaneous grunt, or one that can be elicited by deep palpation, rumen stasis, fever and the presence of an inflammatory exudate in the peritoneal fluid.

Peracute and Acute Mastitis

This occurs in cows within a few days after parturition and is characterized by severe toxemia, swelling of the affected quarters, and abnormal milk.

TREATMENT

Conservative Therapy

Uncomplicated cases of retained fetal membranes without any evidence of clinical toxemia usually do not require parenteral or intrauterine treatment. The placenta is typically retained for an average of 7 days. Cows with retained fetal membranes and tenesmus should be examined vaginally to ensure that there is no evidence of injury to the vagina or cervix. In cows with tenesmus, if the placenta is detached and loose it should be removed by careful traction. Forceful removal of the placenta should be avoided.

Antimicrobial Agents

Cows with retained fetal membranes but **without systemic illness** should be monitored, but treatment with antimicrobial agents is not indicated. Antibiotic treatment with IV or IM oxytetracycline (10 mg/kg BW, daily) before placental shedding delays detachment of the placenta; this finding is consistent with the concept that intrauterine bacterial infection facilitates placental detachment.

Cows with retained fetal membranes **complicated by septic metritis and toxemia** should be treated with antimicrobial agents daily for several days or until recovery occurs. Death can occur in untreated animals. Because of the mixed bacterial flora in the postpartum uterus with a retained placenta, broad-spectrum antimicrobials are recommended. Procaine penicillin (22,000 U/kg BW intramuscularly every 12–24 h) and ceftiofur (1–2.2 mg/kg BW intramuscularly every 24 h) for 3 to 5 days are preferred treatments, with some support from clinical trials for the administration of ampicillin (10–11 mg/kg BW intramuscularly)[14] or oxytetracycline (11 mg/kg BW intravenously every 24 h) for 3 to 5 days. Ceftiofur increases the cure rate and milk yield and decreases rectal temperature when administered to dairy cows with fever and vaginal discharge or dystocia. Subcutaneous administration of ceftiofur (1 mg/kg BW) achieves concentrations of ceftiofur derivatives in uterine tissue and lochial fluid that exceeded the reported minimal inhibitory concentrations for common metritis pathogens. Treatment with a longer acting formulation of ceftiofur (ceftiofur crystalline free acid) subcutaneously into the base of the ear at 6.6 mg/kg may not provide an adequate duration of antibiotic concentration in endometrial tissue and lochia in cows with puerperal metritis, and current data do not support using this one-dose ceftiofur treatment regimen instead of daily subcutaneous ceftiofur injections for 3 to 5 days.[15] A recent randomized clinical trial indicated that the administration of ceftiofur crystalline free acid (6.6 mg/kg) subcutaneously twice into the base of the ear on days 0 and 3 was effective in treating puerperal metritis, with the second dose given in the opposite ear.[16] Care should be exercised when injecting ceftiofur crystalline free acid subcutaneously into the base of the ear because acute death has been associated with neurologic sequelae caused by intraarterial injection. Ampicillin increased the pregnancy rate and decreased the cure rate, compared with ceftiofur, in cattle that were also treated with intrauterine ampicillin and cloxacillin. Generally, oxytetracycline use should be confined to the first 5 to 7 days postpartum when *E. coli* predominates, because it is likely to be ineffective against *T. pyogenes* in the endometrium. Oxytetracycline at 30 mg/kg BW intravenously as a single dose in cows with retained fetal membranes resulted in concentrations of the antimicrobial in uterine secretions, placenta, and cotyledon for 32 to 36 hours. Two intramuscular injections of regular formulations of oxytetracycline at 25 mg/kg BW resulted in lower peak concentrations, but these were maintained for 144 hours. Parenteral oxytetracycline appears to decrease endotoxin production, as indicated by the severity of leukopenia in cattle with retained placenta.

In **severely affected cases**, large amounts of balanced isotonic crystalloid fluids, electrolytes, and glucose by continuous intravenous infusion may be necessary and often result in a marked beneficial response within 24 to 48 hours. The uterus should always be examined by palpation per rectum and vaginally to determine the degree of uterine involution, the thickness of the uterine wall, the volume of the uterus, the nature of the luminal contents, and the degree of attachment of the placenta to the cotyledons. This can be done daily to assess progress. Uterine fluids should be drained by creating a siphon if sufficiently liquid in nature, although care must be taken to ensure that the tube does not penetrate a friable uterine wall. The placenta will invariably be expelled within 6 to 8 days, and usually within 4 to 6 days, if parenteral antimicrobial and supportive therapy is provided. The use of antimicrobial agents must be accompanied by appropriate withdrawal periods for the milk produced by treated animals.

Intrauterine Medication

The necessity for intrauterine medication is controversial. There is limited evidence, if any, that the intrauterine infusion of antimicrobial agents with or without lytic enzymes and estrogens has any beneficial effect on the treatment of puerperal metritis. Nevertheless, a wide variety of antimicrobial agents have been used for intrauterine medication for retained placenta and metritis in cows, although generally β-lactam–resistant antibiotics should be administered because the uterine lumen can contain β-lactamase–producing bacteria. Intrauterine infusion of 0.5 g of the first-generation cephalosporin cephapirin improved the reproductive performance of cows with metritis, but only when administered after 26 days in milk. Intrauterine infusion of 1 g of the third-generation cephalosporin ceftiofur in 20 mL of sterile water once between 14 and 20 days of lactation had no effect on reproductive performance but decreased the risk of culling and increased the time to culling.

Tetracycline products (5–6 g) are commonly administered but should be administered as a powder dissolved in an appropriate volume of 0.9% NaCl, because vehicles such

as propylene glycol can irritate the endometrium. Intrauterine infusion of oxytetracycline decreases lochial odor and the incidence of fever in cattle with retained placenta. The combination of 8 g of oxytetracycline dehydrate (40 ml of solution) by intrauterine infusion through a disposable uterine catheter twice at 72 to 96 h apart and amoxicillin trihydrate (15mg/kg BW intramuscularly every 48 hours for a total of three injections) increased conception rate at first insemination and percent pregnant at 150 days in milk compared with treatment with amoxicillin alone.[17] In cattle with retained placenta, intrauterine administration of a povidone-based oxytetracycline solution (5 g daily until expulsion) combined with fenprostalene (1 mg subcutaneously) did not alter the time to detachment of the placenta but increased the frequency of pyometra; this finding was consistent with the concept that intrauterine bacterial infection facilitates placental detachment. Milk from cows treated by intrauterine infusion of antimicrobial agents should be discarded for an appropriate period of time to avoid illegal residues. Generally, intrauterine treatment may achieve effective endometrial antibiotic concentrations, but antibiotic concentrations in deeper myometrial tissue are usually too low to be effective, hence, the preference for systemic treatment in cattle with puerperal metritis.

Intrauterine administration of antiseptics (0.5% povidone iodine, 0.1% chlorhexidine), hyperosmotic agents (7.2% NaCl solution, 50% dextrose), and proprietary organic formulations[18] as a lavage or infusion has been done, particularly on organic dairies, but studies with a negative control group demonstrating efficacy are lacking.

Ancillary Treatment and Control

Portions of retained placenta protruding from the vagina should be wrapped in a plastic rectal sleeve to minimize wicking of fecal bacteria after defecation, although this supposition has not been verified. Alternatively, protruding remnants of placenta can be excised, although this may prolong to the time to expulsion because the decreased placental weight may interfere with traction on the remaining placenta in the uterine lumen. Complete manual removal is often requested by the producer but is not recommended because studies have not demonstrated its efficacy.

Nonsteroidal antiinflammatory drugs are often administered as part of the initial treatment of toxic metritis, purportedly to address fever and clinical signs of endotoxemia. The administration of one dose of the NSAID flunixin meglumine (2.2 mg/kg intravenously) at the start of treatment of puerperal metritis in dairy cows in addition to antibiotics did not improve the outcome compared with administration of antibiotics alone.[19] The addition of flunixin meglumine (1.1 mg/kg, route not stated, daily for 3 days) to the treatment of puerperal metritis in dairy cows with parenteral ceftiofur (1 mg/kg, subcutaneously or intramuscularly [route of administration not clear] daily for 5 days) did not improve the clinical cure rate, serum or blood concentrations of inflammatory biomarkers such as serum amyloid A and fibrinogen, or the elimination of bacteria from the uterus.[20]

The infusion of collagenase solution (200,000 U dissolved in 1 L of 0.9% NaCl containing 40 mg calcium chloride and sodium bicarbonate) into the umbilical arteries within 12 hours of parturition is an effective treatment for retained placenta. Collagenase injection therefore provides an effective method for preventing septic metritis in cattle with retained placenta. However, the collagenase solution is expensive and not widely available, and the technique is difficult in some animals because of difficulty in identifying intact umbilical arteries for injection. As a result, collagenase injection is rarely performed in clinical veterinary practice. The efficacy of umbilical artery infusion with antimicrobial agents has not been adequately evaluated.

Ecbolic drugs have been proposed for the prevention and treatment of retained placenta in cattle. These include prostaglandins, ergot derivatives, oxytocin, and β_2-adrenoceptor antagonists. The rationale for their use is that they stimulate uterine contractions and physically aid in the expulsion of the fetal membranes. Generally, the consensus is that they are ineffective after the diagnosis of a retained placenta is recognized. However, their use may be effective if used immediately after calving. In particular, the frequent intramuscular administration of oxytocin appears to provide the most effective means of preventing metritis, with a recommended protocol of 20 IU every 3 hours for postpartum days 0 to 3, 30 IU every 2 hours for postpartum days 4 to 6, and 40 IU every 2 hours for postpartum days 7 to 10. A large study found that intramuscular injection of oxytocin (30 IU) immediately after parturition and 2 to 4 hours later decreased the incidence of retained placenta and the calving-to-conception interval. Fenprostalene at 1 mg subcutaneously, 25 mg dinoprost tromethamine intramuscularly, or 20 IU oxytocin given to a large number of dairy cows in five commercial dairy herds did not reduce the incidence of retained fetal membranes or improve reproductive performance. A detailed review failed to identify any evidence supporting the use of estrogen or prostaglandins in the first 7 to 10 days postpartum.[21]

The finding that retained placenta can be caused by neutrophil dysfunction at calving provides the basis for epidemiologic evidence that deficiency of trace minerals or vitamins (such as selenium and vitamin E) is associated with an increased incidence of retained placenta. In regions deficient in selenium, supplementation of the diet up to 0.3 ppm can decrease the incidence of retained placenta in herds that are fed a total mixed ration. Selenium can also be administered by intraruminal boluses or parenteral administration of vitamin E/selenium preparations during the dry period.

Subcutaneous vaccination with protein subunits or inactivated bacterial components of *E. coli* (expressing the *fimH* virulence factor), *F. necrophorum* (producing the protein leukotoxin), and *T. pyogenes* (producing the protein pyolysin) can prevent puerperal metritis and result in improved reproductive performance.[22] It is anticipated that a commercial vaccine will be produced incorporating one or more of these agents.

Identification of Affected Cows

Cows affected with retained placenta and puerperal metritis should be identified and recorded in the records system and examined 30 to 40 days after parturition for evidence of further complications such as pyometra.

TREATMENT AND CONTROL

Treatment

For cows with fetid smelling metritis and rectal temperature ≥39.5°C:
- Procaine penicillin (22,000 U/kg body weight [BW] intramuscularly [IM] every 12–24 h for 3–5 days). (R-1)
- Ceftiofur (1.1–2.2 mg/kg BW IM every 24 h for 3–5 days). (R-1)
- Ceftiofur crystalline free acid (6.6 mg/kg BW subcutaneously every 3 days for two treatments). (R-2)
- Ampicillin (10–11 mg/kg BW IM every 24 h for 3–5 days). (R-2)
- Oxytetracycline (11 mg/kg BW IV every 24 h for 3–5 days). (R-2)
- Oxytetracycline dihydrate (8 g) by intrauterine infusion twice at 72 to 96 h apart combined with amoxicillin trihydrate (15 mg/kg BW IM every 48 hours for a total of three injections). (R-2)
- Carefully siphon off voluminous uterine fluid. (R-2)
- Administer intrauterine treatment and manual removal of placenta. (R-3)
- Parenteral administration of nonsteroidal antiinflammatory drugs. (R-3)

For cows with metritis and rectal temperature <39.5°C:
- Monitor rectal temperature daily, institute treatment when temperature >39.5°C. (R-1)

Control

Ensure adequate vitamin E and selenium status. (R-1)

Wrap retained placenta with palpation sleeve or remove placenta hanging from perineum. (R-2)

Hypovolemic, Hemorrhagic, Maldistributive, and Obstructive Shock

SYNOPSIS

Etiology Shock caused by a reduction in venous return (circuit failure) secondary to hypovolemia, hemorrhage, maldistribution of blood or obstruction, to venous return.

Clinical findings Depression and weakness, subnormal temperature, elevated heart rate with weak thready pulse, cold skin and extremities, prolonged capillary refill time. Progressive development without aggressive fluid therapy and collapse and death from irreversible shock.

Clinical pathology Increased blood or plasma L-lactate concentration, decreased venous oxygen tension, evidence of multiple organ dysfunction. Decreased central venous pressure, low mean arterial blood pressure terminally. Changes in heart rate, activity level, and blood or plasma L-lactate concentration indicate the efficacy of treatment.

Necropsy findings None specific for hypovolemic or maldistributive shock; the source of hemorrhage may be apparent in hemorrhagic shock.

Diagnostic confirmation Clinical signs, blood or plasma L-lactate concentrations, venous oxygen tension.

Treatment Aggressive fluid therapy based on intravenous isotonic crystalloid solutions and possibly colloid solutions. Blood transfusion or stroma-free hemoglobin administration for hemorrhagic shock. Initial treatment by rapid infusion with small-volume hypertonic saline solutions gives rapid but transient resuscitative effect. Antimicrobial agents and nonsteroidal antiinflammatory drugs in maldistributive shock caused by endotoxemia.

ETIOLOGY

The circulatory system consists of a pump (the heart) and a circuit (the vasculature). Circulatory shock can result from abnormal functioning of the pump or circuit, or both. It is clinically very important to differentiate **pump failure** (cardiogenic shock caused by acute or chronic heart failure) from **circuit failure**, because the diagnosis and treatment of cardiogenic shock is vastly different from that of circuit shock. Cardiogenic shock is covered in detail in Chapter 10, whereas circuit failure is addressed in the following section.

Circuit failure occurs whenever the cardiac output is reduced below a critical point because of inadequate venous return to the heart. There are four main ways that circuit failure occurs:

1. **Hypovolemic shock** occurs when there is a reduction in circulating blood volume caused by loss of blood, plasma, or free water.
2. **Hemorrhagic shock** occurs when there is a reduction in circulating blood volume caused by the rapid loss of blood.
3. **Maldistributive shock** occurs when there is a reduction in circulating blood volume caused by increased capillary permeability, pooling of blood in capacitance vessels (such as the veins in the splanchnic circulation), or pooling of plasma in a large third space such as the thoracic or abdominal cavities.
4. **Obstructive shock** occurs when there is an acute reduction in venous return caused by a mechanical obstruction, such as pericardial tamponade or pulmonary artery thrombosis. Obstructive shock is extremely rare in large animals.

Regardless of the initiating cause for circuit failure and inadequate venous return, tissue hypoperfusion results, leading to impaired oxygen uptake and anaerobic metabolism. The end result of inadequate tissue perfusion is the development of multiple organ failure, L-lactate acidemia, and strong ion (metabolic) acidosis, manifested as the **hypodynamic stage** of shock. Hypovolemia and poor tissue perfusion result in cold extremities, elevated heart rate, a weak thready pulse, decreased capillary refill times, and altered mental status. Cardiac arrhythmias may occur because of myocardial ischemia and electrolyte and acid-base disturbance. There is anorexia and gastrointestinal stasis. Signs of renal failure include anuria or oliguria and azotemia.

Common causes of circuit failure in large animals are as follows.

Hypovolemic Shock

- Fluid loss and dehydration, such as in neonatal calf diarrhea and burn injury, especially when fluid loss is severe and rapid
- Fluid loss into the gastrointestinal tract caused by acute intestinal obstruction

Hemorrhagic Shock

Acute hemorrhage with loss of 35% or more of total blood volume, equivalent to an acute blood loss of 2.8% of BW (assuming blood volume is 8% of BW) will lead to clinical signs of severe hemorrhagic shock. In contrast, acute hemorrhage with loss of less than 10% of total blood volume (equivalent to an acute blood loss of less than 0.8% of BW) produces minimal detectable clinical changes.

Traumatic injury or spontaneous rupture of a large blood vessel are common reasons for acute hemorrhage. Any sort of minor surgical wound, e.g., castration or dehorning, may lead to excess hemorrhage after which there is a hemorrhagic tendency caused by defects of clotting. Some of the more common causes of hemorrhagic shock are as follows.

Cattle, Sheep, and Goats

- Spontaneous pulmonary hemorrhage associated with caudal vena caval syndrome
- Abomasal ulcer, sometimes originating from a bovine viral leukosis lesion (cattle)
- Enzootic hematuria with bleeding from a bladder lesion (cattle)
- Pyelonephritis with bleeding from a renal lesion (cattle)
- Intraabdominal hemorrhage as a result of arterial aneurysm, possibly associated with copper deficiency (cattle)
- Laceration of arteries in the wall of the vagina as a result of dystocia
- Ruptured middle uterine artery during uterine prolapse or torsion of uterus
- Cardiac tamponade caused by rupture of the coronary artery or ventricular chamber, rupture of the aorta (see Chapter 1)

- Rupture of liver associated with dystocia in lambs, and in older lambs possibly associated with vitamin E deficiency

Horses

- Ethmoidal hematoma
- Exercise-induced pulmonary hemorrhage
- Rupture of the middle uterine, uteroovarian (especially right side), or iliac artery associated with parturition, more commonly in aged mares
- Nasal bleeding from hemorrhage into the guttural pouch, from carotid or maxillary arteries with guttural pouch mycosis or associated with rupture of the longus capitis muscle following trauma
- Rupture of mesenteric arteries secondary to strongyle larval migration
- Splenic hematoma or rupture following blunt trauma
- Rupture of liver with hyperlipemia
- Hemangioma, hemangiosarcoma, squamous cell carcinoma of the stomach, and other neoplasia
- Persistent bleeding from the vulva in association with ulcerated varicose veins on the dorsal wall of the vagina
- Congenital venous aneurysm (rare)

Pigs

- Esophagogastric ulceration
- Proliferative hemorrhagic enteropathy
- Rupture of liver in hepatosis dietetica
- Congenital neonatal bleeding, e.g., umbilical hemorrhage

Maldistributive Shock

- Endotoxemia in neonatal septicemia, salmonellosis, coliform mastitis in lactating dairy cattle, toxic metritis in cattle
- Septic shock caused by gram-positive bacterial septicemia
- Too sudden reduction of pressure in a body cavity, e.g., by rapid withdrawal of ascitic fluid

Obstructive Shock

- Pericardial tamponade

PATHOGENESIS

Hypovolemic Shock

When cardiac output falls as a result of decreased venous return, the carotid and aortic baroreceptors stimulate the sympathetic nerves and adrenal medulla to release catecholamines resulting in vasoconstriction in vessels with α-adrenergic receptors. Vasoconstriction leads to **decreased renal perfusion**, which activates the RAAS, inducing sodium and water retention. The decrease in renal perfusion can result in renal ischemia and nephrosis if the ischemia is sufficiently severe and prolonged (see Chapter 13). Hypovolemia also stimulates the release of antidiuretic hormone (vasopressin). There is contraction of the spleen and venous capacitance vessels, an increased peripheral vascular resistance, and an increase in heart rate in an attempt to maintain cardiac output and blood perfusion through the coronary and cerebral blood vessels.

Water shifts from the interstitial space to the vascular space in response to the contraction of precapillary arterioles. In the initial stages of hypovolemic failure the primary signs are those of interstitial fluid depletion and dehydration, with dry mucous membranes, sunken eyes, and decreased skin turgor. Peripheral vasoconstriction in the face of continued hypovolemia and falling cardiac output results in the opening of arteriovenous shunts and decreased perfusion of organ systems, with resultant damage from hypoxia and tissue acidosis and the development of clinical signs of peripheral vascular failure and shock. Arterial blood pressure falls terminally, and a decrease in mean arterial pressure indicates a complete lack of cardiovascular reserve. The rate at which hypovolemia develops profoundly affects the outcome because compensatory mechanisms are more readily overcome by acute than chronic changes.

Hemorrhagic Shock

The major effects of hemorrhage are loss of blood volume (hypovolemic shock), loss of plasma protein (decreased plasma oncotic pressure), and loss of erythrocytes (decreased oxygen-carrying capacity and buffering capacity).

With acute and severe hemorrhage, the rapid loss of blood volume results in hypovolemic shock and the loss of erythrocytes in anemic anoxia. The combination of these two factors is termed hemorrhagic shock and is often fatal. With less severe hemorrhage, the normal compensatory mechanisms, including release of blood stored in the spleen and liver and the withdrawal of fluid from the tissue spaces, may maintain a sufficient circulating blood volume, but the anemia is not relieved and the oncotic pressure of the blood is reduced by dilution of residual plasma protein. The resulting anemia and edema are repaired with time provided the blood loss is halted.

Maldistributive Shock

In normal animals the healthy intestinal mucosa is an effective barrier to the absorption of endotoxin that is present in the gut, and the small amounts of endotoxin that are absorbed into the portal blood are cleared by the liver and do not reach the systemic circulation. When the integrity of the intestine is compromised by factors such as ischemia, trauma, or inflammation, sufficient endotoxin can be absorbed to overwhelm the clearance mechanisms of the liver, and endotoxin may also leak to the peritoneal cavity, gaining access to the systemic circulation. Endotoxin can also be absorbed from sites of local infection, as with diffuse peritonitis, coliform mastitis, and toxic metritis, or released from gram-negative bacteria in the bloodstream. Intestinal mucosal integrity is lost in the terminal stages of circulatory shock caused by tissue hypoxia, and endotoxin translocation from the intestinal tract is markedly increased in the terminal stages of shock, independent of the initiating cause.

Endotoxin and other bacterial toxins cause direct endothelial damage. Endotoxin also activates macrophages and neutrophils provoking the release of a multitude of **inflammatory mediators**, including TNF, IL-1, IL-6, and platelet-activating factor, which lead to endothelial damage, leaky vessels, hypotension and vasculitis, and eventually decreased intravascular volume. Inadequate perfusion of tissue with appropriately oxygenated blood impedes oxidative cellular metabolism and leads to the release of arachidonic acid, which is metabolized by the cyclooxygenase pathway to yield prostaglandins and thromboxane A_2 or by the lipoxygenase pathway to yield leukotrienes. These **eicosanoids** are potent vasoactive compounds. They can act locally or be carried in the circulation to act at distant sites to further adversely affect vascular reactivity and vascular permeability. Endotoxin itself also provokes increased synthesis and release of eicosanoids, and many of the early effects of endotoxin are mediated by these metabolites of arachidonic acid.

A further consequence to tissue hypoxia is damage to endothelium with exposure of collagen; tissue thromboplastin can initiate the intrinsic and extrinsic coagulation cascades, leading to damage to other organ systems and further complications from the development of coagulopathies, including DIC, which may be central to the development of irreversible shock.

In the early **hyperdynamic stage** of endotoxemia and sepsis, there is an increased oxygen demand by peripheral tissue and an increase in heart rate and cardiac output with pulmonary and systemic vasoconstriction. Pulmonary hypertension increases transvascular fluid filtration in the lung, and pulmonary edema can develop when hypertension is accompanied by increased vascular permeability. There is systemic arterial hypoxemia caused by ventilation-perfusion inequalities in the lung and, despite the increase in cardiac output, blood flow may be inadequate to meet the needs of tissue in a hypermetabolic state. The **late hypodynamic** stage of endotoxemia and sepsis is characterized by decreased venous return, decreased cardiac contractility, decreased cardiac output and oxygen delivery, systemic arterial hypoxemia, and decreased mean arterial pressure.

Obstructive Shock

In severe pericardial tamponade, the rapid increase in pericardial fluid volume impedes

diastolic filling of the heart, resulting in decreased cardiac output. A similar response occurs in advanced traumatic reticulopericarditis in cattle that have ingested a wire; however, in the latter condition the obstruction is slow to develop.

CLINICAL FINDINGS

Depression, weakness, and listlessness are accompanied by a fall in temperature to below normal. The skin is cold and skin turgor is decreased. The mucosae are pale gray to white and dry, and capillary refill time is extended beyond 3 to 4 seconds.

There is an increase in heart rate to 120 to 140 beats/min in horses and cattle, with abnormalities of the pulse including small and weak pressure amplitudes (manifested as a "thready" pulse). Cardiac arrhythmias are present terminally. Venous blood pressure is greatly reduced in hypovolemic and hemorrhagic shock and the veins are difficult to raise in response to obstruction. Arterial blood pressure, measured either directly by arterial puncture or by indirect oscillometric methods, is decreased terminally and fails to provide an early indicator of the severity of the circulatory failure.

Anorexia is usual but thirst may be evident and there is anuria or oliguria. Nervous signs include depression, listlessness and obtusion, and coma in the terminal stages.

During the early hyperdynamic stage of maldistributive shock the temperature is normal or elevated, mucous membranes are injected and brick-red in color, there is tachycardia but normal capillary refill time, and the extremities (particularly ears) are cool to the touch. Although these signs are not specific for shock, the recognition of this stage in animals that are at risk for maldistributive shock, such as the neonate or animals with early signs of acute intestinal accident, can allow the early institution of therapy, which will frequently result in a better outcome than therapy instituted when the later stages of shock have manifested.

Therapeutic reversal of maldistributive shock in its later stages is difficult. In contrast, circulatory failure that is a result of hypovolemic or hemorrhagic shock is relatively easily treated and can be successfully reversed, even at stages of profound depression.

CLINICAL PATHOLOGY

The use of clinical pathology is directed at determining the cause and severity of shock and at monitoring the effectiveness of therapy. Volume expansion and restoration of tissue perfusion will usually correct acid-base and strong ion (metabolic) acidosis in the majority of animals with shock, and abnormalities are addressed once fluid balance is established.

Examination of the blood to determine the hematocrit and plasma protein concentration is invaluable in indicating the magnitude of the blood loss in hemorrhagic shock and providing a clinically useful index to the progress of the disease. However, there can be a **delay in the fall** of the hematocrit following hemorrhage for up to 4 to 6 hours because splenic contraction temporarily augments circulating red cell numbers. The hematocrit and plasma protein concentrations usually fall to their lowest levels 12 to 24 hours following hemorrhage, and determination at this time provides a clinically useful index of the amount of blood lost. Signs of a regenerative response (increased hematocrit, presence of reticulocytes, and increased red blood cell volume) should be seen within 4 days of an acute hemorrhage in ruminants and pigs but cannot be used as a guide in the horse. Generally, the hematocrit increases by 1% per day following acute hemorrhage in ruminants.

Abdominocentesis, **thoracocentesis,** and **ultrasound** are used to identify sites of internal bleeding. **Thrombocyte** and **clotting factor** examinations are indicated in cases in which unexplained spontaneous hemorrhages occur.

Monitoring in Shock

Clinical parameters of heart rate, pulse character, mucous membrane color, temperature of the extremities (particularly the ears), and activity level provide extremely useful guides to the efficacy of treatment when performed serially over time. The single most valuable index is the **heart rate**, although, in animals housed in a stable ambient temperature, **peripheral skin temperature** is also a useful clinical guide but not during rapid intravenous fluid administration, because there is a thermal lag of at least 30 minutes before increased blood and heat flow to the periphery is manifested as an increase in skin surface temperature. Blood or plasma **L-lactate concentration** and **venous oxygen tension** provide the most useful measures of the adequacy of oxygen delivery and tissue perfusion and therefore the efficacy of treatment. These two laboratory parameters are much more informative than measurement of **central venous pressure** or **mean arterial blood pressure**, and blood pressure measurement is discussed mainly for historical interest.

Blood or plasma L-lactate concentration, preferably measured in arterial blood or blood from a large vein such as the jugular vein, provides an indication of prognosis and an even more valuable serial measure of the efficacy of treatment. In general terms, plasma L-lactate concentrations are normally less than 1.5 mmol/L and fluctuate slightly depending on diet and time since feeding. Plasma L-lactate concentrations of more than 4 mmol/L indicate the presence of widespread anaerobic metabolism and the need for aggressive therapy, and plasma L-lactate concentrations above 10 mmol/L are associated with a high mortality in humans, pigs, cattle, and horses. Blood L-lactate concentrations are increased in cows with abomasal volvulus; however, blood lactate concentration did not provide an accurate prognostic indicator for survival. Generally, it is the **change in plasma L-lactate concentration after initiation of therapy** that provides the most useful guide to treatment. This change may be monitored by the actual plasma L-lactate concentration or the area under the plasma L-lactate concentration-time relationship. In particular, failure to decrease the plasma L-lactate concentration despite aggressive and appropriate therapy is a poor prognostic sign.

Venous blood oxygen tension (Po_2), preferably measured in a large vein such as the jugular vein, provides an indication of the adequacy of oxygen delivery and is a useful guide to the efficacy of treatment. In general terms, venous Po_2 is normally 35 to 45 mm Hg, arterial Po_2 is normally 90 mm Hg, and the difference between the venous and arterial Po_2 depends on the amount of oxygen extracted by tissues. The oxygen extraction ratio increases in tissues receiving inadequate blood flow as a consequence of the inadequate oxygen delivery; this results in an increased difference between arterial Po_2 and venous Po_2 and a lower value for venous Po_2. **Venous Po_2 below 30 mm Hg** indicates inadequate oxygen delivery and the need for aggressive therapy, such as hemoglobin in erythrocytes or stroma-free solution in hemorrhagic shock and plasma volume expansion in hypovolemic and maldistributive shock. A venous Po_2 below 25 mm Hg indicates severe abnormalities in oxygen delivery, and venous Po_2 below 20 mm Hg indicates impending death. Aggressive resuscitation should always increase venous Po_2 to more than 40 mm Hg, and failure to substantially increase venous Po_2 despite aggressive and appropriate therapy is a poor prognostic sign.

Central venous pressure (CVP) is another measure of hypovolemia, but individual measurements can be misleading and serial measurements should be used. By definition, CVP can only be measured by a catheter placed in a blood vessel within the thorax (typically the cranial vena cava), because this permits measurement of negative values for CVP. Central venous pressure is frequently measured in the jugular vein through a short intravenous catheter; this pressure is more correctly termed jugular venous pressure and, because it cannot be negative, is of much less clinical value than measuring CVP in shocked animals. A general rule of thumb in horses is to administer fluids as long as the CVP remains below 2 cmH_2O (0.2 kPa), and to immediately discontinue fluid administration whenever CVP exceeds 15 cmH_2O (1.5 kPa). The main clinical utility of CVP measurement is

ensuring that volume overload is not occurring. More details on measuring CVP are available in Chapter 10.

Mean arterial blood pressure is an insensitive but specific method for determining the severity of shock and the efficacy of therapy, because mean arterial blood pressure only decreases in the terminal stages of shock, indicating a complete lack of cardiovascular reserve. More details on measuring mean arterial blood pressure are available in Chapter 10.

NECROPSY FINDINGS

In **hemorrhagic shock** there is extreme **pallor** of all tissues, and a thin **watery appearance of the blood** may be accompanied by large extravasations of blood if the hemorrhage has been internal. When the hemorrhage has been **chronic**, anemia and edema are characteristic findings. In obstructive shock there is a large increase in pericardial fluid (usually blood), or the presence of a large thrombus in the cranial or caudal vena cava or pulmonary circulation, or evidence of severe abdominal distension (such as in ruminal tympany). There are **no specific findings** in hypovolemic or maldistributive shock, although in maldistributive shock the capillaries and small vessels of the splanchnic area may be congested and there may be evidence of pulmonary edema. With death from septic shock the major findings relate to the changes as evidence of pulmonary edema. With death from septic shock the major findings relate to the changes associated with the infectious disease. Dehydration is evident in animals dying from hypovolemic shock.

DIFFERENTIAL DIAGNOSIS

Circulatory failure caused by a circuit abnormality can be diagnosed when there is no detectable primary cardiac abnormality and when a primary cause such as hemorrhage, dehydration, or endotoxemia is known to be present. Ideally, endotoxemic or septic shock should be diagnosed in its early hyperdynamic stage and aggressively treated at this stage. This requires knowledge of the risks for shock with various conditions in each of the animal species. Hypovolemic, hemorrhagic, or maldistributive shock should be anticipated:

- In septicemic disease, especially of the neonate
- In acute localized infections
- With intestinal disease, but especially with those in the horse that have acute intestinal accident as part of the differential diagnosis
- When severe trauma occurs
- Where there is severe fluid loss for any reason
- Where decompression of an area is to be practiced (i.e., removal of fluid from a body cavity)
- When there is to be a significant surgical procedure

TREATMENT

Identification of Cause

The identification and, if possible, the immediate elimination of the precipitating cause of the shock is important in cases in which circulatory failure is initiated by conditions that are amenable to surgical correction. Prompt surgical intervention coupled with aggressive fluid therapy may save an animal, whereas delaying surgery until shock is advanced is almost always followed by fatality. This requires a full clinical examination and often ancillary laboratory examination to accurately identify the cause.

The identification of cause will also give some indication of the likelihood of success in treatment. Generally, there is greater success in the treatment and management of hypovolemic and hemorrhagic shock, especially if treatment is instituted early in the clinical course. Effective treatment and management of maldistributive shock is less successful unless the sepsis can be controlled and the source of the endotoxemia eliminated.

Hypovolemic and Maldistributive Shock

The rapid administration of intravenous fluids is the single most important therapy in animals with hypovolemic or maldistributive shock. The goal is to increase venous return, restoring circulatory function and tissue perfusion. Crystalloid solutions (fluids that contain electrolytes) and colloid solutions (fluids that increase the plasma oncotic pressure and expand plasma volume) can be used. The general principles and practice of fluid therapy are extensively discussed in Chapter 5.

Isotonic Crystalloid Solutions

These are the least expensive and most commonly used treatments for hypovolemic and maldistributive shock in large animals. Balanced electrolyte solutions, such as lactated Ringer's solution, are preferable to 0.9% NaCl solutions. Fluids for the restoration of the extracellular fluid volume must contain sodium, but glucose solutions (fluids that provide free water when the glucose is metabolized) are not indicated in the treatment of shock. **Large volumes** of isotonic crystalloid fluids are required. There is no set dose and each case needs to be assessed individually; an initial administration of 1\00 mL/kg by rapid intravenous infusion is not unusual and 50 mL/kg is probably the minimum. Isotonic crystalloid solutions expand the interstitial fluid volume and promote urine flow; however, beneficial responses are absent shortly after the cessation of fluid administration unless the syndrome is resolved.

More fluids are administered as required on the basis of clinical response and the monitoring measures discussed earlier; generally, this involves continuous intravenous infusion during the clinical course. In calves, ruminants, and horses the reestablishment of adequate tissue perfusion by intravenous fluid therapy can often be sustained by oral administration of large volumes of electrolyte solutions.

The disadvantages of the use of isotonic crystalloid solutions are the large volume required for treatment, the requirement for repeated treatment, and a sustained increase in pulmonary artery pressure with the risk for production of pulmonary edema in animals with maldistributive shock caused by endotoxemia. Moreover, the delivery of large volumes of isotonic fluid to large animals takes time and is difficult to accomplish in the field. This has led to the widespread use of **small-volume hypertonic saline solutions** for the initial resuscitation of shocked animals. The intravenous administration of small volumes of hypertonic salt solutions results in a transcompartmental and transcellular shift of fluid into the vascular compartment, with an increase in the circulating volume, cardiac output, and stroke volume and an increase in blood pressure with a reduction in peripheral and pulmonary vascular resistance. However, there is little improvement in renal function, the improvement in hemodynamic function is very **short lived,** and their use must be followed by intravenous isotonic crystalloid fluids.

Hypertonic Saline Solution

This has been used successfully in fluid therapy of hypovolemic, maldistributive, and hemorrhagic shock and is of value for the rapid resuscitative effect and the lower risk for induction of pulmonary edema in animals with endotoxemia. Small volumes (4–5 mL/kg) of hypertonic saline (7.2%, 2400 mOsm/L) are infused intravenously over 4 to 5 min, and the animal is allowed access to fresh water immediately upon completion of the injection.[1] Too rapid an infusion will result in vasodilation and death and too slow an infusion will diminish the resuscitative effect. There is a risk of phlebitis if there is perivascular deposition of hypertonic fluid. Hypertonic sodium lactate solution has been shown to improve fluid balance and mean arterial pressure in pigs with experimentally induced endotoxic shock.[2]

Colloids

The intravenous administration of colloid solutions (plasma, dextran, gelatin polymers, and hydroxyethyl starches) induces a more sustained increase in plasma volume than crystalloid solutions and smaller volumes are required for therapy, but colloid solutions are expensive and are rarely used in cattle and occasionally used in horses, with the exception of blood transfusion. Hydroxyethyl starches, such as hetastarch and tetrastarch, can interfere with coagulation but for the most part the effects are minor and clinically

inapparent.[3] Colloid solutions also have a risk for the induction of pulmonary edema and may also increase risk for coagulopathy. For horses, equine plasma is available commercially but is expensive. The use of hypertonic saline in combination with colloids or infusions containing albumin gives a more sustained response and hypertonic saline-dextran solution (2400 mOsm/L sodium chloride with 6% Dextran 70) at a dose of 5 mL/kg is more effective than hypertonic saline alone.

Hemorrhagic Shock

The source of the hemorrhage should be determined and the cause corrected. The other immediate concern is to replenish the blood volume and a decision must be made if this will be with fluids, whole blood, or stroma free hemoglobin solutions. Blood transfusion replaces all elements of the blood and in cases of severe hemorrhage blood transfusion is the most satisfactory treatment. However, a decision for **blood transfusion** should not be made lightly because the procedure is time-consuming, costly, and carries some risk. The decision to use whole blood in addition to fluids for treatment is based on the need to replace erythrocytes. The hematocrit can be a guide, in combination with clinical assessment, if the hemorrhage started at least 4 hours previously. With acute hemorrhage (<4 hours), transfusion is indicated solely on the basis of the severity of clinical signs. In the period immediately following hemorrhage a hematocrit of 20% is indicative of a significant loss of erythrocytes and the hematocrit should be monitored over the next 24 to 48 hours. If there is a fall to less than 12%, a transfusion of blood is indicated, but a stable packed cell volume (PCV) between 12% and 20% is not usually an indication for transfusion.

The best **anticoagulant** for immediate **blood transfusion** is **sodium citrate,** which is widely available and inexpensive. Citrate complexes calcium and inhibits coagulation; as such the amount of sodium citrate mixed with a volume of blood must be accurately known because excess sodium citrate will induce hypocalcemia when collected blood is transfused into the recipient. Sodium citrate (purchased as a white powder) is dissolved in sterile water to provide a stock solution of 3.85% (weight/volume), which can be autoclaved; the stock solution is subsequently mixed at one part solution to nine parts blood. As an example, 500 mL of 3.85% stock sodium citrate solution is placed at the bottom of a glass bottle and 4.5 L of blood collected to provide a final blood volume of 5 L. Approximately 20 mL of blood for each kg BW can be safely collected from a healthy blood donor (equivalent to 10 L from a 500-kg horse or cow). Do not exceed this volume of collection from the donor, because 40 mL of blood for each kg BW can be lethal. Heparinized blood is not recommended for immediate transfusion because heparin has a much longer half-life in domestic animals than citrate; consequently, if hemorrhage is not controlled there is the potential for heparin to facilitate additional blood loss.

If blood transfusion is to be delayed, then **acid citrate dextrose (ACD)** also known as anticoagulant citrate dextrose is widely recommended based on the addition of dextrose, which purportedly supports erythrocyte metabolism. The beneficial effect of dextrose has probably been overemphasized in domestic animals relative to humans, because human erythrocytes have a similar glucose concentration to plasma. In contrast, erythrocytes from adult domestic animals have a glucose concentration that is much lower than that in plasma and, consequently, a much lower rate of glucose metabolism,[4] potentially minimizing the need for additional glucose. Enthusiastic supporters of using ACD solution can purchase commercial plastic collection kits (usually 450 mL) with the appropriate volume of ACD solution present, but this becomes expensive when contemplating transfusion of an adult horse or cow. Alternatively, 3.6 mL of 50% dextrose solution, 1.6 g of sodium citrate, and 0.5 g citric acid can be dissolved in distilled water to a total volume of 50 mL, which is sufficient to collect 450 mL of blood.

The blood donor should be healthy and easily restrained during collection and free of infectious agents that can be transferred during blood transfusion, including prions. Crossmatching is not routinely performed in cattle, sheep, goats, or alpacas/llamas because these species have a large number of blood group factors and transfusion reactions are rare on the first transfusion. Consideration regarding crossmatching is required in these species if the animal in hemorrhagic shock has been previously transfused; however, often the results are not available fast enough to impact the decision to transfuse animals in shock. Crossmatching is routinely performed in horses if available in a timely manner because the incidence of incompatibility on the first transfusion is much higher in this species. The incidence of adverse events during transfusion in horses was 16% (7/44), characterized by mild urticarial reactions, acute anaphylactic shock, and exacerbation of intravascular hemolysis.[5] Five of the seven horses had some level of incompatibility on major or minor crossmatching, confirming that crossmatching would be beneficial if there is sufficient time and the test is available.

The jugular vein (or both veins) should be aseptically prepared and a bleb of 2% lidocaine placed under the skin to facilitate creating a 5-mm long stab incision through the skin over the site of the jugular vein in the midcervical region (the skin is moved dorsally away from the vein while making the incision). The jugular vein should be distended by application of a knotted rope around the distal cervical region so the knot occludes the jugular vein and facilitates sustained venous distention. A sterilized **12-gauge bleeding trocar** is then placed through the incision and advanced into the lumen of the jugular vein until the hub of the trocar is at skin level. Blood is collected directly into the glass jar as it flows freely, with gentle swirling of the jar contents to mix collected blood with citrate and minimize clot formation. The addition of a connecting tube from the bleeding trocar to the glass jar is not recommended because such tubes usually result in a narrowing of the blood flow with marked slowing of blood collection. Collection of blood into plastic bags is preferred to collection into glass bottles because hemolysis is decreased and clotting factors are maintained and the plastic bag is not easily broken when dropped; however, suitably sized plastic bags may not be readily available. At the completion of blood collection, sustained venous distention is released, the bleeding trocar removed, and one or more sutures are placed in the skin over the site of venipuncture to facilitate hemostasis. The bleeding trocar must be thoroughly cleaned and sterilized after use because plasma adheres tenaciously to the lumen of the trocar; the presence of foreign plasma protein will promote clotting and decreased luminal volume and flow rate when the trocar is used to collect blood from a different animal.

Blood should be administered to the recipient intravenously with an in-dwelling 14-gauge catheter through a commercially available in-line filter that will trap small blood clots. A test administration of 20 mL of blood should be administered and the animal monitored for clinical signs of anaphylaxis, including tachypnea, tachycardia, urticaria, and edema. If these signs are observed the blood transfusion should be immediately stopped. Administration of blood at too rapid a rate may cause overloading of the circulation and acute heart failure, particularly in animals with both circuit and pump failure. An infusion rate of 10 to 20 (mL/kg BW)/h is recommended and 5 to 10 L of blood usually requires an hour to administer to a cow or horse.

Hypertonic saline solution is recommended in the initial treatment of hemorrhagic shock and has been shown to be effective in the treatment of experimental hemorrhagic shock in large animals. Hypertonic saline can be of particular value to the ambulatory clinician, because this therapy can be used in emergency situations for the initial resuscitation of cases of hemorrhagic shock pending transfusion. A further advantage to the ambulatory clinician is the ease of portability of this fluid. The use of hypertonic saline is contraindicated when the hemorrhage has not been controlled, because its use in these cases will result in more protracted bleeding.

Drugs to assist coagulation and arrest hemorrhage are used in some cases, but there is limited information on their efficacy. **Aminocaproic acid** (10 g in 1 L of saline for an adult horse, administered intravenously) has been recommended for the management of hemoperitoneum in the horse. **Formalin** has traditionally been used to control hemorrhage and 10 mL of a 37% solution of formaldehyde or 30 to 150 mL of buffered 10% formalin in 1 L of 0.9% NaCl solution administered rapidly intravenously through an intravenous catheter has been recommended for the control of hemorrhage in horses; however, administration of formaldehyde at levels that did not induce an adverse reaction did not alter measured hemostatic variables in healthy horses. Formaldehyde treatment for hemostasis cannot be recommended for use in horses with the current available data. However, administration of a 5% solution of formalin to healthy goats (at 1.1 mL/kg intravenously) had a transient but detectable effect on decreasing both clotting time and bleeding time. This suggests that the effect of intravenous formalin on hemostasis may be dose dependent, and the optimal dose has yet to be identified in horses. **Ergonovine maleate**, 1 to 3 mg intramuscularly at 3-hour intervals, has also been used to control hemorrhage in the postparturient mare.

Animals should be kept quiet and in a dark stall to minimize excitement and the risk of further hemorrhage. Analgesic drugs should be given with hemorrhagic disease when there is pain, such as rupture and hemorrhage of the broad ligament of the uterus.

Obstructive Shock

The source for the obstruction should be identified and specific remedies applied. Obstructive shock is a rare cause of shock in large animals.

Ancillary Treatment

A large number of drugs have been shown to influence various components of the inflammatory response in septic shock, but none has been shown to alter the eventual outcome, and the interference of one aspect of the inflammatory cascade triggered by endotoxin should not be expected to improve overall survival. The specific treatment of maldistributive shock has been discussed earlier in this chapter.

Corticosteroids

There is considerable controversy over the use of corticosteroids in shock. Experimental studies have shown that they may have value in the prevention of maldistributive shock, but for this to occur corticosteroids must be given before the bacterial or endotoxin challenge. There is little evidence that they are of value in the treatment of hypovolemic, hemorrhagic, or maldistributive shock in animals once clinical signs have developed. Despite this, corticosteroids are frequently used in the treatment of shock in animals. The dose that is used is considerably higher than that used for other indications, for example, a dose of 1 to 2 mg/kg BW of dexamethasone intravenously, which is expensive in adult cattle and horses.

Cyclooxygenase Inhibitors

The use of cyclooxygenase inhibitors such as IV flunixin meglumine (0.25 mg/kg BW) and IM ketoprofen (0.5–2.2 mg/kg BW) has attractions in that they inhibit the production of the vasoactive prostaglandins and thromboxane A_2. This may not be entirely advantageous because the alternate path of metabolism of arachidonic acid is to leukotrienes, which are also potent mediators of inflammation. Treatment of horses with endotoxemia with cyclooxygenase inhibitors does result in a better maintenance of blood pressure and tissue perfusion but does not influence the eventual mortality. Tirilazad mesylate suppresses eicosanoid production and TNF-α activity and has been shown to be of benefit in the treatment of experimental endotoxemia in calves.

Antibiotic Therapy

With maldistributive shock the appropriate antibiotic therapy should be immediately instituted. Antibiotic therapy will not counteract the immediate effects of endotoxin and may theoretically increase the release of endotoxin in the short term, but this should not be a contraindication to antibacterial therapy. Pending the result of bacterial culture and susceptibility testing a broad-spectrum bactericidal antibiotic, or a combination of antibiotics to achieve a broad spectrum, should be used. Gram-negative septicemia in calves or foals, or acute–diffuse peritonitis, must be treated with antibiotics as well as by aggressive fluid therapy if there is to be any chance of survival.

Vasoconstrictors and Vasodilators

The administration of vasoconstrictors and vasodilators in cases of shock remains problematic unless the patient's cardiovascular status is accurately known and can be continuously monitored. Generally, their use is not currently recommended. The administration of a vasoconstrictor substance in a case of low-pressure distributive shock might seem rational because blood pressure would be elevated but it could reduce tissue perfusion still further. α-Adrenergic blockers improve tissue perfusion and cardiac function once the circulating blood volume has been restored, but if hypotension is already present it will be further exacerbated. Dopaminergic agonists may be useful in the early stages of maldistributive shock as long as monitoring is adequate. This is seldom possible in large-animal ambulatory practice and their use in large animals is confined to referral hospitals.

Immunotherapy

Immunotherapy with antibody directed against the **core lipopolysaccharide antigens** of gram-negative bacteria may be of value in the therapy or prevention of shock produced by endotoxin in some diseases but not in others. Immunotherapy has shown some promise in the treatment of shock associated with experimental endotoxemia in horses but none for the control of maldistributive shock associated with gram-negative sepsis in the neonate. Hyperimmune serum is available commercially and may be indicated in those cases when endotoxemia is a risk, in which case it is given before the onset of severe signs. Vaccination with these antigens has proved of value in the reduction of clinical disease produced by endotoxemia and in a reduction of the occurrence of endotoxin-induced shock associated with gram-negative mastitis in cows, although it does not reduce the occurrence of infection of the udder.

Localized Infections

Localized infections are common in farm animals and many are bacterial infections secondary to traumatic injuries. Because most of them have a surgical outcome, by incision and drainage or by excision or amputation, they are not usually included in medical textbooks. They are presented briefly here because of their importance in the differential diagnosis of causes of toxemia and also because of their space-occupying characteristics, which cause compression of other structures. Also, the initial treatment is often medical, especially if the location of the lesion cannot be identified.

ETIOLOGY

Abscesses and similar aggregations of pyogenic material in certain anatomic locations are described elsewhere in this book. The common ones include pharyngeal,

submandibular,[1] retroperitoneal, hepatic,[2,3] splenic, pulmonary, cerebral, pituitary, spinal cord, and subcutaneous abscesses. Other similar lesions include embolic nephritis, guttural pouch empyema, lymphadenitis, pharyngeal phlegmon, osteomyelitis tooth root abscesses, and infections of the umbilicus and associated vessels.

More widespread accumulations of necrotic/toxic pyogenic debris occur and are described under the headings of pericarditis, pleurisy, peritonitis, metritis, mastitis, meningitis, and pyelonephritis.

Other pyogenic lesions worthy of note include the following:

- **Inguinal abscess in horses.** Some of these probably originate as postcastration infections, but some obviously have other origins, possibly as a lymphadenitis arising from drainage of a leg with a chronic skin infection.
- **Traumatic cellulitis and phlegmon in soft tissue,** especially skeletal muscle. The neck is a common site of infection in the horse, with lesions resulting from infected injection sites or the injection of escharotic materials, e.g., iron preparations intended only for intravenous administration. Penetrating traumatic wounds, often severely infected, are among the serious occurrences to the legs and hooves of horses and cattle. These commonly penetrate joint capsules, bursae, and tendon sheaths, and underrun periosteum. In cattle, the common causes are agricultural implements; in horses they are more commonly caused by running into protruding objects, including stakes and fencing material.
- **Abscessation and cellulitis of the tip or the proximal part of the tail.** This occurs in steers in feedlots and rarely extends to the hindquarters and the scrotum; the cause is presumed to originate from the presence of an aggregate of feces on the tip of the tail (manure ball) that gets caught in fencing material. Bacteria isolated from the lesion indicates a mixed infection.
- **Perirectal abscess** occurs in horses, caused usually by minor penetrations of the mucosa during rectal examination. Some of these rupture into the peritoneal cavity, causing acute, fatal peritonitis. Others cause obstruction of the rectum and colic because of the pain and compression that result. They are readily palpable on rectal examination.
- **Perivaginal abscess** occurs in heifers and cows, caused by vaginal tears during parturition, particularly after dystocia. Occasionally these rupture into the peritoneal cavity, causing acute, fatal peritonitis. More commonly, the abscess causes obstruction of the rectum and urethra, with the animal exhibiting signs of abdominal pain and stranguria because of the resultant pain and compression during posturing for defecation and urination. Perivaginal abscesses are readily palpable on rectal and vaginal examination.
- **Urachal abscess.** See omphalitis.
- **Pituitary abscess** occurs in cattle, sheep, and goats[4] as a single entity or in combination with other lesions. Pituitary abscesses cause a wide range of signs with emphasis on dysphagia caused by jawdrop, blindness, and absence of a pupillary light reflex, ataxia, and terminal recumbency with nystagmus and opisthotonus.
- **Facial abscess in cattle and goats.** Facial abscesses secondary to injury of the cheek mucosa caused by plant awns are common in beef cattle being fed hay containing a variety of awns that may penetrate the oral mucosa. *T. pyogenes* (formerly *Arcanobacterium* or *Actinomyces* or *Corynebacterium pyogenes*) is the commonly isolated bacterium. Localized abscesses of the face and neck are common in some flocks of goats and sheep.[5,6] *Corynebacterium pseudotuberculosis* is most commonly isolated, followed by *T. pyogenes* and *Staphylococcus* spp. The abscesses are most common on the jaw and sternal, facial, and cervical regions.
- **Tooth root abscesses in llamas, alpacas, goats, and sheep.** Tooth root abscesses are a common dental disease of llamas and alpacas and are thought to be caused by ingestion of rough or stemmy forages when permanent molars are erupting.[7] Tooth root abscesses can arise without a known cause or may result from trauma, foreign body migration (such as grass seeds), malocclusion and abnormal tooth wear, and periodontal disease. *T. pyogenes* and *F. necrophorum* are most commonly isolated from tooth root abscesses in New World camelids. Tooth root abscesses are most frequently found in mandibular molar teeth in New World camelids,[7] the mandibular incisors in pigs, and the first maxillary molar in horses.

Bacterial Causes of Localized Infection

These include those bacteria that are common skin contaminants in animals, including *T. pyogenes, F. necrophorum,* streptococci, and staphylococci. Clostridial infections are common but occur sporadically. They are described under Malignant edema. *Clostridium pseudotuberculosis* is common as a cause of local suppuration in horses and is the specific cause of caseous lymphadenitis of sheep. *Rhodococcus equi* also causes pulmonary and subcutaneous abscesses in horses and cervical lymphadenitis in pigs. Strangles (*Streptococcus equi* subsp. *equi*), *R. equi* infection in foals, melioidosis, and glanders are all characterized by extensive systemic abscess formation. *Histophilus somni* causes systemic abscess formation in sheep. *Mycobacterium phlei* and other atypical mycobacteria are rare causes of local cellulitis and lymphadenitis/lymphangitis manifesting as "skin tuberculosis" in cattle. Streptococcal cervical abscess in pigs is another specific abscess-forming disease.

PORTAL OF ENTRY

Most localized infections begin as penetrating wounds of the skin, caused accidentally or neglectfully because of failure to disinfect the skin adequately before an injection or incision, as in castration, tail docking, and so forth.

Metastatic implantation from another infectious process, especially endocarditis, carried by blood or lymph, is the next most common cause. In this way a chain of lymph nodes can become infected. Cranial and caudal vena caval syndromes produce similar embolic showers in the lungs.

PATHOGENESIS

The local infection may take the form of a circumscribed aggregation of bacterial debris and necrotic tissue, known as an **abscess**. This may be firmly walled off by a dense fibrotic capsule or be contiguous with normal tissue. When such an abscess occurs in a lymph node it is called a **bubo**; when the infective material is purulent but diffusely spread through tissues, especially along fascial planes, it is known as a **phlegmon**; and when it is inflammatory but not purulent the same lesion is called **cellulitis**.

The species of bacteria in the abscess determines the type of pus present and its odor. Staphylococci produce large quantities of thick yellow pus, and streptococci produce less pus and more serous-like exudates. Pus associated with *T. pyogenes* is deep-colored, yellow or green in color and very thick and tenacious. The pus of *F. necrophorum* is very foul-smelling and usually accompanied by the presence of gas.

Deposition of bacteria in tissues is sufficient to establish infection there in most instances. Conditions that favor abscess development include ischemia, trauma, and the presence of a cavity or a hematoma. A continuing process of pus formation results in enlargement to the stage of pointing and rupturing of an abscess, or spread along the path of least resistance into a nearby cavity or vessel, or discharge to the exterior through a sinus. Continuing discharge through a sinus indicates the persistence of a septic focus, usually a foreign body, such as a grass seed, a sequestrum of necrotic bone, or an osteomyelitis lesion.

CLINICAL FINDINGS

The clinical signs of abscesses and other local aggregations of pyogenic lesions were

described earlier. General clinical findings that suggest the presence of a localized infection, which is not readily obvious clinically, include the following:

- Fever, depression, lack of appetite, all are signs of toxemia.
- Pain resulting in abnormal posture, e.g., arching of the back, or gait abnormality, including severe lameness.
- Weight loss, which can be dramatic in degree and rapidity.
- Obstruction of lymphatic and venous drainage, which can cause local swelling and edema. Sequels to these developments include extensive cellulitis if there is a retrograde spread of infection along lymph drainage channels and phlebitis and thrombophlebitis when there is stasis in the veins.
- Careful palpation under anesthesia or heavy sedation may be necessary to overcome the muscle spasm caused by pain. Calves with extensive abscessation emanating from the navel, and horses with inguinal abscesses, can only be satisfactorily examined by deep abdominal and rectal palpation.
- Radiologic examination may elicit evidence of osteomyelitis, and examination of a fistulous tract may be facilitated in this way, especially if a radiopaque material is infused into the tract.

CLINICAL PATHOLOGY

Hemogram

A complete blood count is helpful in supporting a diagnosis of local abscess. Unless the infection is completely isolated by a fibrous tissue capsule or is small in size relative to the size of the animal (tooth root abscess or osteomyelitis), there will be a leukocytosis with a left shift and an elevation of polymorphonuclear leukocytes in acute lesions or of lymphocytes and monocytes in more chronic ones. A moderate normochromic anemia is usual in chronic lesions, and mild proteinuria is common.

Sample of Lesion for Culture and Staining

Attempts to identify the presence of an infectious agent and to establish its identity are usually undertaken, but care is necessary to avoid spreading infection from a site in which it is presently contained. Techniques used include paracentesis, careful needle aspiration from an abscess, blood culture (with the chances of isolation of bacteria being very small unless there is phlebitis or endocarditis), and aspiration of cerebrospinal fluid. Ultrasonographic guidance is helpful for percutaneous aspiration of deeper seated abscesses.[8]

The isolation of bacteria from a well-contained abscess may be difficult because of the paucity of organisms. Special techniques may be necessary and examination of a smear stained with Gram stain, and perhaps also with Ziehl–Neelsen stain if the circumstances suggest it, is an essential part of the examination. Determination of sensitivity of the bacteria to antibiotics is usually undertaken.

Necropsy Findings

The presence and location of the local infection can be demonstrated at necropsy.

TREATMENT

Drainage of Abscesses

Surgical drainage of readily accessible intact abscesses is the treatment of choice and in most cases the only effective method of therapy. A needle aspirate may be indicated when the nature of the lesion is uncertain. The site is prepared surgically and the abscess is drained, flushed, and topically medicated, usually with a roll of gauze soaked in a 1% povidone iodine solution, which is a stable chemical complex of polyvinylpyrrolidone and elemental iodine, for the first 24 to 48 hours. One roll is used to ensure that all the gauze is removed from the abscess. If the abscess is large then gauze rolls should be tied together to ensure all gauze is removed at the same time. If the abscess has not yet pointed with a soft spot, hot fomentations and hydrotherapy may aid in the maturation of a superficial abscess. An analgesic may be required during this stage of therapy. Deep-seated abscesses may benefit from ultrasonographic-guided aspiration, lavage of the abscess cavity with 0.9% NaCl solution, removal of the remaining saline solution, and injection of potassium penicillin into the abscess cavity.[8] Some abdominal abscesses may only be accessible by surgery.[4,9] Tooth root abscesses require extraction of the affected tooth to effect a cure.

Antimicrobial Agents

Antimicrobial agents given parenterally can be used for the treatment of deep abscesses not readily accessible to surgical drainage. Ideally, a sample of the contents of the abscess should be cultured and antimicrobial susceptibility determined. The agent must achieve high plasma concentrations to facilitate penetration into an abscess, and daily treatment for several days is usually necessary. However, antimicrobial agents alone may be ineffective, even if the organism appears sensitive to the drug in vitro in cases when the abscess is surrounded by a dense capsule—presumably the capsule prevents diffusion of the drug into the abscess cavity. Lipophilic antibiotics, such as rifampin, florfenicol, or macrolides, are theoretically advantageous in penetrating into abscesses. Rifampin should be administered with another antimicrobial agent to delay the development of antibiotic resistance.

Pain

THE PROBLEM OF PAIN

Pain has been described in animals as "an aversive sensory and emotional experience representing an awareness by the animal of damage or threat to the integrity of its tissues." Pain is basically a protective mechanism to ensure that the animal moves away from noxious (damaging) influences, but endogenous pain, arising from internal damaging influences, causes its own physiologic and pathologic problems that require the veterinarian's intervention. In humans, there is an additional psychological parameter to pain and, although it is customary to transpose attitudes from pain in humans to animals, this is a courtesy rather than an established scientific principle.

A major difficulty with pain in animals is the difficulty of pain measurement. Pain is a subjective sensation known by experience that can be described by illustration, but measurement of pain is an indirect activity related to its effects and is an objective phenomenon. A panel report on recognition and alleviation of pain in animals proposed a simplified classification for animal pain and distress as pain, anxiety and fear, stress, suffering, comfort, discomfort, and injury. The recommendations are directed at academics, teachers, and researchers using laboratory animals, as well as the pharmaceutical industry.

Pain is assessed in animals by three methods: (1) **observation of behavior**; (2) measurement of physiologic parameters, including heart rate, blood pressure, sweating and polypnea, that indicate **sympathetic activation**; and (3) measurement of the plasma concentration of factors that indicate sympathetic activation, such as plasma cortisol, epinephrine, norepinephrine, and nonesterified fatty acid concentrations. Behavioral changes are increasingly being used as indirect indicators of pain, but studies lack standardization with respect to definition of behaviors, frequency and duration of monitoring, and interpretation of results. More objective indirect techniques for quantifying pain include the use of force meters, vocalization measures, stride length, and activity using pedometers and

accelerometers.[1] Because of the lability and expense of epinephrine and norepinephrine analyses, and the poor specificity of increased plasma nonesterified fatty acid concentration for pain, the most commonly used laboratory measure of pain is **plasma cortisol concentration**. Cortisol concentrations have also been measured in saliva, urine, and feces to provide a more accurate indicator of basal stress, because plasma cortisol concentrations increase rapidly in response to handling and restraint for blood sampling.

Pain in agricultural animals is a matter of ever-increasing concern, and there is an obvious need to identify, evaluate, prevent, and manage pain in large animals. Many agricultural practices that are thought to be necessary to avoid later painful disease or injury (e.g., disbudding or dehorning of cattle, sheep, and goats;[2] tail docking in piglets and lambs;[3] the Mules operation in Merino sheep;[4] and tooth clipping in baby pigs), to improve animal production and minimize fighting or reproductive-related injuries (e.g., castration, spaying), or to facilitate in animal identification (branding, eartagging, tattooing, or ear notching) are performed by producers without provision of an analgesic agent. It is not our purpose to engage in a discussion on the subject of animal welfare or the prevention of cruelty.

ADVANCES IN ATTITUDE TOWARD PAIN

There is now a greater awareness of the existence and detrimental effects of pain in animals, which has led to widespread implementation of postoperative pain control. New and improved analgesics are being developed and marketed as a result of increased basic and clinical research in pain. The detrimental effects of pain include the following:

- Suffering and stress resulting in delayed healing
- Increased catabolism and decreased feed intake
- Prolonged recovery and longer recumbency, with a greater risk of postoperative complications
- The potential to cause ineffective respiratory ventilation with the development of respiratory acidosis and acidemia
- Self-mutilation
- The potential of acute pain to lead to chronic pain

Pain may be clinically beneficial by acting as a protective mechanism by moving the animal away from the noxious stimulus and providing immobility of the affected part, promoting healing. Pain is a valuable diagnostic aid but, once identified, it is necessary to treat the pain and remove or modify its source if possible.

Once it is accepted that pain is detrimental it then becomes important to recognize and evaluate the severity of the pain. In the past, veterinary science has used an anthropomorphologic approach to the assessment of whether or not an animal is in pain. It is a reasonable elementary approach to compare the effects of pain in animals with those in humans because there are many more similarities in the neuroanatomical, physiologic, and behavioral data between humans and animals than there are differences. However, because of the inherent behavioral and social differences between humans and animals, this approach is limited.

Current research on pain in animals includes visual and subjective assessment of pain supported by physiologic and clinicopathologic measurements. These studies have increased the awareness of the problem of pain in veterinary medicine and resulted in improved information on the use of appropriate analgesics. Analgesics are now more commonly used perioperatively in food-producing animals and horses in New Zealand, Scandinavia, the United Kingdom, and the United States undergoing surgical and painful procedures.[5-8] More research is needed to develop optimal analgesic protocols.

ETIOLOGY

Pain sensations are aroused by different stimuli in different tissues, and the agents that cause pain in one organ do not necessarily do so in another. In animals there are three types of pain:

1. Cutaneous (or superficial)
2. Visceral
3. Somatic (or musculoskeletal)

The causes of each type of pain are listed in the following sections.

Cutaneous or Superficial Pain

Cutaneous or superficial pain is caused by agents or processes that damage the skin, such as burning, freezing, cutting, and crushing. Fire burns, frostbite, severe dermatitis, acute mastitis, laminitis, infected surgical wounds, foot rot, crushing by trauma, conjunctivitis and foreign body in the conjunctival sac are all common causes of pain.

Visceral Pain

Examples of visceral pain include the following:

- Inflammation of serosal surfaces, as in peritonitis, pleurisy, and pericarditis
- Distension of viscera, including the stomach, intestines, ureters, and bladder
- Swelling of organs as in hepatomegaly and splenomegaly
- Inflammation, as in nephritis, peripelvic cellulitis, and enteritis
- Stretching of the mesentery and mediastinum

In the nervous system, swelling of the brain caused by diffuse edema, or of the meninges caused by meningitis, are potent causes of pain. Inflammation of (neuritis) or compression of (neuralgia) peripheral nerves or dorsal nerve roots are also associated with severe pain.

Musculoskeletal (Somatic) Pain

Muscular pain can be caused by lacerations and hematomas of muscle, myositis, and space-occupying lesions of muscle. Osteomyelitis, fractures, arthritis, joint dislocations, and sprains of ligaments and tendons are also obvious causes of severe pain. Among the most painful of injuries are swollen, inflamed lesions of the limbs or joint caused by deep penetrating injury or, in cattle, by extension from foot rot. Amputation of a claw, laminitis, and septic arthritis are in the same category. Ischemia of muscle and generalized muscle tetany, such as occurs in electroimmobilization, also appear to cause pain.

The trauma of surgical wounds is a controversial topic in animal welfare, especially that associated with minor surgical procedures such as dehorning, tail docking, and castration in farm animals. From clinical observation supported by some laboratory examinations, e.g., salivary cortisol concentrations after castration in calves and lambs, it appears that pain after these procedures is short-lived, up to about 3 hours, and the perception of pain is age dependent.[1,9]

PATHOGENESIS

Pain receptors are distributed as end organs in all body systems and organs. They are connected to the CNS by their own sensory nerve fibers with their cell bodies in the dorsal root ganglion of each spinal nerve and via some of the cranial nerves. Intracord neurons connect the peripheral neurons to the thalamus, where pain is perceived, and to the sensory cerebral cortex, where the intensity and localization of the pain are appreciated and the responses to pain are initiated and coordinated.

The stimuli that cause pain vary between organs. The important causes include the following:

- **Skin:** cutting, crushing, freezing, burning
- **Gastrointestinal tract:** distension, spasm, inflamed mucosa, stretching of mesentery
- **Skeletal muscle:** ischemia, traumatic swelling, tearing, rupture, hematoma
- **Synovial membranes and cartilage of joints:** inflammation

Nociception is the normal physiologic process by which pain is perceived. When a tissue is injured by mechanical, thermal, or chemical means, **peripheral nociceptors** (specialized free nerve endings of afferent neurons) are depolarized and the initial stimulus is felt as pain.

Peripheral nociceptors are located in skin, fascia, muscles, tendons, blood vessels, joint capsules, periosteum, subchondral bone, pleura, peritoneum, and viscera. Five

classes of peripheral nociceptor are currently recognized: (1) thermal nociceptors activated by temperatures above 52°C or below 5°C, (2) mechanoheat nociceptors activated by pressure and temperature, (3) polymodal nociceptors, (4) visceral nociceptors, and (5) silent nociceptors. The **first pain** or initial sharp stinging following injury is caused by activation of large-diameter fast-conduction myelinated nerve fibers called **Type IAδ fibers** (thermal nociceptors) or **Type IIAδ fibers** (mechanoheat nociceptors). The **second pain** or slow pain following injury is caused by activation of small-diameter unmyelinated slow-conduction fibers called **C-fibers**; these fibers transmit a painful stimulus that is perceived as a sustained burning sensation that persists past cessation of the initial sharp painful sensation. Visceral nociceptors are activated by diffuse stimulation instead of direct local noxious stimuli. Silent nociceptors are mechanoheat nociceptors activated when sensitized by release of proinflammatory mediators (such as bradykinin, histamine, leukotrienes, eicosanoids, serotonin, substance P, adenosine triphosphate [ATP], low tissue pH, and other constituents of inflammation) into damaged tissues, establishing **peripheral hyperalgesia**. The hyperalgesia during acute pain is thought to promote healing at the injured site.

Central Hypersensitivity and Preemptive Analgesia

A state of altered central processing can also occur in response to chronic activation of peripheral nociceptors, which is called **central hypersensitivity** or "wind up." This central hypersensitivity results in a modified response to subsequent afferent inputs, which last between 10 and 200 times the duration of the initiating stimulus. The net result is that stimuli previously perceived as innocuous, such as touch or pressure, become perceived as painful after the system is sensitized. Preinjury treatment with opioids or local anesthetics prevents or decreases the development of central hypersensitivity and behavioral indicators of pain, but opioids and local anesthetics are less effective if administered after the injury is initiated. It is the establishment of central hypersensitivity that makes pain much more difficult to control once it is established and why analgesics are less effective at this time. Thus the combination of peripheral hyperalgesia (particularly associated with substance P) and central hypersensitivity results in what is called clinical pain.

It has been suggested that by preventing the surgical afferent stimuli from entering the spinal cord, the facilitation of spinal nociceptive processing could be prevented and this would decrease the severity of postoperative pain. This is known as the concept of **preemptive analgesia**. Preoperative administration of an analgesic is more effective than postoperative administration of the same dose; this is relevant to the control of pain associated with elective surgery. Many studies (primarily in humans) have demonstrated that preoperative administration of local anesthetic agents and the administration of NSAIDs or opioids before the patient is recovered from anesthesia are appropriate methods for instituting preemptive analgesia.

The physiologic responses to pain are described in the following sections. Normal responses include the release of the morphine-like endorphin from the brain, providing an endogenous analgesic system, and also cortisol release from the adrenal cortex in response to any stress. The clinical response to pain varies not only with the personality of the patient (some are more stoic than others) but also with various other influences. For example, distraction, as in walking a horse with colic, application of an alternative pain in the forced elevation of the tail of a cow (tail jack), and application of local anesthetic agents all tend to relieve pain. In agricultural animals pain elicits behavioral, physiologic, and clinicopathologic changes. The behavioral responses can be interpreted as a form of distraction, a displacement activity, or as providing an alternative pain. The physiologic and clinicopathologic responses are part of the fight or flight phenomena and reflect sympathetic activation.

CLINICAL FINDINGS

The general clinical findings of pain are described here and the indications of pain associated with individual body systems or organs are described within each category.

Physiologic Responses

Physiologic responses to pain are manifested by the following signs, and the severity of the pain determines the degree of response:

- Tachycardia
- Polypnea
- Pupillary dilatation
- Hyperthermia
- Sweating

The cardiovascular responses of tachycardia and hyperthermia may contribute to a fatal outcome in animals with reduced cardiovascular reserve, for example, when dehydration, acid-base imbalance, and endotoxic shock are also present.

Behavioral Responses

These include abnormal posture and gait when the pain is musculoskeletal (e.g., somatic). The gait abnormalities include lameness, a shuffling gait, and rapid shifting of weight from one leg to another. These are subjects of importance in orthopedic surgery.

The behavioral responses to pain may also include unrelated activities such as **rolling, pawing, crouching, or grinding of teeth** when the pain is visceral. However, the behavioral activities may also be related to the site of the pain, e.g., the horse with colic that looks at its abdomen, or to a particular function, such as pain manifested on coughing, walking, defecating, urinating, and so forth. The behavioral aspects of severe pain are very important in the horse with severe unrelenting visceral pain caused by colic. The rolling, falling, and lunging upward and backward (often falling against walls) can result in severe injury and causes panic in many owners.

Generally, somatic pain is more localized and easily identified than visceral pain. Injuries to limbs are usually identifiable by fractures or localized tendon strain or muscle injury. With severe somatic pain, as with a fracture or septic arthritis, the limb is carried off the ground and no weight is taken on the limb. With lesser lesions more weight-bearing activity is undertaken.

One of the notable factors affecting pain in animals is the analgesic effect of the animal lying on its back or of its adopting a defeated, supine posture. This may be related to the release of endorphins.

More general behavioral responses to pain include **decreased appetite** and average daily rate of gain, adoption of an anxious expression (ears retracted), disinclination to be examined, and aversion to returning to a particular location in which pain has been experienced previously. **Moaning, grunting, and grinding of the teeth** (odontoprisis or bruxism) are generally indicative of pain. If vocalization occurs with each respiration or rumination, the pain appears likely to arise from a lesion in the thoracic or abdominal cavities. When teeth grinding is associated with head pressing it is thought to indicate increased intracranial pressure such as occurs with brain edema or lead poisoning. Grinding of the teeth as a sole sign of pain is usually associated with subacute distension of segments of the alimentary tract. More extreme kinds of vocalization caused by pain include moderate bellowing by cattle, bleating in sheep and goats, and squealing in pigs.

Elicitation of Pain by the Veterinarian

This is an essential part of a clinical examination. The techniques include the following:

- Pressure by palpation, including firm ballottement with the fist and the use of a pole to depress the back in a horse or to arch the back upward from below in a cow
- Pressure by compression, as with hoof testers for detecting the presence of pain in the hoof
- Movement by having the animal walk actively or by passively flexing or extending limbs or neck
- Stimulation of pain related to coughing by eliciting the cough reflex
- Relief of the pain by correction of the lesion

Periodicity and Duration of Pain

Limited duration of pain can be the result of natural recovery or of surgical or medical correction of the problem. Constant pain results from a static state, whereas periodic or intermittent pain is often related to periodic peristaltic movement. In humans and in companion animals some importance also attaches to observing the time of onset of pain, whether it is related to particular functions or happenings and whether the patient gains relief by adopting particular postures or activities. These factors are unlikely to be of importance as an aid to a diagnosis in agricultural animals.

TREATMENT

Several aspects concerning the relief of pain in agricultural animals are important. Cost has always been a deterrent to the use of local anesthetics and analgesics. However, with changing attitudes toward animal pain, this issue is more frequently examined. Treatment of the causative lesion is a major priority, but the treated lesion may remain painful for varying lengths of time. Relief and the control of pain should be a major consideration and the following principles require consideration:

- Relief of pain is a humane act. Improved, less painful methods of castration,[9] dehorning,[2] tail docking,[3] Mules operation in sheep,[4] spaying cattle, and treating painful lesions of the hooves of farm animals must be explored and implemented. Surgical operations, such as laparotomies, must be performed using appropriate analgesia.
- Analgesia may obscure clinical findings that may be necessary to observe, properly diagnose, or maintain surveillance of a case. This is of major importance in equine colic.
- Control of pain is necessary to prevent animals from inflicting serious self-injury associated with uncontrollable behavior as a result of severe visceral pain.
- Analgesics for visceral pain are readily available and relatively effective.
- A major problem in the clinical management of pain is for cases of severe, slowly healing, infected traumatic wounds of the musculoskeletal system. Pain is likely to be very severe, continuous, and to last for periods of up to several weeks. Affected animals cannot bear weight with the affected limb, have great difficulty in moving, lose a great deal of weight, and prefer prolonged recumbency. At the present time, there are no effective analgesics available that can be administered easily and daily for a few weeks without undesirable side effects. The development of such products is urgently required.

Analgesia

The analgesic agents and techniques available include the following:

- Surgical procedures, e.g., neurectomy by section of peripheral nerves, as practiced in horses
- Local destruction of peripheral nerves by chemical means, e.g., the epidural injection of agents such as ethyl alcohol may prevent straining
- Local destruction of peripheral nerves by thermal means, e.g., cautery of the wound edge after gouge dehorning in calves
- Analgesia using nonopioid drugs when sedation is not required or is contraindicated
- Opioid analgesics (narcotic analgesics)

Analgesic Agents

There are seven main types of analgesic agent administered parenterally or topically to large animals:

1. **Local anesthetic agents** such as lidocaine (lignocaine), mepivacaine, and bupivacaine
2. **NSAIDs** such as flunixin meglumine, ketoprofen, phenylbutazone, carprofen, and meloxicam
3. **α_2-Agonists** such as xylazine and detomidine
4. **Opioids** such as morphine, fentanyl, butorphanol, and buprenorphine
5. ***N*-methyl-D-aspartate receptor antagonists** such as ketamine
6. **Vanilloids** such as capsaicin
7. **γ-Aminobutyric acid analogs** such as gabapentin

Generally, local anesthetic agents, α_2-agonists, and opioids are used to provide short-term analgesia (hours), parenteral NSAIDs and topical vanilloids are used to provide long-term analgesia (days to months), and **γ-aminobutyric acid analogs are investigational**. Effective analgesia is best achieved using a **multimodal approach** that incorporates the administration of two or more pharmaceutical agents that attenuate or abolish the transmission, modulation, and perception of pain, providing optimal pain relief (Fig. 4-2). Standard anesthesiology texts should be consulted regarding techniques for local analgesia using regional or peripheral nerve blocks and local anesthetic agents, or for general analgesia using α_2-agonists and opioids.

Local Anesthetic Agents

Lidocaine, mepivacaine, and bupivacaine exert their analgesic effect by addressing both the first pain and second pain after injury by blocking the voltage-gated sodium channels in peripheral nerves, preventing propagation of depolarization. Types IAδ and IIAδ and C-fibers are blocked before other sensory and motor fibers, meaning that it is possible (but sometimes a clinical challenge) to selectively block pain while maintaining the animal's normal motor function. The main advantages of local anesthetic agents are their cost and predictable and local effect, and the main disadvantage is short duration of action. They are usually administered by perineural infiltration in specific or regional nerve blocks. One challenge with lidocaine injection is that formulations are acidic and, consequently,

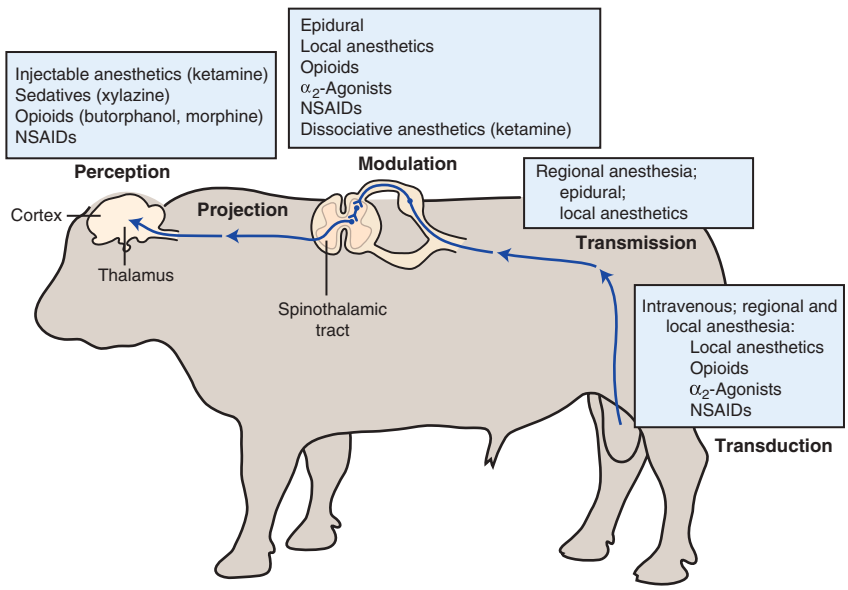

Fig. 4-2 The nociceptive pathway in cattle, identifying the anatomic location of analgesic drug activity. Effective analgesia is best achieved using a multimodal approach that incorporates the administration of two or more pharmaceutical agents that attenuate or abolish the transmission, modulation, and perception of pain. (Reproduced with permission from Coetzee JF. *Vet Clin North Am Food Anim Pract* 2013;29:13.)

burn when injected. The injection pain can be mitigated by mixing 1 mL of 8.4% sodium bicarbonate solution with 10 mL of 2% lidocaine in a 12-mL syringe; this increases the solution pH and reportedly decreases the immediate pain associated with lidocaine injection. The bicarbonate–lidocaine mixture should be used immediately and not stored because the higher pH causes the lidocaine to come out of the solution. Topical formulations of lidocaine (2.5%) and prilocaine (2.5%) are available that appear to be useful for transdermal administration of a local anesthetic in large animals before intravenous catheter placement, venipuncture, arthrocentesis, or collection of cerebrospinal fluid. There is concern in the European Union regarding the use of lignocaine (lidocaine) in food-producing animals because of mutagenic activity and genotoxic characteristics of a lignocaine metabolite, 2,6-xylidine. Procaine is not metabolized to the same metabolite and offers a suitable alternative if lignocaine use is curtailed in food-producing animals.

Nonsteroidal Antiinflammatory Drugs

These drugs appear to exert most of their analgesic effect by addressing the **second pain** (slow pain) caused by sensitization of C-fibers by eicosanoids; NSAIDs are not currently thought to exert a central analgesic effect. Animals receiving NSAIDs should be normally hydrated to minimize potential renal effects such as tubular nephrosis and papillary necrosis (see diseases of the kidney). Combined administration of a systemic NSAID with an intraarticular corticosteroid appeared to be more successful in the treatment of joint pain in horses than single treatment of either agent alone.[10]

Although parturition is painful, current data do not support the routine administration of NSAIDs at parturition because most of the studies completed in cattle have reported an increased incidence of retained placenta in animals treated with NSAIDs; this result is consistent with the current understanding that $PGF_{2\alpha}$ plays an important role in placental detachment.[11] Whether NSAIDs are beneficial in cattle experiencing dystocia remains to be determined.[12,13]

Flunixin Meglumine

This NSAID has excellent antiinflammatory, antipyretic, and analgesic properties, and is the preferred NSAID for acute soft tissue or visceral pain, although it is also efficacious against musculoskeletal pain. Flunixin meglumine provides excellent analgesia in equine colic and postoperative pain. In a comparison of three NSAIDs used to minimize postsurgical pain in horses, flunixin meglumine (1 mg/kg BW), phenylbutazone (4 mg/kg BW), or carprofen (0.7 mg/kg BW) were administered once intravenously. All three NSAIDs were effective in controlling postoperative pain, but the duration of clinical effect was longer for flunixin meglumine (12.8 hours) than carprofen (11.7 hours) or phenylbutazone (8.4 hours). Flunixin meglumine (1.1 mg/kg intravenously) was an effective analgesic in 2- to 3-month-old bull dairy calves undergoing surgical castration; flunixin meglumine administration attenuated the cortisol response and avoided some of the behavioral changes observed in calves castrated without drugs or with lidocaine infusion alone.[1]

The usual loading dose for flunixin meglumine is 1.1 to 2.2 mg/kg BW IV (ruminants) or 1.1 mg/kg BW (horses) followed by a maintenance dose of 1.1 mg/kg BW every 24 hours, although some studies have administered repeated injections at 8 to 12 hours. Flunixin meglumine is usually administered once or twice a day for its analgesic effect and is usually administered parenterally (preferably intravenously because of the rare instances of myonecrosis following intramuscular injections, particularly in horses), although oral formulations exist. Intramuscular doses are rapidly absorbed, with the maximal concentration occurring within 1 hour. Large doses given to individual ponies may, however, be toxic. Toxic effects are similar to those with phenylbutazone and include ulceration of the colon, stomach, and mouth; the latter two are most evident when administered orally. The major disadvantage with flunixin meglumine is the relatively short duration of action and label requirements for intravenous injection in the United States.[14]

Ketoprofen

This NSAID has antiinflammatory, antipyretic, and analgesic properties and is labeled in Europe for the treatment of pain in cattle associated with mastitis, lameness. and trauma (3.3 mg/kg BW intravenously or intramuscularly, every 24 hours for 3 days). Oral formulations are also available in Europe for the treatment of suckling calves. On theoretical grounds, ketoprofen may have analgesic properties superior to currently available NSAIDs because it blocks both the cyclooxygenase and 5-lipoxygenase branches of the arachidonic acid cascade as well as potentially having antibradykinin activity. However, the latter two effects have not been demonstrated in large animals at recommended dose rates. Ketoprofen has been shown to provide analgesia for several hours after gouge dehorning of calves and surgical castration of calves.

Phenylbutazone

This NSAID is used extensively as an oral analgesic for horses, especially for long-term treatment of musculoskeletal pain. It is most effective for the relief of mild to moderate musculoskeletal pain. The half-life of the drug in plasma is about 3.5 hours so that repeated treatment is recommended. A plasma concentration of 20 µg/mL appears to be clinically effective in horses, whereas a plasma concentration of 60 to 90 µg/mL appears to be clinically effective in cattle. After oral use in horses the peak levels in plasma are reached at 2 hours, but after intramuscular injection this does not occur until after 6 hours; thus, the oral or intravenous routes are the usual routes of administration. Unless care is taken to inject the drug slowly when using the intravenous route, severe phlebitis, sometimes causing complete obstruction of the jugular vein, may result. For horses the recommended dose rate is 4.4 mg/kg BW daily for 5 days orally or intravenously. Treatment on day 1 may be at 4.4 mg/kg BW twice, constituting a loading dose. Treatment beyond 5 days may be continued at minimal effective dose rates. However, prolonged use, especially in ponies, at a dose of 10 to 12 mg/kg BW daily for 8 to 10 days, may be followed by ulceration of alimentary tract mucosa, including the oral mucosa, and fatal fluid retention caused by hypoproteinemia. The pathogenesis of these lesions is thought to be caused by a widespread phlebopathy. Phenylbutazone should not be used if there is preexisting gastrointestinal ulceration, clotting deficits, or cardiac or renal dysfunction. Its use should be under close veterinary supervision so that the dose rate may be kept to a minimal effective level and so that it is used only when there is a clear clinical indication to do so. It should be withdrawn if there is no indication of a therapeutic response or if signs of toxicity appear. If there is doubt about toxicity or a prolonged course is advised, periodic hematologic examinations are recommended.

For cattle, the recommended oral dose is 10 to 20 mg/kg BW initially followed by daily doses of 4 to 6 mg/kg BW or every other day dose of 10 to 14 mg/kg BW. Clearance is slowed in neonates, so the dosage protocol would need to be adjusted in suckling calves. The general clinical impression is that phenylbutazone is the most effective analgesic available for the treatment of cattle with painful musculoskeletal conditions. Phenylbutazone is no longer permitted to be administered to female dairy cattle > 20 months of age in the United States because of concerns about meat and milk residues; phenylbutazone is known to induce blood dyscrasias in humans, including aplastic anemia, leukopenia, agranulocytosis, thrombocytopenia, and death. In addition, phenylbutazone is a carcinogen, as determined by the National Toxicology Program. Because of these concerns, phenylbutazone should not be administered to food-producing animals.

Meloxicam

Meloxicam is a longer acting NSAID than flunixin meglumine and has the additional advantage that it can be administered intramuscularly. Meloxicam preferentially binds to COX-2 (the inducible isoform) and

therefore theoretically has decreased side effects in large animals that may result from constitutive COX-1 isoform inhibition, including gastric or abomasal ulceration and proximal tubular injury of the kidneys. Meloxicam has been shown to be an effective analgesic in ruminants undergoing surgical procedures such as dehorning or castration, and it is effective when administered at 0.5 to 1 mg/kg BW orally every 1 to 2 days. However, based on prescription guidelines in the United States, oral meloxicam should only be administered to ruminants when sustained analgesia (>3 days) is needed.

Salicylates

Aspirin or acetylsalicylic acid is the most commonly administered analgesic in cattle but is not very effective, and there is limited clinical evidence of its efficacy. The recommended dose rate is 100 mg/kg BW orally every 12 hours, and oral administration is most common. Because there may be limited absorption from the small intestine, the salicylates may be given intravenously (35 mg/kg BW every 6 hours in cattle; 25 mg/kg BW every 4 hours in horses), but this is no longer practiced with the widespread availability of flunixin meglumine and phenylbutazone.

Carprofen

This is the safest NSAID, because of its weak inhibition of peripheral prostaglandins.

Diclofenac

This NSAID, when given to lambs before castration with bloodless castrators, significantly reduced the time spent trembling or in abnormal postures following the castration procedure. Diclofenac was widely administered to cattle and water buffalo in south Asia until catastrophic declines in the local vulture populations was identified. It was determined that vultures scavenging on cattle carcasses that had been unsuccessfully treated with diclofenac were dying from diclofenac-induced renal failure. Diclofenac was subsequently banned for veterinary use across south Asia in 2006, and since that time vulture populations have made a remarkable comeback.

α_2-Agonists

Xylazine

Xylazine was the first widely used α_2-agonist in large animals and remains the most commonly administered α_2-agonist in ruminants. Xylazine has been shown to be the most effective analgesic for the relief of experimentally induced superficial, deep, and visceral pain in ponies when it was compared with fentanyl, meperidine (pethidine), methadone, oxymorphone, and pentazocine. However, its short duration of action and the accompanying sedation and decreased gastrointestinal motility, respiratory activity, and increased urine formation limit its use as a short-term analgesic. Xylazine appears to produce minimal sedation and analgesia in pigs when administered as a sole agent.

Xylazine is widely used in the horse. Medetomidine and dexmedetomidine are used in the horse when a longer duration of analgesia is required.[15]

Narcotic Analgesics

Meperidine (Demerol, pethidine) is extensively used as an analgesic for visceral pain in the horse. Methadone hydrochloride and pentazocine are also used, to a limited extent, and their use is detailed in the treatment of colic in the horse. Butorphanol, a synthetic narcotic used alone or in combination with xylazine, provides highly effective analgesia in horses.[16]

Generally, narcotic analgesics are not as effective in ruminants as in horses and pigs because they have a distribution of μ and κ receptors different from monogastric animals. In ruminants, opioids produce brief analgesia or no analgesia (depending on the type of stimulus) and higher doses are needed for an effect than in monogastric animals. Opioids also produce behavioral side effects in ruminants. Concern that most opioids are scheduled drugs necessitating extensive record keeping and secure storage, and about meat and milk residues in food-producing animals, further limit the use of opioids in ruminants.

Narcotic agents are used in somatic pain in humans and may have wider applicability in animals. A recent clinical application has been transdermal delivery of fentanyl, which is a potent μ and κ agonist opioid analgesic drug that is highly lipid soluble. Fentanyl patches have been applied to the skin of horses, pigs, sheep, goats, and llamas. The rate and magnitude of uptake is dependent on core temperature and environmental temperature (and therefore blood flow to the skin at the site of the patch), thickness of the skin at the site of the patch, and adherence of the patch to the skin. A significant limitation to the use of opioids is their addictive nature in humans, necessitating storage under strict control with written records of their usage required in most countries.

N-methyl-D-aspartate receptor antagonists

The prototype *N*-methyl-D-aspartate receptor antagonist is ketamine, which modulates central sensitization at subanesthetic doses exerting an antihyperalgesic effect. The analgesic effects of ketamine are most evident in animals with moderate to severe pain or those animals that appear hypersensitive to pain.

Vanilloids

Capsaicin is derived from hot chili peppers (*Capsicum annuum*) and is the main vanilloid used in horses; these agents are characterized by their ability to activate a subpopulation of nociceptor primary afferent neurons. Capsaicin induces a transient primary hyperalgesia that is followed by a sustained period of desensitization that is species, age, dose, and route of administration dependent. The sustained desensitization is responsible for capsaicin's efficacy as an analgesic agent. Capsaicin therefore has dual effects: initial transient primary hyperalgesia (manifested as a burning sensation) and long-term desensitization. Topical application of capsaicin ointment over the site of the palmar digital nerves has been used in horses as an adjunctive method of analgesia in equine laminitis, with demonstrated efficacy. The major clinical disadvantage of using capsaicin is the initial transient primary hyperalgesia.

γ-Aminobutyric Acid Analogs

Gabapentin is the class representative and was originally developed as an antiepileptic agent in humans because it is a structural analog of the inhibitory neurotransmitter γ-aminobutyric acid (GABA). The analgesic effect of gabapentin is focused primarily at chronic or neuropathic pain or as part of multimodal therapy, particularly with NSAIDs. The pharmacokinetics of gabapentin has been determined in horses,[17] beef cattle,[18] and dairy cattle.[19] Generally, gabapentin is rapidly but poorly absorbed in horses when administered orally at 5 mg/kg BW and is rapidly cleared in the horse with an apparent plasma elimination half-life of 3.4 hours. This suggests that gabapentin must be administered frequently (at least every 8 hours) when administered orally to horses.

Balanced (Multimodal) Analgesia

Because multiple mechanisms for pain modulation all act together, the concept of **balanced or multimodal analgesia** has been proposed, similar to the way in which the use of different combinations of sedative and anesthetic agents results in the best aspects of each agent producing balanced anesthesia. Among horses receiving NSAIDs at the end of an anesthetic, those that received butorphanol during surgery required less additional analgesia compared with those that did not receive any opioid. Thus combinations of drugs can be used to produce sequential blocks in nociceptive pathways.

Acupuncture is a popular complementary treatment option for pain in human medicine. Adequate randomized clinical trials that have an appropriate control group, use blinding, and have clinically relevant primary endpoints have yet to be conducted in large animals to determine whether acupuncture is an effective analgesic agent.

Administration Routes

The main routes used for administration of analgesics have been local infiltration, subcutaneous, intramuscular, and intravenous. Other routes, including **oral, epidural, intraarticular,** and **topical**, are now being explored.

Xylazine and **lidocaine** given as **epidural analgesia** abolished pain and tenesmus in cows with acute tail-head trauma, which was characterized by acute, intense pain and discomfort, severe tenesmus, and a limp tail. Extended pain relief was required for up to 3 weeks. Xylazine in the epidural space has also been used to provide analgesia for the castration of bulls. In the horse epidural analgesia using a combination of butorphanol and local anesthetics has been used to provide perineal analgesia.

Supportive Therapy

The application of moist heat to a local lesion causing pain is effective and makes medical sense. Its value depends on how frequently and for how long it can be applied. Providing adequate bedding is important for an animal that is recumbent for long periods or that is likely to injure itself while rolling. A thick straw pack is most useful if it can be kept clean and densely packed. Sawdust is most practical but gets into everything, especially dressings and wounds. Rubber floors and walls, as in recovery wards, are effective but are usually available only for short periods. Distracting a horse with colic by walking it continuously is a common practice to prevent the animal from behavioral activities such as rolling, which may cause self-inflicted injuries. Walking is valuable, but has obvious limitations.

The provision of adequate amounts and quality of feed and water is essential, especially if the animal is immobilized and because appetite is often poor.

Stress

Stress is a systemic state that develops as a result of the long-term application of stressors. It includes pain, which was discussed earlier. **Stressors** are environmental factors that stimulate homeostatic, physiologic, and behavioral responses in excess of normal. The most objective measures of the presence and magnitude of acute stress are activation of the **sympathoadrenal medullary system** and the **HPA axis**, manifested as increases in the plasma concentrations of catecholamines and cortisol, respectively. The importance of stress is that it may

- Lead to the development of psychosomatic disease
- Increase susceptibility to infection
- Represent an unacceptable level of consideration for the welfare of animals
- Reduce the efficiency of production

The general adaptation syndrome, described in humans, has no counterpart in animals, and it is lacking in accurate definitions, precise pathogenesis, and general credibility.

CAUSES OF STRESS

For animals, a satisfactory environment is one that provides thermal comfort, physical comfort, control of disease, and behavioral satisfaction. An environment that is inadequate for these factors will lead to stress. The environmental influences that elicit physiologic responses from animals are outlined next and some can be classified as stressors. The effects of most of these influences on production or performance indices have been measured quantitatively, and many of them have been equated with blood levels of adrenal corticosteroids, which quantify them as stressors in the different species:

- **Road transportation** for prolonged periods, especially during inclement weather and when overcrowded, is considered to be a major stress associated with an increased incidence of infectious disease in all farm animal species. The effects of prolonged road transportation have been measured in young calves, cattle, sheep, and horses.
- **Climate**, especially temperature, either as excessive heat or cold, is a stressor. In particular, a change of climate places great pressure on heat production and conservation mechanisms in, for example, conditions of sudden wind and rain, which affect the comfort of animals.
- **Excessive physical effort**, as in endurance rides for horses, struggling in restrained animals, fear, and the excitement and fear in capture myopathy syndrome in wildlife, are all potential stressors.
- **Pain**, especially analgesia-masked pain in severe colic in horses, is a stressor. The pain of dehorning and castration of farm animals is also a transient stressor, depending on the species and method used.
- **Crowding factors,** such as temperature, humidity, the physical exhaustion associated with standing up for long periods, being walked on, difficulty in getting to food and water, and so forth, are relevant. Two other factors could be important. One is the effect of crowding on behavior; for example, pigs in overcrowded pens appear to bite one another more than when they are housed at lower densities, and are more restless than normal when temperatures in the pens are high. The biting is much more severe between males than between females. Also, it is known that pigs bite each other when establishing precedence in a group, e.g., after mixing of batches, and that this is more severe when feed is short. The other possible factor that might affect the animal's response to crowding is a psychological appreciation of the unattractiveness of crowding (or of isolation). This, however, is an unknown phenomenon in animals.
- **Presence or absence of bedding**. This is a comfort factor separate from temperature and wetness. Whether comfort affects physiologic mechanisms is not currently known.
- **Housing** generally includes the matter of comfort as well as that of maintaining moderate temperatures, but whether there is a factor other than the physical is not known.

- **Nutritional deficiencies** including lack of energy, bulk, and fluid.
- **Quietness versus excitement.** Harassment by humans or other animals sufficient to cause fear does elicit stress response in animals, and this is thought to be one of the significant causes of stress-related diseases in animals. Thus transportation, entry to saleyards, feedlots, fairs, and shows, and simply the mixing of several groups so that competition for superiority in the social order of the group is stimulated, are causes of stress. Entry to an abattoir, which has the additional fear-inspiring factors of noise and smell, is likely to be very stressful for those reasons, but it is unlikely that a fear of impending death is relevant. Such situations are stressful to the point of causing marked elevation of plasma epinephrine concentrations.
- **Herding and flocking instincts**. Animal species that are accustomed to be kept as herds or flocks may be distressed for a period if they are separated from the group.

PATHOGENESIS

Stress is thought to develop when the animal's mechanisms concerned with adapting its body to the environment are extended beyond their normal capacities. The daily (circadian) rhythm of homeostatic and physiologic changes in response to normal daily changes in environment requires the least form of adaptation. Marked changes in environment, such as a dramatic change in weather, on the other hand, place a great strain on adaptation and are classified as stressors.

The body systems that are principally involved in the process of adaptation to the environment are the endocrine system for the long-term responses and the nervous system for the sensory inputs and short-term responses. The endocrine responses are principally the adrenal medullary response, related to the "flight or fight" situation, which requires immediate response, and the adrenal cortical response, which becomes operative if the stressful situation persists.

In humans, a large part of the "stress" state is the result of stimuli arising in the cerebral cortex and is dependent on the capacity to develop fear and anxiety about the effect of existing or anticipated stressful situations. Whether or not these psychological inputs play any part in animal disease is important, but undecided. The evidence seems to suggest that psychic factors do play such a part but that it is relatively minor.

The critical decision in relating stress to disease is to decide when an environmental pressure exceeds that which the animal's adaptive mechanisms can reasonably accommodate, in other words, to define when each of the pressures outlined earlier does, in fact, become a stressor. There is a great dearth of definition on the subject. Probably the most serviceable guideline is "stress is any stimulus, internal or external, chemical or physical or emotional, that excites neurons of the hypothalamus to release corticotrophin-releasing hormone at rates greater than would occur at that time of the day in the absence of the stimulus." This definition uses stress where stressor would have been more commonly used. Other than that, it is acceptable. The critical threshold of stress occurs in the adrenal cortex, and its physical determination is subject to a chemical assay of ACTH. This was the basis of the original "stress and the general adaptation syndrome" as set down by Selye in 1950. The original concept is still attractive because of its simplicity and logic. However, evidence supporting the hypothesis remains limited. The importance of the concept for our animals is unproven. The deficiency in evidence is that of obtaining a standard response to a standard application of a stimulus. There is a great deal of variation between animals, and stimuli that should be significant stressors appear to exert no effect at all on adrenocortical activity.

Stress and Road Transportation

The response of different farm animal species to the effects of road transportation has been examined. In unaccustomed cattle that are forced to run and are then herded together, there are increases in the hematocrit and blood concentrations of catecholamines, cortisol, total lipid, glucose, and lactose. Transportation of calves, 4 to 6 months of age, for only 4 hours results in a leukocytosis with neutrophilia, a decrease in T-lymphocyte population, a suppression of lymphocyte blastogenesis, and enhancement of neutrophil activity. The effect of road transportation on cattle varies according to age: the transportation of 1- to 3-week-old calves for up to 18 hours was not as stressful as in older calves. The lack of response of the younger calves to transport may be caused by their lack of physiologic adaptation to coping with the transportation. During transportation, plasma cortisol concentrations and serum creatine kinase (CK) activities increase. There is clinical evidence of dehydration and increases in serum nonesterified fatty acid, β-hydroxybutyrate, and urea concentrations, which reflect changes in normal feeding patterns. Based on the physiologic measurements and subjective measurements of behavior, a 15-hour transportation period under good conditions is not unacceptable regarding animal welfare. Transportation is exhausting and causes dehydration, but lairage facilitates recovery from both. When sheep are subjected to a journey of up to 24 hours it is best to be done as an uninterrupted trip, because it is the initial stages of loading and transport that are most stressful. In a 15-hour road journey with sheep, the major change in hormone release occurs during the first 3-hour period and is much less in the remaining 12 hours.

The effects of road transport on indices of stress in horses have been examined. A road journey lasting up to 24 hours is not particularly stressful for horses, if they are healthy, accustomed to the trailer and their travel companions, permitted to stop at least as frequently as every 3.75 hours, and traveling in a well-ventilated trailer. There was no indication that road transport was a risk factor for pulmonary disease; however, confinement of horses with their heads elevated for up to 24 hours (similar to during transportation) results in bacterial colonization and multiplication within the lower respiratory tract. Horses are also less physically stressed when facing backward in a trailer.

Based on plasma cortisol concentrations, confinement of young bulls on a truck and motion are considered stressful factors in road transport. Transport stress increases fecal, urine, and tissue losses, with most of the increased loss taking place during the first 5 to 11 hours of transport. During transportation of feeder calves (195 kg) the major portion of transport stress occurs during the early phases of transport; longer periods may not add significantly to the overall stress imposed on the calf. It is possible that the major stress may be related to the handling of the animals during loading and unloading.

Other Possible Sources of Stress

Dehorning dairy calves at 8 weeks of age resulted in an increase in plasma cortisol concentration within 1 hour after the procedure but there was no evidence of prolonged stress.

The effects of maternal dietary restriction of protein and/or metabolizable energy on the humoral antibody response in cows and the absorption of immunoglobulins by their cold-stressed calves indicates that there were no major or sustained differences compared with controls.

Different types of stress also result in distinctive changes in the plasma concentrations of metabolites and hormones. An environmental stress, such as noise, will stimulate a hypothalamic–adrenal–cortex response, whereas a sympathetic–adrenal–medulla response occurs with a stressor such as transportation.

CLINICAL PATHOLOGY

The direct criterion of stress is the assay of plasma ACTH; stress may be indirectly assayed using plasma cortisol concentration, which is a less expensive and more widely available assay. Salivary or fecal cortisol concentration is a good indicator of stress in sheep and cattle. Salivary and fecal samples are easy to collect, and the laboratory assay is simple to perform. Remember that elevation of plasma, salivary, and fecal cortisol concentrations are a normal physiologic

response and do not necessarily imply the existence of a damaging state in the environment. Assays of plasma catecholamines (epinephrine and norepinephrine) are confined to the research setting because these hormones are unstable using standard storage conditions.

Stressors such as weaning, placement in solitary housing or with a new group, and transportation lead to an acute phase response, which is manifested as an immediate increase in serum amyloid A concentration and a slightly delayed increase in serum haptoglobin concentration.[1] The mechanism of the increase is not directly linked to an increased plasma cortisol concentration. Endogenous cortisol release also results in an acute neutrophilia with no left shift.[1]

During prolonged periods of road transportation of cattle and sheep, there are significant changes in serum concentrations of total proteins, nonesterified fatty acids (NEFAs), glucose, CK, β-hydroxybutyrate, and urea. These changes can be used to assess the degree of nutritional stress and the deprivation from feed and water during transportation.[2] Prolonged feed deprivation reduces liver glycogen stores and increases concentrations of NEFAs and ketones in the plasma. Dehydration will elevate the concentrations of plasma proteins and the osmolality of the blood. Physical stress, such as fatigue or exercise, will result in increases in CK. Psychological stressors such as fear result in elevations of cortisol and corticosterone.

STRESS SYNDROMES

Stress-Related Psychosomatic Disease

In humans there is a significant neuronal input from the cerebral cortex to the hypothalamus in response to the psychological pressure generated by stress. The inability to monitor anxiety and feelings of harassment in our animals makes it impossible to determine the presence of psychological stress in them. However, psychosomatic diseases as they occur in humans are almost unknown in farm animals. The pathogenesis of psychosomatic disease appears to be based on the ability of the cerebral cortex to effectively override the normal feedback mechanisms by which the pituitary gland regulates the secretion of corticosteroids from the adrenal cortex. In other words, the normal adaptive mechanisms do not operate and hyperadrenocorticism and adrenal exhaustion develop.

Stress and Susceptibility to Infection

Field observations support the view that stress reduces resistance to infection. This seems to be logical in the presence of higher than normal adrenocortical activity. The most intensively explored relationship of this kind has been that of exposure of calves to weaning and transportation and their subsequent susceptibility to shipping fever. The prevalence appears to be increased and is still further enhanced by the introduction of other stress factors.

Stress and Animal Welfare

The perceived harassment of domesticated animals by humans has become a matter of great concern for the community at large. Intensive animal housing has become an accepted part of present-day agribusiness, but sections of the consuming public are inclined to the view that these practices are cruel. The literature that has built up around this argument sets out to demonstrate that environmental stress in the shape of intensive housing, debeaking, tail docking, and so on, is sufficient to cause a stress reaction as measured by increased corticosteroid secretion. This has not turned out to be the case, and it is understandable in the light of the known variation among animals in their response to environmental circumstances requiring their physiologic adaptation. If it could be shown that this relationship did exist and that the increased adrenocortical activity caused reduction in resistance to infection, the task of the responsible animal welfare person would be much easier. The absence of this experimental data makes the continuing argument less resolvable, but it is now generally accepted that producers have a responsibility to their animals and to society generally to maintain an acceptable standard of humane care of animals. These arguments are usually expressed as codes of animal welfare, to which most concerned people conform. However, they are not statutory directives and are not capable of active enforcement. Some courts of law accept them as guidelines on what the human–animal relationship in agriculture should be. Many aspects of the codes are arbitrary and are understandably heavily sprinkled with anthropomorphic sentiments. The study of ethology, which has expanded greatly during the recent past, may eventually provide some answers to this active, often bitterly fought-over field.

There has been increased adoption of the belief that an animal's welfare, whether on a farm, during transportation, or at a market or slaughterhouse, should be considered in terms of **five freedoms** that reflect ideal states rather than legal standards. The Five Freedoms concept originated with the Brambell Report released in 1965 (Report of the Technical Committee to Enquire into the Welfare of Animals kept under Intensive Livestock Husbandry Systems). This report indicated that livestock should have the freedom "to stand up, lie down, turn around, groom themselves and stretch their limbs." The five freedoms are currently stated as follows:

- **Freedom from Hunger and Thirst:** Ready access to fresh water and a suitable diet that maintains full health and vigor.
- **Freedom from Discomfort:** Provide an appropriate environment including shelter and a comfortable resting area.
- **Freedom from Pain, Injury, or Disease:** Prevent or rapidly diagnose and treat disease.
- **Freedom to Express Normal Behavior:** Provide sufficient space, proper facilities, and an appropriate group structure.
- **Freedom from Fear and Distress:** Ensure that conditions and treatment avoid mental suffering.

Animal welfare can also be viewed using a conceptual framework, with three such frameworks being widely advocated (biological functioning, affective state, and natural living). In the **biological functioning** framework, animals use a variety of behaviors and physiologic responses to cope with the environment; poor production or injury occurs in severe circumstances in which they are unable to adapt to the environment. This framework has been criticized because it does not include an emotional component, although such activation may be inferred by evaluating the magnitude of sympathoadrenal medullary and HPA axes. In the **affective state** framework, animal welfare is viewed as the "net sum of the magnitude of pleasant and unpleasant experiences." Although this is a useful concept, it has been difficult to quantify. Finally, the **natural living** framework is based on the concept that welfare is improved whenever animals can express their normal behaviors; this is best illustrated by "welfare-friendly" production systems, such as free range grazing of sheep flocks and beef cattle herds. When practiced to extremes, natural living can result in animal welfare concerns, such as increased neonatal losses caused by hypothermia in ruminants exposed to cold and windy weather.

The status of animals used in research has always been a bone of contention between the experimenters and some sections of the general public. Generally, these arguments revolve around anthropomorphic propositions that animals are subject to fear of pain, illness, and death in the same way as humans. There is no consistent evidence in physiologic terms that supports these views. However, the public conscience has again achieved a good deal of acceptance to the view that animal experimentation should be controlled and restricted and carefully policed to avoid unnecessary experiments and hardship in animals under our control.

Stress and Metabolic Disease

There is an inclination to label any disease caused by a strong pressure from an environmental factor as a stress disease, for instance, hypocalcemia of sheep and hypomagnesemia of cattle in cold weather, acetonemia and pregnancy toxemia of cattle and sheep on deficient diets, and white muscle disease of

calves and lambs after vigorous exercise. These diseases do have environmental origins, but their causes are much simpler than a complex interaction of the cerebral–cortical–hypothalamic–adrenocortical axis. They can be prevented and cured without any intervention in the stress disease pathogenesis. This is not to say that there is no adrenocortical basis for the pathogenesis of the previously listed diseases, but attempts to establish the relationship have so far been unsuccessful.

Stress and Its Effect on Economic Performance

The constant struggle for domination of other animals in an animal population is most marked in chickens and pigs, and the relationship between status in the hierarchy and productivity in these species has been established with the low-status animals producing less well. It is also known that birds that are highly sensitive and easily startled are poor producers, and they are easily identified and culled.

The relationship between stress and production appears to be a real one. For example, heat stress in the form of high environmental temperatures reduces roughage intake and hence milk production in lactating dairy cows, and the relationships between stress and infertility and stress and mastitis in cattle are also well documented. The sensitivity of animals to environmental stress is greatest at times when they are already affected by metabolic stresses, e.g., during late pregnancy and early lactation. The adoption of a policy of culling erratic, excitable animals appears to have an economic basis.

MANAGEMENT OF STRESS

The widespread public debate about the welfare of food-producing domestic animals dictates that veterinarians, animal scientists, and the livestock industry must develop systems of handling and housing that will minimize stressors and provide an environment that makes the animals most content and at the same time most productive. In civilized human society it should be realistic to expect that the animals that are used for food production or as companions should live their lives free from abuse or adverse exploitation. It will be necessary to determine how best to monitor the well-being of animals and determine whether or not they are under stress. Guidelines dealing with codes of practice for livestock production are available in many countries. In addition to housing, handling, and experimental intervention, it will also be important to give due care to the appropriate selection and use of anesthetics and analgesics when pain is being inflicted, such as in dehorning and castration. The effect of sedatives, such as acepromazine and xylazine on the stress response in cattle, has been examined but the results are inconclusive.

The welfare of animals during transportation is a major issue that has resulted in legislation governing the transport of animals and to define acceptable and unacceptable procedures. Welfare is determined by the length of the trip and the conditions under which animals are transported, including stocking density, ventilation, temperature and humidity, noise, and vibration. Prolonged deprivation of feed and water during long transportation results in hunger and thirst, and methods to minimize these consequences have been developed.

Disturbances of Appetite, Food Intake, and Nutritional Status

Hunger is a purely local subjective sensation arising from gastric hypermotility caused in most cases by lack of distension by food.

Appetite is a conditioned reflex depending on past associations and experience of palatable foods, and is not dependent on hunger contractions of the stomach. The term appetite is used loosely regarding animals and really expresses the degree of hunger as indicated by the food intake. When variations from normal appetite are mentioned, it means variations from normal food intake, with the rare exception of the animal that demonstrates a desire to eat but fails to do so because of a painful condition of the mouth or other disability. Variation in appetite includes increased, decreased, or abnormal appetite.

Hyperorexia, or increased appetite, caused by increased hunger contractions, is manifested by **polyphagia** or increased food intake. Partial absence of appetite (**inappetence**) and complete absence of appetite (**anorexia**) are manifested by varying degrees of decreased food intake (**anophagia**). **Undernutrition** can be defined as a prolonged inadequate supply of nutrients to sustain good health and, in the case of immature or underweight animals, growth potential. For comparison, **malnutrition** is a deficit, imbalance, or excess of nutrients with consequential adverse effects on health and growth potential.[1]

Abnormal appetites include cravings for substances, often normally offensive, other than usual foods. The abnormal appetite may be perverted, a temporary state, or depraved, the permanent or habit stage. Both are manifested by different forms of **pica** or **allotriophagia**.

THIRST

Thirst is an increased desire for water manifested by excessive water intake (polydipsia). The two main stimuli for thirst are increased plasma osmolality and hypovolemia/hypotension. Osmolality is monitored by receptors in the anterior hypothalamus that are outside the blood-brain barrier, whereas "pressure" is monitored by high- and low-pressure baroreceptors in the vascular system and heart. Clinically, diabetes insipidus produces by far the most exaggerated polydipsia.

Specific observations in ponies have shown that water intake is increased in response to either an increase in the osmotic pressure of tissue fluid (from previous water deprivation) or a decrease in the volume of their body fluids (such as from intravenous furosemide administration). Equidae can accommodate and rapidly recover after 72 hours of water deprivation, particularly donkeys and burros, and, consequently, can be considered desert-adapted animals.

The clinical syndrome produced by water deprivation is not well defined. Animals supplied with saline water will drink it with reluctance and, if the salinity is sufficiently great, die of salt poisoning. Cattle at pasture that are totally deprived of water usually become quite excited and are likely to knock down fences and destroy watering points in their frenzy. On examination they exhibit a hollow abdomen, sunken eyes, and the other signs of dehydration. There is excitability with trembling and slight frothing at the mouth. The gait is stiff and uncoordinated and recumbency follows. Abortion of decomposed calves, with dystocia caused by failure of the cervix to dilate, may occur for some time after thirst has been relieved and cause death in survivors. At necropsy there is extensive liquefaction of fat deposits, dehydration, and early fetal death in pregnant cows.

Experimental water deprivation has been recorded in camels, lactating and nonlactating dairy cows, and sheep. In camels death occurred on the seventh to ninth day of total deprivation; BW loss was about 25%. Lactating cows allowed access to only 50% of their regular water supply become very aggressive about the water trough, spend more time near it, and lie down less. After 4 days milk yield is depressed to 74% and body weight to 86% of original figures. There is a significant increase in serum osmolality with increased concentrations of urea, sodium, total protein, and copper. The PCV is increased, as are

activities of creatinine kinase and serum aspartate aminotransferase (AST) activity. With complete deprivation for 72 hours, the changes are similar but there are surprisingly few clinical signs at that time. The composition of the milk does not change markedly and plasma electrolyte concentrations return to normal in 48 hours. Sheep, even pregnant ewes, are capable of surviving even when access to water is limited to only once each 72 hours, but there is a significant loss (26%) of BW. Deprivation of water that allows access to water only once every 96 hours is not compatible with maintaining the pregnancy.

POLYPHAGIA

Starvation, functional diarrhea, chronic gastritis, and abnormalities of digestion, particularly pancreatic deficiency, may result in polyphagia. Metabolic diseases, including diabetes mellitus and hyperthyroidism, are rare in large animals but are causes of polyphagia in other species. Internal parasitism is often associated with poor growth response to more than adequate food intakes.

Although appetite is difficult to assess in animals, it seems to be the only explanation for the behavior of those that grossly overeat on concentrates or other palatable feed. The syndromes associated with overeating are dealt with in Chapter 8.

ANOPHAGIA OR APHAGIA

Decreased food intake may be caused by physical factors, such as painful conditions of the mouth and pharynx, or to lack of desire to eat. Hyperthermia, toxemia, and fever all decrease hunger contractions of the stomach. In species with a simple alimentary tract a deficiency of thiamin in the diet will cause atony of the gut and reduction in food intake. In ruminants a deficiency of cobalt and a heavy infestation with Trichostrongylidae helminths are common causes of anophagia, and low plasma levels of zinc have also been suggested as a cause. In fact alimentary tract stasis from any cause results in anophagia. Some sensations, including severe pain, excitement, and fear, may override hunger sensations and animals used to open range conditions may temporarily refuse to eat when confined in feeding lots or experimental units. Some sheep that have been on pasture become completely anophagic if housed. The cause is unknown and treatment, other than turning out to pasture, is ineffective.

A similar clinical sign is feed aversion, seen most commonly in pigs, which is rejection of particular batches of feed that are contaminated by fungal toxins, e.g., *Fusarium* spp., or by the plant *Delphinium barbeyi.*

One of the important aims in veterinary medicine is to encourage adequate food intake by sick and convalescing animals. Alimentary tract stimulants applied either locally or systemically are of no value unless the primary disease is corrected first. To administer parasympathomimetic drugs parenterally when there is digestive tract atony caused by peritonitis is unlikely to increase food intake. In cattle, the intraruminal administration of 10 to 20 L of rumen juice from a normal cow will often produce excellent results in adult cattle that have been anorexic for several days, provided the primary cause of the anorexia is corrected. The provision of the most palatable feed available is also of value.

Parenteral or oral fluid and electrolyte therapy is indicated in animals that do not eat or drink after a few days. For animals that cannot or will not eat, or in those with intractable intestinal disease, the use of total intravenous feeding (parenteral nutrition) may be indicated. The subject of therapeutic nutrition for farm animals that cannot or will not eat appears to have been ignored. However, in most cases farm animals will begin to eat their normally preferred diets when the original cause of the anophagia or aphagia is removed or corrected. Intensive fluid therapy may be necessary during the convalescence stage of any disease that has affected feed intake and that may result in a mild depression of serum electrolytes.

A reduced feed intake in high-producing dairy cattle during the first few days or weeks of lactation and in fat beef cattle in late pregnancy may result in fatty infiltration and degeneration of the liver and high mortality. Treatment with glucose parenterally and propylene glycol orally to minimize the mobilization of excessive amounts of body fat is indicated.

In nervous anophagia the injection of insulin in amounts sufficient to cause hypoglycemia without causing convulsions is used in human practice, and in animals the use of tranquilizing drugs may achieve the same result.

In ruminants the effects of blood glucose levels on food intake are controversial, but it seems probable that neither blood glucose nor blood acetate levels are important factors in regulating the appetite. The anorexia that is characteristic of acetonemia and pregnancy toxemia of ruminants appears to be the result of the metabolic toxemia in these diseases. Electrolytic lesions in the hypothalamic region can stimulate or depress food intake depending on the area affected. This indicates the probable importance of the hypothalamus in the overall control of appetite.

PICA OR ALLOTRIOPHAGIA

Pica is the ingestion of materials other than normal food and varies from licking to actual eating or drinking. It is associated in most cases with dietary deficiency, either of bulk or, in some cases, more specifically fiber, or of individual nutrients, particularly salt, cobalt, or phosphorus. It is considered as normal behavior in rabbits and foals, where it is thought to be a method of dietary supplementation or refection of the intestinal bacterial flora. Boredom, in the case of animals closely confined, often results in the development of pica. Chronic abdominal pain caused by peritonitis or gastritis and CNS disturbances, including rabies and nervous acetonemia, are also causes of pica.

The type of pica may be defined as follows: **osteophagia,** the chewing of bones; **infantophagia,** the eating of young; **coprophagia,** the eating of feces. Other types include wood eating in sheep, bark eating, the eating of carrion, and cannibalism. Salt hunger can result in coat licking, leather chewing, earth-eating, and the drinking of urine. Urine drinking may also occur if the urine is mixed with palatable material such as silage effluent. Bark eating is a common vice in horses, especially when their diet is lacking in fiber, e.g., when they are grazing irrigated pasture.

CANNIBALISM

Cannibalism may become an important problem in housed animals, particularly swine, who bite one another's tails, often resulting in severe local infections. Although some cases may be caused by dietary deficiencies in protein, iron, or bulk, many seem to be the result of boredom in animals given insufficient space for exercise. A high ambient temperature and generally limited availability of food also appear to contribute. Male castrates are much more often affected than females, and the bites are also much more severe in males. Provision of larger pens or a hanging object to play with, removal of incisor teeth, and the avoidance of mixing animals of different sizes in the same pen are common control measures in pigs. In many instances only one pig in the pen has the habit and his removal may prevent further cases. One common measure that is guaranteed to be successful in terms of tail biting is surgical removal of all tails with scissors during the first few days of life, when the needle teeth are removed. Unfortunately the cannibalistic tendency may then be transferred to ears. As in all types of pica, the habit may survive the correction of the causative factor.

INFANTOPHAGIA

Infantophagia can be important in pigs in two circumstances. In intensively housed sows, especially young gilts, hysterical savaging of each pig as it is born can cause heavy

losses. When sows are grazed and housed at high density on pasture it is not uncommon to find "cannibal" sows who protect their own litters but attack the young pigs of other sows. This diagnosis should be considered when there are unexplained disappearances of young pigs.

SIGNIFICANCE OF PICA

Pica is defined as a depraved or abnormal appetite and may result from a nutritional deficiency or boredom. It may have serious consequences: cannibalism may be the cause of many deaths; poisonings, particularly lead poisoning and botulism, are common sequelae; foreign bodies leading to reticuloperitonitis[1] or lodging in the alimentary tract leading to a luminal obstruction; accumulations of wool, fiber, or sand may cause obstruction; perforation of the esophagus or stomach may result from the ingestion of sharp foreign bodies; and grazing time is often reduced and livestock may wander away from normal grazing. In many cases the actual cause of the pica cannot be determined and corrective measures may have to be prescribed on a trial and error basis.

The majority of observational studies identify a relationship between phosphorus deficiency and pica, particularly in ruminants. Horses exhibiting pica may have iron or copper deficiencies.[2]

STARVATION

Complete deprivation of food causes rapid depletion of glycogen stores and a changeover in metabolism to fat and protein. In the early stages there is hunger, increase in muscle power and endurance, and a loss of body weight. In sheep there is often a depression of serum calcium levels sufficient to cause clinical hypocalcemia. The development of ketosis follows associated with increased fat utilization and an increased serum concentration of NEFAs. Plasma and urine concentrations of allantoin are decreased in goats and sheep during fasting as a result of depressed microbial protein production in the forestomach.[3]

A marked reduction in feed intake in pony mares in late pregnancy is often a precursor of hyperlipemia, a highly fatal disease discussed in Chapter 17. In a case series of chronically starved horses, a low body condition score was accompanied with a lower serum urea nitrogen concentration (caused by low protein intake), a normocytic and normochromic anemia, and an increased serum total bilirubin concentration.[4] The serum urea nitrogen to creatinine concentration ratio is considered a better index of protein wasting than serum albumin or total protein concentrations, with a ratio <15 mg/dL being indicative of protein deprivation or starvation in horses.[4] The most pronounced biochemical changes in ponies and mares occurring as a result of experimental food deprivation is increased serum concentrations of triglycerides, cholesterol, and glutamate dehydrogenase,[5] which reach a peak by the eighth day of fasting but quickly return to normal when feeding is resumed. This degree of change in blood lipids appears to be a characteristic of ponies and horses; it is much higher than that in pigs.

In lactating cows, a short period of starvation results in depression of plasma glucose and an increase in plasma lipid concentrations. Milk yield falls by 70%. On refeeding most levels return to normal in 5 days but blood lipid and milk yield may take as long as 49 days to recover to normal levels. In horses, fecal output falls to zero at day 4 and water intake is virtually zero from that time on, but urine volume is maintained. In spite of the apparent water imbalance there is no appreciable dehydration, and plasma protein levels and PCV stay at normal levels. A significant loss of skin turgor (increase in skin tenting) caused by the disappearance of subcutaneous fat as cachexia develops may occur. Muscular power and activity decrease and the loss of body weight may reach as high as 50% to 60%. The metabolic rate falls and is accompanied by a slowing of the heart and a reduction in stroke volume, amplitude of the pulse, and blood pressure. The circulation is normal as indicated by mucosal color and capillary refill.

In the final stages, when fat stores are depleted, massive protein mobilization occurs and a premortal rise in total urinary nitrogen is observed, whereas blood and urine ketones are likely to diminish from their previous high level. Great weakness of skeletal and cardiac musculature is also present in the terminal stages and death is caused by circulatory failure. During the period of fat utilization there is a considerable reduction in the ability of tissues to use glucose and its administration in large amounts is followed by glycosuria. In such circumstances readily assimilated carbohydrates and proteins should be given in small quantities at frequent intervals but fatty foods may exacerbate the existing ketosis. Diets for animals that have been through a period of great nutritional stress because of deprivation of food or because of illness are described in the following section.

Starvation of farm livestock is an animal welfare issue with economic and ethical considerations. When starving animals are identified by a neighboring farmer or veterinarian they are commonly reported to the appropriate authorities, which may be provincial or state-appointed inspectors (animal care officers) who have the authority to take appropriate action. The animals are examined and corrective action is taken, including possession of the animals and relocating them to a commercial feeding facility. Predicting survival of starved animals is a major challenge. Economics becomes an important aspect because the financial costs of stabilizing a group of starved horses may exceed their free market price. Responsible management of chronically starved commercial animals should include options for immediate euthanasia. Ethical considerations include deciding if certain severely starved animals should be euthanized. In some cases, enforcement officers may be reluctant to recommend mass euthanasia of otherwise healthy horses based on personal aversion.

Chronically starved horses lose body weight, become weak, and their body condition score may decline to below 2 on the basis of 1 to 9, and death is common, especially during cold weather. Chronically starved horses frequently respond poorly to refeeding. About 20% of severely malnourished horses can be expected to die in spite of attempts at refeeding. Recovery of severely malnourished horses to an average body condition score may require 6 to 10 months.

INANITION (MALNUTRITION)

Incomplete starvation—inanition or malnutrition—is a more common field condition than complete starvation. The diet is insufficient in quantity; all essential nutrients are present but in suboptimal amounts. This condition is compatible with life, and generally the same pattern of metabolic change occurs as in complete starvation but to a lesser degree. Thus ketosis, loss of body weight and muscular power, and a fall in metabolic rate occur. As a result of the reduction in metabolic activity there is a fall in body temperature and respiratory and heart rates. In addition there is mental depression, anestrus in cows but not ewes, and increased susceptibility to infection. This increased susceptibility to infection that occurs in some cases of malnutrition cannot be accepted as a general rule. In the present state of knowledge it can only be said that *some* nutritional influences affect resistance to *some* forms of infection.

A significantly reduced food intake also increases susceptibility to some poisons, and this has been related to the effects of starvation on hepatic function. In ruminants, the effects of starvation on the activity of liver enzymes is delayed compared with the effects in monogastric animals, apparently because of the ability of the ruminal store of feed to cushion the effect of starvation for some days. The most striking effect of short-term malnutrition in sheep and cattle compared with rats was the very rapid and large accumulation of neutral fat in hepatocytes. If there is a relative lack of dietary protein over a long period of time, anasarca occurs, particularly in the intermandibular space.

Malnutrition makes a significant contribution to a number of quasispecific diseases, "weaner ill-thrift" and "thin sow syndrome" among them, and these are dealt with in the following section.

Controlled malnutrition in the form of providing submaintenance diets to animals during periods of severe feed shortage is now a nutritional exercise with an extensive supporting literature. For pastured animals it is a fact of economic life that significant loss of body weight is planned and tolerated for some parts of each year because the well-known phenomenon of compensatory growth enables the animal to make up the lost weight, with no disadvantage, during the times of plenty. Animals fed on submaintenance diets undergo metabolic changes reflected in blood and tissue values as well as the more significant changes in weight. Experimental restriction of feed intake to 65% of normal levels in nonlactating, nonpregnant heifers does not cause significant falls in serum calcium and phosphorus levels, nor in plasma AST, lactate dehydrogenase (LDH), or CK activities. Serum alkaline phosphatase (ALP) activity was also maintained. In sheep that are losing weight because of undernutrition there is a significant decrease in plasma creatinine concentration.

Experimental feed restriction, followed by fasting, followed by *ad libitum* access to feed, such as might occur in nature, had no serious ill effects on goats. The goats lost weight significantly but did not overeat on being allowed access to feed.

A deficiency of one or more specific dietary essentials also causes a form of partial starvation (see Chapter 4).

Outbreaks of incomplete starvation may occur in cattle, sheep, and horses that are kept outdoors during the cold winter months in regions of the Northern Hemisphere. The feed usually consists of poor-quality grass hay or cereal grain straw and no grain supplementation. During prolonged exposure to the cold environment the animals will increase their daily intake in an attempt to satisfy maintenance requirements and, in cattle, abomasal impaction with a high case of mortality may occur. Field and postmortem findings indicate complete mobilization of fat in affected animals, including serous atrophy of fat in the bone marrow, and an inability to maintain core body temperature in cold ambient temperatures. The fat percentage in the bone marrow of the femur offers an excellent test to quantify whole-body fat reserves. The test requires drying a bone marrow sample to constant temperature; bone marrow percent fat = (dry weight × 100)/wet weight. Normal animals have a percent fat of 70% to 80% in femur bone marrow; animals dying of starvation usually have a bone marrow percent fat <10% and very low body condition score.[6] Serous atrophy can also be quantified by magnetic resonance imaging of bone marrow fat in the distal limbs,[7] but this appears to provide a complicated and expensive method compared with weighing to constant weight. Animals affected with severe inanition are usually weak and recumbent and may or may not eat when offered a palatable feed.

Malnutrition and starvation may occur in calves under 1 month that are fed poor-quality milk replacers containing excessive quantities of nonmilk carbohydrates and proteins. The diet is not well digested by young calves and chronic diarrhea and gradual malnutrition occur. Affected calves recover quickly when fed cows' whole milk for several days. At necropsy there is a marked reduction in muscle mass, lack of depot fat, and serious atrophy of fat. Starvation may also occur in beef calves sucking poorly nourished heifer dams with an insufficient supply of milk. The mortality will be high during cold weather when the maintenance requirements are increased. Affected calves will initially suck vigorously and persistently, they will attempt to eat dry feed, drink surface water and urine, and bawl for several hours. Eventually they lie in sternal recumbency with their head and neck turned into their flanks and die quietly. The response to therapy is usually unsatisfactory and the case fatality rate is high. The convalescence period in survivors is prolonged and treatment is usually uneconomic. Affected animals must be brought indoors and kept warm and well bedded during treatment and realimentation. Initially, fluid therapy using balanced electrolyte solutions containing glucose and amino acids may be necessary to restore the animal's strength and appetite. This is followed by the provision of controlled amounts of a highly palatable digestible diet. High-quality legume hay is excellent, small amounts of ground grain are of value, and the daily administration of a multiple B vitamin and mineral mixture will replenish those lost during inanition. Skim-milk powder is an excellent source of carbohydrate and protein for young animals that have been partially starved. Adult animals cannot digest large quantities of milk powder because of the relative lack of appropriate digestive enzymes.

Horses that have been ill with a poor appetite should be tempted with green grass first, and failing that tried with good-quality hay, preferably alfalfa. It is best to dilute it with good grass hay to begin with, and increase the mix to 100% legume hay over a week. An average horse will require 1.5 to 2 kg BW/day. Grain can be added mixed with molasses or as a mash. Low-fiber diets are recommended to ensure maximum digestibility. A supplement of B vitamins may be advantageous until full appetite and intake are regained. Horses with broken jaws or that are unable to eat at all for some reason can be allowed to go without food for 3 days, but beyond that time they should be fed by stomach tube. A suitable ration is as follows:

- Electrolyte mixture (NaCl, 10 g; $NaHCO_3$, 15 g; KCl, 75 g; K_2HPO_4, 60 g; $CaCl_2$, 45 g; MgO, 24 g): 210 g
- Water: 21 L
- Dextrose, increased from 300 g/day in 7 days to 900 g
- Dehydrated cottage cheese, increased from 300 g/day in 7 days to 900 g

The ration is divided into two or three equal amounts and fed during 1 day. Adult horses that are weak and recumbent may be supported in a sling to avoid decubitus ulceration and other secondary complications associated with prolonged recumbency.

Weight Loss or Failure to Gain Weight (Ill-Thrift)

This section is concerned with the syndrome of weight loss, or low body condition score (BCS), in the presence of an apparently adequate food supply and a normal appetite. In the absence of any primary disease, an animal or group of animals that presents with this as the problem is a major diagnostic dilemma. Several poorly identified diseases in this category are weaner ill-thrift, thin sow syndrome, thin ewe syndrome, and weak calf syndrome (see other sections of this chapter).

Body weight and **BCS** are sometimes used interchangeably and regarded as synonymous. This is incorrect as body weight, per se, is not a good indicator of BCS because it is closely related to the height and girth of the animal and provides only limited information about body composition.[1] Body weight (live weight) reflects changes in protein and in fat but is influenced by the relative percentages of protein, fat, and water in the body, which can vary depending on physiologic status. Body weight is not a good indicator of energy content per kilogram of body weight, and proportions of fat, protein, and water are highly variable in animals of the same weight.[2] For example, when body mass is depleted there can be selective depletion of fat mass with partial replacement by water so that the amount of mobilized fat can be larger than the loss of body weight.[1-3] Additionally, body weight is substantially influenced by gut fill, and short periods of feed or water withholding, or feed supplementation, can result in marked changes in

body weight without similar changes in body energy content.[2,4] Pregnancy can increase body weight, especially during mid to late gestation, solely because of the growing fetus.

Body condition score is a more useful indicator of both fat-free mass and fat mass in many species. These variables, and in particular fat mass, are closely associated with nutrient requirements, reproductive efficiency, cull value, and risk of disease (for example, laminitis in fat horses) of animal, and estimation of body fat from the BCS or back fat thickness is increasingly important in management of animals.[1,2,4-9] The ideal body condition of an animal must be determined while considering many factors including species, sex, age, reproductive status, lactation status, disease risk, and intended use. For example, the ideal body condition of dairy cows during each stage of lactation is that which optimizes milk production, minimizes reproductive and health disorders, and maximizes economic returns.[2,8]

Body condition score is determined subjectively by observers using a standardized grading system. These grading systems were not developed to assess the fat content (proportion) of the animal but rather to assess "flesh" or the general body condition and are limited because of their subjective nature.[10] Additionally, body condition scoring systems do not provide an assessment of regional adiposity, which might have greater clinical relevance in some species, including horses.[5] Body condition scoring systems have not been validated in all major breeds and uses of animals (validation determines the relationship between BCS and a gold standard measure of body fat, such as deuterium dilution space or carcass analysis) nor has their reliability (intrarater and interrater agreement/repeatability expressed as an intraclass correlation coefficient or, less optimally, a κ or weighted κ statistic) been demonstrated over large numbers of raters. There are reports of an intraclass correlation coefficient of 0.74 for four raters of 21 mares and 75 ponies, and of 0.92 (without details).[11,12] Interrater agreement (weighted κ statistic) among three trained observers for dairy cattle was 0.67 for exact agreement, 0.82 for ± 0.25, and 0.96 for ± 0.5 BCS, based on a <2 to 5 scale.[13] Training of observers markedly improved both interobserver and intraobserver repeatability.[13]

Furthermore, differing rating systems might be used within an industry or between countries such as the use of different body condition scoring methodologies in the United Kingdom (UKBCS) and the United States (USBCS) resulting in the need to develop conversion factors (R^2 = 0.56):[14] USBCS = 1.182 + 0.816 × UKBCS and, UKBCS = 0.131 + 0.681 × USBCS.

A rating system for dairy cattle developed by Elanco Animal Health and subsequently modified is used in the United States (Fig. 4-3) and a methodology for equids is described in Chapter 17).[13] A similar BCS system in dairy cattle is depicted in Fig. 4-4.

Estimation of body composition, including proportions of fat and fat-free mass, can be made using tracer dilution technologies (isotopes or chemical traces such as urea or antipyrine) or ultrasonographic imaging. The gold standard is the analysis of carcass composition, but this technique requires the death of the animal and is time-consuming and expensive. Use of tracer technologies and in particular deuterium oxide has become more common in experimental studies but has limited utility in clinical practice situations.[4] More practical is the use of ultrasound to determine subcutaneous fat thickness, or retroperitonal fat depth (usually perirenal), as an indicator of body energy stores. This methodology has been well

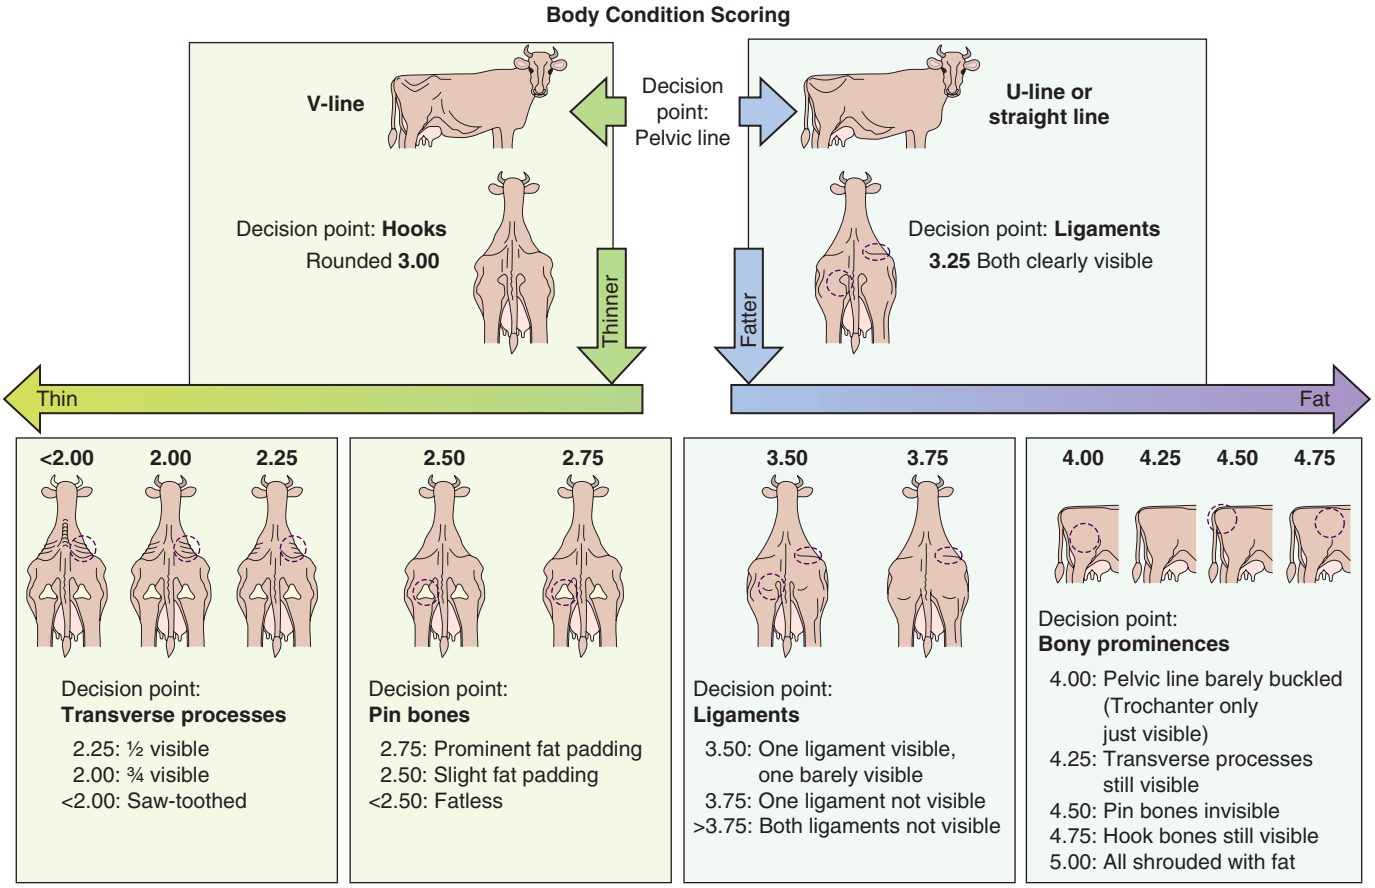

Fig. 4-4 Body condition scoring system modified from earlier work. (From Isensee A et al. *Animal* 2014; 8(12):1971-1977.)

developed in cattle (Fig. 4-5) and pigs and less so in horses.[3,5,7,16-18]

Measurement of bioelectrical impedance is used to assess carcass composition of cattle and to estimate changes in body water in horses.[19-21] Thermal imaging and use of digitized images have been investigated for the assessment of BCS in dairy cows, with a view toward developing automated systems.[17,22]

Detailed next is a checklist of causes that should be considered when an animal has a weight loss problem in the absence of signs indicative of a primary wasting disease.

NUTRITIONAL CAUSES

"Hobby farm malnutrition" is a surprisingly common cause of poor body condition, especially in companion horses. Inexperienced owners keep their animals where they are not able to graze pasture and are entirely dependent on stored feed but underfed for economy's sake or out of ignorance of the nutritional requirements of the animal. Knowledge of the animals' needs and of the approximate energy and protein values of feeds is necessary to prepare an appropriate ration.

The feed and feeding conditions must be inspected as the first step in the diagnostic process to rule out malnutrition (broadly defined as either provision of insufficient feed or of feed that is not appropriate for the species, age, reproductive status, and use of the animal) as a cause of poor body condition. Mature meadow hay might not provide sufficient calorie or protein intake for some animals and "shy" animals or those low in the hierarchy (pecking order) in group-fed animals can be physically prevented from getting a fair share of available feed, especially if **trough space** is inadequate.

This problem is also common when urban people try to raise a few veal calves or sheep to help defray the costs of their rural acreage. It is common in these circumstances to equate rough meadow grass with proper nutrition for young or pregnant ruminants.

Other considerations are as follows:

- Diets that are inadequate in total energy because they cannot replace the energy loss caused by the animal's level of production can be important causes of weight loss in heavy producing animals. This subject is discussed under the heading of production disease. An example is acetonemia of high-producing cows in which body stores of fat and protein are raided to repair the energy deficiency of the diet.
- Malnutrition as a result of a ration that is deficient in an essential trace element is unusual in the management situation being discussed. A nutritional deficiency of cobalt does cause weight loss in ruminants but is likely to have an area effect rather than cause weight loss in single animals. Copper, salt, zinc, potassium, selenium, phosphorus, calcium, and vitamin D deficiencies are also in this category. Experimental nutritional deficiencies of riboflavin, nicotinic acid, pyridoxine, and pantothenic acid in calves and pigs can also be characterized by ill-thrift.
- Inadequate intake of an adequate supply of feed is dealt with under diseases of the mouth and pharynx and is not repeated here, but it is emphasized that the first place for a clinician to look in a thin animal is its mouth. The owner might have forgotten just how old the animal is and one often finds a cow without any incisor teeth attempting to survive on pasture.
- Other factors that reduce an animal's food intake when it is available in adequate amounts include anxiety, the excitement of estrus, new surroundings, loss of a newborn, bad weather, tick or other insect worry, and abomasal displacement.

(Reproduced with permission from Schroder UJ, Staufenbiel R. *J Dairy Sci* 2006;89:1-4.)

EXCESSIVE LOSS OF PROTEIN AND CARBOHYDRATES

- **Protein loss in the feces**. Cases of protein-losing gastroenteropathy are not unusual and can be caused by diseases as common as gastrointestinal parasitism or bovine or ovine paratuberculosis (Johne's disease). The loss can occur through an ulcerative lesion, via a generalized vascular discontinuity, or by exudation through intact mucosa as a result of hydrostatic pressure in blood vessels, e.g., in verminous aneurysm, or lymphatics in cases of lymphangiectasia of the intestine. The identification of a neoplasm (lymphosarcoma or intestinal or gastric adenocarcinoma are the usual ones) or of granulomatous enteritis is not possible without laparotomy and biopsy of the alimentary segment. One is usually led to the possibility of this as a diagnosis by either a low serum total protein or low albumin level in a normal total protein level, and in the absence of other protein loss.
- **Proteinuria** for a lengthy period can cause depletion of body protein stores, resulting in weight loss. Chronic glomerulonephritis is the usual cause. Examination of the urine should be part of every clinical examination of an animal being investigated for weight loss.
- **Internal and external parasitoses** in which blood sucking is a part of the pathogenetic mechanism can result in severe protein loss, as well as anemia per se.

FAULTY DIGESTION, ABSORPTION, OR METABOLISM

Faulty digestion and absorption are commonly manifested by diarrhea, and diseases that have this effect are dealt with under the heading of malabsorption syndromes (see Chapter 7). In grazing ruminants, the principal causes are the nematode worms *Ostertagia, Teladorsagia, Nematodirus, Trichostrongylus, Chabertia, Cooperia,* and *Oesophagostomum* and the flukes *Fasciola* and *Paramphistomum*. In cattle the additional causes are tuberculosis, coccidiosis, sarcosporidiosis, and enzootic calcinosis. In sheep and goats there are Johne's disease, viral pneumonia without clinical pulmonary involvement, and hemonchosis. In horses there are strongylosis, habronemiasis, and heavy infestations with botfly larvae. In pigs there are stephanuriasis, hyostrongylosis (including the thin sow syndrome), infestation with *Macracanthorhynchus hirudinaceus,* and ascariasis. Gastrointestinal neoplasia must also be considered as a possible cause.

- Chronic villous atrophy occurs most severely with intestinal parasitism or as a result of a viral infection.
- Abnormal physical function of the alimentary tract, as in vagus indigestion of cattle and grass sickness in horses, is usually manifested by poor food intake and grossly abnormal feces.
- Inadequate utilization of absorbed nutrients is a characteristic of chronic liver disease. It is usually distinguishable by a low serum albumin concentration (although this is an uncommon manifestation of liver diseases in horses), by liver function tests, and by measurement of activity in serum of liver-derived enzymes. A clinical syndrome including edema, jaundice, photosensitization, and weight loss is a common accompaniment.
- Neoplasia in any organ. The metabolism of the body as a whole is often unbalanced by the presence of a neoplasm so that the animal wastes even though its food intake seems adequate.
- Chronic infection, including specific diseases such as tuberculosis, sarcocystosis, East Coast fever, trypanosomiasis (nagana), maedi-visna, caprine arthritis–encephalitis, enzootic pneumonia of swine, metastatic strangles in horses, and nonspecific infections such as atrophic rhinitis of pigs, abscess, empyema, and chronic peritonitis reduce metabolic activity generally as well as reducing appetite. Both effects are the result of the toxemia caused by tissue breakdown and of toxins produced by the organisms present. Less well understood are the means by which systemic infections, e.g., equine infectious anemia, scrapie in sheep, and other slow viruses, produce a state of weight loss progressing to emaciation.
- Food refusal is a well-recognized syndrome in pigs, which in some cases

is caused by mycotoxins in the feed, and "off feed effects" are similarly encountered in feedlot cattle on rations containing a large proportion of wheat grain.
- Many diseases of other systems, e.g., congestive heart failure, are manifested by weight loss.
- Determination of the **specific cause of weight loss in an individual animal** depends first on differentiation into **one of the three major groups**:
  - Nutritional causes, diagnosed by assessment of the animal's total food intake
  - Protein or carbohydrate loss in the animal's excretions, diagnosed by clinicopathologic laboratory tests
  - Faulty absorption of the food ingested diagnosed by tests of digestion, as set out in Chapter 7.

SHORTFALLS IN PERFORMANCE

The need for economically efficient performance by farm animals introduces another set of criteria, besides freedom from disease, to be taken into consideration when deciding an animal's future. The same comment applies, and much more importantly, when a herd's productivity is being assessed. This is usually done by comparing the subject herd's performances to that of peer herds, or animals in similar environmental and management conditions.

It is usual to use the production indexes that are the essential outputs of the particular enterprise as the criteria of productivity. Thus in dairy herds the criteria could be as follows:
- Milk or butterfat production per cow per lactation (liters per cow or liters per hectare)
- Reproductive efficiency as the mean intercalving interval
- Percentage calf survival to 1 year of age
- Longevity as percentage mortality per year or average age of cows in herd plus culling rate per year
- The culling rate needs to differentiate between sale because of disease or poor production and sale as a productive animal
- Acceptability of product at sale, as indicated by bulk tank milk somatic cell count and rejection of milk because of poor-quality, low-fat content, and low solids-not-fat content

If it is decided that performance falls too far short of the target, an investigation is warranted. Some targets for productivity in each of the animal industries are available, but they vary a great deal between countries depending on the levels of agriculture practiced and the standards of performance expected. For this reason, they are not set down here and neither is the degree of shortfall from the target that is acceptable, which depends heavily on the risk aversion or acceptability in the industry in that country. For example, if the enterprise is heavily capitalized by high-cost housing and land, the standard of performance would be expected to be higher than in a more exploitative situation in which cattle are pastured all year. In the latter, a reasonable flexibility could be included in the assessment of productivity by permitting it to fall within the scope of 2 standard deviations of the mean productivity established by peer herds.

If the performance is below permissible standards, then an investigation should be conducted that should include the following groups of possible causes:
- **Nutrition:** Its adequacy in terms of energy, protein, minerals, vitamins, and water
- **Inheritance:** The genetic background of the herd and the quality of its heritable performance
- **Accommodation:** To include protection from environmental stress by buildings for housed animals and terrain and tree cover for pastured animals; also consideration of population density as affecting access to feed, water, and bedding areas
- **General managerial expertise:** The degree of its application to the individual flock or herd; this is difficult to assess and then only indirectly, e.g., the efficiency of heat detection and achievement of planned calving pattern
- **Disease wastage:** As clinical disease or, more particularly, subclinical disease; the latter may include such things as quarter infection rate as an index of mastitis, fecal egg counts relative to parasite burden, metabolic profile relative to metabolic disease prevalence rate, and so forth

These investigations tend to require special techniques in addition to the clinical examination of individual animals. They are mostly self-evident, but attention is drawn to the section on examination of a herd or flock in Chapter 2. It will be apparent that there is a great deal of merit in having herds and flocks under constant surveillance for productivity and freedom from disease, such as is practiced in modern herd health programs. Monitoring performance and comparing it with targets is the basis of that system.

The specific syndromes that fall within this category of disease, and which are dealt with elsewhere in this book, are ill-thrift of weaner sheep, thin sow syndrome, weak calf syndrome, poor performance syndrome of horses, and low butterfat syndromes and summer slump of milk cows. Two performance shortfalls encountered commonly by field veterinarians are ill-thrift in all species and poor performance syndrome in horses.

UNTHRIFTINESS IN WEANER SHEEP (WEANER ILL-THRIFT)

ETIOLOGY

Several factors have been associated with this syndrome in lambs, goat kids, and calves. Contributing causes include intestinal parasitism, coccidiosis, infection with *Mycoplasma ovis* (eperythrozoonosis), suboptimal animal husbandry, and nutritional deficiencies. The latter can be in the form of inadequate gross nutrition (a lack of energy or protein) or a deficiency of trace elements (copper, cobalt, selenium, and zinc) or vitamins (thiamin, vitamin A, vitamin D, and vitamin E).

The syndrome is often multifactorial, with a combination of management, nutritional, and infectious causes involved that can be a challenge to identify and correct.[1]

SYNOPSIS

Etiology Several, often interacting causes, including poor management and animal husbandry; parasitism; trace element and vitamin deficiencies; the amount, quality, and palatability of pasture and fungal infestations of pasture.

Epidemiology Loss of weight after weaning, hence failure to achieve target

weights for adequate survival and mating. This is often despite the presence of ample feed and at times when adult sheep are faring well.

Clinical findings Poor body condition and wool growth, failure to thrive, and gradually accumulating mortalities.

Lesions Inanition; little body fat, involution of rumen papillae, and poor mineralization of long bones and ribs, often with evidence of healing fractures.

Diagnostic confirmation Examination of weight profile of mob and pastures being grazed. Laboratory testing for contributing causes, such as worm egg counts for internal parasitism or blood and tissue tests for trace element status. Response to treatment or provision of the required nutritional supplement, such as energy (usually most cost-effectively in the form of cereal grains), protein (legume grains such as field peas or lupins), trace elements, or vitamins.

Treatment and control Correction of gross nutritional or trace element deficiencies and review of the management calendar, including length of mating period, month of lambing, and proactive monitoring of body weights and worm egg counts at and after weaning. "Imprint feeding" of cereal grains to lambs while they are still on the ewes; 20 g per head on at least three occasions will help weaner sheep recognize and start consuming supplementary grain rations before they start losing excessive weight.

Poor quality or unpalatable pasture can be a cause of ill-thrift, or at least associated with it, and moving animals to a better quality pasture will often help alleviate the problem. This has been observed with many pasture species, especially rank or senescent swards, including phalaris (*Phalaris aquatica*), perennial rye grass (*Lolium perenne*), setaria grass (*Setaria sphacelata*), tall fescue (*Festuca arundinaceae*), and turnips (*Brassica repens*). Infestation of pasture grasses with endophyte fungi may be a contributing factor to ill-thrift and poor growth rates, such as with *Acremonium lolii* in perennial rye grass and "summer syndrome" of calves associated with *A. coenophialum* infestation of tall fescue. Infection of pasture species with toxigenic *Fusarium* spp. has been associated with ill-thrift in lambs in South Africa, New Zealand, and Australia. Pasture and soil fungi have also been suspected of being associated with ill-thrift in sheep in eastern Canada.

EPIDEMIOLOGY

The syndrome appears to be most severe in the Southern Hemisphere, but this may be because Merino sheep are more prevalent. The disease is most common in this breed, which may be due in part to their timorous nature, which makes weaning, and the need to graze as a mob by themselves, more stressful and traumatic than for most other breeds. For example, the average postweaning mortality in a national survey of 1400 sheep producers in Australia was 4.6%, with 44% of farms having "high" mortalities (exceeding a benchmark of 4% per annum).[1] High mortality was reported on 50% of farms with predominantly Merino sheep, but also on 32% of farms with predominantly crossbreeds, and there was a postweaning mortality >10% on 14% of farms.

Factors that contribute to weaner ill-thrift include the following:

- Overstocking (overcrowding) on pasture.
- Poor quality or an inadequate amount of pasture.
- Lambs that are light (<20 kg) at weaning, with the lightest 20% of a mob having three times the risk of mortality than the middle 20%. A target for a weaning weight of at least 22 kg for Merinos, or 45% of mature weight, is commonly used.[2-4]
- Merino ewes often have poor milk production, hence management of the ewe flock, such as maintaining ewes at target condition scores from mating and throughout pregnancy, is critical to achieve target weaning weights.[4]
- Postweaning growth rate: Increasing growth from 10 to 20 g/day reduces the risk of mortality by 70%[3] and a target for growth in the immediate postweaning period of 30g/day (1 kg/month) is sufficient to significantly reduce the risk of mortality.[2,4]
- Other management factors likely to lead to low weaning weights and subsequent unthriftiness are extended mating periods (lambs born late in the season), ewes in low condition score (light lambs and poor milk supply), and multiple birth lambs.

Weaner ill-thrift does occur in breeds other than the Merino[1] and is also reported in the Northern Hemisphere. The economic effects can be disastrous for individual flocks and have been estimated at up to USD$58M over the entire industry in Australia.[5] Decreased growth and delayed maturation can mean a poor performance at the first (maiden) lambing. A high proportion of weaner deaths in wool flocks reduces the ability to select replacement ewes, decreasing the rate of genetic gain (although ram genetics are overwhelmingly more important in a wool flock). There is also a substantial decrease in the amount and quality of weaner wool which, in Merino flocks, is usually the finest and most valuable from any age group.

CLINICAL AND NECROPSY FINDINGS

As the name indicates, this syndrome in weaned sheep is manifested primarily by poor body condition and a failure to thrive. Within an affected group not all lambs are equally affected and there will be a range of weight or condition scores. Those lambs in very poor condition are often anemic, may have diarrhea, and there are sporadic but continuing mortalities. The sheep will often have been treated with anthelmintics with no favorable response. There are often no abnormal findings at gross postmortem, other than those associated with emaciation. Poor development of rumen papillae may be obvious grossly, villous atrophy is often found on histologic examination of the small intestine, and the mineralization of long bones and ribs may be reduced because of chronic malnutrition. This can lead to thin cortices and fractures when sheep are handled, such as for shearing or crutching.

DIFFERENTIAL DIAGNOSIS

When faced with this problem the initial approach should be to examine for the most likely cause, namely a deficiency in energy or protein intake. A physical examination of affected sheep should include an examination of the teeth to ensure that there is no excessive wear, or even breaking of the incisors (e.g., if the sheep are being fed roots).

The internal parasite status of the group should be examined by appropriate techniques, such as worm egg counts or total worm counts. Clinical or subclinical infestations with nematodes are common occurrences at this time in the sheep's life, before immunity is properly developed and when pasture contamination can be high.

Infections with coccidia, cryptosporidia, or *Mycoplasma* (*Eperythrozoon*) *ovis* are significant causes of ill-thrift and should be examined by fecal flotation and blood smears, respectively.

The trace element status of the group should be examined if the cause cannot be attributed to gross nutritional deficiencies (inadequate energy or protein) or internal parasites. The most common trace element deficiencies are copper, selenium, and cobalt. These are typically associated with specific geographic areas, soil types, and differing patterns of soil ingestion through wet and dry seasons. If trace element deficiency is a contributing factor it is likely that there will be some prior history of this problem in the area. Diagnosis by response to supplementation is a common approach, and the diagnostic aspects of the trace element deficiencies are outlined under their specific headings.

Examination of the previously mentioned possible causes can be time-consuming and costly, and there are a proportion of cases in which no clear cause can be identified.

Infectious agents can produce enteric lesions and ill-thrift (e.g., coronavirus and yersiniosis), with the malabsorption of nutrients manifested by weight loss and by chronic diarrhea. These can be differentiated on the initial gross postmortem or in samples submitted for culture and histopathology.

PORCINE FAILURE TO THRIVE

This is a clinical syndrome recognized in the United States and Canada since 2007[1] and in Spain.[2] It has also been called porcine cachectic syndrome or porcine cachexia. It is characterized by anorexia of nursery piglets, progressive loss of bodily condition, and lethargy over the next 1 to 3 weeks. Morbidity may be low but the case mortality is high and many require culling.

ETIOLOGY

The etiology for porcine failure to thrive has not yet been established. It may include both infectious and noninfectious factors. This syndrome was first identified in a high-health herd and all the usual culprits were ruled out, although both viral and bacterial agents were found.[3,4] Some eminent pig veterinarians think that the disease is related mainly to suboptimum management before weaning.

EPIDEMIOLOGY

It occurs around weaning not just postweaning. Villous atrophy and enteritis are the main features.

PATHOGENESIS

Some think porcine failure to thrive is a postweaning location issue, whereas others think it is a source farm issue. There are no infectious, nutritional, managemental, or environmental factors to explain the clinical signs.

CLINICAL SIGNS

At weaning affected pigs are of average to above average weight. Within 60 to 72 hours of weaning they are still active, alert, and without fever, but they are flat-sided and have an empty abdomen. Within 7 days they are anorectic with rough hair coats and lethargic. Their heads are down and their muscles are slack. They are unwilling to move and often sneeze. The pigs deteriorate and die within 2 to 3 weeks.

Some groups from the same source are affected but not others. It may occur several times and then disappear for a long period. Some pigs on the affected farms show repetitive oral behavior such as licking, chewing, or chomping. The crucial time appears to be around 96 hours postweaning. At this time the pigs rest their heads on the backs of their fellows and start chomping.

PATHOLOGY

It is difficult to say whether the lesions are the cause of the condition or are the result of inappetence and starvation. Subgross pathology shows a severe villous atrophy, rhinitis, and gastritis but not in the *pars esophagea*. There are no fat reserves remaining in the carcass.

In the early cases in 2007, the most obvious lesions were histologic and included superficial lymphocytic fundic gastritis, atrophic enteritis with many immature cells, villous atrophy, superficial colitis, lymphocytic and neutrophilic rhinitis, mild nonsuppurative meningoencephalitis, and thymic atrophy.

TREATMENT

Until a cause is found it is difficult to work out a reliable treatment, and in many cases pigs are too badly affected for anything other than euthanasia. It is essential that pigs find food and water and it may be necessary to introduce gruel feeding. Few pigs respond to the special care they might have in hospital accommodation (supplemental heat, electrolytes, special high-milk feed supplements, moistened feed, and individual pig feeding).

CONTROL

There is none at the moment.

Physical Exercise and Associated Disorders

The act of performing physical work requires expenditure of energy at rates above the resting metabolic rate. Increases in metabolic rate can be supported by anaerobic metabolism through the use of intramuscular ATP stores and conversion of glycogen or glucose to lactate for short periods of time. Ultimately, however, all energy is derived by aerobic metabolism and is limited by the rate of delivery of oxygen to tissue and its utilization in mitochondria. To support the increased energy expenditure required to perform work, such as racing, carrying a rider, or pulling a cart, the metabolic rate is increased. Increases in metabolic rate are supported by increases in oxygen delivery to tissue and carbon dioxide removal. Increased oxygen consumption is dependent on an increase in oxygen delivery to tissues, which is possible by increases in cardiac output, muscle blood flow and, in horses, an increase in hemoglobin concentration with a concomitant increase in the oxygen-carrying capacity of blood. The increased transport of oxygen from the air to the blood is accomplished principally by increases in respiratory rate and tidal volume. Factors that affect oxygen transport from the air to the mitochondria have the potential to impair performance. For instance, laryngeal hemiplegia reduces minute ventilation and exacerbates the normal exercise-associated hypoxemia in horses, atrial fibrillation decreases cardiac output and hence oxygen delivery to tissues, and anemia reduces the oxygen-carrying capacity of the blood.

The increase in cardiac output with exercise of maximal intensity in horses is very large; horses have a cardiac output of about 75 (mL/min)/kg at rest and 750 (mL/min)/kg (300 L/min for a 400-kg horse) during maximal exercise. Associated with the increase in cardiac output are increases in right atrial, pulmonary arterial, and aortic blood pressures. Systemic arterial blood pressure during exercise increases as the intensity of exercise increases with values for systolic, mean, and diastolic pressures increasing from 115, 100, and 80 mm Hg (15.3, 13.3, and 10.6 kPa) at rest to 205, 160, and 120 mm Hg (27.3, 21.3, and 16kPa), respectively, during intense exercise.

Pulmonary artery pressure increases from a mean of approximately 25 mm Hg (3.3 kPa) to almost 100 mm Hg (13.3 kPa) during intense exercise. The increase in pulmonary artery pressure with exercise may contribute to exercise-induced pulmonary hemorrhage.

The increase in metabolic rate during exercise causes a marked increase in metabolic heat generation with a subsequent increase in body temperature. The increase in body temperature is dependent on the intensity and duration of exercise and the ability of the horse to dissipate heat from the body. Intense exercise of short duration is associated with marked increases in body temperature but such increases rarely cause disease. However, prolonged exercise of moderate intensity, especially if performed in hot and humid conditions, may be associated with rectal temperatures in excess of 42.5°C (108.5°F). Heat is dissipated primarily by evaporation of sweat from the skin surface. Sweating results in a loss of body water and electrolytes, including sodium, potassium, calcium, and chloride. The size of these losses can be sufficient to cause dehydration and abnormalities of serum electrolyte concentrations and also impaired cardiovascular and thermoregulatory function.

Recovery from exercise is influenced by the fitness of the individual, with fitter horses recovering more rapidly; the intensity and

duration of the exercise bout; and activity during recovery. Horses allowed to walk after a bout of intense exercise recuperate more quickly than do horses that are not allowed to walk. Recovery is delayed if the horse cannot drink to replenish body water or in hot and humid conditions.

EXERCISE-ASSOCIATED DISEASES

Many exercise-induced diseases are associated with specific activities. For instance, heat stroke and exhaustion are very rare in Standardbred and Thoroughbred horses raced over distances of up to 3 miles (5km) but common in horses participating in endurance races (50–100km) or the second day of 3-day event competitions. Conversely, exercise-induced pulmonary hemorrhage occurs only in horses that race or compete at high speed and is very uncommon in draft breeds. The exercise-associated diseases exertional rhabdomyolysis, synchronous diaphragmatic flutter, hyperthermia, and exercise-induced pulmonary hemorrhage are dealt with in other sections of this book.

EXHAUSTION

All physical work, if of sufficient intensity and duration, causes fatigue. The mechanisms underlying fatigue vary with the type of work or exercise performed. Thus fatigue in a racehorse running 3 km at high speed has a different genesis from fatigue than an endurance horse that has run 100 km at low speed. Typically, Standardbred and Thoroughbred racehorses recover quickly and exhaustion rarely occurs. However, horses performing endurance exercise require longer to recover, and the processes associated with fatigue may progress to the extent that recovery is delayed or impossible without treatment.[1] This results in illness in some competitors after racing and elimination of some horses from competition during the endurance race.[2] The failure to recover and the clinical and clinicopathologic signs associated with this have been labeled *exhausted horse syndrome*.

The exhausted horse syndrome is associated with endurance races, 3-day eventing, trail riding, and fox and bird hunting; these are all activities in which there is prolonged submaximal exercise. The likelihood of the disorder is increased in unfit horses or when horses are exercised in hot and humid conditions, especially if they are not accustomed to such conditions.

PATHOGENESIS

The pathogenesis of exhaustion is complicated but probably involves depletion of body glycogen and electrolytes, especially sodium, chloride, and potassium; hypovolemia caused by large losses of water in sweat; hyperthermia; and acid-base disturbances. Endurance exercise is associated with the production of large amounts of heat, which are dissipated primarily by evaporation of sweat. Approximately 11 L of sweat are lost each hour during submaximal exercise, and this loss causes a significant decline in total body water, sodium, potassium, and chloride content and serum concentrations of these ions. Loss of chloride causes a metabolic alkalosis. Hypovolemia impairs thermoregulation by reducing blood flow to the skin and probably results in a reduction in gastrointestinal blood flow contributing to intestinal ischemia and development of ileus. Body temperature increases to dangerous levels (43°C; 109°F), and the horse cannot continue to exercise. Excessive increases in body temperature can overwhelm mechanisms to ensure that the brain of horses does not overheat, resulting in signs of CNS dysfunction.[1] If the exercise-induced abnormalities are sufficiently severe then the combination of hyperthermia and dehydration can initiate a cascade of events terminating in shock, multiple organ failure, and death.

CLINICAL SIGNS

The clinical signs of the exhausted horse syndrome include failure to continue to exercise, depression, weakness, failure to eat and drink, delayed return of heart rate and rectal temperature to normal values, poor skin turgor and capillary refill time, a stiff stilted gait consistent with rhabdomyolysis, and decrease or absent borborygmi. Urine is concentrated and the horse ceases to urinate.

Colic occurs in horses after endurance racing and can be related to abnormalities in gastrointestinal motility secondary to fluid and electrolyte abnormalities and hyperthermia.[3-6] Lesions in horses taken to surgery most commonly involve the small intestine, and affected horses have signs typical of acute small intestinal obstruction compounded by signs of exhaustion.[3] Most endurance horses with postracing colic respond to cooling and correction of fluid and electrolyte abnormalities with development of surgical lesions.[4]

Clinicopathologic examination reveals hemoconcentration, hypochloremia, hypokalemia, and variable changes in serum sodium concentration. There is usually a metabolic alkalosis (increased blood bicarbonate concentration), although some severely affected horses will also have a metabolic acidosis associated with increased blood lactate concentration. Serum creatinine and urea nitrogen concentrations are increased because of dehydration and/or renal disease. Serum creatine kinase activity is markedly increased in horses with rhabdomyolysis.

TREATMENT

Treatment consists of rapid restoration of hydration status, correction of electrolyte and acid-base abnormalities, and reduction in body temperature. Fluid therapy is addressed in detail in Chapter 5. Suitable fluids for administration to exhausted horses are Ringer's solution, isotonic sodium chloride with added potassium chloride (10 mEq/L), and calcium gluconate (10–20 mL of 24% solution per liter). Theoretically, lactated Ringer's solution should not be given to horses with metabolic alkalosis, but clinical experience indicates its safety and efficacy.

Horses should be aggressively cooled by application of cold water or water and ice. In spite of folklore to the contrary, application of ice cold water to hyperthermic horses is not dangerous or associated with rhabdomyolysis. The NSAIDs for pain relief can be given when the horse is no longer hypovolemic. Horses with colic should have a full examination for that condition, including passing of a nasogastric tube to ensure that there is no distension of the stomach.

PREVENTION

Prevention rests in ensuring that participating horses are adequately trained for the event and acclimated to the environmental conditions. Horses should be healthy, preferably as determined by a veterinary examination before the race, and should be monitored during the event for signs of excessive fatigue, dehydration, or hyperthermia.

POOR RACING PERFORMANCE AND EXERCISE INTOLERANCE IN HORSES

The definition of poor racing performance is difficult. Horses that have a proven record of performing well and then fail to perform at their previous level are readily apparent, and a physical cause of the reduction in performance can often be identified. More difficult are the horses that do not have a history of satisfactory performance and are best labeled as *failure to perform to expectation*. Horses in this group might indeed have a clinical abnormality, but commonly the reason is lack of innate ability or inadequate training. Both of these causes must be raised with the owner and trainer carefully and tactfully, and only after a thorough examination of the horse.

Exercise intolerance in racehorses is best defined as the inability to race at speeds previously attained by that horse or attained by peers. In its most extreme form exercise intolerance is evident as failure to complete the race, whereas its mildest form is evident as a slight decrement in performance, such as losing a race by several lengths or 1 or 2 seconds, or failure to perform to expectation.

APPROACH TO THE HORSE WITH EXERCISE INTOLERANCE

Horses with a history of a recent decrement in performance or those that are not performing to expectation should be examined in a systematic fashion.

History

A detailed history should be collected that focuses on documenting the reduction in performance, its time course, and the presence and evolution of any clinical signs. This can be accomplished by asking the following questions of the owner or trainer:

- **What evidence is there of poor performance?** This query should focus on providing objective evidence of a reduction in performance through examination of race times or results. This also allows the severity of the reduction in performance to be documented.
- **What is the horse's training schedule?** The training regimen should be appropriate for the horse's level of competition.
- **Describe the horse's exercise intolerance**. Does it start the race strongly and "fade" in the last part of the race, or is it unable to maintain a suitable speed for the complete race? Is the horse slow to recover its normal respiratory rate after exercise? Can it sweat? Does it consistently veer or "pull" toward one side?
- **Is there any history of illness in this horse or other horses in the same stable or at the race track**? Has the horse had a fever or been inappetent? Is the horse on any medication? Specific attention should be paid to any history of respiratory disease.
- **Does the horse make an unusual noise associated with respiration when running?** Horses with upper airway obstructions almost always make an abnormal noise during exercise.
- **Does the horse cough either at rest, during, or after exercise?** Coughing can be an indication of lower respiratory tract disease.
- **Has the horse ever had blood at the nostrils after exercise or has it been diagnosed as having exercise-induced pulmonary hemorrhage?**
- **Is the horse lame?** Does it ever show signs of muscle stiffness or abnormal gait?
- **What is the history of anthelmintic administration?**

Clinical Examination

A thorough clinical examination should be performed. The physical examination should include a detailed examination of the musculoskeletal, cardiovascular, and respiratory systems and should include the collection of samples of body fluids for laboratory analysis as indicated by the historical data or clinical examination. Ancillary testing, such as radiography, endoscopy, nuclear scintigraphy, and stress testing, are available at larger centers and might be indicated in some cases.

The horse should be examined at rest for evidence of musculoskeletal disease and then should be observed at the walk and trot for signs of lameness. Subtle lameness that is sufficient to impair performance can be difficult to detect in a horse slowly trotting, and other examinations, such as observation during and after high-speed running at a track, radiography, and nuclear scintigraphy, can be necessary. The major muscle groups, including the quadriceps, should be palpated for firmness or pain suggestive of rhabdomyolysis.

The heart should be auscultated carefully for evidence of valvular incompetence or arrhythmias. Mild (grade II–III/VI) systolic ejection murmurs heard loudest on the left thorax are common in fit racehorses and should not be mistaken for evidence of valvular disease. Electrocardiography to diagnose abnormalities of rhythm (for example, atrial fibrillation) or echocardiography to demonstrate the extent of valvular lesions are indicated if abnormalities are detected on cardiac auscultation.

The respiratory system should be carefully examined by auscultation of the thorax in a quiet area. The thorax should be auscultated initially with the horse at rest; if no abnormalities are detected the horse's tidal volume should be increased by rebreathing air from a large bag held over its nose, or by exercise. Radiography of the thorax may demonstrate changes consistent with exercise-induced pulmonary hemorrhage, recurrent airway obstruction, or pneumonia. Aspirates of tracheal fluid or bronchoalveolar lavage fluid should be examined for evidence of inflammation or hemorrhage.[1,2] The upper respiratory tract, including pharynx, larynx, trachea, and carina, should be examined with a flexible endoscope.

Laboratory Testing

Collection of blood and urine samples for laboratory analysis is indicated if specific abnormalities are detected on physical examination or there is historical data suggesting the need to more closely examine some body systems. For instance, exercise-associated rhabdomyolysis can be confirmed by measurement of serum CK and AST activity. However, blood samples are often submitted for analysis as a matter of routine. Specific attention should be paid to the hemogram, in particular the white blood cell count, for evidence of inflammation and the hematocrit for evidence of anemia. Care should be taken to not assign minor abnormalities an undue importance until corroborating evidence is obtained. Tracheal or bronchoalveolar lavage fluid can provide evidence of lower respiratory tract disease.[2] Examination of feces for helminth ova might demonstrate parasitism.

Exercise Stress Testing

Examination of horses during and after high-speed exercise is now routine in many referral centers and practices specializing in sports medicine. Such examinations in the past had to be conducted on a treadmill if dynamic endoscopic examinations or electrocardiographic examinations were to be performed, but this is no longer the case. Endoscopic and electrocardiographic examinations of horses exercising in the field, and ideally undertaking exercise tasks that mimic their day-to-day activities and competition, are now readily achieved in real time.[3-8] Dynamic endoscopy allows visualization of the upper airway of horses under actual working conditions (racing, dressage, and reining) and avoids the risks and limitations of horses exercising on a treadmill,[3,7,9] although this risk is comparatively small with 0.6% of horses sustaining an important injury during examination.[10] Examination of ridden horses under saddle also provides the opportunity to examine the horse–saddle–rider interaction, including saddle fit and girth tension, which is an important cause of poor performance in some classes of equitation.[11]

Values of a number of performance-related variables have been determined for Standardbred and Thoroughbred racehorses, with better athletes having greater aerobic capacity. However, at this time the main use of high-speed exercise testing is the detection of exercise-induced arrhythmia (such as paroxysmal ventricular tachycardia or atrial fibrillation), rhabdomyolysis, and upper airway obstruction. Upper airway obstruction is a common cause of poor performance that can often be diagnosed by rhinolaryngoscopic examination of horses at rest or after brief nasal occlusion. However, some causes of obstruction are best diagnosed using rhinolaryngoscopy during exercise.[12]

CAUSES OF EXERCISE INTOLERANCE OR POOR PERFORMANCE

Any disease that adversely affects the normal function of a horse has the potential to impair performance, and these are dealt with extensively in textbooks on equine sports medicine. Listed in the following sections are some common causes of exercise intolerance in racehorses.

Musculoskeletal System

- Lameness is a common cause of poor performance. Subtle lameness can be difficult to detect but be sufficient to cause a decrement in performance. Causes and diagnosis of lameness are discussed in textbooks on that topic and are not further covered here.
- Rhabdomyolysis (see Chapter 15)

Cardiovascular System

Poor performance attributable to cardiovascular disease can be caused by the following:

- Atrial fibrillation is usually readily detected on examination of heart sounds or pulse and confirmed by electrocardiographic examination. Paroxysmal atrial fibrillation induced by exercise that resolves soon after exercise ceases causes poor performance and is difficult to diagnose.
- Ventricular arrhythmias[4,5]
- Valvular incompetence, such as mitral or tricuspid regurgitation secondary to acquired or congenital disease; endocarditis is rare in horses.
- Congenital anomalies including ventricular septal defect
- Myocarditis or myocardial disease (rare)
- Aortoiliac thrombosis

Respiratory System

Upper Airways (See Obstructive Diseases of the Equine Larynx)

- Laryngeal hemiplegia
- Intermittent dorsal displacement of the soft palate
- Epiglottic entrapment
- Epiglottic hypoplasia
- Arytenoid chondritis
- Pharyngeal cysts
- Upper air obstruction associated with hyperkalemic periodic paralysis
- Guttural pouch empyema
- Retropharyngeal abscesses
- Redundant or flaccid alar folds

Lower Airways

- Pneumonia secondary to influenza virus or equine herpesvirus-1 or equine herpesvirus-4 infection
- Parasitic pneumonia caused by *Dictyocaulus arnfieldi*
- Severe exercise-induced pulmonary hemorrhage
- Lower airway inflammatory disease and recurrent airway obstruction
- Granulomatous pneumonia

Hematologic and Biochemical Abnormalities

Anemia

- Parasitism, especially caused by *Strongylus* sp. and cyathostomes
- Chronic disease, such as the presence of an abscess
- Equine infectious anemia
- Piroplasmosis
- Gastric ulceration (anemia is an unusual manifestation of this disease)
- Iron deficiency (which is rare)
- Administration of inhibitors of folic acid synthesis or prolonged oral administration of inactive folic acid
- Phenylbutazone toxicity
- Excessive phlebotomy
- Gastric squamous cell carcinoma
- Administration of recombinant human erythropoietin

Hypoproteinemia

- Parasitism, especially caused by *Strongylus* sp. and cyathostomes
- Malnutrition, especially inadequate protein intake
- Protein-losing enteropathy such as lymphosarcoma or granulomatous enteritis

Electrolyte Abnormalities

- Hypokalemia and hyponatremia secondary to excessive losses in sweat and inadequate intake

Nervous System Disease

- Spinal ataxia caused by cervical compressive myelopathy (static or dynamic), equine protozoal myeloencephalitis, and equine degenerative myelopathy
- Sweeney
- Stringhalt

Miscellaneous

- Hypothyroidism (very rare)
- Pituitary tumor (equine Cushing's disease)
- Iatrogenic hypoadrenocorticism
- Hepatic disease of any cause, but beware of iron overload
- Renal disease
- Secondary nutritional hyperparathyroidism
- Malnutrition
- Performance-altering drug administration such as β-adrenergic antagonists (beta blockers) or sedatives

TREATMENT

Treatment should be directed toward correcting the underlying disease. Routine administration of hematinics to horses with a normal hemogram is unnecessary. If after careful and comprehensive examination an organic cause for the poor performance is not found, attention should be given to the horse's training program. Training programs for horses are described in Further reading (see below).

Sudden or Unexpected Death

When an animal is found dead without having been previously observed to be ill, a diagnosis, even after necropsy examination, is often difficult because of the absence of a detailed history and clinical findings. A checklist of diseases for consideration when sudden or unexpected death occurs in a single animal or group of animals is provided later. All death is sudden, but the focus on an investigation of sudden death is that it was unexpected. Details of each of the diseases listed are available in other sections of this book. This list applies particularly to cattle, but some occurrences in other species are noted. It is necessary to point out the difference between "found dead" and "sudden and unexpected death."

When animals are observed infrequently, for example, at weekly intervals, it is possible for them to be ill with obvious clinical signs for some days without being observed. In these circumstances the list of possible diagnoses is very large. It is also correspondingly large when animals are kept together in large groups and are not observed as individuals. This is likely to happen in beef cattle, especially in feedlots or as calves with dams at pasture, when the animals are unaccustomed to human presence and move away when approached.

SUDDEN OR UNEXPECTED DEATH IN SINGLE ANIMALS

SPONTANEOUS INTERNAL HEMORRHAGE

This condition could be caused by cardiac tamponade in cows, ruptured aorta or atrium, inherited aortic aneurysm, or verminous mesenteric arterial aneurysm in horses and esophagogastric ulcer or intestinal hemorrhagic syndrome in pigs. Aortic rupture and aortopulmonary fistulation should be considered as a potential cause of sudden death in Friesian horses.[1]

RUPTURE OF INTERNAL CAROTID ARTERY ANEURYSM

This condition may occur secondary to mycosis of the guttural pouch of the horse.

In one survey of sudden deaths in horses while racing, most (68%) were undiagnosed, although it was assumed that they died of exercise-associated ventricular arrhythmias. Of those that were diagnosed, most deaths were caused by spontaneous hemorrhage. Similar conclusions have resulted from other surveys. Most reported cases of sudden death in the horse are the result of cardiovascular accidents. Fracture of the pelvis can result in fatal hemorrhage within the gluteal muscles of the horse and rupture of the middle uterine artery at parturition in cattle may occur with uterine prolapse.

PERACUTE ENDOGENOUS TOXEMIA

Peracute endogenous toxemia can arise from rupture of the stomach of horses, abomasum of cows, and the colon in mares at foaling. Large amounts of gastrointestinal contents are deposited rapidly into the peritoneal cavity. In newborn animals, especially foals, fulminating infections are the commonest cause.

Peracute exogenous toxemia in a single animal could be as a result of snakebite, but the snake would have to be very poisonous and the animal of small body weight (such as an adult sheep or goat) to cause death without any observable illness.

TRANSPORTATION STRESS

Transportation can result in sudden death in stress-susceptible animals. The best known example of this is porcine stress syndrome (PSS), during which stress appears to be the sole causative factor in death. Transportation results in a death rate from PSS of 2.0 per 1000 slaughter age pigs in Germany and 0.6 to 3.4 per 1000 slaughter age pigs in the Czech Republic.[2]

TRAUMA

Trauma may cause death by either internal hemorrhage or damage to the CNS, especially the brain or atlantooccipital joint sufficient to damage the medulla oblongata. In most cases the trauma is evident: there has been fighting, or a fall has occurred, or the animal has attempted to jump an obstacle. In horses a free gallop downhill may result in a serious fall or collision with, for example, a wall, especially if the ground is slippery.

Inapparent trauma usually occurs when animals are tied up by halter and rush backward when frightened or are startled by an electric fence and the halter shank is long. Sometimes the animal will plunge forward and hit its forehead between the eyes on a protruding small object such as a bolt used in a fence. Sadism, especially by the insertion of whip handles or pitchfork handles into the anus or vulva, may also be inapparent.

GASTROINTESTINAL CONDITIONS

Gastric rupture in the horse may occur following overeating highly fermentable feed, administration of excessive quantities of fluids by nasogastric tube, gastric impaction, or when gastric motility is markedly reduced in acute grass sickness or gastric distension with fluid. Peracute enteritis in the horse can cause rapid unexpected death.

Volvulus or gastrointestinal accidents account for almost 50% of sudden deaths in sows, followed next by gastric ulceration, retained fetuses, and toxemia.

Recumbent cattle that become lodged in a small hollow in the ground may die of bloat because the cardia becomes covered with ruminal fluid and eructation is not possible.

IATROGENIC DEATHS

Iatrogenic deaths may be caused by overdose with intravenous solutions of calcium salts in an excited cow, too-rapid fluid infusion in an animal with pulmonary edema, intravenous injection of procaine penicillin suspension, and intravenous injections of ivermectin in horses. These are not hard to diagnose and the producer or veterinarian is usually obviously embarrassed.

One of the most sudden death occurrences is the anaphylactoid reaction in a horse to an intravenous injection of an allergen such as crystalline penicillin. Death occurs in about 60 seconds. Intraarterial injections of ceftiofur, penicillin, or phenothiazine tranquilizers have also been reported to cause sudden death. This has been documented in a small number of cattle given subcutaneous injections of ceftiofur crystalline free acid suspension at the base of the ear; 0.1% of cattle in one report died suddenly and unexpectedly because of inadvertent intraarterial injection with migration to the cerebral vasculature.[3]

SUDDEN DEATH IN HORSES

An analysis of the cause of sudden death over a 20-year period was completed in Victoria, Australia. The risk in flat starts was 0.08 to 0.10 per 1000 starts, whereas the risk in jump starts was three to four times higher at 0.26 to 0.36 per 1000 starts.[4] An analysis was made of the causes of death in horses and ponies over 1 year of age that died suddenly and unexpectedly. No cause of death was found in 31% of cases and 16% died from the following causes: hemorrhage in the respiratory tract and CNS and adverse drug reactions. Cardiovascular lesions were the cause in 14% and the remaining 3% had lesions of the gastrointestinal tract.

Sudden death in racehorses is commonly caused by massive hemorrhage into the lungs, abdomen, or brain. In horses that were found dead but appeared normal when last seen, the cause of death was not determined in 33% of cases. Lesions of the gastrointestinal tract were the cause of death in 39% and respiratory tract lesions in 9%. Lesions of both the CNS and cardiovascular system were the cause of death in 5%, and the remaining 10% had miscellaneous causes.

Hyperkalemic periodic paralysis should be considered as a potential cause of sudden death in certain lines of Quarter Horses, Appaloosas, and Paints because of a single point mutation in the α-subunit of the muscle sodium gene.

SUDDEN OR UNEXPECTED DEATH IN A GROUP OF ANIMALS

The following diseases could affect single animals if the animals were housed or run singly.

LIGHTNING STRIKE OR ELECTROCUTION

This usually affects a number of animals that are found together in a pile or group. Rarely, electrical current only electrifies a contact object intermittently and deaths will be intermittent. In most cases the history and an examination of the environment reveals the cause.

NUTRITIONAL DEFICIENCY AND POISONING

At pasture, sudden death may come from the sudden exposure of the cattle to plants that cause bloat, hypomagnesemia, cyanide or nitrite poisoning, fluoroacetate poisoning, microcystins (produced by algae in a stagnant lake or pond), or acute interstitial pneumonia.[5] Acute myocardiopathy in young animals on diets deficient in vitamin E or selenium is in this group, as is inherited myocardiopathy in Herefords. Gross nutritional deficiency of copper in cattle causes "falling disease," which is a manifestation of acute myocardiopathy.

Acute myocardiopathy and heart failure is associated with poisons in *Phalaris* spp. pasture; grass nematodes on *Lolium rigidum;* the hemlocks *Cicuta* and *Oenanthe* spp.; and the weeds *Fadogia, Pachystigma, Pavetta, Asclepius eriocarpa, Cryptostegia* and *Albizia,* and *Cassia* spp. The trees oleander and yew (*Taxus* spp.) may also be causes, and those species containing fluoroacetate, such as the gidgee tree and the weeds *Gastrolobium, Oxylobium, Dichapetalum,* and *Ixiolaena* spp., may be implicated. There are a number of plants that cause cardiac irregularity and some sudden deaths, e.g., *Urginea* and *Kalanchoe* spp., but more commonly congestive heart failure is caused. Monensin, lasalocid, and salinomycin toxicities are increasingly common causes in horses and, to a less extent, cows.[5]

ACCESS TO POTENT POISONS

Access to potent poisons may occur in housed animals or in those fed prepared feeds. A select number of herbicides, insecticides, rodenticides, and metals

account for the majority of poisonings, with country to country variation and species differences.[6,7]

There are few poisons that cause sudden death without premonitory signs. Cyanide is one, but is an unlikely poison in these circumstances. Monensin, mixed in a feed for cattle that is then fed to horses, or fed in excess to cattle, does cause death by heart failure. Organophosphates are more likely, but clinical signs are usually apparent. Lead is in a similar category; however, very soluble lead salts can cause death quickly in young animals.[8]

DISEASES ASSOCIATED WITH INFECTIOUS AGENTS

These diseases cause septicemia or toxemia, and include anthrax, blackleg, hemorrhagic septicemia, and (especially in sheep, but occasionally in cattle) peracute pasteurellosis. In pigs, mulberry heart disease and perhaps gut edema should be considered. In horses, colitis is probably the only disease that will cause sudden death. In sheep and young cattle, enterotoxemia associated with *Clostridium perfringens* should be included and this may be involved in rumen overload in feedlot cattle on heavy grain feed. Circumstances, feeding practices, climate, and season of the year usually give some clue as to the cause of death.

NEONATAL AND YOUNG ANIMALS

In very young, including neonatal, animals, congenital defects that are incompatible with life—prematurity, septicemia because of poor immune status or toxemia associated with particular pathogens, especially *E. coli,* and hypothyroidism—are important causes of sudden death.

ANAPHYLAXIS

Anaphylaxis after injection of biological materials, including vaccines and sera, is usually an obvious diagnosis, but its occurrence in animals at pasture can cause obscure deaths. In these circumstances it usually affects one animal and clinical illness is often observed. A similar occurrence is sudden death in a high proportion of piglets injected with an iron preparation when their selenium–vitamin E status is low.

PROCEDURE FOR INVESTIGATION OF SUDDEN DEATH

The procedure for investigating sudden death is as follows:

- Keep excellent records because of the probability of insurance enquiry or litigation.
- Take a careful history, which may indicate changes of feed composition or source, exposure to poisons, or administration of potentially toxic preparations.
- Make a careful examination of the environment to look for potential sources of pathogens. Be especially careful if electrocution is possible; wet concrete floors can be lethal when combined with electrical current unless rubber boots are worn.
- Carefully examine dead animals for signs of struggle, frothy nasal discharge, unclotted blood from natural orifices, bloat, pallor or otherwise of mucosae, burn marks on the body (especially on the feet), or signs of trauma or of having been restrained. Pay particular attention to the forehead by palpating the frontal bones, because these may have been fractured with a heavy blunt object without much damage to the skin or hair.
- Ensure that typical cadavers are examined at necropsy, preferably by specialist pathologists at independent laboratories, in which opinions are more likely to be considered authoritative and unbiased.
- Collect samples of suspect materials for analysis. Preferably, collect two samples, one to be analyzed and one to be made available to a feed company, if indicated.

CYANOBACTERIA (BLUE-GREEN ALGAE) TOXICOSIS

SYNOPSIS

Etiology Toxins from cyanobacteria in blooms on stagnant fresh or brackish water in lakes, ponds, reservoir, billabongs

Epidemiology Outbreaks with high mortality when sole source of drinking water is polluted by toxigenic algae

Clinical pathology Elevation of liver enzymes, electrolyte abnormalities, hypoglycemia (microcystins), or possible acetylcholinesterase depression [anatoxin-a(s)]

Lesions Sudden death caused by massive hepatic necrosis (microcystins) or respiratory arrest (anatoxins). Hepatomegaly and hepatic necrosis (microcystins); no lesions (anatoxins); cyanobacteria in alimentary tract (both).

Diagnosis confirmation Positive identification of toxin(s) in water source and animal fluids or tissue confirms diagnosis; liquid chromatography mass spectrometry using animal tissue available for some toxins (microcystins)

Treatment None

Control Avoidance of contaminated water; judicious use of algaecides; watershed management

ETIOLOGY

There are over 2000 species of cyanobacteria with at least 80 known to be toxigenic.[1] The cyanobacteria, commonly referred to as blue-green algae, form dense blooms in fresh or brackish bodies of warm, stagnant water. Ingestion of cyanobacteria or their toxins liberated from ruptured cells results in clinical signs. Toxicity is species specific and some species, such as *Anabaena flos-aquae,* produce more than one toxin. Cyanotoxins associated with large-animal poisonings include:[1-3]

- **Microcystins.** These are potent hepatotoxins produced by many different cyanobacteria including several species of *Anabaena, Anabaenopsis, Microcystis, Planktothrix, Nostoc,* and *Oscillatoria.*
- **Anatoxins.** Toxins in this group are potent neurotoxins produced primarily by several species of *Anabaena* and a few species of *Planktothrix.*
- **Various freshwater toxins.** Included in this group are cyanotoxins known to cause toxicity in animals. Toxins, produced by a variety of cyanobacteria, include saxitoxins, cylindrospermopsin, nodularins, and most recently β-*N*-methylamino-L-alanine (BMAA).[4,5]

EPIDEMIOLOGY

Occurrence

Cyanobacterial toxins are associated with outbreaks of poisoning in farm animals that drink contaminated water. Lakes, reservoirs, ponds, waterholes, and other nonturbulent water sources are all affected, especially when the organisms are concentrated by onshore winds so that large quantities may be ingested. Typically the surface of the water has a bluish green sheen or pea green to iridescent neon green streaks. Often the algae accumulate along the shoreline where animals have easy access and the water is shallow and more stagnant. In small waterholes and reservoirs the surface water is often completely covered with a very thick coat of gelatinous organisms (algae bloom), and animals are unable to drink without ingesting some of the algae. Cyanobacteria are found in every continent except Antarctica and toxicoses has been recorded in most

countries, especially the United States, Canada, Scandinavia, Japan, South Africa, Australia, and New Zealand.[2,3,6,7] The cyanobacterial toxins affect all animals and birds and those found in brackish and marine waters are associated with mortalities in fish.[3] Death, while the normal outcome, occasionally does not occur, especially if animals are able to avoid ingesting large amounts of contaminated water.

Risk Factors

Heavy growth commonly occurs in the late summer to autumn period. Factors promoting growth of the organisms and increasing the chances of animals being poisoned include warm water temperatures, low water depths, sunshine, and onshore winds.[1-3] In addition, a high concentration of other nutrients such as nitrogen and phosphorus associated with fertilizer runoff or feces/urine contamination may play a role.[2,8]

PATHOGENESIS

Microcystins

These toxins are potent hepatotoxins affecting virtually every animal species as well as some plant species. The toxins are found inside the cyanobacteria and released by cell damage or death. When an animal drinks contaminated water, the acid pH of the stomach liberates microcystins from the algae and toxicosis occurs. The toxin enters hepatocytes via the bile acid carriers and inhibits protein phosphatases 1 and 2A resulting in cytoskeleton and actin filament changes, hepatocyte necrosis, and cell death.[1] Other mechanisms such as free radical induction and mitochondrial changes affect the liver as well.[1] Animal death occurs from intrahepatic hemorrhage.

Anatoxins

Three important subgroups of anatoxins, all potent neurotoxins, have been identified in animal poisonings. One subgroup, homoanatoxin-a, has not yet been associated with large-animal poisonings, but with neurotoxicosis and death in New Zealand dogs.[9]

Anatoxin-a

This neurotoxin is a potent agonist at nicotinic acetylcholine receptors both at the neuromuscular junctions and neurons.[1,6] Prolonged and continuous stimulation at the neuromuscular junction results in weakness, respiratory paralysis, and death. Dopamine and norepinephrine are released secondary to modulation at the neuronal nicotinic acetylcholine receptors.[10]

Homoanatoxin-a

Toxicologic properties of this toxin are similar to anatoxin-a.[9]

Anatoxin-a(s)

The chemical structure and mechanism of action of this toxin are different from the other two anatoxins. Anatoxin-a(s) is an irreversible acetylcholinesterase inhibitor with a mechanism of action similar to organophosphorus containing pesticides.[1,11] Continued nicotinic receptor stimulation from increased amounts of acetylcholine result in ataxia, seizures, respiratory arrest, and death. Unlike organophosphorus compounds, anatoxin-a(s) affects only the peripheral nervous system (i.e., no central effects).[11]

Various Freshwater Toxins

The toxins listed next are not as common as microcystins and anatoxins but worthy of note because they have been associated in some manner with large-animal poisonings.

- **Saxitoxins.** Toxins in this group are generally associated with paralytic shellfish poisoning in small animals, but a group of Australian sheep became symptomatic and died after exposure to *Anabaena circinalis*.[3] Saxitoxin, a potent neurotoxin, selectively blocks voltage-gated sodium channels causing neuromuscular weakness, respiratory arrest, and death.[1,6]
- **Cylindrospermopsin.** This toxin, produced by several species of cyanobacteria including *Cylindrospermopsis raciborskii,* has been implicated in the death of cattle. It inhibits protein synthesis and thus affects several organs in the body including the heart, lungs, liver, and kidneys.
- **Nodularins.** This potent hepatotoxin is produced primarily by the cyanobacteria *Nodularia spumigena* and has caused death in sheep and other livestock.[1,3,12] The mechanism of action is similar to microcystins with death the normal outcome.
- **BMAA.** This potent neurotoxin produced by the cyanobacteria *Hydrilla verticillata* was recently associated with the development of avian vacuolar myelinopathy.[4,5] The toxin has also been associated with several degenerative human neurologic diseases, and it has been hypothesized that BMAA may play a role in the onset of equine motor neuron disease.[13]

CLINICAL FINDINGS

Microcystins

The clinical picture has been well described in livestock, swine, and horses.[1,3,8] Most are found dead or die within a few hours. Vomiting, diarrhea, ataxia, and shock occur in early deaths; those that live for a few hours show agitation and irritability, ataxia, recumbency, and seizures before death. In the less acute cases there is severe liver damage manifested by anorexia, stupor or hypersensitivity, ruminal atony, dehydration, recumbency, jaundice, and photosensitization in cattle and sheep. Many apparently unaffected and recovered animals die in the ensuing 3 months. Affected pigs are anorexic and show dullness, vomiting, lethargy, tremor, frothing at the mouth, coughing, sneezing, dyspnea, and dysentery.

Anatoxins

Affected animals are commonly found dead. Clinical signs may become apparent within 15 minutes after exposure. In acute cases the affected animals have muscle tremor, stupor, staggering, recumbency, and in some cases hyperesthesia to touch so that slight stimulation provokes a seizure with opisthotonus. Death is from respiratory arrest. Animals exposed to anatoxin-a(s) also have excess salivation as well as lacrimation, vomiting, and diarrhea.

CLINICAL PATHOLOGY

Microcystins

Chemical analysis shows increased liver enzymes, electrolyte abnormalities (hyperkalemia), hypoglycemia, and hypoalbuminemia in all species.[1,3] Clinical pathologic findings rated in order of frequency in sheep exposed to microcystins are high serum concentrations of bile acids, glutamate dehydrogenase, γ-glutamyl transferase and serum bilirubin, and reduced serum concentration of albumin.

Anatoxins

There are no anatoxins.

NECROPSY FINDINGS

Necropsy findings in microcystin toxicity vary depending on when death occurred. Gross postmortem examinations show enlarged livers with dark-brown to a bluish parenchyma.[14] Microscopic lesions are consistent with centrilobular hepatic necrosis.[1] Other lesions include generalized petechiation, plasma transudates in body cavities, and congestion of most viscera. Severe gastroenteritis with intestinal hemorrhage and severe bloody diarrhea has also been observed in some outbreaks. There are no specific necropsy findings in animals dying of anatoxin toxicity.

Diagnosis

The presence of cyanobacteria in the source water and gastrointestinal tract is not diagnostic. Identification of the specific toxin in the water and animal tissues or fluids is needed to make a diagnosis. The toxins may disappear from the water within 2 to 3 days so samples should be taken as soon as possible after the poisonings occur. A specimen of the bloom material should be immediately preserved for identification, because degeneration of cells is rapid during transport to the laboratory. Laboratory examination for the presence of high concentrations of known toxic cyanobacteria is required. Many assays, including ELISAs, are available to routinely confirm the presence of microcystins in suspect water, but few are useful for

anatoxins.[15] Within the past few years, liquid chromatography mass spectrometry (LC/MS/MS) has been successfully used to measure the microcystin concentration found in body tissues. No such test is routinely available for anatoxins.[16,17] The diagnosis of anatoxin a(s) intoxication may be supported by acetylcholinesterase testing, although the presence of organophosphorus and carbamate pesticides needs to be ruled out.[1]

DIFFERENTIAL DIAGNOSIS

Diagnosis confirmation is made by positive assay for the algal toxins in suspect water and animal body tissues or fluids.

Microcystins
- Alfatoxin toxicosis
- Carbon disulfide ingestion
- Hepatotoxic chemicals (chlorinated hydrocarbons, phenols, etc.)
- Mushroom ingestion (amatoxins)
- Paraquat toxicosis
- Pyrrolizidine alkaloids, other hepatotoxic plants
- Phomopsin toxicosis
- Sporidesmin toxicosis

Anatoxins
- Anthrax
- Atrial fibrillation
- Cyanide toxicosis
- Electrocution or lightning strike
- Ionophore toxicosis
- Plant poisonings
- Rupture of major vessel (aorta, uterine arteries)
- Trauma

TREATMENT

There are no specific antidotes, and treatment is unrewarding.

CONTROL

The two principles involved are prevention of ingestion of floating bloom material by animals and preventing the addition of nutrients that promote cyanobacterial growth to the water.[2,8]

Prevent the Ingestion of Toxins

- Prevent access to contaminated water. Move livestock to a clean water source or draw drinking water from a site away from the bloom.
- Keep bloom away from water intake by use of a floating boom.
- Add precipitants, e.g., lime, ferric alum, and gypsum, which remove algae without release of toxin and remove phosphates (see later).
- Algaecides such as copper sulfate are still used but the routine, unregulated use is no longer recommended. The killed cyanobacteria release toxins into the water, so it cannot be used as drinking water for at least 5 days. The algaecides also damage other vegetation and may ultimately promote further cyanobacterial blooms.

Prevent the Addition of Nutrients to Water

- Fence off water sources from direct livestock access so no manure or urine is added to the watershed or directly to the water.
- Precipitate phosphates with lime, gypsum, and ferric alum. This is useful only for small reservoirs or ponds.
- Mechanically aerate bottom layers of water body; this is useful only for large water reservoirs.
- Exert catchment control and minimize use of phosphate fertilizers and inflow of sewage.
- Filter the inflow by enhancing reed bed and wetland growth.
- Buffer afforestation and vegetation generally along the banks of watercourses.

Diseases Associated With Physical Agents

LIGHTNING STRIKE AND ELECTROCUTION

SYNOPSIS

Etiology Exposure to high-voltage electric currents

Epidemiology Single or multiple cases. Following a thunderstorm dead animals at pasture may be under trees or along fence lines. Posterior paralysis in housed pigs

Clinical findings Bone fractures, temporary unconsciousness, or immediate death. In recovered animals residual nervous signs may persist. Posterior paralysis in pigs

Necropsy findings Singe and burn marks with some cases. Fractures of long bones in some cases and of lumbar vertebrae in swine

Diagnostic confirmation Difficult. History and environmental evidence of lightning or electric shock exposure and no postmortem lesions of other causes of disease

ETIOLOGY

The three common causes are flashes of linear lightning during thunderstorms, broken overhead electrical transmission wires that usually carry very high voltages, and faulty electrical wiring in cowsheds and barns.

Lightning-related injury or death can occur through five primary mechanisms[1,2]:

1. Direct strikes
2. Side flashes emanating from tall objects such as trees hit by lightning
3. Ground currents (step potentials or step voltages) occur with each strike and are the most common mechanism in four-legged species because after injection of current into the earth, a potential gradient develops that can initiate current entering the animal from one set of feet, leaving the body by the other set of feet. In contrast to humans, this current crosses essential organs, such as the heart and liver, causing death.
4. Contact, from touching long conductors, such as railings, cables, and fences can be fatal.

5. Upward leaders that emanate from high ground and tall objects when downward leaders approach ground

During lightning strike trees, fences, barns, and pools of water may become electrified, and it is not unusual for damp ground to act as a conductor for electricity passing along the roots of stricken trees. Animals electrocuted by standing on electrified earth are unlikely to show burn marks on the body. Oak trees are particularly prone to lightning strike and because of their spreading foliage and extensive root system, are common mediators of electrocution deaths in pastured animals. Poplar, elm, walnut, beech, ash, and conifers are also mediators of electrocution to animals that shelter under them.

Electrical transmission wires are most dangerous when they fall into pools of water, as they are likely to do during the storms that bring the wires down. In such cases, the entire pool is electrified and animals passing through it may be killed instantly. Electrocution can also occur from this source without obvious evidence of line fault.

In accidents caused by **faulty wiring**, voltages of 110 to 220 V are sufficient to kill adult cattle provided they make good contact with the source and the ground. Water pumps and milking machines are the common sources of electricity that may electrify water pipes or the milk line through the earth wire or a short circuit. The use of very heavy fuse wire (30–60 A) may cause continuance of the trouble, which could be avoided if lower capacity fuses were used. In situations of electrical fault, certain farm owners will choose to try to circumvent it by improper use of fuse breakers that can lead to substantial risk of electrocution hazard.

EPIDEMIOLOGY

The area incidence is never high but heavy mortalities may occur on individual farms when a barn or a group of animals sheltering under a tree is struck. Approximately 90% of deaths occur in cattle in Belgium.[2] Risk factors include documented cloud-to-ground lightning strikes at about the time of death of animals and the presence of open water and tall trees.[2] As many as 20 head of cattle may be killed by one lightning flash. Most fatalities caused by lightning strike occur during the summer months when the animals are at pasture.[2,3]

Behavioral abnormalities of housed animals may indicate the presence of faulty wiring in barns. Deaths caused by electrocution in barns can occur at any time.

PATHOGENESIS

Tissue damage from electrical trauma is induced by the direct effects of the electric current and the development of heat and tissue ischemia. Exposure to high-voltage electrical currents causes severe **nervous shock** with complete unconsciousness and flaccid paralysis. In some instances, focal destruction of nervous tissue occurs and **residual signs of damage** to the nervous system persist after nervous shock disappears. Death when it occurs is usually caused by paralysis of vital medullary centers. Ventricular fibrillation can also occur and contribute to death. **Superficial burns** may be evident at the site of contact with the current or along the path of flow from the point of contact to ground. The burn is produced by heat generated from the resistance of tissues to the passage of the electricity. **Fractures** are thought to be the result of sudden and profound muscular contraction.

CLINICAL FINDINGS

Deaths caused by lightning strike can be detected by an examination of the dead animal and its environment with additional information provided by lightning location data.[2]

Varying degrees of shock occur. With high-voltage currents and good earth contacts such as wet concrete floors, water, and damp earth, the animal may fall dead without a struggle. Singeing and burning are likely to occur because of the severity of the shock. The burns may be localized to the muzzle or feet and be in the form of radial deposits of carbon with or without disruption of tissue, or they may appear as treelike, branching patterns of singeing running down the trunk and limbs. Acute blindness linked to lightning flash injury has occurred in a horse. The injuries were consistent with acute and severe flash injury.[4]

In less severe shocks, the animal falls unconscious, **suddenly collapses**, or may struggle, followed by a period of unconsciousness varying from several minutes to several hours. When consciousness is regained, or the animal is removed from the electric field, the animal may rise and be perfectly normal, or show depression, blindness, ataxia, posterior paralysis, monoplegia, and cutaneous hyperesthesia. In some cases there may be more local signs including nystagmus and unilateral paralysis. Sloughing of the skin at the sites of burns may occur after a few days. These signs may persist or disappear gradually over a period of 1 to 2 weeks. With electrocution in **pigs** caused either by lightning strike or wiring faults, the major signs are related to spinal injury or to fracture of the ileum, ischium, and the transverse processes of the lumbar vertebrae with a large number of animals exhibiting apparent lameness and especially posterior paralysis. Vestibular disease is described as a sequela to lightning strike in horses.

The actual occurrence of electric shock often is not observed and electrocution should always be considered in the differential diagnosis of spinal or pelvic fracture or injury in pigs.

With minor shocks, especially as they occur in barns on low-voltage domestic current, the animal may be knocked down or remain standing. Consciousness is not lost and the clinical picture is one of restlessness. The animal may kick violently at the stanchion or the dividing rail. The attacks may be intermittent and occur only when the cattle supply a good ground contact such as standing in the gutter, when they are drinking, or when they are wet. Dairy farmers are often unaffected in the same environment because their boots provide effective insulation.

CLINICAL PATHOLOGY

Laboratory examinations are of no value in diagnosis.

NECROPSY FINDINGS

If electrocution is suspected it is best to ensure that possible **sources of electric power** are shut off before proceeding with a postmortem examination.

Diagnostic lesions are often minimal but singe marks on or under the skin, or damage to the environment, or both, occur in about 90% of lightning deaths. Rigor mortis develops but passes quickly.

In cattle, anthrax is often a consideration as the carcass decomposes rapidly and blood may exude from the external orifices. The pupils are usually dilated and the anus relaxed. All viscera are congested and the blood is dark and unclotted. Petechial hemorrhages may occur throughout the body, including the trachea, endocardium, meninges, and CNS. The superficial lymph nodes, particularly the prescapular and the interior cervical, are often hemorrhagic. Superficial singeing of the hair, burn marks on the feet or muzzle, and internal or subcutaneous extravasations of blood in arboreal patterns also occur.

In some cases of electrocution there are longitudinal **fractures** of long bones and in incidents involving pigs, local hemorrhage and extensive fractures of the bones in the pelvic area are observed. Fractures of the lumbar vertebrae have also been described in electrocuted swine.

Theoretically, the passage of electric current through tissue may cause cell nuclei to elongate and assume orientations parallel to one another. Skin lesions can be examined histologically for this change and hyperconcentration of skeletal muscle fibers may also be observed.

DIFFERENTIAL DIAGNOSIS

Great care must be taken in accepting an owner's suggestion that an animal has been killed or injured by lightning strike. Insurance against loss by lightning is commonly carried and the many other causes of sudden death or injury are seldom covered by insurance. To minimize the possibility of conflict and potential future legal problems it is wise to have a representative of the insurance

company present at the autopsy so that all may agree on the diagnosis.

To make the diagnosis, there should be a history of exposure and evidence of sudden injury or death. In the latter case, half-chewed food may still be present in the mouth. Burns on the skin, scorching of the grass, and tearing of the bark on nearby trees are also accepted as contributory evidence. The possibility of electrocution caused by faulty wiring should be considered when sudden shocks or death occur in animals confined in stanchions. Differentials include:

- Other causes of sudden death
- In pigs, other causes of posterior paresis/paralysis

DIAGNOSIS

A model to predict the likelihood that death of an animal at pasture was caused by lightning strike has been developed. Factors significantly associated with lightning strike death in the multivariable model were age, presence of a tree or open water in the near surroundings, tympany, and presence of feed in the oral cavity at the time of investigation.[2] This basic model had a sensitivity (Se) of 54% and a specificity (Sp) of 88%. The predictive value was improved by combining the model based on the veterinary expert investigation (circumstantial evidence and pathologic findings), together with the detection of cloud-to-ground (CG) lightning at the time and location of death (Se 89%; Sp 67%).[2]

TREATMENT

Central nervous system stimulants and artificial respiration should be provided for unconscious animals, but in most instances the animals are dead or recovered before treatment can be instituted.

CONTROL

Precautions taken to avoid lightning strike in animals are largely ineffective, but proper installation of all electric equipment in barns and milking parlors is essential to prevent losses. All motors should be earthed to a special iron spike or pipe driven at least 2.5 m into the ground, preferably in a damp spot, and electrical machinery that has potential contact with animals should be shielded. Earthing to water pipes should not be permitted. Minimum amperage fuses should be used to provide protection in cases of short-circuiting.

STRAY VOLTAGE

SYNOPSIS

Etiology Minor voltage (<10 V) in the animal environment causing mild electric shock

Epidemiology Risk with any electrified housing system but most recognized in dairy cattle and pig housing

Clinical findings Behavioral changes in feeding or eating patterns, reluctance to move freely in some areas of buildings at levels of 2 V or higher in some but not all animals. Claims for increased disease incidence and decreased production not substantiated experimentally

Diagnostic confirmation Demonstration of stray voltage with amelioration of the problem when this is corrected

ETIOLOGY

The term *stray voltage* is used to denote minor (<10 V) electrical voltage between two points that can be accessed by an animal resulting in a current flow through the animal. **Other terms** that have been used for stray voltage include *free electricity, tingle voltage,* and *transient voltage.* The terms *neutral to earth voltage* or *neutral to ground voltage* usually apply to the voltage measured between the service entrance neutral bus and a reference ground rod. **Cow contact voltage** refers to voltage measured between a potential cow contact, such as a drinker, and the ground.

The source and cause of the problem is complex. Stray voltage can be caused by leakage of current from electrical installations, electric and magnetic induction from high voltage lines, or faulty connections between the electrical circuit and earth.[1]

Depending on the current, exposure to stray voltage can produce minor electrical shock and discomfort to animals. Voltages occurring in barns at the level of the animal are usually low and are not felt by humans because of the insulation provided by clothing and footwear.

EPIDEMIOLOGY

The potential presence of stray voltage has been recognized for many years. The possible relation to production and disease gained particular attention in the 1980s when different surveys indicated that over 50% of dairy farms had significant cow contact voltage, and more current studies indicate a continuing problem. Deteriorating wiring, poor wire insulation, and older buildings are **risk factors.** Heavy milking cows are thought more sensitive to electric shock; scratched, infected, and sore muzzles and hooves may increase sensitivity.

PATHOGENESIS

The reaction of the animal to stray voltage will depend on the current flow, or shock, which is related directly to the voltage and inversely to the **impedance** to flow in the animal.[2] The impedance decreases as body weight increases because of an increase of the surface of contact and the pressure exerted by the hooves on the floor and, with pigs, current flow at the same voltage is higher through a gilt or sow than through a piglet. There are some differences in impedance between different pathways in animals (e.g., mouth to hooves or udder to hooves), but there can also be individual animal **variation in sensitivity** to stray voltage.[3] Generally, the problem will only be suspected if the stray voltage is high enough so that a significant proportion of the herd shows signs.

The reactivity of **cows** to different voltage levels has been studied, and the **lowest behavioral perception** is observed at 1 to 2 V for the most sensitive cows and moderate behavioral responses at 1.5 to 3 V. With **pigs**, feeding and drinking behavior is affected at 5 V but not at 2 V, and resting time is disturbed at 8 V.

CLINICAL FINDINGS

Behavioral Changes

The behavioral responses exhibited by **cows** exposed to stray voltage depend on the site at which the voltage occurs and the strength of the current flow. Stray voltage in the **milking parlor** results in a reluctance to enter the parlor, a reluctance to cross the floor grids, extreme nervousness while in the parlor, and rapid exit or stampeding from the parlor. Where stray voltage occurs at **drinkers** cows may show reluctance to drink, with lapping of water rather than full drinking and crowding at the drinker resulting in one cow being the ground while others drink. Cows that are experiencing current flow are restless, they may tremble, the back is arched and the head is elevated with the ears held back rigidly, and there is frequent urination and defecation.

In **pigs**, restlessness, increased aggressiveness, and changes in drinking and feeding patterns have been associated with stray voltage.

Effects on Production and Disease

Field observations suggested that stray voltage in the milking parlor at milking time may result in incomplete milk letdown, increased milking times, elevated somatic cell counts, an increased incidence of clinical mastitis, and poor production. However, **controlled trials** have consistently reported behavioral changes, as well as transiently elevated blood cortisol levels in cows exposed to stray voltage above a certain threshold, but failed to identify any effect on somatic cell counts, mastitis incidence, or milk production.[1,2,4] Similarly no effect of stray voltage on the incidence of disease in pigs could be identified. It was concluded that exposure to stray voltage at the levels of 2 to 4 V may be

a mild stressor but does not impair productivity or increase the occurrence rate of production diseases.

DIFFERENTIAL DIAGNOSIS

The presence of stray voltage should be suspected where animals exhibit behavioral abnormalities and for the present, it is probably wise to consider it as part of the differential of problems of production inefficiency.

Cow contact voltage can be measured with a sensitive voltmeter, but the ground must be well established. The measurement of the neutral to earth voltage does not give a good prediction of cow contact voltage and is not recommended as the sole measure for the risk of stray voltage on the farm. In most instances a qualified electrician is required to correct the problem. The use of a commercially available tingle voltage filter has been recorded to significantly reduce stray levels.

ENVIRONMENTAL POLLUTANTS AND NOISE

Pollution From Outside the Farm

Deposition of contaminants in soil and water and on plants can derive from a large number of sources including atmospheric pollution, residues from the petroleum and metalliferous industries (both mining and smelting), persistent pesticides, and the application of sludge. Deposition in soil, but not on plants, does not preclude poisoning of animals because soil can comprise a significant proportion of the dry matter intake of grazing ruminants. Pollutants exert their effect through direct toxicity, immunosuppression or, in the case of some heavy metals, by the competitive induction of trace element deficiencies.

Mine spills and **smelter emissions** have been associated with soil and water contamination with a number of different heavy metals. Aluminum smelter emissions result in fluorosis in Easter Grey Kangaroos in Australia.[1,2] Cattle grazing near lead, zinc, or vanadium mines have increased concentrations of lead, cadmium, and vanadium in body tissues and biochemical evidence of intoxication.[3-7] Cattle grazing pasture and drinking water near former uranium mines have elevated concentrations of radionuclides.[8] Water from mines is also potentially toxic to livestock that drink it. Pastures adjacent to **major roads** and animals grazing them are also contaminated by heavy metals from vehicle emissions. Blood and tail hair can be analyzed to detect abnormal concentrations of many pollutants, including heavy metals.[9,10] Cattle grazing near a lead and zinc industrial processing area had higher blood concentrations of lead, lower hematocrit and hemoglobin concentration, and higher serum activity of alanine transaminase and AST than did cattle from an uncontaminated area.[11] Similarly, young cattle grazing near a zinc and lead mine had evidence of subclinical toxicosis (blood lead 6–35 µg/dL and elevated blood aminolevulinic acid dehydrogenase activity) compared with reference ranges.[6]

Cattle will readily ingest petroleum products, and the toxicology of **oil field pollutants** has been reviewed. Another important group of compounds is the polychlorinated biphenyls and the **polybrominated biphenyls** and the chlorinated hydrocarbons. These substances are extensively used in agriculture and in industry. They have very long half-lives and, although they are not in themselves dangerous, they cause a great deal of trouble if they get into the human food chain and become deposited in fatty tissues.

Pollution From Farms

Pollution of the environment by animal feces and urine is now a matter of great importance, especially to intensive animal farmers located near population centers. There are increasing regulations governing livestock farming, effluent disposal, nitrogen and mineral cycles, and odor emission, and there are increasing regulatory actions or private lawsuits against farms that offend. This is not a subject for a text on veterinary medicine, although efforts to minimize nitrogen, phosphorus, and potassium fecal outputs by dietary manipulation and water restriction have potential veterinary and welfare implications.

Slurry application to pastures and runoff to streams and groundwater introduce health problems such as salmonellosis, cryptosporidiosis, leptospirosis, and mycobacteriosis. Shallow wells near animal accommodation are also likely to contain high levels of nitrates derived from nitrogen filtering through surrounding earth. Such water is a potential source of nitrate poisoning, especially in pigs.

One of the important pollutants for housed animals is **ammonia** from urine.[12] When it is combined with dust, it can cause severe inflammation of the respiratory mucosae. **Dust** may be the carrier of pathogenic bacteria or viruses or antigens that provoke a hypersensitivity reaction, e.g., interstitial pneumonia. Carbon monoxide and hydrogen sulfide from **slurry pits** can cause mortality in both animals and humans. The highest risk is during agitation of the slurry, when they are released. Sulfur dioxide is also an environmental contaminant capable of causing respiratory tract irritation in animals.

Noise

Animals are more susceptible to high-pitched noise than are humans, and the elimination of such noises in working facilities improves the **orderly handling** of cattle and sheep. Pollution by noise, a matter of increasing importance for veterinarians who police codes of practice for animal welfare and for those who are called upon to act as expert witnesses in cases involving excessive noise and its effects on animals, is also an important subject.

The effects of a sonic bang from **aircraft** are short-lived and are caused by fear reactions but include injury from sudden flight, killing of young by mink and rabbits, suffocation in panic-stricken chickens, and reduced egg production. Cattle and goats are unaffected and the effect on livestock and wildlife from the noise produced by low-flying aircraft appears minimal.[13]

WIND FARMS AND ELECTRIC AND MAGNETIC FIELDS

Electric and magnetic fields are generated from the transmission of electricity through high tension lines. Electrical transmission lines and electrically powered devices generate an **extremely low frequency magnetic field** (50–60 Hz), whereas electronic devices emit a **high-frequency electromagnetic radiation** (300 MHz to 300 GHz). Livestock are exposed to these fields when high-voltage lines pass through rural areas. German veterinarians have expressed concern for livestock health from the effect of radiofrequency electromagnetic fields associated with the establishment of a national mobile phone network. Current work suggests the major biological effect of high-frequency electromagnetic radiation is localized heating, which is usually very minor relative to diurnal temperature changes and changes in

core temperature in response to different ambient conditions. The evidence supporting an effect of electromagnetic fields on circadian rhythms in a variety of species such as cows and lambs, via alteration in melatonin or cortisol secretion, is contradictory and the consensus view is one of no effect.

There is no apparent effect of high-voltage transmission lines on any health outcome in humans, with the possible exception of an increased risk of childhood leukemia. There appears to be no effect on the behavioral or feeding patterns or the reproductive performance of cattle grazed under or near high-voltage transmission lines. There is no consistent detectable effect of high-voltage transmission lines on reproductive performance or growth rate in animals.

Wind farms have become commonplace in parts of Europe, North America, and Australia as society is becoming increasingly interested in using alternative energy sources to fossil fuels. The environmental concern about wind farms is focused on four alterations produced by wind turbines: (1) an extremely low frequency magnetic field; (2) a high-frequency electromagnetic radiation; (3) a low-frequency noise and shadow flicker; and (4) infrasound, which is a sound wave inaudible to humans because of its extremely low frequency (1–20 Hz). No adverse health effects of exposure to wind farms have been identified, except for increased mortality of specific migrating bird species and bats by hitting rotating wind turbine blades and population shifts as a result of habitat alteration; the latter is primarily the result of building access roads and preparing ground to support large wind farms.

RADIATION INJURY

SYNOPSIS

Etiology Ionizing radiation from radionuclides in environment or feed resulting from exploded nuclear bombs or nuclear power plant accidents

Epidemiology Type, severity, and extent of exposure will depend on atmospheric conditions and the radionuclides released.

Clinical findings Anorexia, depression, and severe diarrhea in acute sickness. Bone marrow depression with anemia and septicemic disease

Clinical pathology Neutropenia and thrombocytopenia, bone marrow depression

Necropsy findings Hemorrhagic and ulcerative lesions in the alimentary tract. Pneumonia, general septicemia

Diagnostic confirmation Radiation exposure from nuclear disaster

Public health considerations Animals exposed to radioactive material also serve as reservoirs for radioactive material that could be passed to humans in meat, milk, and other animal products. This hazard to humans is a problem of public health and is primarily addressed by establishing tolerance limits for contamination in animal products for human food and by changes in agronomic practices and policy.[1-5] The following discussion is restricted to the effects of irradiation on the health of animals exposed to it.

ETIOLOGY

Radiation injury can be caused in a number of ways including nuclear bombs, contamination from nuclear power plant accidents, and exposure to x-rays, but the effects on the tissues are the same, with differences occurring only in the depth of penetration and the degree of injury caused. The radiation emitted by radionuclides has a similar biological effect to external irradiation by x-rays because both sources are **ionizing**—they remove electrons from their orbits causing atoms within animal tissue to produce pairs of charged ions, which are the instruments of the biological damage. Atomic explosions can also injure through the effects of blast and heat.

EPIDEMIOLOGY

Incidence and Case Fatality

There is considerable variation in the effects of an atomic explosion, or a nuclear power plant accident, depending on the distance from and the time after the blast, whether the explosion occurs in the air or on the ground surface, and the types of radionuclides released. With nuclear explosions, animals within the range of immediate irradiation are more severely affected than those exposed only to the "fallout" of radionuclides on pasture. However, grazing animals are exposed to very great risk because of this fallout. The area in which direct radiation effects occur is significantly smaller than that where "intervention levels" for radionuclides are exceeded.

Risk Factors

Animal

Radiosensitivity differs between animal species when death is defined as the endpoint. Horses are more resistant to whole-body radiation than other animal species. Sheep appear the most susceptible and die earlier than cattle at equivalent exposure doses. Pigs are the least susceptible to low radiation. Age is also a risk factor and calves are more susceptible than adult cattle and are prone to develop respiratory and enteric disease, effects that are uncommon in adult cattle that commonly show hemorrhagic disease.

Nature of Radiation

Of the radioactive materials produced by an atomic explosion, a number of **radionuclides**, including iodine-131, barium-140, strontium-89 and strontium-90, and cesium-134 and cesium-137 are likely to enter biological systems. Of these, radioactive iodine, barium, and strontium-89 are of less importance because of their short **half-lives**. On the other hand, strontium-90, cesium-134, and cesium-137 may occur in very large quantities and have long half-lives and are therefore of greatest biological significance.[6] If a sufficient amount of these radionuclides is ingested and tissue levels of them reach critical points, injury similar to that produced by external irradiation will occur. Cesium-134 and cesium-137 are of particular concern because of their biological mobility. They behave metabolically like potassium and are distributed widely through the body.[6] Both are beta and gamma emitters and effectively will administer a dose of whole-body radiation to an animal ingesting pasture contaminated with them. Iodine-131 behaves like stable iodine and is concentrated in the thyroid gland.

Soil type can influence radionuclide intake by animals grazing contaminated pastures. Persisting concentrations of radiocesium in plants are associated with acid soils with high organic and low clay content. In mineral soils, cesium is strongly bound to clay particles, which limits its uptake by plants; clay minerals, such as bentonite, fed to ruminants will reduce the alimentary absorption of radiocesium. Animal contamination is further influenced by **differences in uptake** of radionuclides by different pasture species and animal breed differences in **grazing behavior.**

Zoonotic Implications

Radionuclides are excreted in the **milk**[2] of animals and are present in the **meat**,[1] posing a risk for humans consuming them. Radioiodine transfer to the milk of sheep and goats is considerably greater than to that of cows. The half-life of radioiodine is sufficiently short that contaminated milk could be diverted to stored dairy products, although this would not have public acceptance. The

maximum permissible concentration of radioactive substances in meat is reached at much lower levels of pasture contamination than would be required to cause physical injury to the cattle or sheep; in most countries it is set at around 1000 to 2000 Becquerels (Bq) per kg fresh weight.[4]

PATHOGENESIS

The acute radiation syndromes from acute radiation usually occur within the first few days after exposure to whole-body radiation to 30 to 60 days depending on the radiation dose. Based on the dose, the major manifestations have been divided into three major presentations, central nervous system (CNS), gastrointestinal, and hemorrhagic, but there is considerable overlap in clinical signs at all but the high doses that result in the peracute CNS syndrome.

Doses greater than 80 to 100 Gray (Gy) induce rapid damage to blood vessels, changes in permeability, and an increase in intracranial pressure with death in 2 to 5 days. Gastrointestinal disease results when the radiation dose ranges between 10 and 80 Gy and results from damage to the rapidly dividing undifferentiated cells in crypts of intestinal villi, which are the progenitor cells to the differentiated enterocytes of the intestinal villi. Damage to bone marrow stem cells is the main cause of death at whole-body doses between 2 and 10 Gy with death in large animals occurring 6 to 8 weeks after exposure. Clinical disease is slow in development after exposure because the effect of this damage is not evident until the death of existing circulating blood cells. The effects are the result of decreased granulocytes, platelets, and red cells and are manifested with increased susceptibility to infection, bleeding syndromes, and anemia.

Initially there is a lymphopenia followed by a depression of granulocyte and platelet counts. The leukopenia permits invasion by bacteria from the alimentary tract and **bacteremia** and septicemia develop 1 to 4 weeks after irradiation. The clotting mechanism and antibody production are impaired and facilitate the invasion. Progressive necrosis of the gut wall without inflammation is characteristic. Thrombocytopenic hemorrhage into the lymphatic system and other tissues leads to the development of a profound anemia.

The activity of **germinative epithelium** is also profoundly depressed; if the animal survives the early stages listed earlier, the hair commences to shed, the skin to ulcerate, and a gross reduction in fertility occurs. Degenerative changes in the lens of the eye, particularly cataract, may also occur. **Long-term effects** in animals are of less concern than in man because of the short life span of animals and any genetic damage can be removed by selective breeding. Very long-term effects of irradiation include a high rate of **mutations** and a high incidence of tumors, mostly of the hemopoietic system, and an increased risk for squamous cell carcinoma of the skin.

Thyroid damage by iodine-131 does not appear a major risk for ruminants. The thyroid gland of the sheep is more radiosensitive than that of the cow but very high and sustained doses of iodine are required to produce damage, and clinical signs in thyroid-damaged ruminants are minimal.

CLINICAL FINDINGS

Acute Syndrome

After immediate irradiation with high doses death occurs from damage to the CNS. At lesser doses damage to the alimentary tract occurs and, particularly in young animals, there is a resulting intense, refractory diarrhea. Death occurs in a few days from dehydration and electrolyte imbalance. Local contact of radioactive materials to skin causes changes within a few hours. Observable lesions vary from depilation and slight desquamation to extensive necrosis, depending on the irradiation dose.

Subacute Syndrome

Immediately after irradiation with median doses there is an **initial phase** of "radiation sickness" characterized by anorexia, vomiting in pigs, and profound lethargy, which lasts from several hours to several days.

The **second phase** is one of apparent normality lasting until 1 to 4 weeks after irradiation. This is followed by a **third phase** in which most deaths occur associated with damage to stem cells in bone marrow and secondary infections. Clinical signs vary with the nature of the infection and the age of the animal. Calves commonly develop respiratory and enteric disease with fever, weakness, and diarrhea developing to melena and dysentery, sometimes with tenesmus. Anorexia is complete but there is great thirst. Weakness, recumbency, and hyperirritability are present. Respiration is rapid with panting and there is a profuse sometimes blood-stained nasal discharge. In adult cattle severe anemia and septicemia occur.

Generally, if the animal survives this period, there is a **long period of convalescence,** which is accompanied by failure to make normal weight gains, alopecia, sterility, and lenticular defects. The sterility may be permanent, or normal fertility may be restored by the end of 8 months in pigs and 2 years in cattle. During the ensuing years, recovered animals may produce mutant offspring. Tumors, especially of the hemopoietic system and of areas of skin that suffer radiation injury, are also likely to occur.

Experimental irradiation of pregnant animals causes fetal death and resorption, defects of individual organ and limb development, decreased survival of young born alive, and depressed growth rate and fertility of surviving young. The type of abnormality depends on the stage of pregnancy at which exposure is experienced.

Chronic Exposure

Chronic exposure to gamma and mixed neutron-gamma radiation for several years produces lenticular opacities. Levels of irradiation that cause lesions in the human lens are the same levels that create similar opacities in the lens of cattle, but are not the same for pigs or burros.

CLINICAL PATHOLOGY

In cattle receiving median somatic doses, the **total leukocyte count** falls precipitately during the first few days after irradiation with the peak of fall at the 15th to 25th post-irradiation (PI) day. In this species, the most sensitive leukocyte is the **neutrophil**, in contrast to the lymphocyte, which is most seriously affected by irradiation in humans.

Platelet counts begin to decrease from a normal of 500,000/mm on PI day 7 to 40,000/mm at about PI day 21.

Erythrocyte counts and hematocrit levels also fall and prothrombin times increase in parallel to the other changes mentioned. The return to preirradiation levels requires about a year for granulocytes and platelets and from 4 to 5 years for agranulocytes.

NECROPSY FINDINGS

Gastroenteritis, varying from hemorrhagic to ulcerative, is constant and ulceration of the pharyngeal mucosa and pulmonary edema occur commonly. Hemorrhages into tissues are also characteristic and include all degrees from petechiae and ecchymoses to hematomas and large extravasations. In experimentally produced irradiation sickness, severe fibrinous pneumonia, pleuropneumonia, and pericarditis are common. Degeneration of many tissues, but especially bone marrow, intestinal mucosa, and lymphoid tissue, is evident histologically. Evidence of secondary bacterial invasion is usually seen. Confirmation of the diagnosis usually requires documentation of exposure to radiation.

Samples for Confirmation of Diagnosis

Histology samples from the jejunum, lymph node, and bone marrow are used for confirmation.

DIFFERENTIAL DIAGNOSIS

The subacute syndrome closely resembles poisoning by bracken fern in cattle and by trichloroethylene-extracted soybean meal, but the diagnosis will usually depend on a knowledge of exposure to irradiation.

CONTROL

The problems of veterinary civil defense in the event of thermonuclear warfare are too extensive to discuss here, and the necessary information is provided by most

governments. The use of clay minerals and iron-hexacyanoferrates in the feed can bind and **restrict the uptake** of radiocesium from the alimentary tract of ruminants but is impractical for widespread use. Long-term control of exposure rests can be accomplished with changes in agronomic practices.

VOLCANIC ERUPTIONS

Active and potentially active volcanic chains exist in several countries in close proximity to significant livestock production areas. Major volcanic eruptions are rare, but the experiences of the eruptions of Mount Hecla in Iceland, Mount St. Helens in the United States, the Lonquimay complex in the Southern Andes, Mount Ruape hu in New Zealand, and in Eyjafjallajokull, Iceland[1] suggest that while most are inconvenient to orderly livestock production, and usually have minimal effects on animal health, some can cause catastrophic losses of livestock, long-term destocking, and have a large economic impact. The 1991 eruption of the Vulcan Hudson in South America directly killed over one million livestock through deposition of ash on pasture resulting in severe continuing economic loss to the sheep grazing areas of Patagonia.[2] There is also the potential for volcanic ash to leach important mineral nutrients, such as sulfur, from soils, affecting productivity of grazing enterprises.[3]

Blast and Gas Damage

Volcanic eruption can result in devastation of land areas from the effects of lateral blast and pyroclastic, laval, and mudflows. Livestock losses that occur in this way can be total, but the affected areas are restricted to the immediate vicinity of the eruption. Toxic gases from the eruption may accumulate in close low-lying areas and result in the death of animals in those areas.

Ash Hazards

Significantly greater land areas can be affected by tephra fallout consisting of ash and rock fragments from the volcanic eruption. The size of the sector affected by ash fallout will be determined by the strength and direction of winds at the altitude reached by the ash column at the time of the eruption, but several thousand square kilometers can receive ash fallout varying from a light dusting to falls several centimeters in depth.

The hazards to livestock during the fallout period appear minimal, although in areas where the ash fall is heavy, there is virtually total darkness. Animals, particularly sheep, mill about excessively and some die of **suffocation** or **misadventure,** including drowning.

The immediate effect of the fallout is to blanket pastures with ash, and in heavy fallout areas taller succulents may become lodged and unavailable for grazing.[2] Livestock may be forced to graze more robust, but toxic, plant species if stored feeds are not provided, and loss from **plant poisoning** was observed following the Mount St. Helens eruption. **Hypocalcemia**, apparently resulting from food deprivation, was also observed in the immediate postfallout period with Mount St. Helens and was also recorded following the Mount Hecla eruption.

Ash fallout may have a devastating effect on insect life, and this may be followed soon afterward by death from starvation of **insectivorous avian species**. This might be misinterpreted by the public as evidence of ash toxicity.

Toxic Chemicals

Potential hazards to livestock health exist in the chemical composition of ash. In the fallout from Mount St. Helens and from Mount Ruapehu several potentially toxic heavy metals and trace elements were present, but none in a concentration sufficient to be a hazard to livestock health. During the airborne stage, wind sorting of the dust into particles of varying size, shape, and density results in area variation in the composition of the fallout. Consequently, area variations in chemical analysis over the fallout area can occur. Analyses based on acid-leachable or water-soluble analysis are more relevant to immediate animal health than those reporting total content.

Death resulted from acute **fluorine poisoning** in association with high fluoride levels in ash and ash-contaminated grasses and water in the period immediately following the Mount Hecla, Lonquimay, and other eruptions.[4,5] It is therefore advisable to remove livestock from ash-contaminated pastures until this hazard is determined. In most circumstances, this will necessitate removal to indoor housing and ***feeding of stored feed and well water if they are available.***

Physical Properties

The ash particulate count in air and the respiratory exposure to livestock is highest during the fallout period, but can remain high for long periods following the fallout when ground ash is disturbed by animal movement, winds, and normal farming practices. A significant proportion of this material is of **small particulate size** and is **respirable**. Chemical and/or physical irritation of the respiratory tract, with a significant increase in the prevalence of respiratory disease, might be expected in these circumstances. This did not occur following the Mount St. Helens eruption, even in animals with known preexisting respiratory disease, and it was not a reported problem following the eruption of Mount Hecla. Signs of irritation such as lacrimation were observed widely but with no untoward sequelae.

Long-Term Effects

Volcanic ash is composed predominantly of pumiceous volcanic glass and crystalline mineral silicates such as feldspar. These materials have no innate pulmonary toxicity. Volcanic ash may also contain variable amounts of free crystalline silica such as quartz, cristobalite, and tridymite which, if present in respirable-sized particles for prolonged exposure periods, can induce pulmonary fibrosis.

Silicosis is primarily a human health concern, although spontaneous silicosis is recorded in livestock. While it is a concern with all eruptions, the long-term health history of animals and man following volcanic eruptions suggests this hazard is minimal.

In the vicinity of Mount St. Helens there have been two appreciable effects on livestock health:

- There has been a marked increase in the incidence of **hypomagnesemia** in cattle in the semiarid channeled scab lands of central Washington. This has possibly resulted from the reflective nature of the ash layer on the soil reducing soil temperature increase during early grass growth and thus reducing magnesium uptake. Grass magnesium concentrations are low and potassium levels are high, but there are no preeruption values for comparison.
- There has been an increase in the severity of **selenium deficiency**. The association between selenium deficiency and recent volcanic origin soils is well recognized. Problems have been corrected by additional and more intensive selenium supplementation.

Animals might ingest considerable quantities of ash from grazing contaminated pastures or from hay subsequently prepared from these areas. There is little field evidence for disturbance of **digestive function** in livestock following the Mount St. Helens or Mount Ruapehu eruptions, and feeding trials of ash to cattle and sheep have shown no clinical or postmortem evidence of untoward effects or any depression of production except that associated with decreased feed palatability at high ash feed levels. There is evidence that long-term inhalation of volcanic gases exacerbates the lesions caused by lung worm infestation in sheep in Hawaii.[6]

BUSHFIRE (GRASS FIRE) INJURY (THERMAL BURNS)

SYNOPSIS

Etiology Thermal or smoke inhalation injury from fire

Epidemiology Large numbers of livestock with thermal burns in bush and grass (prairie) fires. Smoke inhalation injury more common in horses rescued from barn fires

Clinical findings Edema and thermal injury in skin. Upper respiratory signs in the short term and lower respiratory disease in the longer term, with smoke inhalation

Treatment Palliative local therapy, fluid therapy to prevent shock with superficial thermal injury. Maintenance of airway and lower respiratory function with smoke inhalation. The major dilemma with treatment is the conflict between the welfare of the animals and the responsibility to the owner.

ETIOLOGY

Heat, carbon monoxide, and toxic gases are the cause of injury and death in fires. Most fire victims have thermal burns. The treatment of burns is usually a surgical subject, but there are aspects of bushfire or forest fire injury that warrant discussion in a textbook of large-animal medicine. For example, when large numbers of animals are affected the most important questions are whether to treat them and what to treat them with. Alternatively, if they are not to be treated a decision must be made as to whether they are humanely destroyed or salvaged for meat. When large numbers of animals are burned there is also often a problem with pastures and supplementary feed, such as hay, being destroyed by the fire. There is also a moral conflict for the veterinarian between the welfare of the animals and his or her responsibility to the owner.

EPIDEMIOLOGY

Forest Fires

Although no written information is readily available about forest fires in softwood forests it is assumed that few animals would survive the suffocating effects of intense heat and high smoke concentration. The intensity of the heat arises from the fact that the entire forest from leaves to trunks is burned.

In hardwood forests, such as eucalyptus forests in Australia, the heat may not be so severe if only the tops of the trees are destroyed. Underbrush is burned but the tree trunks may only be scorched and usually survive to regrow. Depending on the density of the forest and the amount of underbrush, many badly burned animals may survive and will need to be assessed. The most severe burns are on the lower surfaces and undersurfaces of the body and are caused by burning of the litter on the forest floor.

Grass Fires

The most serious situation is caused by a grass or prairie fire which, because of the short period of intense heat generated by the wind-driven fire, will burn but not necessarily kill animals. The fires can be extensive and involve contingent farms and large numbers of animals. Many animals will die of suffocation, especially sheep, but a majority will often survive with various states of burn injury.

Barn Fires

Animals may die of carbon monoxide poisoning and asphyxiation, or be burned all over, but some may be rescued without burns but with the risk of smoke-induced respiratory injury. Animals trapped, but subsequently rescued, in barn fires are usually horses.

There are a number of problems for veterinarians created by a large number of burned livestock:

- National or regional disaster services are usually responsible for dealing with the damage to property and welfare problems of humans. They are often poorly equipped to deal with animal problems, yet assume authority over their fate in the temporary absence of the owners. The normal reaction of the average person is to judge that burn injuries are much more serious than in fact they are, hence many burned animals are often unnecessarily destroyed.
- Facilities for penning and treating burned animals will often have been partially or completely destroyed by the fire, so mustering to inspect the affected animals may need improvised or temporary yards.
- The presence and amount of insurance also exerts an influence on the owner's decision on the course to be followed. If most livestock are protected by fire insurance there will be no argument with a veterinarian's decision that severely burned animals should be immediately destroyed for humane reasons.
- Salvage for slaughter is often difficult to arrange at short notice for such large numbers and often has logistical problems in the form of burned yards and fencing. Public sentiment is also often against this practice, and the quality of meat from burned animals can be severely downgraded. However, subsequent slaughter must be kept in mind as an option for animals that will have impaired functions because of burns, such as ewes and cows with teat injuries and rams and bulls with preputial and scrotal burns.

CLINICAL FINDINGS

Burn Injury

The parts most affected by burning are the face, especially the eyelids; conjunctivae and lips; the undersurface of the body, especially udder, teats, and perineum; and the coronets. Badly damaged corneas take many weeks to heal, but badly swollen lips and eyelids can appear almost normal within 48 hours. Marked edema is always a feature of skin burns in animals, but badly burned skin will be dry and ready to slough in a week.

The teats of dairy cows may be damaged to the point where they will not be milkable by machine, with heifers usually having the worst prognosis. Burns to the prepuce of wethers and rams may induce urethral obstruction. This will usually not be apparent until some days later; thus reinspection of groups assessed as not needing immediate destruction should always be a priority.

Separation of the coronary band from the hoof is commonly seen after burns from grass fires. There is usually a serous exudate at the separation of the hoof and coronet, which can become struck by blowflies. Footbathing in appropriate insecticides, which may be an off-label use, can effectively prevent or treat strikes. Sloughing of the entire hoof may occur, especially following fires that generate intense heat, and secondary infections can exacerbate these lesions.

TREATMENT

Decision Criteria

An accurate assessment and prognosis for survival is essential if suffering is to be kept to a minimum, while at the same time allowing as many livestock that can be economically salvaged the chance to recover. The extent of burns varies widely, depending on the nature of the fire and location of individuals within a mob of sheep or cattle as the fire passes. Except for recently shorn sheep, the fleece, although charred, protects the sheep's body from intense heat. Critical areas for burns are the bare areas of skin, such as on the legs, udder, and breech.

Burned skin is inflamed and hot immediately after the fire, then blackens over the next 2 to 3 days and goes hard and dry, with a leathery feel. Thus burns inspected within 24 hours of a fire will appear progressively worse over the next few days.

A major decision must be made at the outset whether to treat each affected animal or whether to destroy it on humane grounds. This decision is more easily made when assessing individual animals rather than mobs or whole flocks/herds.

Recommended criteria for deciding the fate of sheep burned by pasture fire depend

Table 4-1 A simple method of categorizing livestock affected by burns and appropriate actions for each category

	Prognosis	Action
Group 1	Survival unlikely	Immediate humane destruction. If large numbers they are usually shot and buried in a pit.
Group 2	Better than a 50–75% chance of survival	Treat and monitor in smaller paddocks on the farm; check every 1–2 days for dyspnea and recumbency; some may need to be subsequently destroyed and/or some sent for salvage slaughter at an abattoir; remainder retained in flock
Group 3	Minimal skin damage: often scorched wool and face/ears (check feet)	Minimal supervision; let out into a larger paddock and check for dyspnea and lameness (initially at 4–7 days)

on the presence of burns to the hooves and legs below the carpal and tarsal joints, which cause local swelling and a dry leathery appearance of the skin. Such sheep are often recumbent or immobile, unable to graze, and likely to die and should be humanely destroyed as soon as practicable. Burns that do not cause swelling of the lower limbs, or to other parts of the body, are not likely to be fatal or to produce chronic ill health, unless they affect a large part (more than 15% to 20%) of the body surface. A simple key for categorizing large numbers of sheep into three groups after a fire is shown in Table 4-1.

Animals that are unconscious or very distressed, cannot walk, or have severe difficulty in breathing are poor prospects for recovery and are best euthanized as soon as possible. It may be necessary to monitor sheep after a fire before deciding what to do with them. Several reinspections of a mob at 7 to 14 days, and then progressively longer intervals, may be required. It is necessary at all times to consider the need to avoid inflicting suffering on the animals and to consider the farmer's need to retrieve his assets and recover his business after the fire. If the animals are insured against fire it is also highly desirable to keep written records and advise the insurer of what recommendations have been made.

Animals that have been trapped in a burning building are likely to be burned all over and to have upper and lower respiratory damage from smoke inhalation. With individual animals of high value, bronchoscopy can aid in establishing the severity of this injury. Burning insulation and material from the ceiling can fall on animals and inflict severe (third-degree) burns along the back.

The disposal of euthanized livestock also requires appropriate planning. In large events this is often in a pit constructed by local authorities on the farm or on nearby public land.

Skin Burns

Extensive skin burns are accompanied by fluid shifts, vascular leakage, protein loss, and the potential for hypovolemia. The initial therapy is with crystalloid and colloid fluids as discussed earlier. Tetanus prophylaxis and topical antibiotics, silver sulfadiazine, and aloe vera gel are appropriate therapies. Nonsteroidal antiinflammatory agents can decrease the inflammatory response and help in pain management, but glucocorticoids may potentiate burn sepsis and so prophylactic antibacterial treatments are often advisable. In horses, euthanasia is recommended if greater than 50% of the body surface is affected.

Smoke Inhalation

Tracheostomy may be required to maintain the upper airway. Bronchodilators such as aminophylline or terbutaline sulfate are used to relieve reflex bronchoconstriction and humidified oxygen and local hydration by fluid nebulization to relieve hypoxemia. Corticosteroids are used to reduce airway inflammation in animals with minimal cutaneous burns.

Diagnosis of Inherited Disease

Genetic disorders are a small but important cause of wastage in farmed animals and, with increasing access to genomic analysis and technology, are more readily recognized and categorized. Most occur in purebred animals and the simplest to understand and control are inherited as autosomal recessive traits with a clear phenotype and expression in the young animal. The recessive mode of inheritance means that heterozygotes can, in the absence of available testing, remain in the population, with disease only occurring when homozygous-affected animals are produced as a result of mating of heterozygous parents. An example of this situation is that of severe combined immunodeficiency syndrome in Arabian foals.

Dominant disorders tend to be self-limiting because of lack of viability of affected offspring or because affected animals are readily identified and excluded from the breeding pool.

A more complex situation is when heterozygotic animals have characteristics that are desired and when the homozygotic animal is severely or lethally affected. In this situation there is an imperative to select for the mutation by breeding desired heterozygotes. An example is Quarter Horses with hyperkalemic periodic paralysis (see Chapter 15) in which the heterozygote is favored because it performs better in halter class competitions. Another example is in the original Dexter cattle in which the slightly dwarfed Dexter phenotype is dominant to the normal and is selected for. Animals homozygous for the gene abort with a nonviable "bulldog" type fetus. Sex-linked disorders may occur but are uncommon. Some monogenic disorders may arise de novo because of new mutations of germ plasm. Those with a dominant mode of inheritance are present in offspring of the animal in question, usually affecting genes for structural proteins such as collagen. A new mutation should be considered with disorders such as osteogenesis imperfecta or skin fragility. The proportion of offspring with the defect may vary depending on what stage of gametogenesis the mutation occurred.

Inbreeding, knowingly or unknowingly practiced, is an important feature in the manifestation of most outbreaks of a recessive disorder. Founder effect is an aspect of this that has been important when new breeds have been introduced to a country by importation of genetic material from a small number of individuals. Artificial breeding on a large and international scale has sometimes exacerbated this, particularly in cattle but also in horses.

Genetic disorders can be manifested as disease or bodily malformation. When diagnosed, an entity may reflect the tip of an iceberg only, and it can be expected that many other cases go undiagnosed. Spread across an industry their economic importance may be limited, but as particular disorders tend to be concentrated in certain herds/flocks they may have considerable importance to an individual breeder, particularly those involved with pedigree breeding. Animal welfare is also a concern to be

addressed, which is driven by a greater awareness of ethical standards in livestock production and by potential market access requirements.

The advent of genome-wide association studies has allowed the detection of polygenic associations with production traits or propensity for disease.[1-3] Examples include double muscling in Belgium Blue cattle,[3] recurrent laryngeal neuropathy[4-7] and guttural pouch tympany in horses,[7] and mastitis[2] and resistance to mycobacterial disease in cattle.[2] Although these analyses are useful, the emphasis on genetic disease remains the determination of associations with mutations in single genes. This situation is changing as more complex genomic analyses become more widely available.

The two main problems for the clinician investigating a suspected inherited disorder are to confirm a primary genetic cause and then to institute control in a cost-effective manner.

DIAGNOSIS

For a number of inherited diseases or malformations known to occur in a breed, morphology or histopathology may be so characteristic as to be essentially pathognomonic. However, for some disorders environmental agents (teratogens) may cause similar morphologic anomalies, e.g., arthrogryposis, so care should be taken. Pedigree analysis may help if there are sufficient animals of known breeding to show that the incidence of the disorder follows a Mendelian pattern. However, in many herds/flocks animals may be closely related and pedigree analysis can sometimes be misleading and produce a fictitious relationship between inheritance and disease. As the biochemical anomaly is now known for many diseases, or perhaps can be deduced from histopathologic lesions, laboratory tests may confirm a presumptive diagnosis. Test mating of a sire to daughters, related females, or females that have given birth to an affected animal is the ultimate confirmation of the genetic nature of a disorder, provided the appropriate numbers of progeny are generated. Disproving a genetic cause of a disorder may be as important as proving it. Matings of a sire to produce a minimum of 24 progeny from his daughters or 12 from putative heterozygotes (females that have given birth to affected individuals) are usually considered satisfactory numbers to exclude a likely inherited cause if no affected individuals are born ($P < 0.5$). The birth of a proportion of affected offspring is strong evidence of inheritance. The use of superovulation and embryo transfer techniques may facilitate this, particularly if insufficient daughters or putative heterozygotes are available. The time to accomplish this may be decreased by caesarian section of the surrogate dams if the defect can be detected in the fetuses.

The degree of inbreeding is an important indicator of whether a congenital disorder is inherited or not. Consistency of the defect is a characteristic of inherited disorders, but there may be some variation in age of onset or expressivity of lesions. Other epidemiologic factors include the occurrence of the defect over more than 1 year and occurrence or repetition of it in the same mating group, but not in others on the property.

CONTROL OF INHERITED DISEASE

Appropriate control measures may vary, depending on the importance of the disorder, and may be aimed at the herd/flock level or at the breed as a whole. It may be prospective but, at the farm level, it is mainly reactive with the purpose of preventing further losses by immediate action. This should include not breeding from putative heterozygous sires or females that should preferably be culled. Replacement sires are best acquired from another breeder but, if the defect is common in the breed, then the risk may remain and crossbreeding with a sire from another breed may be considered if the type of farm operation permits it. If a test is available for detecting heterozygous animals then this can be used in new sire selection.

Control of genetic disorders in pedigree herds is more complex and to be effective depends on ability to detect heterozygotes or prove animals do not carry the recessive gene in question. Test mating is time-consuming, expensive, and of limited application. The explosion of knowledge concerning the biochemical and molecular genetic basis of inherited diseases across species has opened up effective means of diagnosing genotype for many of them. Control may be at an individual herd/flock level or applied to all at risk. It is best instigated with the help of breed societies who may exert control over the fate of animals diagnosed as heterozygous through control of registrations. Apart from the accuracy of genetic tests in genotype diagnosis, there is the added advantage that particularly valuable animals may be kept within the herd/flock for breeding because their offspring can in turn be tested as normal or heterozygous.

The first generation of tests for heterozygotes was biochemical based on knowledge of the enzyme deficiency and the gene dosage phenomenon. Heterozygous animals with one normal and one mutant gene have enzyme values midway between normal and diseased values, although there may be some overlap. Supplementary tests or knowledge of the parents' genotype may assist with clarification of equivocal results. Such tests were used to control the economically important lysosomal storage diseases α-mannosidosis in Angus and Murray Grey cattle in New Zealand and Australia and glycogen storage disease type II in Shorthorn and Brahman cattle in Australia. These have now given way to more accurate second-generation technology based on DNA for these diseases as well as a number of others.

The genome for the major farm species is known and genome-wide analyses now routine. When the abnormal gene or genes is known then it is much simpler to define the mutation and through molecular diagnostics detect affected or carrier animals.

Artificial breeding techniques have the capacity to spread undesirable genotypes widely before they are recognized. Many artificial breeding organizations involved in the dairy industry prospectively screen for genetic disorders by mating prospective sires over a proportion of their daughters. This is possible because of the time taken to prove a sire before he enters the industry on a large scale.

ONLINE MENDELIAN INHERITANCE IN ANIMALS

Online Mendelian Inheritance in Animals (OMIA) is a database of genes, inherited disorders, and traits in animal species (other than human and mouse) authored by Professor Frank Nicholas of the University of Sydney, Australia, with help from many people over the years.[8] The database contains textual information and references as well as links to relevant records from Online Mendelian Inheritance in Man (OMIM), PubMed, Gene, and soon to be NCBI's phenotype database.

Disturbances of Free Water, Electrolytes, Acid-Base Balance, and Oncotic Pressure

5

There are many diseases of farm animals in which there are disturbances of body fluids (free water), electrolytes, and acid-base balance. A disturbance of body water balance in which more fluid is lost from the body than is absorbed results in reduction in circulating blood volume and in **dehydration** of the tissues. In contrast, the rapid ingestion of large quantities of water can lead to overhydration (**water intoxication**).

Electrolyte imbalances occur commonly as a result of loss of electrolytes, shifts of certain electrolytes, or relative changes in concentrations caused by loss of water. Common electrolyte imbalances include hyponatremia, hypokalemia, hyperkalemia, hypocalcemia, hypochloremia, and hypophosphatemia.

Acid-base imbalances, either **acidemia** or **alkalemia**, occur as a result of the addition of acid and depletion of alkali reserve, or the loss of acid with a relative increase in alkali reserve.

Decreased **oncotic pressure** is caused by hypoalbuminemia or hypoproteinemia and results from severe gastrointestinal disease, renal glomerular disease, peritonitis, pleuritis, extensive burns, hepatic failure, chronic malnutrition, and severe starvation (increased loss of plasma protein, decreased production of plasma protein, or third spacing of plasma protein). The most common clinical sign of decreased oncotic pressure is generalized edema. Increased oncotic pressure occurs less frequently, and the most common cause is decreased free water from dehydration.

Under most conditions, disturbances of free water, electrolyte, acid-base balance, and oncotic pressure occur simultaneously, in varying degrees, depending on the initial cause. Each major abnormality will be described separately here with an emphasis on etiology, pathogenesis, clinical pathology, and treatment. However, it is important to remember that actual disease states in animals in which treatments with fluids and electrolytes are contemplated are rarely caused by single abnormalities. In most cases it is a combination of dehydration together with an electrolyte deficit, and often without a disturbance of the acid-base balance, that necessitates treatment.

Dehydration

ETIOLOGY

There are two major causes of dehydration (decrease in free water):

- Inadequate water intake
- Excessive fluid loss

Deprivation of water, a lack of thirst caused by toxemia, and the inability to drink water as in esophageal obstruction are examples of dehydration from inadequate water intake. The most common cause of dehydration is when excessive fluid is lost. Diarrhea is the most common reason for excessive fluid loss, although vomiting, polyuria, and loss of fluid from extensive skin wounds or by copious sweating may be important in sporadic cases. Severe dehydration also occurs in acute carbohydrate engorgement in ruminants, acute intestinal obstruction and diffuse peritonitis in all species, and in dilatation and volvulus of the abomasum. In most forms of dehydration (deprivation of drinking water being an exception), the serious loss, and the one that needs correction, is not the fluid but the electrolytes (Fig. 5-1).

The ability to survive for long periods without water in hot climates represents a form of animal adaptation that is of some importance. This adaptation has been examined in camels and in Merino sheep. In the latter, the ability to survive in dry, arid conditions depends on a number of factors, including the insulating ability of the fleece, the ability to carry water reserves in the rumen and extracellular fluid space, the ability to adjust electrolyte concentrations in several fluid locations, the ability of the kidney to conserve water, and the ability to maintain the circulation with a lower plasma volume. Dehydrated mammals in hot environments can save water by reducing the rate of panting and sweating and regulating body temperature above hydrated levels. Sweating is a significant avenue of evaporative heat loss in goats when they are hydrated and when exposed to high ambient temperatures above 40°C.

Observations of drinking behavior of cattle transported to the abattoir indicate that those animals that had been sold in livestock markets before arrival at the abattoir are thirstier and more tired than cattle sent directly from farms. This indicates inadequate water intake and dehydration.

PATHOGENESIS

Two factors are involved in the pathogenesis of dehydration:

- Depression of tissue water content with resulting interference in tissue metabolism
- Reduction in the free water content of blood

The initial response to negative water balance is the withdrawal of fluid from the tissues and the maintenance of normal blood volume. The fluid is drained primarily from the intracellular and interstitial fluid spaces. Essential organs, including the CNS, heart, and skeleton, contribute little and the major loss occurs from connective tissue, muscle, and skin. The loss of fluid from the interstitial and intracellular spaces results in loss of skin elasticity, dryness of the skin and mucosa, and a reduction and retraction of the eyeball (enophthalmia) caused by reduction in the volume of the postorbital fat deposits. In the goat, total body water may be reduced as much as 44% before death occurs.

The secondary response to continued negative water balance is a reduction in the fluid content of the blood causing a reduction in circulating blood volume (**volume depletion**) and an increase in the concentration of the blood (**hemoconcentration**). Because of the hemoconcentration, there is an increase in the viscosity of the blood, which impedes blood flow and may exacerbate peripheral circulatory failure. The loss in circulating blood volume also contributes to the mental depression of dehydrated animals, which is

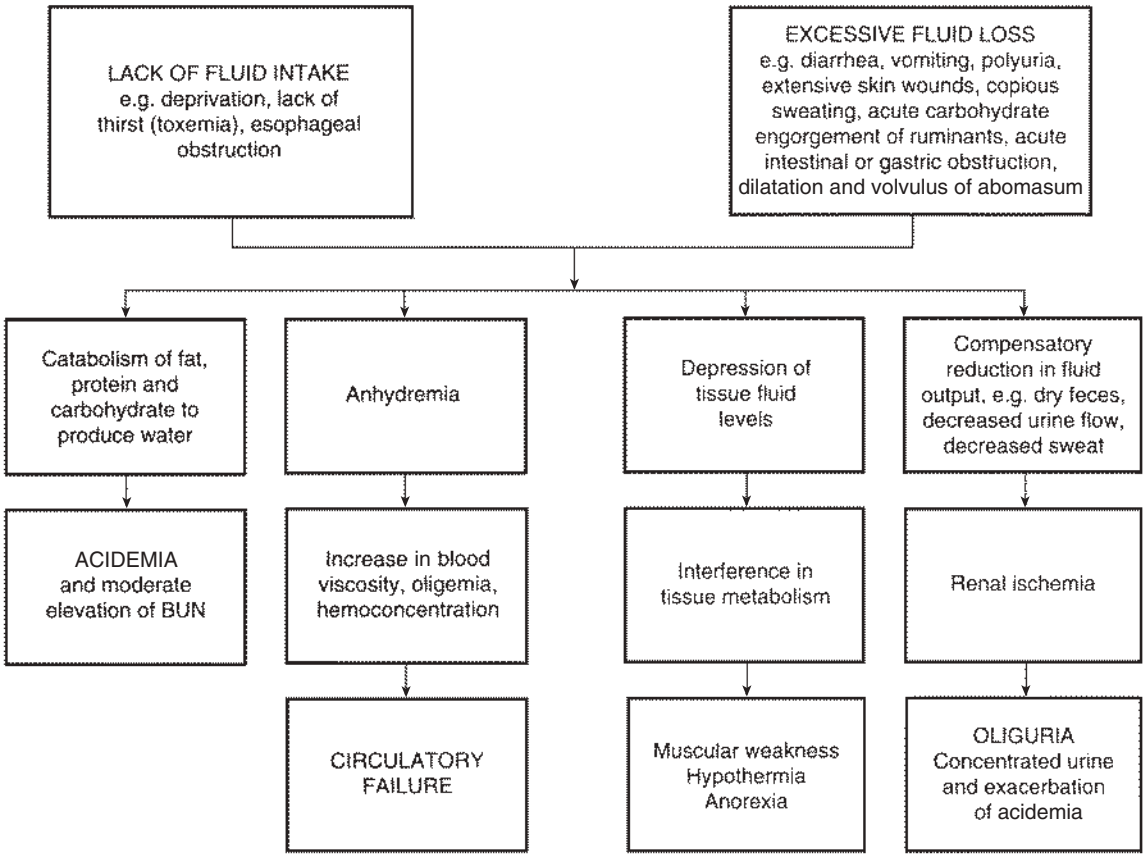

Fig. 5-1 Etiology and pathogenesis of dehydration.

also caused by varying degrees of acidemia and toxemia depending on the cause of the dehydration. In deprivation of water and electrolytes or in deprivation of water alone or inability to consume water in an otherwise normal animal (e.g., esophageal obstruction), the dehydration is minimal because the kidney compensates effectively by decreasing urine output and increasing urine osmolality. In addition, water is preserved by reduced fecal output and increased absorption, which results in dehydration of the contents of the rumen and large intestine, which in turn results in dry, scant feces.

In calves with acute diarrhea there is increased fecal output of water compared with normal calves, but the total water losses are not much greater than in normal calves. In the diarrheic calf the kidney compensates very effectively for fecal water loss, and the plasma volume can be maintained if there is an adequate oral fluid intake. Urine excretion decreases, the urine becomes progressively more concentrated, and the renal insufficiency may accentuate preexisting acidemia and electrolyte imbalance, hence, the importance of restoring renal blood flow and renal function. The newborn calf is able to concentrate urine at almost the same level as the adult. This illustrates the importance of oral fluid and electrolyte intake during diarrhea to compensate for continuous losses. However, it is possible for metabolic acidosis to occur in diarrheic calves and goat kids that are not dehydrated.

Goats are more sensitive to water deprivation during pregnancy and lactation than during anestrus. Water deprivation for 30 hours causes a marked increase in the plasma osmolality and plasma sodium concentration in pregnant and lactating goats, which drink more than goats in anestrus.

The dehydration in horses used for endurance rides is hypotonic, in which both sodium and water are lost through sweating. This may account for the lack of thirst in some dehydrated horses with exhaustion syndrome. Weight losses of 10 to 15 kg/h may occur in horses exercising in high environmental temperatures exceeding 32°C (89°F), and a horse weighing 450 kg can lose 45 L of fluid in a 3-hour ride.

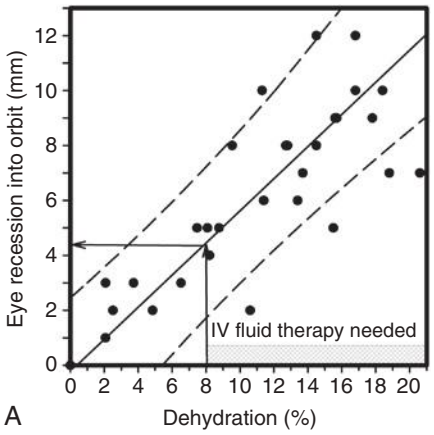
Dehydration exerts important effects on tissue metabolism. There is an increase in the breakdown of fat, then carbohydrate, and finally protein to produce water of metabolism. The increased endogenous metabolism under relatively anaerobic conditions results in the formation of acid metabolites and the development of metabolic acidosis. Urine formation decreases because of the restriction of renal blood flow and this, together with the increased endogenous metabolism, causes a moderate increase in plasma concentration of urea nitrogen. The body temperature may increase slightly initially (as in dehydration hyperthermia) because of insufficient fluid to maintain the loss of heat by evaporation. The onset of sweating in steers after exposure to high environmental temperatures has been shown to be delayed by dehydration.

Dehydration may cause death, especially in acute intestinal obstruction, vomiting, and diarrhea, but it is chiefly a contributory cause of death when combined with other systemic states, such as acidosis, electrolyte imbalances, toxemia, and septicemia.

CLINICAL FINDINGS

The first and most important clinical finding in dehydration is **dryness** and **wrinkling of the skin**, which gives the body and face a shrunken appearance. The eyes recede into the sockets, and the skin subsides slowly after being picked up into a fold. The dehydration is usually much more marked if water and electrolyte losses have been occurring over a period of several days. Peracute and acute losses may not be obvious clinically because major loss will have occurred from the intravascular compartment and only minor shifts have occurred from the interstitial spaces. Sunken eyes and inelastic skin are not remarkable clinical findings of dehydration in the horse.

The best indicator of hydration status in dairy calves has been demonstrated to be the **degree of recession of the eye into the orbit**.



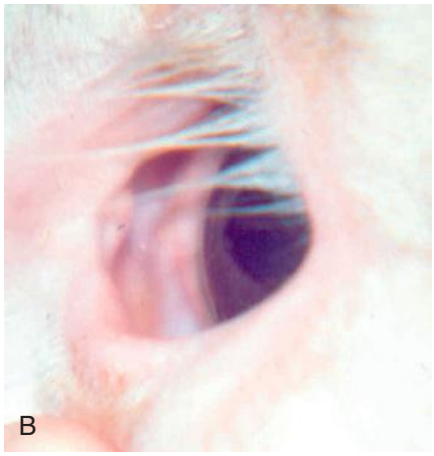


Fig. 5-2 **A,** Association between eye recession into the orbit and dehydration as a percent of body weight in milk-fed calves with experimentally induced diarrhea and dehydration. The filled circles in the left panel are individual data points, the solid line is the linear regression line, and the dashed lines are the 95% confidence interval for prediction. Intravenous fluid is recommended when dehydration is estimated at 8% or more of body weight, equivalent to an eye recession into the orbit of 4 mm or more. **B,** The calf has an 8-mm eye recession into the orbit, equivalent to being 14% dehydrated. (Reprinted with permission from Constable PD et al. *J Am Vet Med Assoc* 1998;212(7):991-996.)

Hydration status is assessed by gently rolling the lower eyelid out to its normal position and estimating the distance of eye recession in millimeters. This distance is multiplied by 1.7 to provide an estimate of the degree of dehydration as a percentage of euhydrated body weight (BW; Fig. 5-2). The second best indicator of hydration status in calves is the elasticity of the skin of the neck and lateral thorax, which are assessed by pinching the skin between the fingers, rotating the skin fold 90°, and noting the time required after release of the skin fold for the skin fold to disappear (normally <2 s). The elasticity of the skin fold on the upper or lower eyelid is a poor indicator of hydration status in calves and is not recommended. The best method for assessing hydration status in adult cattle and other large animals has not been determined, but it is likely that eye recession and skin tent duration in the neck region provide the most accurate and sensitive methods for estimating hydration status. The presence or absence of mucous membrane moistness may provide a sensitive indication of dehydration in dairy calves, but it was not useful as a predictor of hydration status in Brahman-cross calves housed in a hot environment.[1] Hydration status may also be more difficult to clinically evaluate in sheep.[2]

In diarrheic calves, the severity of dehydration, hypothermia, and metabolic acidosis are associated with the degree of mental depression. The combined effects of acidemia and dehydration also contribute to hypothermia.

Loss of BW occurs rapidly in dehydration, and muscular weakness and inappetence or anorexia is common. In horses deprived of water for 72 hours there is a mean BW loss of about 15%, and 95% of the animals have a urine specific gravity of 1.042, a urine osmolality of 1310 mOsm/kg, and a urine osmolality/serum osmolality ratio of 4:14. Prerenal azotemia also develops.

The degree of thirst present will depend on the presence or absence of other diseases causing an inflammatory response or endotoxemia. In primary water deprivation, dehydrated animals are very thirsty when offered water. In dehydration secondary to enteritis associated with severe inflammation, acidemia, and electrolyte imbalance there may be no desire to drink. Horses that become dehydrated in endurance rides may refuse to drink, and the administration of water by oral intubation and enemas may be necessary. In cattle on pasture and deprived of water for up to 9 days and then given access to water, there will be staggering, falling, convulsions, and some death—signs similar to salt poisoning in pigs. Experimental restriction of the water intake in lactating dairy cattle for up to 4 days may reduce milk yield by 75% and decrease BW by 14%. A 10% reduction in water intake causes a drop in milk production that may be difficult to detect. Behavioral changes are obvious: cows spend considerable time licking the water bowls. In cold climates, cattle are often forced to eat snow as a source of water. The snow must be soft enough so that it can be scooped up by the cattle and 3 to 5 days are necessary for the animals to adjust to the absence of water and become dependent on snow. During this time there is some loss of BW. Lactating ewes relying on snow as a source of free water reduce their total water turnover by approximately 35%.

CLINICAL PATHOLOGY

Dehydration is characterized by an increase in the packed cell volume (PCV) and total serum protein concentration, although the latter response may be modified by the presence of severe enteritis, peritonitis, or proteinuria.

Water Intoxication

SYNOPSIS

Etiology Rapid ingestion of large quantities of water

Epidemiology Access to water by thirsty calves, or calves that have been marginally deprived of water for some time

Clinical findings Dark red urine, weakness, and depression

Clinical pathology Hemoglobinuria, hemoglobinemia, hypoosmolality, hyponatremia, and hypochloremia

Necropsy findings Hemoglobinuria and renal cortical necrosis

Diagnostic confirmation Epidemiologic, presence of hyponatremia and hypochloremia; rule out other causes of intravascular hemolysis

Treatment Time, possibly intravenous hypertonic saline but usually too late to be effective

The rapid ingestion of large amounts of water by young calves with normal serum sodium concentrations may result in intravascular hemolysis, hemoglobinemia, and hemoglobinuria. In contrast, water ingestion in hypernatremic animals may result in cerebral edema, but it does not produce hemoglobinuria. The cerebral edema syndrome is described in sodium chloride poisoning. Water intoxication (acute overhydration) is described here.

ETIOLOGY

The ingestion of excessive quantities of water when animals are very thirsty may result in overhydration, which is also called water intoxication. The primary cause of acute overhydration is a rapid decrease in the osmolality of the small intestinal contents, which are normally isotonic to plasma. Such a rapid decrease in luminal osmolality occurs within 5 minutes of water ingestion because thirsty calves close their esophageal groove when drinking. This results in a large volume of water in the abomasum, which is subsequently emptied into the duodenum. Free water rapidly moves from the small intestinal lumen into the intravascular compartment because of the large surface area for absorption in the small intestine and development of an osmotic gradient between the small intestinal lumen and intestinal capillary bed. The end result is a rapid decrease in plasma osmolality and expansion and rupture of erythrocytes, leading to intravascular hemolysis, hemoglobinemia, hemoglobinuria, hyponatremia, hypochloremia, and a decrease in plasma protein concentration from preingestion.

EPIDEMIOLOGY

The syndrome has been reported from several countries but is uncommon. Calves 2 to 4 months of age are most commonly affected, but the disease is also recorded in adult cattle, sheep, and pygmy goats. Water intoxication occurs in calves in normal husbandry systems when animals that have had limited access to water are suddenly given free access. Commonly water intoxication occurs when calves previously fed a milk-replacer diet but no other fluid, or weaned calves that have been on a starter diet but limited water, are turned out to pasture or to yards where water is freely available. Calves that are not fed supplementary salt or that have lost salt as a result of severe exercise or high environmental temperatures may be at higher risk, but the syndrome also occurs where salt has not been restricted. The majority of calves show clinical signs within minutes to hours of access to water.

The condition has been reproduced in calves by gavage with water at 12% of BW.

CLINICAL FINDINGS

Hemoglobinuria as a result of intravascular hemolysis is prominent, and there may be a moderate to severe hemolytic anemia. Dark red urine is passed shortly following access to water. Additional signs include tachycardia and hypothermia if the temperature of the water ingested is below body temperature. Affected animals are usually depressed and weak. (Fig. 5-3)

CLINICAL PATHOLOGY

Hemoglobinuria and hemoglobinemia are evident and there is hypoosmolality, hyponatremia, and hypochloremia. Serum total protein and albumin concentration may be decreased, but are usually within the normal range, because animals are usually mildly dehydrated and thirsty before ingesting large volumes of water.

Fig. 5-3 Hemoglobinuria in a Holstein–Friesian heifer calf that had not been provided free access to water. The calf voluntarily drank 5 L in 5 minutes and voided red-tinged urine (on floor and in white container) 30 minutes later.

Postmortem Findings

Marked pallor of the carcass and renal cortical necrosis caused by hemoglobinemic nephrosis may be evident histologically.

DIFFERENTIAL DIAGNOSIS

- Other causes of intravascular hemolysis and hemoglobinuria

TREATMENT

Treatment of affected animals is usually not attempted because hypoosmotic lysis has already occurred when clinical signs have manifested, and serum osmolality is usually gradually increasing as the distal convoluted tubules eliminate excessive free water. Hypertonic saline (7.2% NaCl, 5 mL/kg BW over 5 minutes intravenously) is usually administered to correct the hyponatremia and hypochloremia, but treatment is not necessary in mild cases. Case fatality is low, and hemoglobinuria persists for only a few hours.

CONTROL

Water intoxication is not common and can be avoided by preventing thirsty animals from having unlimited access to water. Calves should have free access to water as soon as they are born.

Electrolyte Imbalances

Most electrolyte imbalances are caused by a net loss of electrolytes associated with diseases of the alimentary tract. Sweating, excessive salivation and vomiting, and exudation from burns also result in electrolyte losses, but are of minor importance in farm animals, with the exception of sweating in the horse and dysphagia in ruminants. The electrolytes of major concern are sodium, chloride, potassium, calcium, phosphorus, and magnesium. Losses of bicarbonate are presented later.

HYPONATREMIA

Sodium is the most abundant ion in the extracellular fluid and is chiefly responsible for the maintenance of osmotic pressure of the extracellular fluid. The most common cause of hyponatremia is increased loss of sodium through the intestinal tract in enteropathies (Fig. 5-4). This is particularly marked in the horse with acute diarrhea and to a moderate extent in calves with acute diarrhea. The sodium is lost at the expense of the extracellular fluid. In calves with acute diarrhea caused by enterotoxigenic *Escherichia coli* the sodium concentration of the intestinal fluid secreted in response to the enterotoxin is similar to that of plasma, and hyponatremia usually occurs (**hypotonic dehydration**). Animals affected with diarrhea of several days' duration continue to lose large quantities of sodium, and the hyponatremia may become severe. Hyponatremia can become severe when sodium-free water or 5% dextrose are used as the only fluid therapy in animals already hyponatremic. Hyponatremia can also occur in animals with proximal tubular dysfunction.

Hyponatremia causes an increase in the renal excretion of water in an attempt to maintain normal osmotic pressure, which results in a decrease in the extracellular fluid space, leading to a decreased circulating blood volume, hypotension, peripheral circulatory failure, and ultimately renal failure. Muscular weakness, hypothermia, and marked dehydration are common findings.

Isotonic dehydration occurs when there is a parallel loss of sodium and water. **Hypertonic dehydration**, which is uncommon, occurs when there is a loss or deprivation of water with minor losses or deprivation of sodium. Hypertonic dehydration can occur in animals that are unable to consume water because of an esophageal obstruction. The dehydration in isotonic and hypertonic dehydration is mild compared with the marked clinical dehydration that can occur in hypotonic dehydration accompanied by marked loss of water and concentration of the extracellular space (Fig. 5-5).

There are no clinical signs that are characteristic of hyponatremia. There is usually dehydration, muscular weakness, and mental depression, which occur with other disturbances of both water and electrolytes and with acid-base imbalance. Similarly, there are no clinical signs that are characteristic of hypochloremia. However, hyponatremia affects the osmotic pressure of the extracellular fluid, and hypochloremia promotes the reabsorption of bicarbonate and further development of alkalosis. Polyuria and polydipsia occur in cattle with dietary sodium chloride deficiency.

Hypotonic hyponatremia results in **cerebral edema** caused by water entry to the brain; however, if hyponatremia is slow to develop, solutes can leave brain tissue at a sufficiently fast enough rate to mitigate the development of cerebral edema. Clinical neurologic sequelae of hyponatremia are primarily determined by the speed of onset of

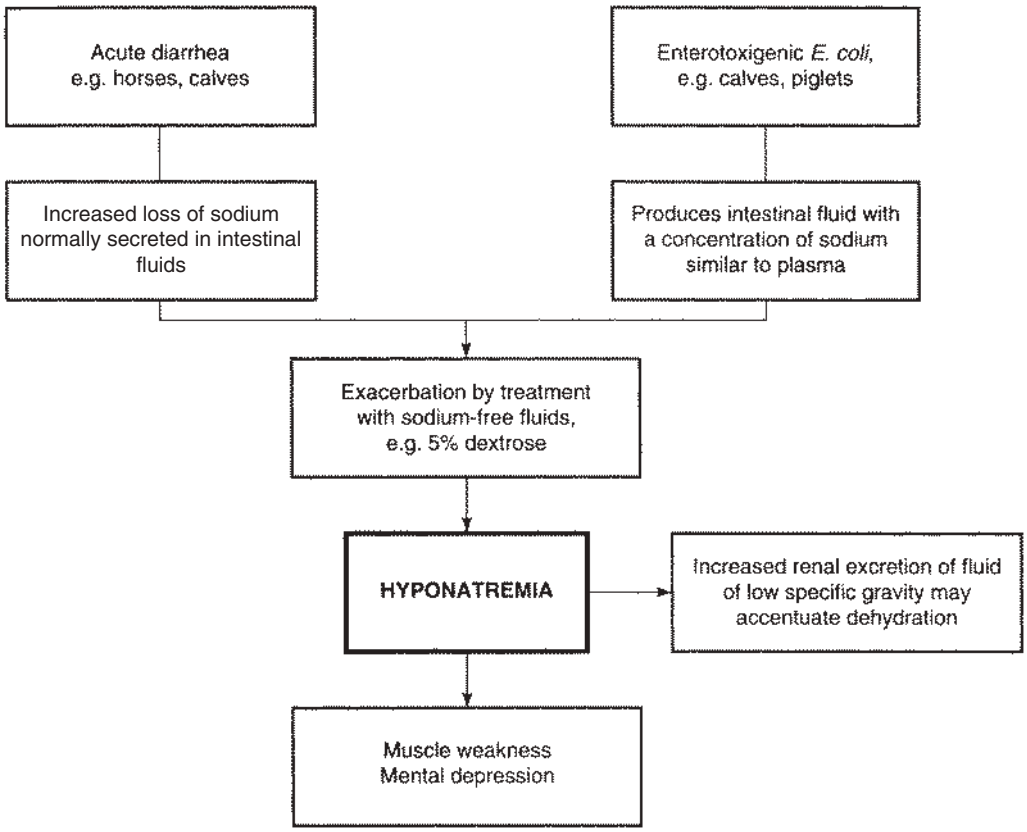

Fig. 5-4 Etiology and pathogenesis of hyponatremia.

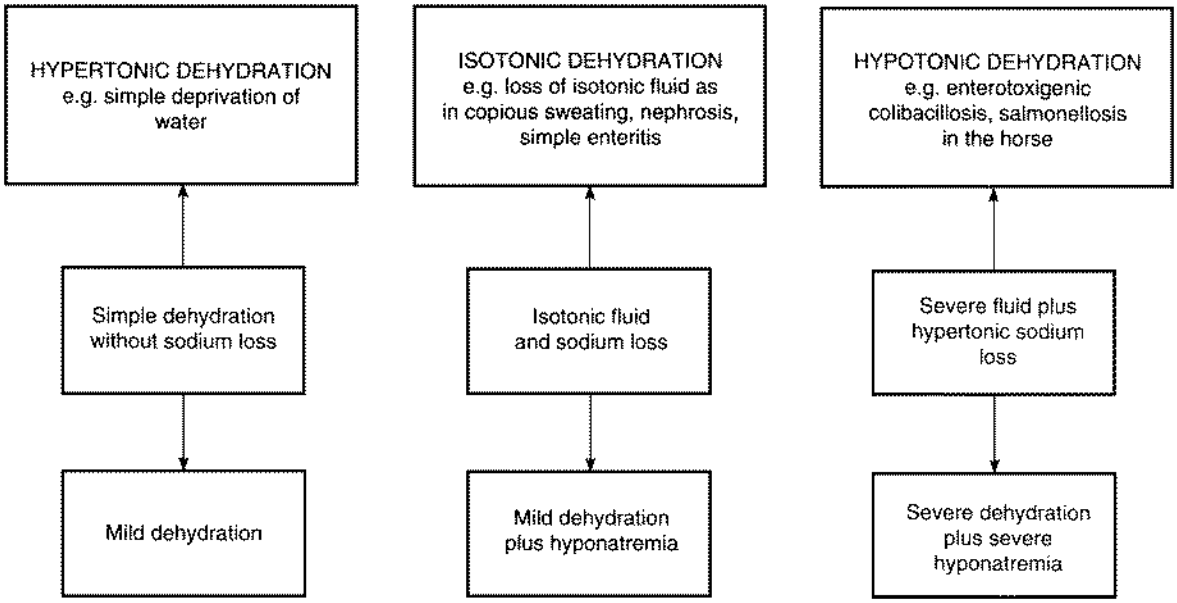

Fig. 5-5 Types of dehydration.

hyponatremia and the rapidity by which marked hyponatremia (serum sodium concentration <120 mEq/L) is corrected. Too rapid correction of chronic hyponatremia (defined as hyponatremia >48 hours) should be avoided because of the potential for **demyelination of pontine and extrapontine neurons** that can produce severe neurologic deficits. These deficits are not well described in agricultural animals, but in humans, rapid correction of chronic hyponatremia has been associated with improvement of neurologic abnormalities within 1 to 2 days, followed by the development of progressive ataxia, dysphagia, myoclonus, spastic tetraparesis, and death within 2 to 5 days. Current recommendations are to increase serum sodium concentration by 8 mEq/L/day in large animals with chronic hyponatremia. This is clinically managed by infusing 1 L of a mixture of 7.2, 5.0, and 0.9% NaCl solutions

(all commercially available), which are assumed to distribute 100% within the extracellular space.[1] To estimate the effect of 1 L of the NaCl infusate on serum sodium concentration ([Na]), the following formula is applied:

$$\begin{aligned} &Change\ in\ serum\,[Na] \\ &= (infusate\,[Na] - serum\,[Na])/ \\ &\quad (total\ body\ water + 1) \end{aligned}$$

where total body water is estimated in liters from the BW in kilograms using a standard formula of 60% BW for adult animals. With a targeted increase of 8 mEq/L over 24 hours and an infusion volume of 1 L, this equation can be rearranged to calculate the required infusate [Na] in mEq/L to be administered intravenously over 24 hours in 1 L of fluid:

$$\begin{aligned} Infusate\,[Na] = 8 \times (0.6 \times \{BW\ in\ kg\} + 1) \\ - serum\,[Na]. \end{aligned}$$

HYPERNATREMIA

Hypernatremia is most commonly caused by water restriction or mixing errors in neonatal animals, particularly in milk-replacer solutions or oral electrolyte formulations administered to neonatal calves with diarrhea as part of the treatment of dehydration. Hypernatremia appears to be increasing in North America in dairy calves fed milk replacer because milk-replacer formulations are increasingly dependent on whey from cheese manufacture, and whey has a high sodium concentration. Less common causes of hypernatremia include high-salinity water.[2] Hypernatremia occurs transiently after hypertonic saline (7.2% NaCl) administration, but serum sodium concentrations never exceed 170 mEq/L and may occasionally exceed 160 mEq/L for a few minutes. Transient episodes of mild hypernatremia caused by intravenous hypertonic saline administration are not thought to have any clinical consequences.

Clinically relevant hypernatremia occurs when serum sodium concentrations exceed 160 mEq/L, with significant mortality occurring whenever serum sodium concentrations exceed 180 to 190 mEq/L before treatment is instituted. The clinical signs of hypernatremia are nonspecific and include weakness, depression, inappetence, abnormal posture, recumbency, apparent blindness, and muscle twitching, particularly of the facial muscles (Fig. 5-6). Some animals may convulse shortly before death. Cerebral depression is caused by inhibition of neuronal cell glycolysis. Less severely affected animals may exhibit a mania for water. Hypernatremia has been associated with persistent hyperglycemia in New World camelids, in which it has been assumed that hyperglycemia-induced diuresis has resulted in excessive free water loss with inadequate water intake.

Correction of hypernatremia is challenging because too rapid a rate of correction can result in cerebral edema and brain herniation through the foramen magnum, particularly in animals with chronic hypernatremia. Treatment of hypernatremia focuses on identifying and removing the underlying cause (such as incorrectly mixed milk replacer) and slowly reducing the serum sodium concentration, with a reduction of serum [Na] of 0.5 to 1.0 mEq/L/h being a goal (10 mEq/L decrease per day representing an ideal goal). The preferred method for decreasing serum [Na] concentration is by oral administration of sodium containing electrolytes. The first equation presented earlier can be applied to the use of intravenous fluids for correction of hypernatremia.

Fig. 5-6 Calf with neurologic signs of hypernatremia, including abnormal mentation and posture and fasciculation of facial muscles. (From Byers SR, Lear AS, Van Metre DC: Sodium balance and the dysnatremias, *Vet Clin Food Anim* 2014;30:333-350).

HYPOCHLOREMIA

Hypochloremia occurs as a result of an increase in the net loss of the electrolyte in the intestinal tract in acute intestinal obstruction, dilatation and impaction, and volvulus of the abomasum and in enteritis (Fig. 5-7). Normally a large amount of chloride is secreted in the abomasum by the mucosal cells in exchange for bicarbonate, which moves into the plasma. The hydrogen, chloride, and potassium ions secreted in gastric juice are normally absorbed by the small intestine. Failure of abomasal emptying and obstruction of the proximal part of the small intestine will result in the sequestration of large quantities of chloride, hydrogen, and potassium ions, which leads to a **hypochloremic hypokalemic metabolic alkalosis**. A severe hypochloremia can be experimentally produced in calves by feeding them a low-chloride diet and daily removal of abomasal contents. Clinical findings include anorexia, weight loss, lethargy, mild polydipsia, and polyuria. A marked metabolic alkalosis occurs resulting in hypokalemia, hyponatremia, azotemia, and death.

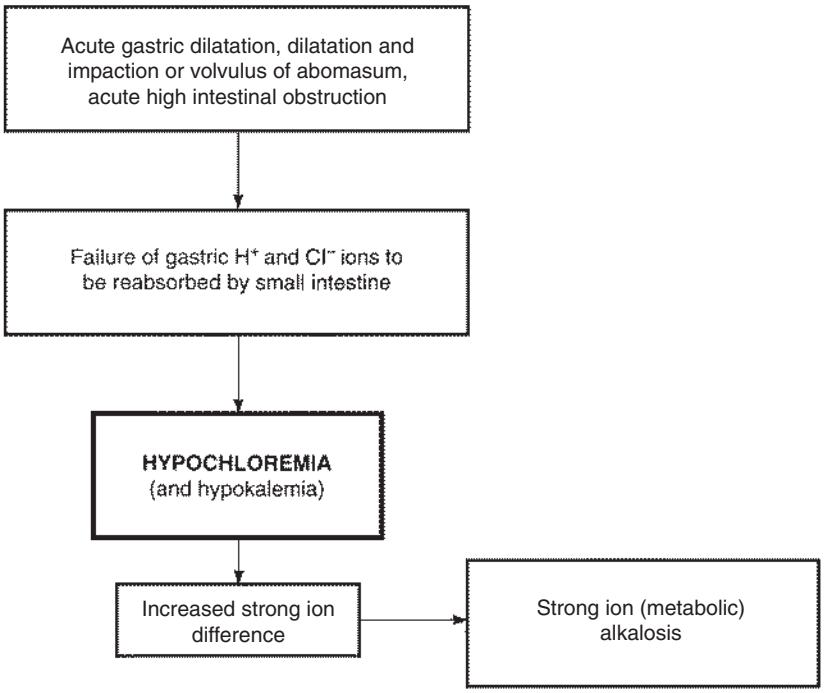

Fig. 5-7 Etiology and pathogenesis of hypochloremia.

HYPOKALEMIA

Hypokalemia may occur as a result of decreased dietary intake, increased renal excretion, abomasal stasis, intestinal obstruction and enteritis, and repeated administration of corticosteroids with mineralocorticoid activity (Fig. 5-8). The prolonged use of potassium-free solutions in fluid therapy for diarrheic animals may result in excessive renal excretion of potassium and hypokalemia. Calves with neonatal diarrhea can have marked depletion of their body potassium stores, particularly when a marked acidemia and metabolic acidosis is present, and the calves have had a low milk intake and a long history of diarrhea.[3] Alkalosis may result in an exchange of potassium ions for hydrogen ions in the renal tubular fluid, resulting in hypokalemia. Hypokalemia can cause muscle weakness, prolonged unexplained recumbency, inability to hold up the head, anorexia, muscular tremors and, if severe enough, coma. The treatment of ketosis in lactating dairy cows with multiple dosages of isoflupredone, a glucocorticoid with some mineralocorticoid activity, can cause hypokalemia and recumbency, with a high case fatality rate.

Hypokalemia (defined as serum or plasma potassium concentration <3.9 mEq/L) is common in lactating dairy cows with left displaced abomasum (LDA), right displaced abomasum (RDA), abomasal volvulus (AV), abomasal impaction, clinical mastitis, dystocia, retained placenta, and hepatic lipidosis.[4] The high prevalence of hypokalemia in sick lactating dairy cows is most likely caused by a combination of decreased dry matter intake; alkalemia from sequestration of chloride in the gastrointestinal tract in cattle with LDA, RDA, AV, or decreased abomasal emptying rate; hyperinsulinemia secondary to hyperglycemia;[5,6] the obligatory loss of potassium in milk (1.4 g of potassium per liter of milk); sympathetic nervous system activation; aldosterone release in response to hypovolemia and the need for sodium retention; and decreased whole-body potassium stores caused by the relatively low muscle mass in dairy cows. Whole-body depletion of potassium may be present in healthy dairy cattle immediately after calving, based on the results of potassium balance studies, studies documenting decreased skeletal muscle potassium content at calving, and decreased urine potassium concentrations immediately after calving. A low serum potassium concentration was a significant predictor of nonsurvival in cattle undergoing surgical correction of LDA or treatment of hepatic lipidosis.[4]

Metabolic alkalosis and hypokalemia in cattle are often accompanied by muscular weakness and **paradoxical aciduria**. Hypokalemia causes muscle weakness by lowering the resting potential of membranes, resulting in decreased excitability of neuromuscular tissue. Thus the differential diagnosis of the animal with muscle weakness should always include hypokalemia.

Hypokalemia and alkalemia also are often directly related because of the renal response to either. Hypokalemia from true body deficits of potassium will cause decreased intracellular concentration of this ion. The intracellular deficit of potassium and excess of hydrogen will cause hydrogen secretion into the urine when distal sodium reabsorption is required. This situation exists in alkalemia and metabolic alkalosis, in which sodium bicarbonate reabsorption in the proximal nephron is decreased because of the excess of plasma bicarbonate. Distal nephron avidity for sodium is increased to protect extracellular fluid volume, and the increased distal sodium reabsorption is at the expense of hydrogen secretion, although it is contrary to the need of acid retention in the presence of alkalosis. In other words, the kidney prioritizes maintenance of plasma volume above that of acid-base balance, presumably because respiratory compensation can usually keep blood pH within the normal physiologic range. Because electroneutrality of extracellular fluid must be maintained by

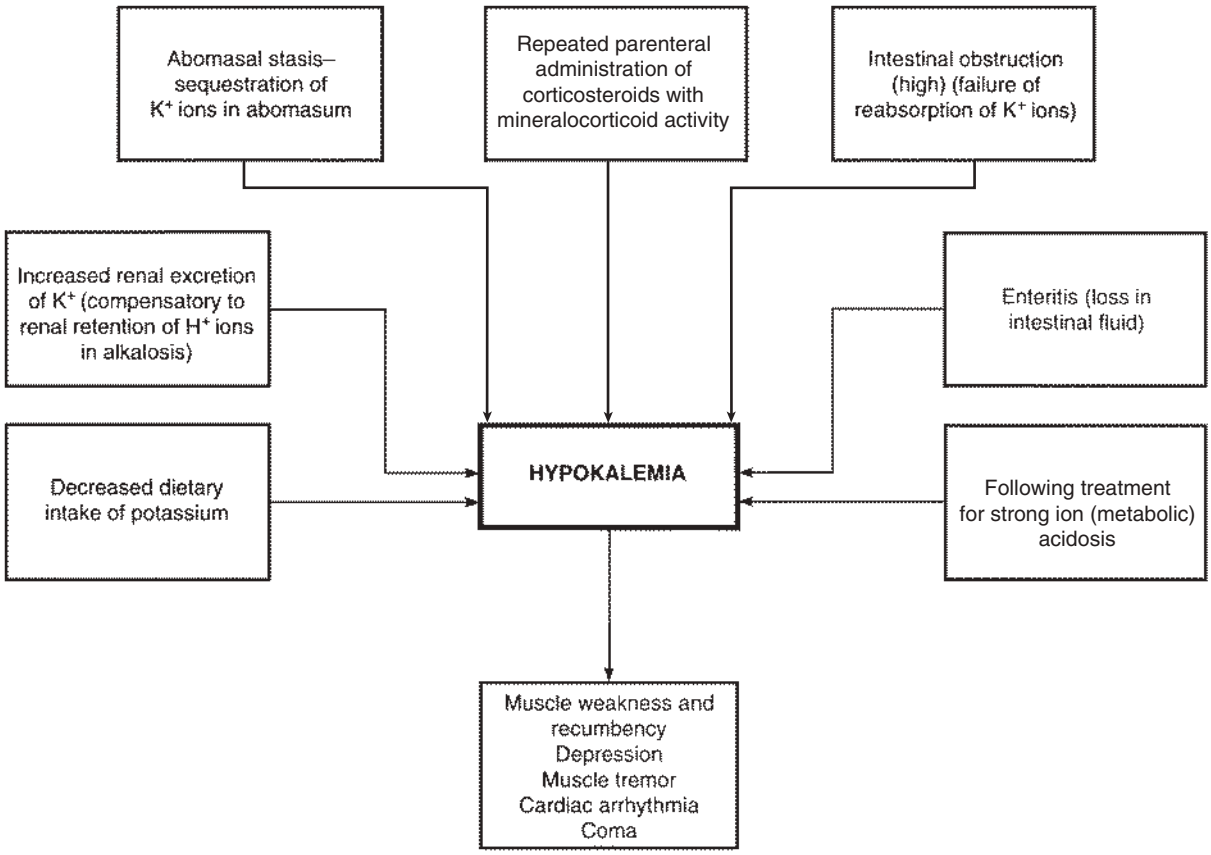

Fig. 5-8 Etiology and pathogenesis of hypokalemia.

reabsorbing an equivalent charge of cations and anions, the reabsorption rates of chloride and bicarbonate in the kidneys are inversely proportional to each other. Thus with excess trapping of chloride in the abomasum, the kidneys will compensate for the resulting hypochloremia by increasing bicarbonate reabsorption, which may proceed until metabolic alkalosis and alkalemia develop.

Because potassium is the major intracellular cation, the measurement of plasma or serum potassium is not a reliable indication of whole-body potassium status. Extremely low plasma or serum concentrations or high concentrations are usually indicative of a potassium imbalance often associated with other electrolyte and acid-base imbalances. In alkalemia, for example, potassium leaves the extracellular space and becomes concentrated in the cells. This may result in low serum potassium concentrations when there might not be potassium depletion of the body. Conversely, in severe acidemia and metabolic acidosis of calves with acute diarrhea, the potassium leaves the cells and moves into the extracellular fluid. This results in hyperkalemia in some cases in which the body potassium is normal or even decreased. When changes occur in the concentration of intracellular and extracellular potassium, the ratio of intracellular to extracellular potassium may decrease by as much as 30% to 50%, which results in a decrease in the resting membrane potential. This is thought to be the explanation for the effects of hypokalemia and hyperkalemia on muscle function.

The potassium concentration of red blood cells does not appear to provide a more accurate indicator of whole-body potassium deficit in horses and ruminants than the actual plasma or serum concentration.[4] There is marked cow-to-cow variability in the erythrocyte potassium concentration (7–70 mmol/L) and sodium concentration (15–87 mmol/L) of healthy cattle that has a genetic basis with no breed influence. Moreover, no relationship between plasma and erythrocyte potassium concentrations could be identified in a study of 180 cows. Milk potassium concentration is theoretically more sensitive than serum or plasma potassium concentration in detecting whole-body potassium depletion in individual cows because milk potassium concentration is constant for an individual cow over a short time period. However, milk potassium concentration changes during lactation, being 42 mmol/L in early lactation, 40 mmol/L in midlactation, and 27 mmol/L in late lactation, with a mean bulk milk tank potassium concentration of 37 mmol/L. Milk potassium concentration also increases in quarters with clinical or subclinical mastitis. As a consequence of these two factors, there is marked individual variation in milk potassium concentration in healthy cattle, with variations of up to 50% occurring among cows. The large cow-to-cow variability in milk potassium concentration makes it difficult to identify a suitable cut point that accurately predicts whole-body potassium depletion in sick lactating dairy cows.[4] However, monitoring milk potassium concentration in individual cows without clinical or subclinical mastitis may have clinical utility as a monitoring tool to gauge the response to therapy with KCl.

Skeletal muscle potassium content provides the most sensitive and specific method for assessing whole-body potassium status.[4,7] Skeletal muscle is considered the best tissue to sample because it contains approximately 75% of the whole-body stores of potassium. A standardized muscle should be obtained for analysis in cattle because differences in potassium content of greater than 15% are present in individual animals, and this muscle-to-muscle variation is greater than that produced by breed.[7]

The treatment of hypochloremic, hypokalemic alkalosis requires correction of extracellular fluid volume and sodium and chloride deficits with 0.9% NaCl infusions and oral KCl. The provision of adequate chloride ion allows sodium to be reabsorbed without bicarbonate. Increased proximal reabsorption of sodium will decrease distal acid secretion because less sodium is presented to the distal nephron. As less bicarbonate is reabsorbed and less acid secreted, the metabolic alkalosis is resolved. Specially formulated solutions containing potassium are necessary in cases of severe hypokalemia and small-intestinal obstruction.

Potassium should be administered intravenously or orally. The intravenous route is used only for the initial treatment of recumbent ruminants with severe hypokalemia and rumen atony because it is much more dangerous and expensive than oral treatment. The most aggressive **intravenous treatment** protocol is an isotonic solution of KCl (1.15% KCl), which should be administered at less than 3.2 mL/kg/h, equivalent to a maximal delivery rate of 0.5 mEq of K^+/kg BW per hour. Higher rates of potassium administration run the risk of inducing hemodynamically important arrhythmias, including ventricular premature complexes that can lead to ventricular fibrillation and death. A less aggressive intravenous treatment is an isotonic equimolar mixture of NaCl (0.45% NaCl) and KCl (0.58% KCl), and the least aggressive intravenous treatment is the addition of 10 mmol of KCl/L of Ringer's solution, which will increase the solution osmolarity to 329 mOsm/L. Clinical experience with oral administration of KCl has markedly decreased the number of adult ruminants treated with intravenous KCl.

Oral potassium administration is the method of choice for treating lactating dairy cattle with hypokalemia. The absorption efficiency of potassium on a typical lactating dairy cow diet ranges from 74% to 88%, with potassium absorbed in the forestomach and small intestine and forestomach absorption predominating. Rumen fluid in cattle usually has a potassium concentration of 24 to 85 mEq/L, and rumen fluid potassium concentration and potassium absorption are strongly and linearly dependent on potassium intake. This indicates that increasing rumen potassium concentration by the oral administration of KCl will directly lead to increased potassium absorption. Oral administration of KCl therefore provides the optimal salt formulation for treating cattle with hypokalemia because potassium is needed in cattle with whole-body potassium depletion, and chloride is needed in cattle with alkalemia and pH-induced compartmental shift of potassium to the intracellular space.[7]

Current treatment recommendations are to administer 120 g of feed grade KCl orally twice at a 12-hour interval to inappetent dairy cattle with hypokalemia, providing a total 24-hour dose of 240 g of KCl; this dose is equivalent to a daily KCl dose of 0.4 g/kg BW for a 600-kg dairy cow.[4,7] Daily oral doses of KCl exceeding 0.4 g/kg BW are not currently recommended, except in cattle with profound hypokalemia, because they have the potential to result in diarrhea, excessive salivation, muscular tremors of the legs, labored breathing, convulsions, and death.[4,7] Oral administration of 0.58 g of KCl/kg BW was toxic in 6-month-old Holstein calves, manifested by excessive salivation, muscular tremors of the legs and excitability, and a peak plasma potassium concentration of 9.0 mEq/L. Extrapolating this toxic dose in normokalemic calves to hypokalemic 600-kg cows suggests that a daily dose of 240 g KCl approaches the upper limit of safety.

Hypokalemia also occurs following treatment of the horse affected with metabolic acidosis and hyponatremia, and probably reflects whole-body potassium depletion. Horses used for endurance rides may be affected by hypokalemia, hypocalcemia, and alkalosis caused by loss of electrolytes during the competition. Synchronous diaphragmatic flutter also occurs, which may be the result of the electrolyte imbalance (particularly hypocalcemia) causing hyperirritability of the phrenic nerve. Inappetent horses often have whole-body potassium depletion and would benefit from supplementary dietary potassium (25–50 g/day KCl).

HYPERKALEMIA

Hyperkalemia is not as common in farm animals as hypokalemia, and is most common in severe metabolic acidosis and acidemia. The classic description for the development of hyperkalemia in metabolic acidosis involves a purported redistribution of potassium from the intracellular space to the extracellular space because a large

proportion of the excess hydrogen ions are buffered intracellularly. Thus potassium is supposedly exchanged with hydrogen ions across the cell membrane to maintain electroneutrality. Although widely accepted, this purported mechanism has never had a sound physicochemical basis because a decrease in plasma pH from 7.4 to 7.0 (equivalent to an increase in plasma hydrogen ion activity from 40 to 100 nEq/L) would decrease plasma [K] from 7.0 to 6.99994 mEq/L on the basis of electrochemical exchange of cations. Not only is such a decrease physiologically irrelevant, but the decrease is undetectable using current laboratory equipment.[8] An attractive hypothesis for the development of hyperkalemia in acidemic animals is that the low intracellular pH slows Na-K-ATPase activity causing potassium ions to leak down a concentration gradient from the intracellular to the extracellular space; however, there is no experimental data indicating that Na-K-ATPase activity is directly influenced by pH within the physiologic range. Low intracellular pH does exert a marked effect on phosphofructokinase activity in the glycolytic pathway; with Na-K-ATPase activity dependent on ATP availability, decreased phosphofructokinase activity presents a potential pathway for acidemia-induced hyperkalemia. Hampered insulin-dependent cellular potassium uptake in states of acidemia presents a second potential mechanism for the association between hyperkalemia and acidemia; mild declines in blood pH can induce insulin resistance. Because insulin triggers a transcellular shift of glucose and potassium, tissue resistance to insulin has the potential to contribute to hyperkalemia. A third potential mechanism for acidemia-induced hyperkalemia is activation of a cell membrane potassium channel called TREK-1 by low intracellular pH, resulting in potassium efflux from the cell.[8] An interesting recent finding is that hyperkalemia is much less common in neonatal calves with acidemia caused by hyper D-lactatemia than in calves with acidemia and plasma D-lactate concentrations within the reference interval.[9]

Hyperkalemia is potentially more life-threatening than hypokalemia. Hyperkalemia (when over 7–8 mmol/L) has a profound effect on cardiac function. There is usually marked bradycardia and arrhythmia, and sudden cardiac arrest may occur. Electrocardiogram (ECG) changes in experimentally induced hyperkalemia in the horse have been described. The changes include four successive stages as hyperkalemia increased. There was a widening and lowering of amplitude followed by inversion and disappearance of the P wave; an increase in the amplitude of the T wave; an increase in the QRS interval, with some irregularity in the ventricular rate; and periods of cardiac arrest that became terminal or were followed by ventricular fibrillation. The minimum plasma potassium concentration required to induce ECG changes was 6 to 7 mmol/L, and severe cardiotoxic effects occurred at levels between 8 and 11 mmol/L. The effects of hyperkalemia on the ECG are exacerbated by the presence of hyponatremia, which is common in neonatal calves with diarrhea.

Hyperkalemia has traditionally been treated by intravenous administration of sodium bicarbonate, glucose, insulin, and sometimes calcium. Because hyperkalemia is most strongly associated with a decreased glomerular filtration rate, the primary treatment goal in hyperkalemia is to reestablish normal renal blood flow and rate of urine formation by the administration of sodium-containing fluids,[9] particularly sodium containing fluids that also produce rapid alkalinization, such as 1.3% sodium bicarbonate.[10] Hypertonic saline has been shown to be just as effective as hypertonic sodium bicarbonate in decreasing hyperkalemia and hyperkalemia-associated bradyarrhythmias as a result of sodium-induced intracellular movement of potassium, extracellular volume expansion, and the strong ion effect of increasing the serum concentration of a strong cation.[8] Calcium counteracts the effect of hyperkalemia on the resting membrane potential by increasing the threshold potential to a higher value, returning an appropriate difference between resting and threshold potentials. Calcium can be administered intravenously at 0.2 to 0.4 mL of a 23% calcium gluconate solution/kg BW. In summary, the focus of treatment in hyperkalemia should be optimizing renal blood flow and glomerular filtration rate by plasma volume expansion, correction of acidemia, and increasing the serum sodium concentration. Glucose and insulin are not routinely needed to correct hyperkalemia, but can be administered to animals not responding to reestablishment of a normal rate of urine production and correction of acidemia.

Hyperkalemic periodic paralysis occurs in heavily muscled Quarter Horses. Affected horses become weak, may stand base-wide, and are reluctant to move. Sweating commonly occurs and generalized muscle fasciculations are apparent. Affected horses remain bright and alert but may yawn and do not eat or drink. Some horses become recumbent and may appear to be in a state of flaccidity. Attacks may occur in a rest period following exercise or at random. During the episode the serum potassium concentration is elevated by up to twofold and returns to normal values when the animal recovers. Treatment consists of sodium bicarbonate, hypertonic saline, or 5% dextrose given intravenously, possibly with insulin.

HYPOCALCEMIA

The calcium fractions in plasma are in equilibrium and exist in three forms: free (43% of total); bound to proteins in a salt-type manner (49%); and complexed to other compounds in plasma such as bicarbonate, lactate, citrate, sulfate, and phosphate (8%). The ionized (free) calcium fraction is the biologically active form of calcium and therefore is the preferred method of calcium measurement. The ionized calcium concentration ($c\mathrm{Ca}^{2+}$) in bovine plasma is primarily dependent on the total calcium concentration, with total protein concentration explaining 85% of the variation in $c\mathrm{Ca}^{2+}$. Ionized calcium concentration is dependent to a lesser extent on pH, the plasma concentration of albumin (and therefore total protein), lactate, and chloride, and the temperature and ionic strength.

Ionized calcium concentration should be measured on an anaerobically collected blood sample, and should be reported as the measured $c\mathrm{Ca}^{2+}$ at the actual pH of the patient. Correction of the measured ionized calcium concentration to a pH of 7.40 is routinely applied in experimental studies to assist in the interpretation of measured values relative to a reference range. This should only be done in samples that were not anaerobically collected and where there is loss of carbon dioxide from the sample (such as in a vacutainer tube). In this case a pH-corrected $c\mathrm{Ca}^{2+}$ is used only to correct for CO_2 loss. The formula most commonly used for pH correction of $c\mathrm{Ca}^{2+}$ in ruminant and equine plasma is $c\mathrm{Ca}^{2+}\text{corrected} = c\mathrm{Ca}^{2+} \times 10^{(-0.24 \times \{7.40 - \mathrm{pH}\})}$. Small differences in the measured value for $c\mathrm{Ca}^{2+}$ exist, depending on whether the blood sample is anaerobically collected using sodium heparin or calcium-balanced heparin.

Hypocalcemia or milk fever may occur in recently calved mature dairy cows that have been inappetent or anorexic for a few days. Hypocalcemia can be caused by a reduction in dry matter intake because of illness or it may be the earliest stages of hypocalcemic parturient paresis. The clinical findings include anorexia; mild tachycardia with a reduction in the intensity of the heart sounds and occasionally an arrhythmia; a decrease in the frequency and amplitude of rumen contractions or complete ruminal stasis; and a decrease or complete absence of feces, which may last from 6 to 36 hours if untreated.

Hypocalcemia cases often mimic intestinal obstruction and create problems in the differential diagnosis. Affected cattle may not exhibit any evidence of muscular weakness, and the detection of the hypocalcemic state can be elusive. The total serum calcium concentrations range from 1.5 to 2.0 mmol/L and the response to intravenous therapy is usually good, although recovery may require several hours before the appetite returns to normal and feces are passed.

Calcium can be administered by the intravenous, subcutaneous, or oral route. **Calcium gluconate** and **calcium borogluconate** are the preferred forms for intravenous

and subcutaneous administration because $CaCl_2$ causes extensive necrosis and sloughs of tissue when administered perivascularly. Compared with calcium gluconate, calcium borogluconate has improved solubility and shelf-life. Plasma ionized calcium concentrations are increased to a greater extent following $CaCl_2$ treatment when high equimolar solutions of $CaCl_2$ and calcium gluconate are administered, leading to more cardiac arrhythmias during $CaCl_2$ administration. A typical treatment for an adult lactating dairy cow with periparturient hypocalcemia is 500 mL of 23% calcium borogluconate by slow intravenous injection with cardiac auscultation; this provides 10.7 g of calcium. Although the calculated calcium deficit in a recumbent periparturient dairy cow is 4 g, additional calcium should be provided to overcome the continued loss of calcium in milk. A field study comparing the effectiveness of different doses of calcium for treating periparturient milk fever determined that 9 g of calcium was superior to 6 g. A good rule of thumb for administering 23% calcium borogluconate solutions (2.14 g calcium/100 mL) to cows with periparturient hypocalcemia is therefore to administer 1 mL/kg BW. There do not appear to be any clinically important advantages to slow administration of the solution over 6 hours, compared with over 15 min.

The normal cardiac response to **intravenous calcium administration** is an increase in the strength of cardiac contraction and a slowing of the heart rate. Intravenous administration is continued until the first arrhythmia is detected (a bradyarrhythmia such as a prolonged pause); the rate of intravenous administration is then slowed until a second arrhythmia is detected, at which time intravenous administration is discontinued and the remainder of the solution is placed subcutaneously over the lateral thorax. This treatment method individually titrates the calcium dose required for each animal. Auscultation of the heart is an absolute requirement during treatment: visual monitoring of the jugular pulse at the base of the neck does not allow the early detection of bradyarrhythmias, making it more likely that the cow will receive a toxic and possibly lethal dose of calcium. The maximum safe rate of calcium administration in cattle is 0.07 mEq of Ca^{2+}/kg BW per minute, which is equivalent to 0.065 mL 23% calcium borogluconate per kilogram BW per minute. For a 500-kg normocalcemic dairy cow, this corresponds to a maximum safe rate of administration of 33 mL/min. Typical rates of administration through a 14-gauge needle are 50 mL/min; this rate of administration is safe for cows with hypocalcemia, provided cardiac auscultation is performed during administration. Intravenous administration of calcium gluconate or calcium chloride to horses increased serum calcium concentrations by approximately 35% and resulted in hypomagnesemia, hypokalemia, and hyperphosphatemia, induced diuresis, and increased excretion of calcium, magnesium, potassium, sodium, phosphate, and chloride.[11]

Subcutaneous administration of calcium solutions has been practiced for many years as part of the treatment of hypocalcemic cattle. To facilitate calcium absorption, it is preferable to administer no more than 125 mL at a site. A 14-gauge needle is placed subcutaneously over the lateral thorax, 125 mL is administered, and the needle is redirected and another 125 mL is administered. The process is then repeated on the other side of the cow. The effectiveness of subcutaneous administration of calcium has been documented in healthy normal cows, and subcutaneous calcium injections appear to be absorbed by cows with periparturient hypocalcemia at a fast enough rate to be clinically effective. Subcutaneous administration of calcium gluconate in recumbent cows can therefore be expected to have some efficacy in improving plasma calcium concentrations; such treatment can be administered by producers until a veterinarian can arrive to administer intravenous calcium gluconate. Calcium chloride is not recommended for subcutaneous administration because of extensive tissue damage; the addition of dextrose to the administered calcium is also not recommended because it increases the tonicity of the solution and propensity for bacterial infection and development of abscesses. Rectal calcium administration is not recommended because it causes severe mucosal injury and tenesmus and does not increase plasma concentrations of calcium.

Oral administration of calcium has also been practiced for many years, usually by ororuminal intubation of calcium borogluconate solutions designed for parenteral administration. Over the past decade there has been increased interest in improving the efficacy of oral calcium formulations. The results of a number of studies indicate that oral calcium salts are effective at increasing plasma calcium concentration; orally administered calcium is absorbed by a dose-dependent passive diffusion process across ruminal epithelium and a dose-independent calcium-binding protein mechanism in the small intestine that is modulated by vitamin D. Rapid correction of hypocalcemia by oral calcium administration is predominantly by passive ruminal diffusion because small intestinal absorption is too slow to be of clinical value.

Two calcium formulations are currently recommended for oral administration to ruminants, $CaCl_2$ and calcium propionate, but most commercially available products contain 50 g of $CaCl_2$. Calcium lactate does not appear to be absorbed in appreciable quantities when administered orally to cows in a large volume of water (20 L) followed immediately by oral administration of sodium phosphate; this result may have been caused by formation of calcium-phosphate complexes in the rumen.[12] Calcium chloride has the advantage of low cost and low volume (because of its high solubility), but $CaCl_2$ can severely damage the pharynx and esophagus in ruminants with reduced swallowing ability, can lead to necrosis of the forestomach and abomasum when administered in high doses, and can lead to aspiration pneumonia when administered as a drench. Calcium propionate has the advantage that it is less irritating than $CaCl_2$ while providing a gluconeogenic substrate (propionate), but the disadvantages of calcium propionate are higher volumes and cost. Oral calcium solutions should only be administered to cattle that have normal swallowing ability, precluding their administration to animals with advanced clinical signs of hypocalcemia. Higher plasma calcium concentrations are obtained more quickly when calcium solutions are drenched after administration of vasopressin to induce esophageal groove closure, or when the calcium solution is administered as a drench instead of ororuminal intubation. Calcium solutions are suspected to have a higher likelihood of aspiration pneumonia than calcium gels (with a consistency similar to toothpaste), although this supposition does not appear to have been verified. Commercially available formulations of calcium gels contain 50 g of $CaCl_2$ and increase plasma calcium concentrations within 30 to 60 minutes and for at least 6 hours. Retreatment at 12-hour intervals (if needed) therefore appears to be indicated and provides 100 g of $CaCl_2$ and 37 g of calcium over 24 hours, but more aggressive treatment protocols are not recommended.

HYPOPHOSPATEMIA

Hypophosphatemia occurs in cattle under conditions similar to those of hypocalcemia. A decrease in feed intake or alimentary tract stasis will result in a decrease in serum inorganic phosphate concentration. Acute recumbency in lactating dairy cattle may be associated with marginal phosphorus deficiency, although a cause-and-effect relationship between hypophosphatemia and recumbency has not been established. However, many inappetent and weak cows have marginal hypophosphatemia and clinically appear to benefit from normalization of their plasma concentration of phosphate. As such, it is currently recommended that ruminants with marked hypophosphatemia and signs of illness should be treated with phosphorus-containing solutions.

Almost all commercially available intravenous solutions for treating hypophosphatemia use **phosphite** (PO_2^{2-}) or **hypophosphite** (PO_3^{3-}) salts as the source of phosphorus because these salts are very soluble, even in the presence of calcium and

magnesium. However, the phosphorus in phosphite and hypophosphite is unavailable to mammals, meaning that the vast majority of "phosphate"-containing solutions are not efficacious in treating hypophosphatemia.[13] Instead, the **monobasic monophosphate form of sodium phosphate (NaH_2PO_4)** should be administered. The pH of the solution should be mildly acidic (pH 5.8) to maintain phosphate solubility in cold weather, but this is not needed when solutions are stored in warm ambient temperatures. A recommended treatment to an adult lactating dairy cow with severe hypophosphatemia is 300 mL of 10% NaH_2PO_4 (monohydrate) solution by slow intravenous injection; this provides 7 g of phosphate (2.3 g of inorganic phosphate), and increases plasma phosphate concentrations for at least 6 hours. Human enema formulations that contain a mixture of monobasic sodium phosphate monohydrate and dibasic sodium phosphate heptahydrate in a buffered solution have also been administered intravenously to cattle with hypophosphatemia but are not recommended. This human enema solution is extremely hypertonic and must be diluted before administration. A major drawback with intravenous administration of phosphate solutions is that they should not be administered within 2 hours of intravenous calcium administration because of concerns that calcium-phosphate precipitates may be formed in the plasma of cattle with treatment-induced hypercalcemia and hyperphosphatemia. This has traditionally been evaluated by calculating the **calcium-phosphorus product**, in which metastatic calcification may occur if the product of serum calcium concentration and serum phosphate concentration (both in mg/dL) exceeds 70.

Hypophosphatemia is more safely treated by administration of **oral monosodium phosphate**, and this is the preferred method of administration in ruminants with rumen motility. Oral administration also results in a more prolonged increase in plasma phosphorus concentration. Recommended dose is 200 to 350 g of feed grade monosodium phosphate ($NaH_2PO_4.2H_2O$, contains 50–70 g of phosphate) administered in gelatin boluses, drench, or by ororuminal intubation.[12] Phosphorus in other feed grade minerals (such as bone meal or dicalcium phosphate) is poorly available and is not recommended for the treatment of hypophosphatemia.

HYPOMAGNESEMIA

Magnesium is usually administered parenterally only when a ruminant exhibits clinical signs of hypomagnesemia. Treatment of hypomagnesemia is more dangerous (to the animal and clinician) and less satisfying than treatment of periparturient hypocalcemia; the response to treatment is much slower in hypomagnesemia presumably because magnesium concentrations must be normalized in cerebrospinal fluid (CSF), which turns over at approximately 1% per minute.

Treatment of hypomagnesemia has historically used 25% Epsom salts solution (magnesium sulfate heptahydrate; $MgSO_4.6H_2O$); this solution concentration was selected because it provided approximately 1 mmol of magnesium per liter. It should be noted that 25% Epsom salts solution is markedly hypertonic (2028 mOsm/L). A typical treatment for an adult cow has been slow intravenous administration (over at least 5 min) of 100 mL of the 25% Epsom salts solution, which provides 2.5 g of magnesium (25 mg of magnesium per mL of solution). More recently, hypomagnesemia has been treated using commercially available combined calcium and magnesium solutions; 500 mL of these solutions typically contain 1.6 to 2.7 g of magnesium in the form of a borogluconate, chloride, or hypophosphite salt. Although the calculated extracellular deficit in a cow with hypomagnesemia is 2 g of magnesium, additional magnesium should be provided to correct presumed intracellular deficiencies and to overcome the anticipated urinary loss of magnesium. Combined calcium and magnesium solutions are preferred for intravenous administration to 25% Epsom salts solution because ruminants with hypomagnesemia frequently have hypocalcemia, and hypercalcemia provides some protection against the toxic effects of hypermagnesemia. Moreover, administration of solutions containing magnesium as the only cation increases the risk of developing cardiac and respiratory failure during treatment. The maximum safe rate of administration of magnesium in cattle is 0.08 mEq Mg^{2+}/kg of BW per minute, which is equivalent to 0.04 mL 25% Epsom salts per kilogram of BW per minute. For a 500-kg beef cow with hypomagnesemia, this corresponds to a maximum safe rate of administration of 20 mL/min.

Magnesium-containing solutions (such as 25% Epsom salts solution) can also be administered subcutaneously, although this frequently leads to necrosis of the skin, particularly when 50% Epsom salts solution is administered. Only combined calcium and magnesium solutions should therefore be administered subcutaneously.

The oral bioavailability of magnesium is low and much lower than that of calcium. Accordingly, oral administration of magnesium is not recommended for the treatment of hypomagnesemia, but is essential for the prevention of hypomagnesemia. Magnesium absorption from the rumen is facilitated by volatile fatty acids but decreased by potassium and the ammonium ion.

Rectal administration may be the only practical and safe method for treating a convulsing hypomagnesemic beef cow. After evacuating the rectal contents, an enema containing 60 g of Epsom salts (magnesium sulfate heptahydrate) or magnesium chloride in 200 mL of water can be placed in the descending colon (and not the rectum) and the tail held down for 5 minutes; this increases plasma magnesium concentrations within 10 minutes. However, enema solutions can be prematurely evacuated, eliminating the chance for therapeutic success, and some degree of colonic mucosal injury is expected because of the high osmolarity of 30% solutions (approximately 2400 mOsm/L). The safety of this treatment protocol does not appear to have been evaluated, although a 50-mL enema of a 30% $MgCl_2.6H_2O$ solution rapidly and effectively increased serum magnesium concentration in 7- to 10-week-old calves and relieved clinical signs of hypomagnesemia.

Oral administration of magnesium hydroxide and magnesium oxide excessively alkalinizes the rumen and can create a severe metabolic alkalosis (strong ion alkalosis), as absorption of magnesium leads to hypermagnesemia and increased plasma strong ion difference (SID). Because oral administration of sodium bicarbonate causes expansion of the plasma volume and creates a metabolic alkalosis (strong ion alkalosis) without hypermagnesemia, it is likely that oral sodium bicarbonate is a more effective treatment for grain overload in ruminants.

Acid-Base Imbalance

The pH of mammsalian blood is maintained within the normal range of 7.35 to 7.45 by its buffer systems, of which hemoglobin (Hb) is the most important, because it has the greatest buffering capacity. However, because the

blood Hb concentration is regulated on the basis of oxygen delivery instead of acid-base balance, rapid changes in Hb concentration occur only with marked changes in hydration status or splenic contraction associated with exercise, and the bicarbonate system is an open buffering system via carbon dioxide loss through the respiratory system. The **bicarbonate system** has traditionally been considered to be the most important buffer. Other buffers in blood are plasma proteins and phosphate. The addition of relatively large amounts of acid or alkali to the blood is necessary before its buffering capacity is exhausted and its pH changed. Changes from normal acid-base balance toward alkalemia or acidemia are common in sick animals and make a significant contribution to the observed clinical signs.

The traditional approach for assessing acid-base balance focuses on how plasma carbon dioxide tension (P_{CO_2}), plasma bicarbonate concentration ($[HCO_3^-]$), the negative logarithm of the apparent dissociation constant (pK_1') for plasma carbonic acid (H_2CO_3), and the solubility of CO_2 in plasma (S) interact to determine plasma pH. This relationship is most often expressed as the **Henderson–Hasselbalch equation**: $pH = pK_1' + \log([HCO_3^-]/S \times P_{CO_2})$. The evaluation of acid-base balance using the Henderson–Hasselbalch equation has historically used pH as an overall measure of acid-base status, P_{CO_2} as an independent measure of the respiratory component of acid-base balance, and extracellular base excess and actual HCO_3^- concentration or standard HCO_3^- as a measure of the nonrespiratory (also called metabolic) component of acid-base balance.

When using the traditional Henderson–Hasselbalch approach, **four primary** acid-base **disturbances** can be distinguished: **respiratory acidosis** (increased P_{CO_2}), **respiratory alkalosis** (decreased P_{CO_2}), **metabolic acidosis** (decreased extracellular base excess or actual HCO_3^- concentration), and **metabolic alkalosis** (increased extracellular base excess or actual HCO_3^- concentration). The anion gap (AG) is easily calculated from the results of serum biochemical analysis and is used to determine whether unmeasured anions (UAs) are present. The Henderson–Hasselbalch equation has a long history of use and remains widely and routinely used in the clinical management of acid-base disorders. These advantages should not be overlooked. The principal disadvantage of the Henderson–Hasselbalch equation is that it is more descriptive than mechanistic, decreasing the value of the approach in explaining the cause of acid-base changes during disease. This is because the Henderson–Hasselbalch equation fails to distinguish among the effects of independent and dependent variables on plasma pH.

Actual plasma HCO_3^- concentration in units of mmol/L is not measured but calculated using the Henderson–Hasselbalch equation and measured values for pH and P_{CO_2}:

$$[HCO_3^-] = S \times P_{CO_2} \times 10^{(pH - pK1')}$$

The values for pK_1' and S at 37°C are 6.105 and 0.0307 per mm Hg, respectively, for normal mammalian blood. The equation at 37°C is

$$[HCO_3^-] = 0.0307 \times P_{CO_2} \times 10^{(pH - 6.105)}$$

Because actual HCO_3^- concentration is calculated from pH and P_{CO_2}, it can never provide an independent measure of the nonrespiratory component of an acid-base disturbance. A primary decrease in P_{CO_2} (respiratory alkalosis) at normal pH always is accompanied by a decrease in plasma HCO_3^- concentration (which would be interpreted as a metabolic acidosis). Likewise, a primary increase in P_{CO_2} (respiratory acidosis) at normal pH always produces an increase in plasma HCO_3^- concentration (which would be interpreted as a metabolic alkalosis). In both cases, the actual HCO_3^- concentration is dependent on the pH and P_{CO_2}, providing no additional information as to the cause of the acid-base imbalance other than that obtained by knowledge of the pH and P_{CO_2}. It is therefore illogical to use the actual HCO_3^- concentration to define the nonrespiratory (metabolic) component of an acid-base disturbance.

The current use of actual HCO_3^- concentration in the evaluation of acid-base status results from Van Slyke's work in 1924, in which pH and total CO_2 (which is highly correlated with actual $[HCO_3^-]$) could be measured more accurately than P_{CO_2}. This led to the graphical depiction of the curvilinear HCO_3^-–pH relationship, the so-called Davenport diagram, to represent acid-base disturbances (Fig. 5-9). With the later development of accurate and practical laboratory methods in the 1950s to measure P_{CO_2}, acid-base derangements were graphically depicted as approximately linear $\log(P_{CO_2})$–pH relationships. This development led directly to the **base excess** concept.

The normal range of plasma bicarbonate in large animals is 24 to 30 mmol/L (this should be compared with the normal range in humans, which is 22–24 mmol/L). In mild metabolic acidosis the bicarbonate concentration is in the range of 20 to 24 mmol/L, moderate metabolic acidosis is 14 to 18 mmol/L, and in severe cases the values are below 10 mmol/L and carry a grave

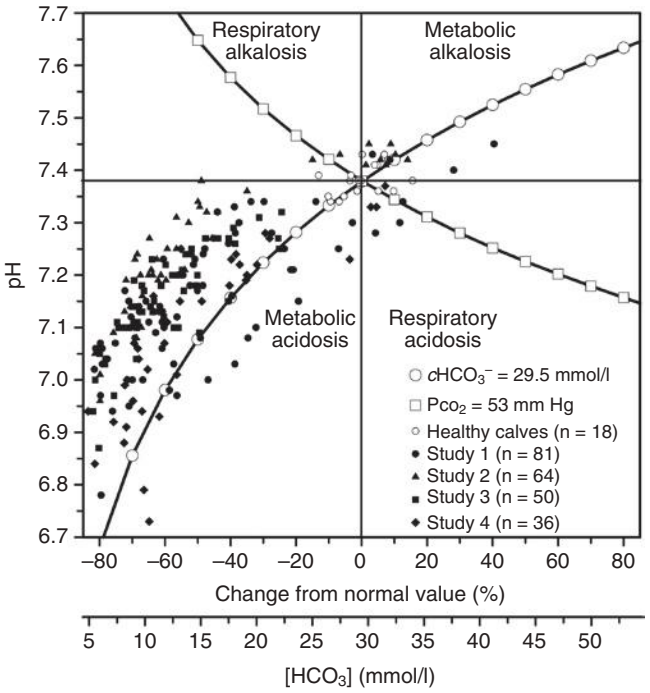

Fig. 5-9 Spider plot revealing the association between changes in two variables of the Henderson–Hasselbalch equation, plasma bicarbonate concentration ($cHCO_3^-$) and carbon dioxide tension (P_{CO_2}), on venous blood pH in 231 sick calves, most of which had diarrhea. The spider plot was obtained by systematically varying one input variable ($cHCO_3^-$ or P_{CO_2}) while holding the remaining input variables at their reference values for calf venous plasma. Reference values for the two input variables for calf plasma were 29.5 mmol/L for $cHCO_3^-$ (large open circles) and 53 mm Hg for P_{CO_2} (open squares). The solid vertical and horizontal lines indicate that venous blood pH = 7.38 when $cHCO_3^-$ and P_{CO_2} are at their reference values. Note that the individual data points are displaced from the predicted pH–$cHCO_3^-$ relationship. This displacement indicates that changes in plasma $cHCO_3^-$ do not account for all of the changes in blood pH in sick calves. (Reproduced with permission from Constable PD, *Vet Clin North Am Food Anim Pract* 2014;30:295-316.)

prognosis. The levels of P_{CO_2}, P_{O_2}, plasma bicarbonate, and blood pH can be used to determine the degree of compensation, if any, that has taken place. In metabolic acidosis there may be a compensatory decrease in P_{CO_2} caused by hyperventilation; in metabolic alkalosis there may be an increase in P_{CO_2} caused by hypoventilation. In respiratory acidosis caused by severe pneumonia the arterial P_{O_2} will be markedly decreased.

The **base excess** value directly expresses the amount (usually expressed in units of mEq/L) of strong base (or acid) added per liter of blood or plasma, when the normal mean base excess value is arbitrarily fixed at zero. As such, the base excess is defined as the amount of strong acid (such as HCl) needed to titrate the pH of 100% oxygenated human blood to 7.40 at 37°C and at a P_{CO_2} of 40 mm Hg. By definition, the normal base excess value for humans is 0 mEq/L (range is −2 to +2 mEq/L), and a base excess of more than +2 mEq/L indicates metabolic alkalosis, whereas a value of less than −2 mEq/L (negative base excess value or base deficit) reflects metabolic acidosis. The **normal range of base excess** in large animals is 0 to 6 mEq/L.

Mathematical formulas and nomograms are available to calculate base excess from measured pH, P_{CO_2}, and blood Hb concentration. Base excess is usually expressed as BE_{ECF} (also called **standard base excess** or **in vivo base excess**). Extracellular base excess is the preferred measurement because this formulation provides the best clinical estimate of the required mmol/L of HCO_3^- required to correct metabolic acidosis and because it assumes a fixed Hb concentration of 5 g/dL. Clearly, the BE_{ECF} value will be incorrect when applied to animals with anemia or polycythemia; however, the error introduced by this approximation is small and usually clinically insignificant.

Most blood gas analyzers calculate base excess in units of mEq/L using Siggaard–Andersen's empirical equation derived from his nomogram with Hb concentration [Hb] and actual HCO_3^- concentrations in mmol/L:

$$BE_{blood} = (1 - 0.023 \times [Hb]) \times ([HCO_3^-] - 24.4 + (7.7 + 2.3 \times [Hb]) \times (pH - 7.40),$$

which is equivalent to the following expression when [Hb] = 3.1 mmol/L = 5 g/dL:

$$BE_{ECF} = 0.93 \times ([actual\ HCO_3^-] - 24.4 + 14.83 \times (pH - 7.40)$$

The calculated BE_{ECF} value assumes normal serum protein concentration (7.2 g/dL) providing an inaccurate estimate of the magnitude of a metabolic acidosis or alkalosis in domestic animals with hypoproteinemia or hyperproteinemia. The ability of BE_{ECF} and actual HCO_3^- concentration to accurately characterize the metabolic component of acid-base status has been controversial for many years, although BE_{ECF} has advantages compared with actual HCO_3^- concentration. The major advantages of the base excess approach are that BE_{ECF} is theoretically related to SID and is independent of respiratory activity. On this basis, when using the traditional Henderson–Hasselbalch approach to acid-base balance, the recommended approach is to use pH as an overall index of acid-base status, P_{CO_2} as an index of the respiratory component, and standard (in vivo) base excess as an index of the nonrespiratory (metabolic) component (Fig. 5-10).

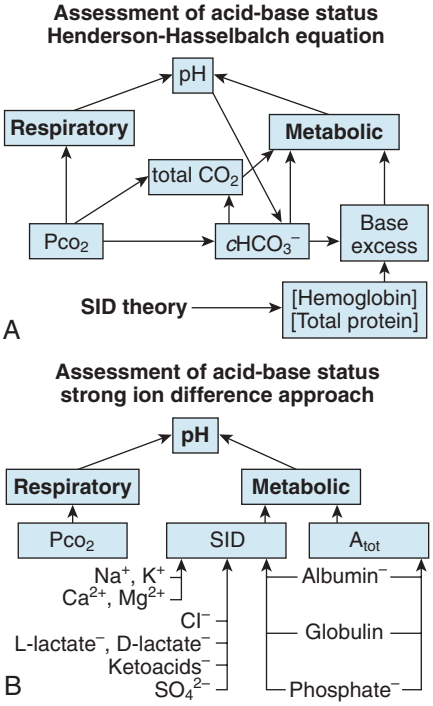

Fig. 5-10 Evaluation of acid-base balance using the traditional Henderson–Hasselbalch equation **(A)** and strong ion difference (SID) theory **(B)**. The Henderson–Hasselbalch equation posits that blood pH is dependent on the respiratory system, as assessed by the partial pressure of carbon dioxide (P_{CO_2}), and metabolism, as assessed by the bicarbonate concentration ($cHCO_3^-$) or base excess. **A,** It highlights one of the fundamental flaws with using the Henderson–Hasselbalch equation in that blood pH cannot be dependent on $cHCO_3^-$ because bicarbonate concentration is calculated from blood pH and P_{CO_2}. **B,** For comparison, this conveys that the strong ion approach to acid-base balance posits that blood pH is dependent on the respiratory system, assessed by P_{CO_2}, and on metabolism, assessed by the SID and concentration of nonvolatile buffers (A_{tot}, such as albumin, globulin, and phosphate) in plasma. (Reproduced with permission from Constable PD: Clinical assessment of acid-base status: Strong ion difference theory, *Vet Clin North Am Food Anim Pract* 1999;15:447-71).

The **strong ion approach** to acid-base balance provides a revolutionary method to assess acid-base balance, which is becoming more widely adopted. In particular, the strong ion model is thought to provide a more accurate assessment of acid-base status than the traditional Henderson–Hasselbalch approach and can identify complex mixed acid-base disorders.[1,2,3,4] This strong ion approach differs in three important areas from the traditional bicarbonate-centered application of the Henderson–Hasselbalch equation: (1) acid-base balance is examined using a systems approach, (2) a clear conceptual distinction is made between dependent variables (such as pH and $[HCO_3^-]$) and the independent variables, and (3) the effects of protein concentration on acid-base balance are considered.

The strong ion approach reduces the chemical reactions in plasma to that of simple ions in solution. This assumption can be made because the quantitatively important plasma cations (Na^+, K^+, Ca^{2+}, and Mg^{2+}) and anions (Cl^-, HCO_3^-, protein, lactate, sulfate, and ketoacids) bind each other in a saltlike manner. Plasma ions (such as Cu^{2+}, Fe^{2+}, Fe^{3+}, Zn^{2+}, Co^{2+}, and Mn^{2+}) that enter into oxidation–reduction reactions, complex ion interactions, and precipitation reactions are not categorized as simple ions but are assumed to be quantitatively unimportant in determining plasma pH, primarily because their plasma concentrations are low.

Simple ions in plasma can be differentiated into two main types, nonbuffer ions (strong ions or strong electrolytes) and buffer ions. Strong ions are fully dissociated at physiologic pH and therefore exert no buffering effect. Strong ions do, however, exert an electrical effect because the sum of completely dissociated cations does not equal the sum of completely dissociated anions. Stewart termed this difference the SID. Because strong ions do not participate in chemical reactions in plasma at physiologic pH, they act as a collective positive unit of charge.

In contrast to strong ions, **buffer ions** are derived from plasma weak acids and bases that are not fully dissociated at physiologic pH. The conventional dissociation reaction for a weak acid (HA), conjugate base (A^-) pair is

$$HA \rightleftharpoons H^+ + A^-$$

and, at equilibrium, an apparent weak acid dissociation constant (Ka) can be calculated adopting the accepted convention regarding hydrated solutes as $K\text{a} = [H^+][A^-]/[HA]$. For a weak acid to act as an effective buffer, its pKa (defined as the negative logarithm of the weak acid dissociation constant Ka) lies within the range of pH ± 1.5.

Conceptually, the buffer ions can be subdivided into volatile buffer ions (HCO_3^-) and nonvolatile buffer ions (non-HCO_3^-). Bicarbonate is considered separately because this buffer system is an open system in arterial plasma; rapid changes in carbon dioxide

tension and hence arterial plasma HCO_3^- concentration can be readily induced through alterations in respiratory activity. In contrast, the non-HCO_3^- buffer system is a closed system containing a fixed quantity of buffer. Another important physiologic distinction between these two buffer systems is that an open buffer system such as HCO_3^- can be effective beyond the limits of pH = p*K*a ± 1.5. Finally, it should be appreciated that HCO_3^- is a homogeneous buffer ion, whereas the nonvolatile buffer ion (A^-) represents a diverse and heterogeneous group of plasma buffers (albumin, globulin, and phosphate) that is being modeled as a single buffer. Another assumption in Stewart's strong ion model is that HA and A^- do not take part in plasma reactions that result in the net destruction or creation of HA or A^-. This is because when HA dissociates it ceases to be HA (therefore decreasing plasma [HA]) and becomes A^- (therefore increasing plasma [A^-]). The sum of [HA] and [A^-] (called A_{TOT}) therefore remains constant through conservation of mass:

$$[A_{TOT}] = [HA] + [A^-]$$

In summary, the strong ion approach assumes that plasma ions act as either strong ions, volatile buffer ions (HCO_3^-), or nonvolatile buffer ions (A^-). Plasma therefore contains three types of charged entity: SID, HCO_3^-, and A^-. The requirement for electroneutrality dictates that at all times the SID equals the sum of bicarbonate buffer ion activity (HCO_3^-) and nonvolatile buffer ion activity (A^-), such that SID − HCO_3 − A^- = 0. This equation obviously assumes that all ionized entities in plasma can be classified as either a strong ion (SID), a volatile buffer ion (HCO_3^-), or a nonvolatile buffer ion (A^-; see Fig. 5-9).

An equation **relating plasma pH to three independent variables (P_{CO_2}, SID, and A_{TOT})** and three constants (K_a, K_1, and *S*) has been developed based on these assumptions. The most important factors that determine plasma pH are P_{CO_2}, SID, and the concentrations of individual nonvolatile plasma buffers (albumin, globulins, and phosphate). A change in any one of these variables will produce a direct and predictable change in plasma pH. Using the strong ion approach, six **primary acid-base disturbances can be distinguished** (Fig. 5-11) instead of the four primary acid-base disturbances (respiratory acidosis, respiratory alkalosis, metabolic acidosis, and metabolic alkalosis) differentiated when using the traditional Henderson–Hasselbalch approach. The strong ion approach indicates that acidemia results from an increase in P_{CO_2} and nonvolatile buffer concentration, or from a decrease in SID. Alkalemia results from a decrease in P_{CO_2} and nonvolatile buffer concentration, or from an increase in SID. The unmeasured strong anion concentration is quantified by calculating the strong ion gap (SIG).

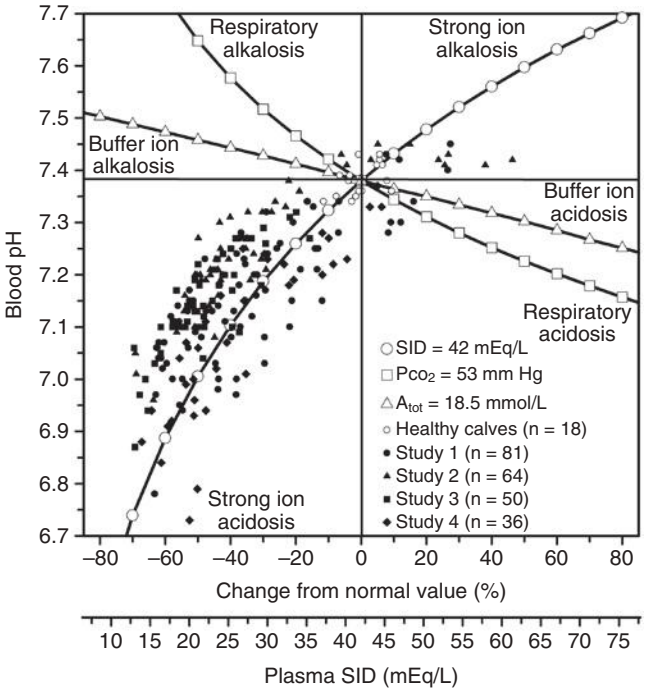

Fig. 5-11 Spider plot revealing the association among changes in three independent variables of the simplified strong ion equation, strong ion difference (SID, open circles), carbon dioxide tension (P_{CO_2}, open squares), and the plasma concentration of nonvolatile buffers (A_{tot}, open triangles), on venous blood pH in 231 sick calves, most of which had diarrhea. The spider plot was obtained by systematically varying one input variable (SID, P_{CO_2}, or A_{tot}) while holding the remaining input variables at their reference values for calf venous plasma (42 mEq/L for SID), 53 mm Hg for P_{CO_2}, and 18.5 mmol/L for A_{tot}. The solid vertical and horizontal lines indicate that venous blood pH = 7.38 when SID, P_{CO_2}, and A_{tot} are at their reference values. Note that the individual data points are located more centrally around the predicted pH–SID relationship than for the pH–cHCO_3^- relationship identified in Figure 5.9. This is because changes in plasma protein concentration (and therefore A_{tot}) caused by changes in hydration status account for some of the change in blood pH. The plot also indicates the six primary acid-base disturbances (respiratory, strong ion, or nonvolatile buffer ion acidosis and alkalosis) and the relative effect of each disturbance on blood pH in the neonatal calf. Note that changes in SID have the greatest relative effect on blood pH. (Adapted from Constable PD, Stämpfli HR, Navetat H, et al.: Use of a quantitative strong ion approach to determine the mechanism for acid-base abnormalities in sick calves with or without diarrhea. *J Vet Intern Med* 2005;19:581-9. IN Constable PD: Acid-Base Assessment When and How to Apply the Henderson-Hasselbalch Equation and Strong Ion Different theory, *Vet Clin Food Anim*. 2014;30:295-316.)

ACIDEMIA

ETIOLOGY

The traditional Henderson–Hasselbalch approach to acid-base balance indicates that general causes of nonrespiratory **(metabolic) acidosis** can be divided into three categories on the basis of pathogenesis (Fig. 5-12):

- Excessive loss of base (bicarbonate)
- Accumulation of endogenous or exogenous acid
- Combination of both of these processes

For comparison, the strong ion approach indicates that general causes of nonrespiratory (metabolic) acidosis can be divided into **two categories: strong ion acidosis** caused by a decrease in strong cation concentration (hyponatremia) or increase in strong anion concentration (hyperchloremia, hyper L-lactatemia, hyper D-lactatemia, and ketoacidosis), and **nonvolatile buffer ion acidosis** caused by an increase in albumin, globulin, and phosphate concentration.

Some common specific causes include acute diarrhea in newborn animals, acute enteritis in adult cattle and horses, and carbohydrate engorgement in ruminants and horses. Metabolic acidosis without dehydration, which is probably caused by hyper D-lactatemia, has been described in neonatal goat kids and neonatal calves.[4] Respiratory acidosis also occurs when there is retention of carbon dioxide in the blood as a result of interference with normal respiratory exchange. Thus pneumonia, severe pulmonary emphysema, depression of the respiratory center, and left-sided heart failure may all be accompanied by respiratory acidosis. Metabolic acidosis occurs in the newborn at the time of parturition if this is prolonged and difficult. It is also common in shock with peripheral circulatory failure and anaerobic oxidation. A decrease in renal excretion of

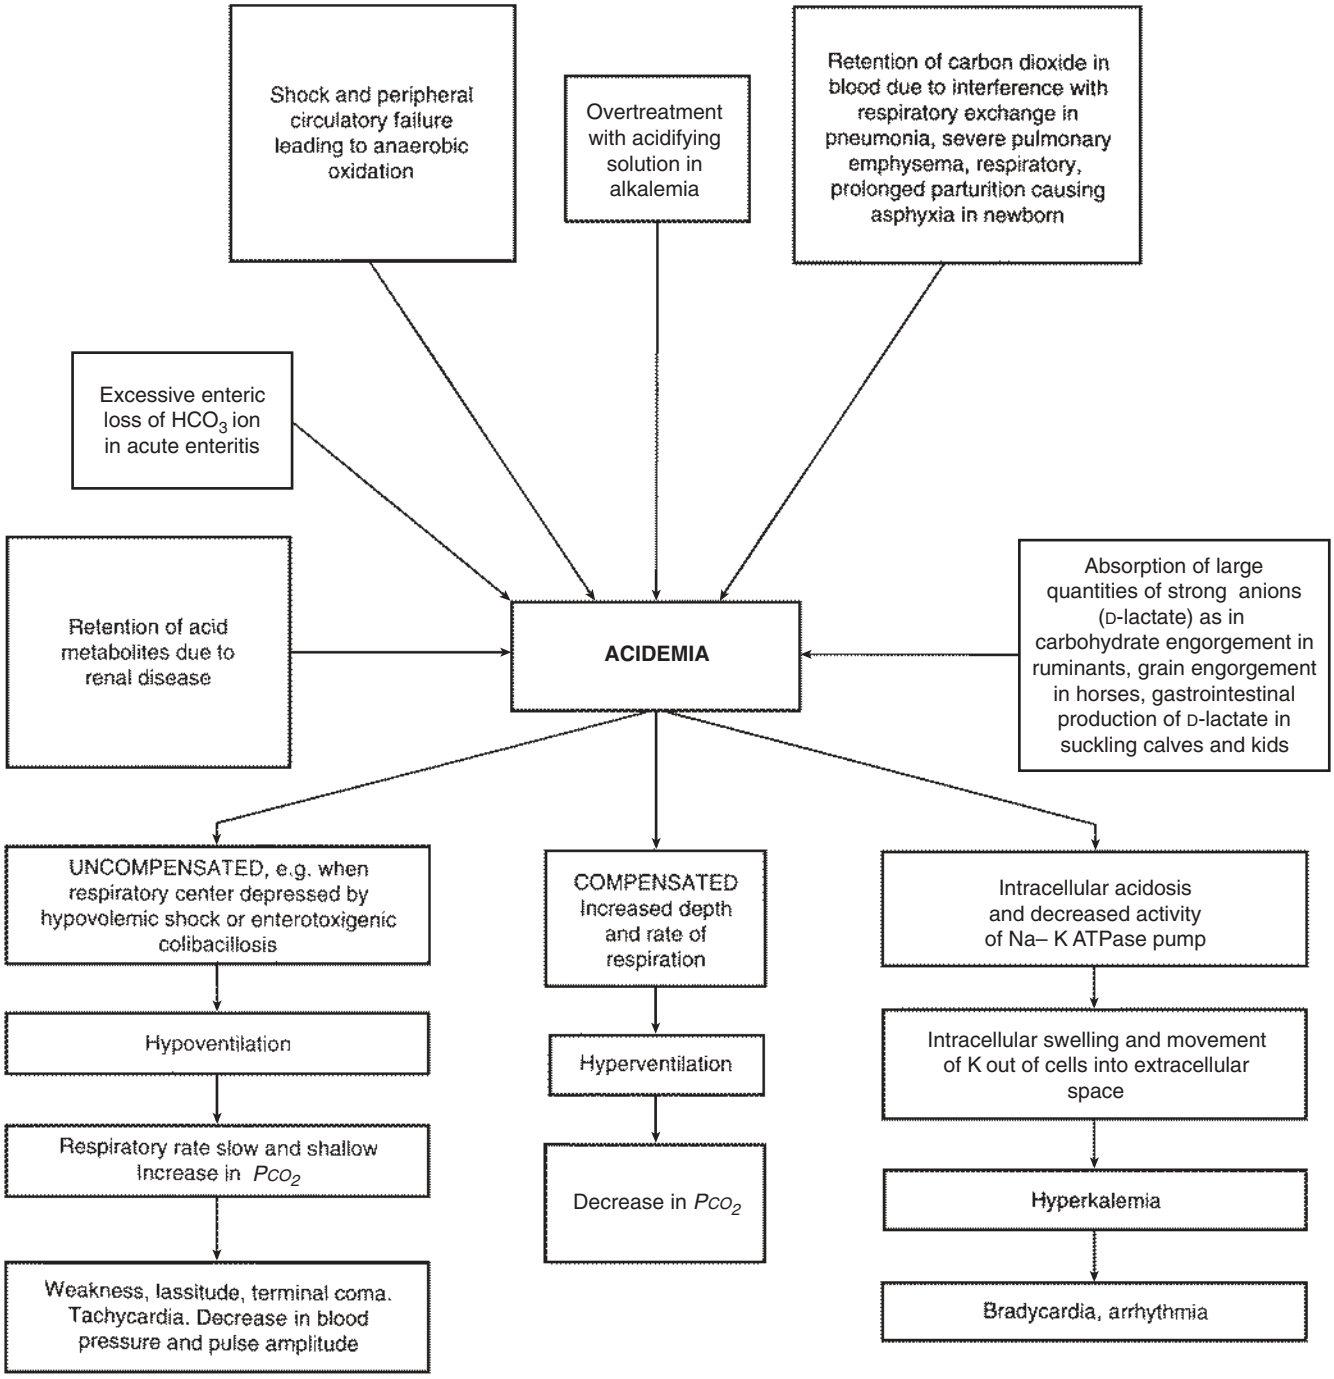

Fig. 5-12 Etiology and pathogenesis of acidemia.

acid in renal insufficiency or renal failure also contributes to a metabolic acidosis. The administration of excessive quantities of acidifying solutions for the treatment of metabolic alkalosis also may cause acidosis. Acute intestinal obstruction in the horse is commonly accompanied by metabolic acidosis, whereas in adult ruminants it is accompanied by alkalosis, at least initially.

PATHOGENESIS

The traditional Henderson–Hasselbalch approach indicates that metabolic acidosis is characterized by a low arterial blood pH and a low plasma bicarbonate concentration, following the loss of bicarbonate or the addition of hydrogen ions. Extracellular and intracellular buffering and respiratory compensation minimize the change in pH until the kidney can excrete sufficient hydrogen ions to correct the acid-base imbalance. Generally, the body will tolerate a pH range of 7.0 to 7.6, although survival has been reported at pH values beyond these limits for short periods, particularly in neonatal animals with diarrhea.

Acidemia generally depresses cardiac contractility and cardiac output in the denervated heart. In the intact animal, however, activation of the sympathetic nervous system in response to acidemia causes increased cardiac contractility, increased heart rate, and increased cardiac output. In acidemia, the myocardial response to catecholamines is not depressed until the blood pH is below 7.0 to 7.1. The increased carbon dioxide tension of the blood and depletion of bicarbonate causes an increase in the depth and then the rate of respiration by stimulation of the

respiratory center (**Kussmaul breathing**). However, when hypovolemic shock is severe enough, there is often depressed respiratory function, resulting in the additional accumulation of hydrogen ions; thus the acidemia is accentuated.

Acidemia causes varying degrees of depression of the central nervous system (CNS) and muscular weakness. Central nervous abnormalities may develop in neonatal foals that develop severe respiratory compromise, resulting in hypoxemia and hypercapnia, because of the reduced ability of the CSF to buffer acid-base changes. Carbon dioxide concentration within the CNS may have an effect on respiratory rate, neurotransmitter activity, CNS activity, cerebral blood flow, and cerebral extracellular fluid volume. If the blood–CSF and brain–CSF interfaces in the neonate are immature and unable to adequately compensate for vascular changes in CO_2, the hypercapnia may contribute to the CNS abnormalities that are often seen in sick newborn foals. The increased cerebral blood flow may be associated with cerebral edema, resulting in the depression of cerebral activity observed in these same foals.

The increased urinary excretion of acids in acidosis also causes polyuria, which may be sufficiently severe to cause dehydration or accentuate concomitant dehydration. Urine pH is also likely to be decreased in herbivores; however, aciduria may not always be present because of concurrent electrolyte and free water abnormalities.

CLINICAL FINDINGS

The major clinical manifestation of metabolic acidosis is mental depression and varying degrees of muscular weakness, depending on the mechanism for acidemia. Newborn calves, lambs, and goat kids with profound acidemia and metabolic acidosis are depressed, weak, and reluctant to suck. In severe acidemia, affected animals may be in lateral recumbency and appear to be in a state of coma. The depth and rate of respirations may be increased because of the increased P_{CO_2}. Respiratory compensation is normally evident when the bicarbonate level is diminished to 50% of normal. Calves affected with severe acidemia and dehydration caused by acute diarrhea may be unable to compensate because of depressed respiratory function. Their respiratory rate will be much slower and the depth of respiration much more shallow than normal. There is usually tachycardia, which becomes worse as the acidosis becomes more severe, and the amplitude of the pulse and blood pressure both decrease. A concomitant hyperkalemia will cause bradycardia, heart block, sudden collapse, and rapid death. This is particularly evident when animals with acidosis and hyperkalemia are transported and handled for treatment. The increased muscular activity appears to accentuate the abnormalities, and sudden death is not uncommon. Weakness, lassitude, and terminal coma are frequent observations. An interesting recent observation is that experimentally induced acute acidemia and metabolic acidosis (jugular venous blood pH 6.96; base excess −22 mEq/L) in healthy neonatal calves, following intravenous administration of 4 L of a mixture of HCl and NaCl solutions, produced no clinically detectable abnormalities.[5] This finding suggests acidemia must be chronic to produce clinically apparent abnormalities, or that most of the clinical abnormalities observed in acidemic patients are caused by their disease process and concurrent electrolyte and energetic abnormalities.

A syndrome of metabolic acidosis with minimal signs of dehydration or diarrhea has been described in calves from 1 to 4 weeks of age.[4] Affected calves are depressed, weak, and ataxic, and the suck and menace reflexes may be weak or absent. Some calves appear comatose. Similar clinical presentations have also occurred in lambs and goat kids with no apparent history of previous diarrhea.[6-8] The abnormal laboratory findings include a reduced venous blood pH, P_{CO_2} and bicarbonate ion concentration, marked hyper D-lactatemia, elevated blood urea nitrogen, increased AG, and a neutrophilic leukocytosis with a left shift. Many of the clinical signs appear to be primarily the consequence of hyper D-lactatemia. The intravenous administration of 2.5 to 4.5 L of isotonic (1.3%) sodium bicarbonate solution, the amount depending on the severity of the condition, is necessary to return the neonatal calf to health.

ALKALEMIA

ETIOLOGY AND PATHOGENESIS

Alkalemia is caused by an increased absorption of alkali, excessive loss of acid, or a deficit of carbon dioxide (Fig. 5-13). Abomasal atony caused by dilatation, impaction, or torsion of the abomasum is one of the most common causes of alkalemia in cattle. There is continuous secretion of hydrochloric acid and potassium into the abomasum, with failure of evacuation of the abomasal contents into the duodenum for absorption. Sequestration of hydrochloric acid and potassium occurs in the abomasum, along with reflux into the rumen, all of which results in a hypochloremic, hypokalemic alkalosis. In metabolic alkalosis, potassium will shift from the extracellular to the intracellular space, resulting in a hypokalemia when there may not be depletion of total body potassium. In cattle with metabolic alkalosis there is a paradoxical aciduria, which is not well understood but may be caused by severe electrolyte depletion placing limits on the kidney to regulate acid-base balance. Paradoxical aciduria must be differentiated from postparturient aciduria, which has been reported to occur in dairy cows.

Metabolic alkalosis has been recorded in cows with severe coliform mastitis, but the pathogenesis is unknown.

CLINICAL FINDINGS

The clinical findings of alkalosis are not characteristic enough to be recognized reliably. Alkalosis results in slow, shallow respirations in an attempt to preserve carbon dioxide. Muscular tremors and tetany with tonic and clonic convulsions may occur in extreme alkalemia (pH > 7.60) because of marked pH changes and possibly depression of the ionized fraction of serum calcium. Hyperpnea and dyspnea may also occur in the terminal stages.

Oncotic Pressure and Edema

ETIOLOGY

Decreased plasma oncotic pressure caused by hypoalbuminemia or hypoproteinemia is the most common cause of generalized symmetric edema. However, edema can also result from three other causes: **increased hydrostatic pressure** in capillaries and veins caused by chronic (congestive) heart failure or obstruction to venous return; **increased capillary permeability** in endotoxemia, part of the allergic response, vasculitis, and damage to the vascular endothelium; or **obstruction to lymphatic flow**.

Decreased Plasma Oncotic Pressure

Decreased total protein concentration in plasma, and particularly decreased plasma albumin concentration, will result in symmetric ventral edema. Hypoalbuminemia is more important than hypoglobulinemia in inducing edema formation because albumin provides the largest contribution to plasma oncotic pressure. Hypoalbuminemia can result from **increased loss** (caused by blood-sucking parasites or across the gastrointestinal tract, kidneys, or into a large third space such as the pleural or peritoneal cavities), **decreased production** (as in chronic hepatic failure), or **decreased intake**:

- Chronic blood loss, especially in heavy infestations with blood-sucking parasites such as *Strongylus* spp. in the horse; *Fasciola* spp. in ruminants; *Haemonchus* spp. in ruminants of all ages, especially goats; and *Bunostomum* spp. in calves
- Protein-losing gastroenteropathies as in Johne's disease and amyloidosis in adult cattle and right dorsal colitis in horses; proliferative enteropathy in foals caused by *Lawsonia intracellularis;* heavy infestation with nematode parasites in ruminants, particularly *Ostertagia* spp. in young cattle and cyathostomiasis in horses
- Glomerulonephropathies, such as amyloidosis in adult cattle and inherited

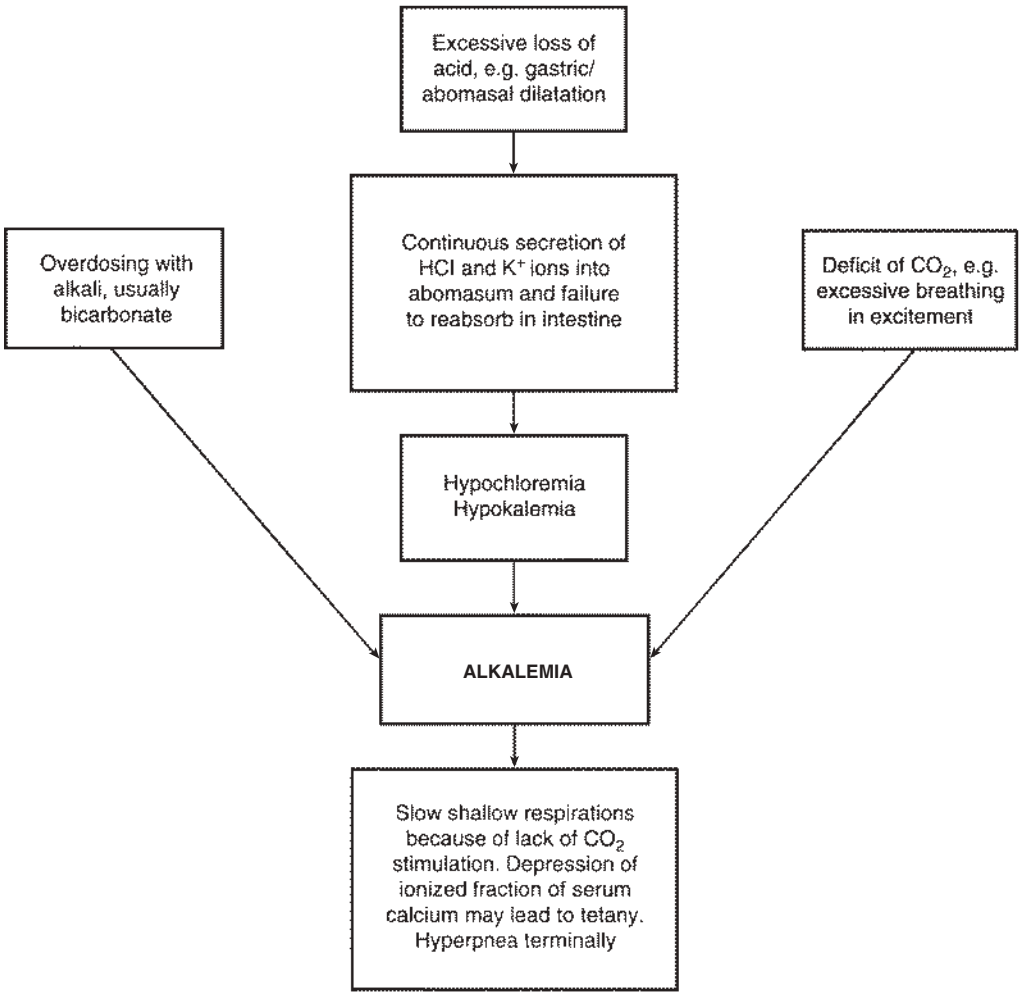

Fig. 5-13 Etiology and pathogenesis of alkalemia.

glomerulonephritis in Finnish Landrace lambs
- Chronic liver damage causing failure of plasma protein synthesis (rare and terminal in large animals)
- Terminally in prolonged malnutrition with low dietary protein intakes, e.g., ruminants at range in drought time

Increased Hydrostatic Pressure

Increased hydrostatic pressure can be caused by the following:
- Symmetric ventral edema in chronic (congestive) heart failure and symmetric pulmonary edema in acute heart failure
- Generalized edema in enzootic calcinosis of cattle
- Local symmetric ventral edema in udder edema in late pregnancy from compression of veins and lymphatics by the developing mammary gland (and possibly the enlarging fetus and uterus), causing mammary or ventral edema in cows (particularly heifers), mares, and occasionally ewes. Sodium and potassium intakes and cation–anion differences in the diet contribute to the severity of udder edema. Edema resolves 5 to 10 days following parturition.
- Local edema by compressive lesions on veins (as in thymic lymphosarcoma with compression of the cranial vena cava) draining other anatomic locations
- Local edema in portal hypertension caused by hepatic fibrosis causing ascites (rare in large animals)

Increased Capillary Permeability

Increased capillary permeability can be caused by the following:
- Endotoxemia
- Allergic edema as in urticaria and angioneurotic edema caused by local liberation of vasodilators
- Toxic damage to vascular endothelium or vasculitis such as in anthrax, gas gangrene, and malignant edema in ruminants; edema disease of pigs; mulberry heart disease in pigs; equine viral arteritis, equine infectious anemia, and purpura hemorrhagica in horses; and heartwater (cowdriosis) in ruminants

Obstruction to Lymphatic Flow

- Part of the edema caused by tumors or inflammatory swellings is lymphatic obstruction. Extensive fluid loss also originates from granulomatous lesions on serous surfaces. Ascites or hydrothorax may result.
- Congenital in inherited lymphatic obstruction edema of Ayrshire and Hereford calves
- Sporadic lymphangitis (big leg) of horses
- Edema of the lower limbs of horses immobilized because of injury or illness

PATHOGENESIS

Edema is the excessive accumulation of fluid in the interstitial space of tissue caused by a disturbance in the mechanism of fluid interchange among capillaries, the interstitial space, and the lymphatic vessels. At the arteriolar end of the capillaries the hydrostatic pressure of the blood is sufficient to overcome its oncotic pressure, and fluid tends to pass into the interstitial space. At the venous end of the capillaries the position is reversed

and fluid tends to return to the vascular system. The pressure differences are not great, but there is a large area for exchange, and a small increase in hydrostatic pressure or a small decrease in oncotic pressure leads to failure of the fluid to return to the capillaries.

Increased fluid passage into the interstitial space can also occur where there is increased vascular permeability caused by vascular damage. Under these circumstances, fluid accumulates in the interstitial space when the fluid flux across the endothelium is greater than the ability of the lymphatic system to drain it. Alternatively, capillary hydrostatic pressure, oncotic pressure, and vascular permeability might be normal, but fluid and vascular permeability can accumulate in the interstitial space when lymphatic drainage is occluded.

Edema of the lower limbs of immobilized horses (*filling*) is usually ascribed to poor lymphatic or venous return caused by inactivity of the *foot pump*. Lower limb edema in horses may also be related to changes in the hematocrit and plasma protein concentration in the distal limb vasculature as a result of inactivity.

CLINICAL FINDINGS

Accumulation of edematous transudate in subcutaneous tissues is referred to as **anasarca**, in the peritoneal cavity as **ascites**, in the pleural cavities as **hydrothorax,** and in the pericardial sac as **hydropericardium**. Anasarca in large animals is usually confined to the ventral wall of the abdomen and thorax, the brisket and, if the animal is grazing, the intermandibular space because of the large hydrostatic pressure gradient between the submandibular space and heart. Intermandibular edema may be less evident in animals housed because they do not have to lower their heads to feed. Edema of the limbs is uncommon in cattle, sheep, and pigs but is quite common in horses when the venous return is obstructed or there is a lack of muscular movement. Hydrothorax is not common with generalized edema and is usually an indication of an obstructive intrathoracic lesion. Local edema of the head in the horse is a common lesion in African horse sickness and purpura hemorrhagica.

Edematous swellings are **soft**, **painless,** and **cool to the touch** and **pit on pressure**. In ascites there is distension of the abdomen and the fluid can be detected by a fluid thrill on tactile percussion, fluid sounds on succussion, and by paracentesis. A level top line of fluid may be detectable by any of these means. In the pleural cavities and pericardial sac the clinical signs produced by the fluid accumulation include restriction of cardiac movements, embarrassment of respiration, and collapse of the ventral parts of the lungs. The heart sounds and respiratory sounds are muffled, and the presence of fluid may be ascertained by percussion and thoracocentesis or pericardiocentesis.

More localized edemas cause more localized signs: pulmonary edema is accompanied by respiratory distress and in some cases by an outpouring of froth from the nose; cerebral edema is manifested by severe nervous signs of altered mentation. A not uncommon entity is a large edematous plaque around the umbilicus in yearling horses. The plaque develops rapidly, causes no apparent illness, and subsides spontaneously after about 7 days. Thrombophlebitis is a common cause of localized edema, particularly of the head in horses and cattle with thrombophlebitis of both jugular veins. Head edema usually occurs in affected animals only when there is rapid and complete occlusion of both jugular veins by thrombophlebitis; a slower rate of jugular vein occlusion permits development of collateral veins for venous drainage of the head.

CLINICAL PATHOLOGY

Cytologic examination of a sample of fluid reveals an absence of inflammatory cells in which edema is the result of decreased plasma oncotic pressure (hypoalbuminemia), increased hydrostatic pressure, and increased vascular permeability or obstruction to lymphatic flow. Thoracocentesis or abdominocentesis is useful to differentiate the causes of fluid accumulation, in conjunction with measurement of serum albumin concentration and mean central venous pressure.

Examinations should always be directed toward determining the mechanism for hypoalbuminemia; in particular, the renal and gastrointestinal systems and liver are examined for evidence of disease and altered function. Generally, the serum albumin concentration is usually less than 15 g/L in animals with generalized edema caused by decreased plasma oncotic pressure. Generalized edema should always be expected whenever serum albumin concentration is less than 10 g/L.

NECROPSY FINDINGS

The nature of the accumulation of fluid in most cases is obvious on gross postmortem examination, but the determination of the cause of the disease that has resulted in hypoalbuminemia may require further histologic and cultural examination. Necropsy findings for the specific diseases in which edema is a feature are given in later chapters.

DIFFERENTIAL DIAGNOSIS

- Rupture of urethra or bladder for differentiation of ascites
- Peritonitis or pleuritis for accumulation of fluid in abdominal or pleural cavities
- Cellulitis for local edema

TREATMENT

The treatment of edema should be aimed at correcting the cause, whether it is decreased plasma oncotic pressure, increased hydrostatic pressure, increased endothelial permeability, or obstruction to lymphatic drainage. Hypoalbuminemia may require the administration of colloids such as plasma or Dextran 70, although this is only a short-term measure and is expensive. Chronic (congestive) heart failure may need to be treated with digoxin and thrombophlebitis of the jugular veins may need specific treatment (see Chapter 10). Parasitic gastroenteritis requires administration of the appropriate anthelmintic, obstructive edema requires removal of the physical cause, and increased permeability edema requires resolution of the cause of endothelial damage.

Ancillary nonspecific measures include restriction of the amount of salt in the diet and the use of diuretics. Diuretics may relieve the effects of pressure temporarily, but the primary cause needs to be addressed for a satisfactory outcome. Aspiration of edema fluid is rarely successful and is not routinely recommended but usually provides temporary relief because the fluid rapidly accumulates.

Naturally Occurring Combined Abnormalities of Free Water, Electrolyte, Acid-Base Balance, and Oncotic Pressure

These abnormalities are seldom primary and are usually secondary to a serious disease state such as abomasal volvulus, rumen overload, or acute intestinal obstruction—diseases that are in themselves life-threatening. Fluid and electrolyte abnormalities are also life-threatening and simple correction of the primary abnormality, for example, removal of a large section of a horse's small intestine, is valueless unless the dehydration,

hyponatremia, and acidosis are also corrected. The variation that can occur in these naturally occurring errors of fluid, electrolyte, and acid-base balance is what makes their diagnosis and treatment so difficult. If it were possible to have instant clinicopathologic advice on what the abnormalities were and how they were progressing as determined by constant laboratory monitoring, there would be little clinical challenge. The increased availability of point-of-care devices have made real-time clinicopathologic values rapidly available; however, economics may preclude use of such equipment. It is therefore necessary to have an understanding of the basic physiology and pathology of these diseases to be able to predict, by clinical examination and examination of the history, the likely deficiencies and imbalances and their degrees of severity.

In the preceding paragraphs the individual abnormalities of fluid and electrolyte homeostasis were described. In most naturally occurring diseases, the abnormalities are complex. For example, the probable events in a case of acute diarrhea are set out diagrammatically in Fig. 5-14. It is important

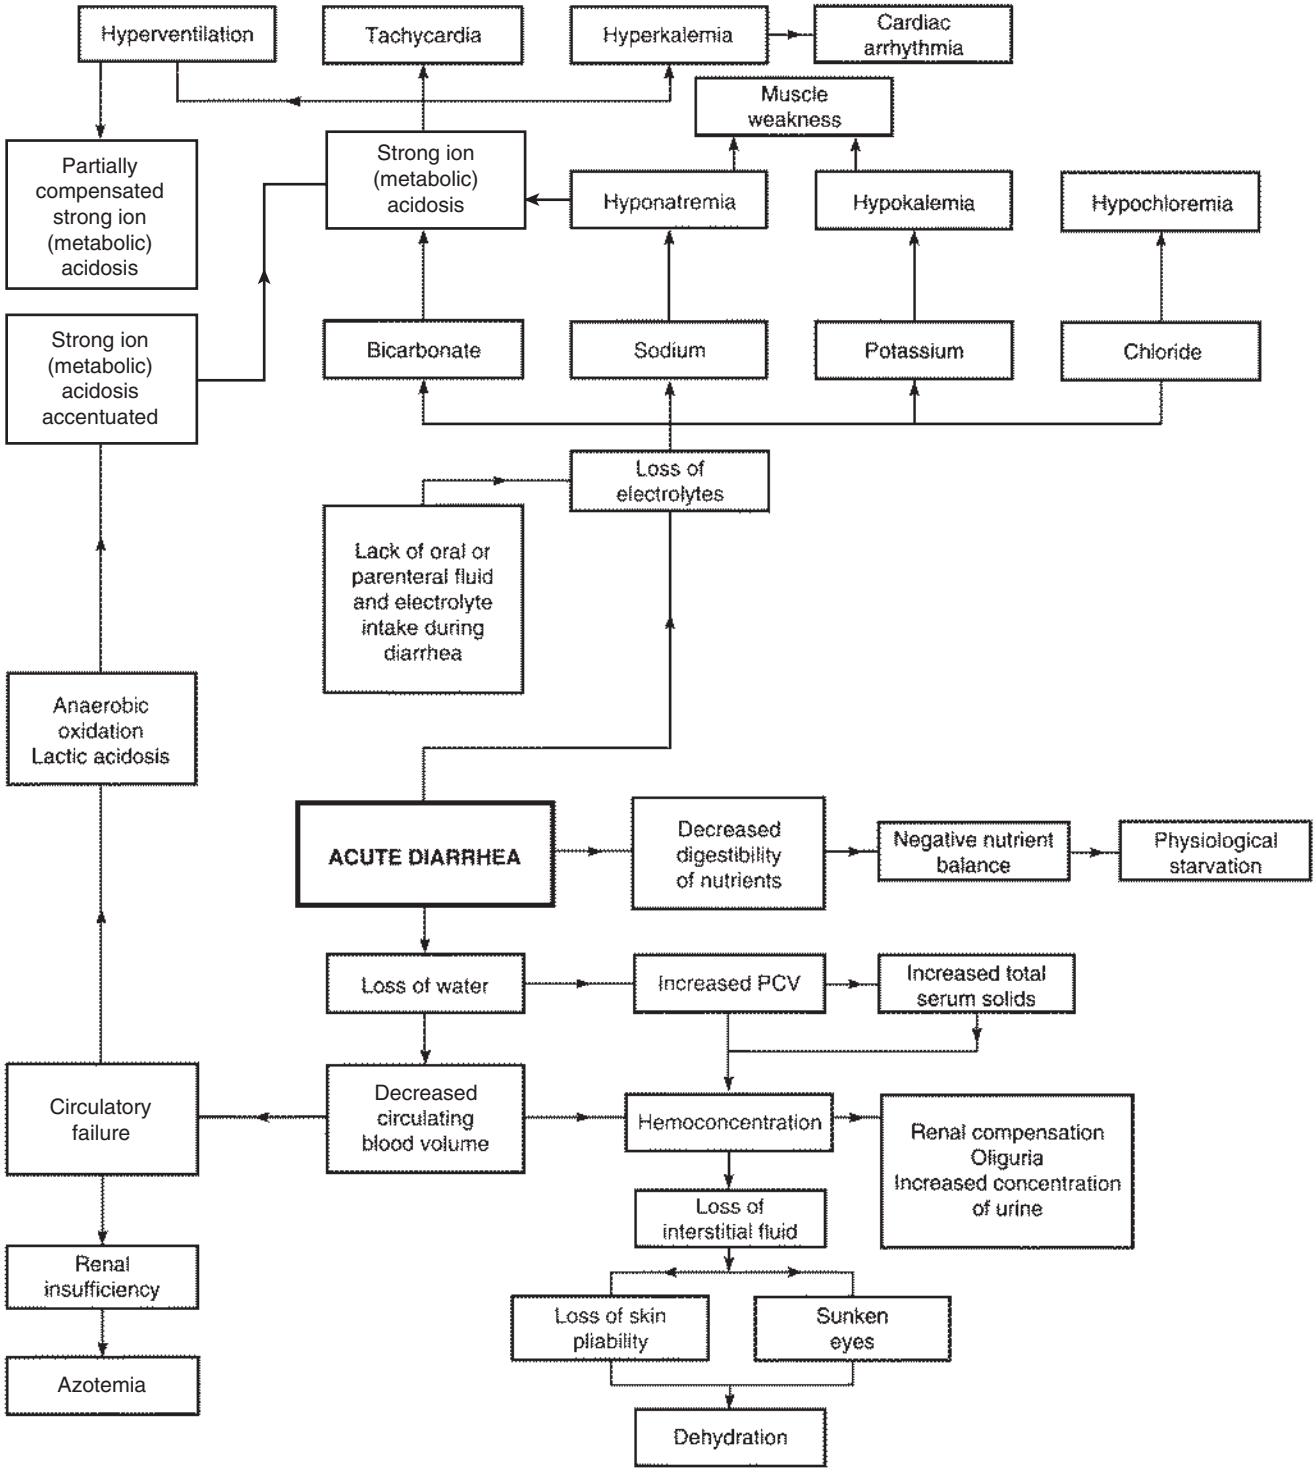

Fig. 5-14 The interrelationships among the changes in body water, electrolytes, and acid-base balance that can occur in diarrhea.

to remember that the variation in fluid and electrolyte imbalance is **dynamic** as a result of the compensatory changes occurring in various organs, especially the respiratory and circulatory systems and the kidneys. It is this volatility that makes clinicopathologic monitoring so important. Some generalizations on the dynamics of fluid and electrolyte status are as follows:

- Total body water and electrolytes are maintained at a homeostatic level by the buffering system of the blood, the lungs, and the kidneys.
- In disturbances of body water and electrolytes, the changes that occur are also dynamic, and there is constant reaction by the homeostatic mechanism to restore the water and electrolyte relationship to normal.
- With some exceptions, it is unusual to find an uncompensated alkalemia or acidemia. A partial compensation in the opposite direction of the primary acid-base imbalance is usually in progress, and it is important to determine the nature of the primary disturbance for the selection of rational therapy. A useful rule of thumb is that the primary disturbance (acidosis and alkalosis) is indicated by whether the blood pH is increased (alkalosis) or decreased (acidosis) relative to the mean value for the species examined.
- Often, the nature of the primary disturbance can be determined from a consideration of the history and the clinical findings.
- Dehydration caused by deprivation of water and electrolytes (lack of water or inability to drink) is mild and animals may appear only mildly dehydrated even after several days of water deprivation. The feces are hard and dry, the rumen contents are firm and dry, and urine volume is considerably decreased.
- With the exception of clinical dehydration, the clinical findings of electrolyte and acid-base imbalances are not characteristic.
- Without laboratory evaluation, the nature and degree of electrolyte and acid-base imbalance must be assumed and estimated based on the history of the affected animal and the changes that are most likely to have occurred.

NATURE OF THE DISEASE AND HISTORY

The **history of the case**, the **length of time** the animal has been affected, and the **tentative diagnosis** will provide a clinical assessment of the possible nature and degree of electrolyte and acid-base imbalance. Animals affected with acute diarrhea caused by infectious enteritis are likely to be in a state of metabolic acidosis and hyponatremia. In intestinal obstruction of the horse, there are varying degrees of dehydration and metabolic acidosis. Obstruction of the upper intestinal tract, or abomasal stasis, is characterized by varying degrees of dehydration and metabolic alkalosis with hypochloremia and hypokalemia. Chronic renal disease is characterized by hyponatremia and hypochloremia. Chronic inappetence in herbivores is characterized by hypokalemia, particularly in lactating ruminants. A combination of the clinical assessment and the available laboratory evaluation will allow the clinician to make the most rational approach to treatment.

The information on the duration of illness must be accurate or it will be misleading. The sequence of clinical findings in the history may indicate the trend in severity. Animals that have had a profuse watery diarrhea for 18 to 24 hours may be severely acidemic. Acute intestinal obstruction in cattle is not as severe as in the horse. Acute gastric or intestinal rupture in the horse or in cattle is usually rapidly fatal. Acidosis in grain overload in cattle may be fatal in 24 to 48 hours; acidosis in the horse with grain overload may be much more rapidly fatal because electrolyte disturbances are more severe in the horse.

CLINICAL FINDINGS

Dehydration is usually obvious clinically and determination of the PCV and serum or plasma total protein concentration will improve the assessment and provide values for daily comparison of response to treatment.

A normal rectal **temperature** is not a good prognostic guide, but a subnormal temperature suggests a worsening situation.

A gradually progressive **tachycardia** indicates that the patient is deteriorating. Generally, in the horse, a heart rate up to 60 beats/min suggests a minor lesion (but not always), a heart rate of 60 to 80 beats/min is in the danger area, 80 to 100 beats/min is serious, and more than 100 beats/min is commonly premortal (except in intestinal tympany that may be relieved).

A **cold clammy skin** that remains tented for more than 30 seconds suggests severe dehydration. **Cyanosis of the oral mucous membranes and a capillary refill time of more than 4 seconds** suggests a poor prognosis, as does rapid respiration (three to four times normal) with intermittent hyperpnea and apnea.

Muscular tremors and leg buckling are grave signs in the horse and are commonly followed by collapse and death. The inability of any dehydrated animal to stand (other reasons being eliminated) is ominous. **Severe depression** and dullness are commonly observed in acute conditions, and coma is usually terminal.

Metabolic acidosis is characterized by varying degrees of mental depression, decreased or absent suckle in neonatal animals, weakness, and ataxia. Some of the depression and weakness will be caused by dehydration, acidemia, or hyper D-lactatemia, although interestingly, acute and profound acidemia (jugular venous blood pH 6.96) in neonatal calves was not associated with depression or muscular weakness.[1] This is in contrast to the results of other studies in calves with more chronic and profound acidemia that profound acidemia is associated with decreased suckle and other clinical signs.[2,3] In newborn animals with metabolic acidosis associated with diarrhea, a failure to suck and the lack of a suck reflex are common.[4,5] Hyper D-lactatemia should be suspected in neonatal calves with a slowed or absent palpebral reflex, and profound acidemia and metabolic acidosis should be suspected in neonatal calves that stand unsteadily or have an inability to stand or have a delayed or absent reaction to acoustic, optical, or painful stimuli such as venipuncture.[4] Hyper D-lactatemia should also be suspected in neonatal lambs and goat kids with decreased or absent suckle that appear somnolent with varying degrees of ataxia.[6-8]

CLINICAL PATHOLOGY

Some representative laboratory values in examples of body water and electrolyte disturbances are given in Table 5-1.

Packed Cell Volume and Total Serum Protein or Plasma Protein

The PCV and the **total serum protein** or **plasma protein concentration** (historically called **total solids**) will indicate the severity of water loss. Anemic animals and those affected with diseases causing hypoproteinemia may provide misleading values. Neonatal animals often provide misleading values because of the variability of PCV in newborn animals and large differences in the transfer of colostral immunoglobulins.

The normal range depends on the age and species of animal, previous excitement, and the presence of anemia or hypoproteinemia. A PCV of 30% to 40% is considered normal; between 40% and 50%, fluid therapy may or may not be necessary; between 50% and 60%, fluids are necessary for recovery; and above 60% intensive fluid therapy is necessary and the prognosis is unfavorable. A total serum protein concentration of 6.0 to 7.5 g/dL is usually considered normal, at 8 to 10 g/dL fluids are needed and the prognosis is favorable, and above 10 g/dL the prognosis is unfavorable.

Total CO_2

A useful screening test for acid-base status in animals without evidence of respiratory disease is the total CO_2. Total CO_2 is defined as the amount of total carbon dioxide in plasma that can be liberated with a strong acid, and it can be calculated from the results of routine blood gas analysis as total $CO_2 = [HCO_3^-] + \text{dissolved } CO_2 + [H_2CO_3]$. The $[HCO_3^-]$ is calculated using the

Table 5-1 Representative laboratory values (mean ± sd) in body water and electrolyte disturbances

Clinical pathology	Acute diarrhea in horse	Acute diarrhea in calf	Metabolic alkalosis caused by abomasal dilatation impaction/ volvulus in cattle	Acute intestinal obstruction in horse	Acute carbohydrate engorgement in ruminants
Packed cell volume (%)	60 ± 7	45.3 ± 7.0	42 ± 6	64 ± 5	45 ± 6
Total serum solids (g/dL)	10 ± 2	8.6 ± 1.5	8.2 ± 1.5	11.5 ± 1.5	8.5 ± 1.8
Blood pH (venous)	7.10 ± 0.15	7.08 ± 0.12	7.49 ± 0.15	7.15 ± 0.04	7.10 ± 0.05
Plasma bicarbonate (mmol/L)	12 ± 3	13.7 ± 4.2	35.4 ± 5.7	18 ± 6	12.5 ± 3.5
Partial pressure of carbon dioxide (mm Hg)	45 ± 8	46.8 ± 6.4	46.4 ± 7.5	48 ± 6	40 ± 6
Serum sodium (mmol/L)	126 ± 3	138 ± 9.4	138.5 ± 5.4	135 ± 5	132 ± 4
Serum chloride (mmol/L)	99 ± 3	101.4 ± 7.5	88.6 ± 12.8	98 ± 4	93 ± 3
Serum potassium (mmol/L)	3.0 ± 1.2	7.4 ± 1.6	3.4 ± 0.6	3.8 ± 0.6	5.0 ± 2.5
Blood urea nitrogen (mg/dL)	60 ± 30	50.1 ± 30.5	40 ± 15	65 ± 35	55 ± 25

Henderson–Hasselbalch equation and the dissolved CO_2 is equal to $S \times P_{CO_2}$, whereas $[H_2CO_3]$ is negligible.

Many automatic serum biochemical analyzers directly measure total CO_2 (instead of calculating its value from the results of blood gas analysis), but for total CO_2 measurement it is important that blood collection tubes are completely filled before serum is harvested: failure to completely fill the blood tubes promotes escape of CO_2 from serum into the partial vacuum above, resulting in measured total CO_2 values that underestimate true serum total CO_2. It is also important that large partially evacuated tubes are used to collect the blood sample; this is because the air to blood sample ratio is higher in small tubes (3 mL or less in sample volume), leading to lower measured values for total CO_2 even with complete filling of the tube. As a consequence, total CO_2 is most accurately measured when partially evacuated tubes of 4- to 10-mL sample volume are used,[9] and samples are stored at 4°C.[10] Because changes in total CO_2 reflect changes in actual bicarbonate concentration, total CO_2 can never provide an independent measure of the nonrespiratory component of an acid-base disturbance. Total CO_2 does, however, provide a useful screening test for the presence of acid-base disturbances in domestic animals without clinical evidence of respiratory disease. In the absence of respiratory disease, a decrease in total CO_2 indicates a metabolic acidosis, whereas an increase in total CO_2 indicates metabolic alkalosis. Total CO_2 has historically been measured using the Harleco apparatus, although this methodology is no longer used because of the wide availability of point-of-care analyzers for blood gas and pH assessment.

Blood Gas and pH Analysis

Blood collected anaerobically into a glass syringe and stored in iced water represents the reference method for blood gas and pH analysis, but glass syringes are no longer used clinically because of their cost, fragility, and inability to be sterilized. Polypropylene syringes have replaced glass syringes for blood gas and pH analysis; however, clinicians should be aware that small differences exist in blood pH and gas measurements when syringes from different manufacturers are used.[11]

The method used for collection of an anaerobically collected blood sample for blood gas and pH analysis differs depending on whether the clinical interest is on the **respiratory system** (which requires collection of an **arterial blood sample**) or **metabolic status** (usually best evaluated using a blood sample from a large vein such as the **jugular vein**). Because respiratory disease that is clinically relevant can usually be detected during the physical examination of large animals,[12] most blood samples collected for blood gas and pH analysis are collected from the jugular vein.

If the primary clinical interest is an acid-base assessment of a large animal, then a jugular venous blood sample should be anaerobically obtained in a 3-mL polypropylene syringe that has been previously coated internally with sodium heparin (by drawing sodium heparin into the syringe barrel and then expelling all heparin from the syringe into the barrel before blood collection). Three milliliters of air should then be drawn into the syringe and forcibly expelled; this process is repeated three times. Evacuating the syringe in this manner ensures that minimal heparin is retained to dilute the blood sample, but a sufficient quantity is still present to prevent coagulation. Alternatively, commercially available polypropylene syringes that contain lyophilized lithium heparin can be used, but these syringes are considerably more expensive than standard polypropylene syringes.[13] Air bubbles should be immediately removed from the blood in the syringe after collection by holding the syringe vertically and tapping the syringe forcefully with a finger so that bubbles are dislodged and float upward. Once all visible bubbles are removed, a small amount of blood is expelled with the syringe still held vertically so that the syringe hub and needle lumen no longer contain air bubbles. A cork is then placed on the end of the needle to prevent loss of CO_2 and addition of O_2 to the blood sample. Jugular venous blood samples can predict arterial blood gas values of pH, P_{CO_2}, bicarbonate concentration, total CO_2, and base excess in animals that do not have respiratory disease, but only accurately predict blood pH in animals with respiratory disease.[14,15] Changes in jugular venous P_{O_2} over time are reflective of the direction and magnitude of the change in arterial P_{O_2}.[16]

Generally, the blood sample should be analyzed as soon as possible and preferably within 30 minutes of collection. The method used for **storage** of an anaerobically collected blood sample for blood gas and pH analysis differs depending on whether the sample was collected from an artery or large vein. Venous blood samples should be stored in ice water (0°C) until analysis.[17] This will minimize any time-related changes in the measured values for pH and P_{CO_2} and therefore the calculated values for base excess and total CO_2, which occur when blood is held at room temperature (20°C) or higher ambient temperatures, particularly in blood samples with high white blood cell concentrations. If the primary interest is evaluation of the respiratory system, an arterial blood sample should

be obtained in the same manner as a venous sample; however, the sample should be kept at body temperature (preferable) or room temperature before blood gas and pH analysis is performed, which should be completed as soon as possible. This is because storing 3-mL polypropylene syringes in ice water (0°C) facilitates oxygen diffusion through the barrel of the syringe, causing a preanalytical increase in P_{O_2}. Partially evacuated blood collection tubes should never be used for blood gas and pH analysis because they are not completely evacuated; consequently, an anaerobic blood sample cannot be obtained for analysis. Use of partially evacuated tubes always results in higher values for blood P_{O_2} and lower values for blood P_{CO_2} because oxygen and carbon dioxide in the blood equilibrate with the oxygen-rich and carbon dioxide–poor air within the tube.[18]

Use of point-of-care clinical analyzing systems has greatly facilitated routine evaluation of acid-base status in domestic animals and, generally, point-of-care systems are sufficiently accurate for clinical use.[19] A thorough assessment of acid-base status requires blood gas analysis and serum biochemical analysis, with blood samples obtained from a major vein or any artery. If serum total protein, albumin, and phosphate concentrations are approximately normal, then acid-base status should be evaluated using blood pH, P_{CO_2}, and extracellular base excess concentration. This is the traditional Henderson–Hasselbalch approach. The presence of unidentified anions should be investigated by calculating the AG. If serum total protein, albumin, and phosphate concentrations are markedly abnormal, then acid-base status should be evaluated using blood pH, P_{CO_2}, measured SID, and A_{TOT}. This is the simplified strong ion approach. The presence of unidentified strong ions should be investigated by calculating the SIG.

Normal blood pH for most domestic animals varies from 7.35 to 7.45 (venous blood). The degree of acidemia encountered includes moderate acidemia (pH 7.30–7.25), severe acidemia (pH 7.25–7.20), and grave acidemia (pH 7.10–7.00), which is associated with a high fatality rate, except in neonatal animals.

Blood or Plasma L-Lactate Concentration

The blood or plasma L-lactate concentration provides valuable information about the adequacy of oxygen delivery to the tissues, providing a means for assessing the severity of cardiovascular or pulmonary dysfunction, monitoring the response to treatment, and formulating a prognosis for survival. The normal plasma L-lactate concentration in large animals is generally considered to be less than 1.5 mmol/L. Increases in plasma L-lactate concentration have been categorized as mild (2.5–4.9 mmol/L), moderate (5.0–9.9 mmol/L), and severe (≥10 mmol/L), with L-lactate concentrations greater than 10 mmol/L associated with a high mortality in humans, pigs, and horses.

A number of inexpensive handheld point-of-care devices are now available to measure blood L-lactate concentration. Most devices measure L-lactate concentration in whole blood through a two-step process on a specialized reagent strip. The L-lactate concentration is measured by placing a drop of blood onto the reagent strip; the blood seeps through a protective mesh on which the erythrocytes are retained and only plasma reaches the detection area. A chemical reaction takes place, and a change in color or current is rapidly detected and converted to an L-lactate concentration using a proprietary algorithm. Values can be displayed as whole blood or plasma based on a mathematical function of the analyzer. A number of method comparison studies have shown these units to be clinically useful, particularly when blood L-lactate concentrations are <15 mmol/L.

Studies in critically ill human patients have shown excellent correlations between blood L-lactate concentration in arterial blood, pulmonary arterial blood, central venous blood, and blood obtained from a peripheral vein, indicating that jugular venous blood L-lactate concentration provides an accurate reflection of pulmonary arterial or systemic arterial blood L-lactate concentrations, which are regarded as the gold standard sites for measuring blood L-lactate concentration. Consequently, jugular venous blood L-lactate concentrations are now routinely measured in critically ill large animals, with the clinical emphasis on evaluating the change in L-lactate concentration over time.[20-22] This is because the change in L-lactate concentration over time (particularly to an intervention) has greater prognostic ability than the actual L-lactate concentration at one point in time.

Serum Electrolytes

Serum electrolyte concentrations indicate the severity of the electrolyte losses and the necessity for replacement with either balanced electrolyte solution or specific electrolyte solution. Serum concentrations of **sodium, chloride, and potassium** are usually determined. The total deficit for each electrolyte can be estimated using the standard formula presented under calculation of electrolyte requirements.

Serum electrolyte concentrations depend on the initial cause and the severity of the disease. For example, in most cases of acute diarrhea there is hyponatremia and metabolic acidosis, which are usually marked in the horse with acute diarrhea. The serum concentration of chloride may be normal or subnormal in acute diarrhea. The serum concentration of potassium will be below normal initially, but as acidemia develops and becomes severe **hyperkalemia** may occur. In cattle with **abomasal hypomotility** there will be a **hypochloremic hypokalemic metabolic alkalosis.**

Water and electrolyte abnormalities are classified into three types based on the measurement of electrolytes and osmolality (assuming plasma osmolality in healthy large animals approximates 285 mosm/kg):

- **Hypertonic dehydration** (true dehydration/desiccation): Osmolality greater than 300 mosm/kg, associated with water deprivation, some acute gastrointestinal problems, and some types of diarrhea
- **Hypotonic dehydration** (acute desalting water loss): Osmolality less than 270 mOsm/kg, associated with acute diarrhea, particularly secretory diarrheas such as salmonellosis
- **Isotonic dehydration:** Normal electrolyte and osmolality levels, as in horses losing electrolytes and water in almost equal proportions

Urea and Creatinine

Urea and **creatinine** are metabolic breakdown constituents that can be used to assess the degree of dehydration and to distinguish among prerenal, renal, and postrenal uremia. The plasma/serum concentrations of urea and creatinine concentration will be elevated, depending on the severity of the dehydration and decrease in circulating blood volume. Following treatment with fluids and electrolytes in prerenal uremia, the concentrations of urea and creatinine will decline. Plasma creatinine concentration varies directly with the muscle mass in healthy animals, and, consequently, is much higher in beef bulls than dairy cows. Plasma urea concentration varies directly with the protein intake in healthy animals, and, consequently, is increased in ruminants on a high-protein diet.

Blood or Plasma Glucose

Plasma glucose concentration can be determined using conventional laboratory techniques (hexokinase assay), which require submission of heparinized blood samples to a laboratory as soon as possible to avoid erroneous results caused by erythrocyte glycolysis. Quantitative, rapid, low-cost point-of-care methods for determining blood glucose concentrations are now widely available, but many units are designed for analysis of human blood and are not suitable for use in large animals because they incorrectly assume intraerythrocyte glucose concentration is the same as plasma glucose concentration (which is the case in most primates). In all of the domestic animals examined, intraerythrocyte glucose concentration is lower than plasma glucose concentration, and, consequently, the measured blood glucose value depends on the hematocrit, which is usually assumed to be fixed and approximately 44%. Consequently, preferred point-of-care glucose meters should use a species-specific algorithm for correcting the

measured whole blood value, or should also measure hematocrit and use an additional algorithm to correct the measured whole blood value for deviations of hematocrit from the assumed value of 44%.

Anion Gap

Acid-base balance has traditionally been evaluated by using the Henderson–Hasselbalch equation to characterize four primary acid-base disturbances (i.e., respiratory acidosis and alkalosis, metabolic acidosis, alkalosis) and by calculating the AG to estimate the UA concentration. Evaluation of the AG has become routine in many medical institutions. The calculation takes little time, is essentially without cost, and is valuable in assessing a variety of clinical conditions in which electrolyte imbalances occur.

The reference range for AG depends partly on the formula used for calculation. Some investigators prefer not to include the potassium concentration when calculating the AG on the basis that $[K^+]$ varies to a much smaller degree than does $[Na^+]$, $[Cl^-]$, and $[HCO_3^-]$; therefore it exerts minimal influence on the AG. However, the consensus is that $[K^+]$ should be included in the calculation of AG in large animals. Other investigators substitute the measured total CO_2 value for $[HCO_3^-]$, permitting calculation of the AG from serum or plasma biochemical analysis without the need for blood gas determination.

The AG represents the difference between the concentration of [UA] and [UC] in serum (with square brackets representing concentration), which can be expressed in the equation:

$$[Na^+]+[K^+]+[UC]=[Cl^-]+[HCO_3^-]+[UA],$$

which can be rearranged to

$$[UA]-[UC]=AG=([Na^+]+[K^+])-([Cl^-]+[HCO_3^-])$$

A change in [UA] or [UC] will cause a change in the AG. Under normal circumstances, approximately two thirds of the AG originates from the net negative charge of serum proteins, and the remainder represents the serum concentration of phosphate and strong anions, such as L-lactate, sulfate, β-OH butyrate, aceto-acetate, and anions associated with uremia.

The reference range for an AG depends on the age and species. The normal range for 2- to 3-week-old foals is 9 to 22 mEq/L, which is higher than that for 2-year-old horses (range 8–13 mEq/L). The 95% confidence interval for the range of AG for adult animals varies for different species: 8 to 13 mEq/L (horse), 14 to 20 mEq/L (cow), and 17 to 29 mEq/L (sheep). The AG values greater than 30 mEq/L have been observed in critically ill cattle; the increase is attributed to an increase in blood lactate and keto-acid concentration as well as to anions associated with uremia (Fig. 5-15).

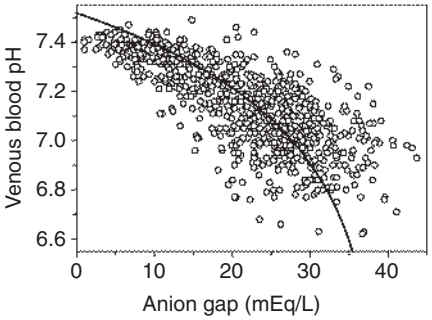

Fig. 5-15 Relationship between venous blood pH and anion gap (AG) in 806 neonatal calves with diarrhea. The thick line represents the result of nonlinear regression analysis: $pH = \log_{10}(39.7 - AG) + 5.92$. (Reproduced with permission from Trefz FM, Constable PD, Lorenz I. *J Vet Intern Med* 2015;29:678-687.)

A potentially valuable clinical use for the AG is in estimating a value for plasma L-lactate concentration, and this is why calculation of the AG has been considered a "poor man's plasma L-lactate concentration." The correlation between AG and plasma L-lactate concentrations is excellent in horses with intestinal disease. The AG in adult cattle is only moderately correlated with L-lactate concentrations and is similarly correlated with serum phosphate and creatinine concentrations in neonatal calves and adult cattle, as well as with serum albumin and total protein concentrations in adult cattle.[24] The AG determination is of limited usefulness in predicting blood L-lactate concentration in sick cattle, whereas the correlation between AG and serum concentration in sick cattle suggests that an increased AG should suggest the potential presence of uremic anions.

In summary, the determinants and utility of the AG in predicting hyperlactatemia are as follows:

- The AG in critically ill cattle is influenced by at least three factors: blood L-lactate concentration and the serum concentrations of phosphate and creatinine.
- There is a substantial quantity of UAs in sick cattle (approximately 7 mEq/L), which implies that either unidentified cations or anions other than chloride, bicarbonate, L-lactate, pyruvate, β-OH butyrate, or phosphate are present in critically ill cattle or that the formula used to assign protein charge was inaccurate.
- The correlation coefficient between AG and blood L-lactate concentration is similar to that observed in human patients and less than that seen in sick horses.
- The AG appears to predict blood L-lactate concentration more accurately in neonatal calves with experimental diarrhea than that in adult cattle with spontaneously occurring abomasal volvulus. The effects of acidemia on the AG and electrolyte concentration can vary depending on the cause of the acidosis and the species involved. Experimentally in horses, the infusion of L-lactic acid and D- and L-lactic acid results in acidosis with a high AG. An infusion of hydrochloric acid causes metabolic acidosis with a decreased AG. Infusions of isotonic saline (0.9% NaCl) cause mild acidosis with no significant change in AG.

Strong Ion Gap

The **SIG** represents the concentration of unmeasured strong ions in plasma and is more specific in detecting the presence of unmeasured strong ions in plasma than the AG. Moreover, the results of every study that has compared SIG with AG have demonstrated that SIG has greater explanatory power.

The SIG concept is a logical extension of the AG concept and was developed using the SID approach to express SIG in terms of other factors:

$$SIG=\{A_{TOT}/(1+10^{(pKa-pH)})\}-AG$$

where SIG represents the difference between unmeasured strong cation concentration and unmeasured strong anion concentration in plasma or serum. Calculation of the SIG requires species-specific values for the total plasma concentration of nonvolatile weak acids (A_{TOT}; i.e., the total concentration of plasma nonvolatile buffers such as albumin, globulin, and phosphate) and the negative logarithm to the base 10 (pK_a) of the effective dissociation constant (K_a) for plasma nonvolatile buffers. Values for A_{TOT} and pK_a have been determined for the plasma of horses (A_{TOT}, 15.0 mmol/L = 0.22 mmol/g of total protein or 0.47 mmol/g of albumin; pK_a, 6.66) and calves (A_{TOT}, 23.1 mmol/L = 0.41 mmol/g of total protein or 0.75 mmol/g of albumin; pK_a, 7.08).

The reference range for SIG is generally −5 to +5 mEq/L. An increase in SIG above 5 mEq/L (which occurs rarely) reflects an increase in unmeasured strong cations or a decrease in unmeasured strong anions. A decrease in SIG below −5 mEq/L (a common occurrence) reflects a decrease in unmeasured strong cations or, more likely, an increase in unmeasured strong anions (Fig. 5-16).

The SIG offers a more accurate approach to identifying unmeasured strong ions in plasma than does the AG. The critical difference between the AG and SIG is that the SIG provides an estimate of the difference between unmeasured strong cations and strong anions, whereas AG provides an estimate of the difference between UCs and anions (including strong ions and nonvolatile buffer ions such as albumin, globulin,

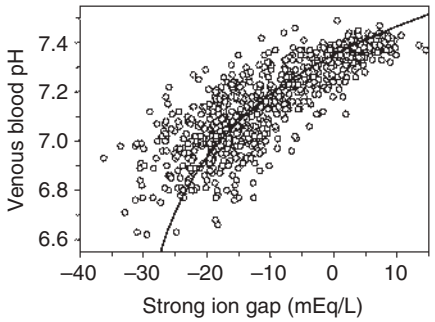

Fig. 5-16 Relationship between venous blood pH and strong ion gap (SIG) in 806 neonatal calves with diarrhea. The thick line represents the result of nonlinear regression analysis: pH = $\log_{10}$ (SIG + 32.4) + 5.84. (Reproduced with permission from Trefz FM, Constable PD, Lorenz I. *J Vet Intern Med* 2015;29:678-687.)

and phosphate). A change in SIG therefore provides a more specific method for detecting a change in unmeasured strong ions (such as lactate) than a change in AG.[23,24]

Osmolal Gap

Evaluation of the osmolal gap is a means of detecting an increased amount of abnormal osmotically active solute in the blood. The osmolal gap is the difference between the measured plasma osmolality and the osmolality calculated from the plasma concentration of normally measured solutes. Sodium and potassium and their associated anions, along with glucose and urea, constitute the majority of normal osmotically active solutes. The following formula is recommended with plasma/serum glucose and urea measured in units of mg/dL,[25] although many clinicians disregard the contribution of urea on the basis that it is an ineffective osmole that easily crosses cell membranes:

$$1.90\times([Na^+]+[K^+])+(glucose/18)+(urea/2.8)+5.0.$$

Examination of the triad of **calculated osmolality**, **measured osmolality,** and the **osmolal gap** is beneficial in the diagnosis and prognosis of a number of diseases.

Arterial, Jugular, or Central Venous Blood Pressure

Arterial blood pressure is occasionally measured in referral centers in which the technical assistance and instrumentation are readily available. Mean arterial blood pressure provides a rough guide for the presence and severity of terminal shock but not for the severity or extent of the initiating lesion. Methods for measuring mean arterial blood pressure are summarized in Chapter 10.

Jugular venous pressure (or preferably central venous pressure) is occasionally measured in referral centers to monitor the response to fluid administration. Normal pressure is 2 to 10 cmH_2O (0.3–1.0 kPa), referenced to the point of the shoulder (scapulohumeral joint). Below 2 cmH_2O (0.3 kPa) requires fluid therapy; above 15 cmH_2O (1.5 kPa) indicates cardiac failure and volume overload. Mean central venous pressure provided a sensitive method for detecting hypovolemia in horses having blood removed at 16 mL/kg; the significant reduction in mean central venous pressure occurred in the absence of a change in heart rate.[17] Methods for measuring jugular venous pressure or central venous pressure are summarized in Chapter 10.

Total Body Water

The most practical way to measure change in body water is to measure the **change in BW** by weighing the animal on admission and at a standard time each day, usually before the morning feeding. This is most valuable in animals admitted to a hospital with clinical signs consistent with severe dehydration. Simultaneous measurement of hematocrit and plasma protein concentration using refractometry provides a low-cost but clinically valuable method for monitoring changes in extracellular fluid volume from admission. The clinical utility of frequent weighing can be improved by periodically weighing the food offered and eaten as well as determining the weight of feces produced. More exact estimates are provided if urine is collected and weighed, although this is usually only feasible in neonatal calves and small ruminants. Losses in milk volume also need to be accounted for if the method is used in lactating dairy cattle.

Bioelectrical impedance analysis has been used in horses to detect acute changes in fluid volume in horses, although impedance analysis appears to have more applications in research studies than in the critical care of dehydrated or shocked animals. The method uses a head–tail configuration (although other configurations have been used) and requires shaving two areas of skin over the right cranial border of the first cervical vertebra and over the caudal aspect of the right tuber ischia and cleaning the skin with alcohol. Subdermal platinum electrodes are then fixed in place.[27,28] These electrodes provide the best signal-to-noise ratio but are not practical for use in the field; noninvasive carbon fiber electrodes appear to provide a good option for field work. Adhesive electrodes are used for humans but do not work well in horses. A multifrequency bioimpedance analyzer measures the resistance and reactance between the electrodes at multiple frequencies at the two sites and uses proprietary algorithms to calculate extracellular fluid volume, intracellular fluid volume, and total body water. As currently used, the method does not appear to have sufficient sensitivity for routine clinical use because it was unable to detect a 20% change in blood volume caused by hemorrhage and underestimated the actual contraction and expansion of the extracellular fluid volume in adult horses administered furosemide and intravenous large-volume crystalloid solutions.[27] In addition, when applied to 48 kg BW neonatal foals with an estimated extracellular fluid volume of 17.4 L, the 95% confidence interval for the volume estimated by bioelectrical impedance was 20% of the actual value with the estimate ranging from 15.6 to 19.2 L.[28]

The sodium dilution principle has also been used to estimate changes in extracellular and intracellular volume in horses. The method requires measurement of serum sodium concentration, urine sodium concentration, and BW, and makes the assumption that sodium ions and water remain constant over time in physiologic fluids, except for measured "ins" and "outs" that reflect intravenous fluid administration and urine production. The method requires validation in clinically ill horses before recommending its use.[29]

The reference method for measuring total body water in horses before and after exercise uses orally administered deuterium oxide followed by a series of blood samples taken for analysis. Mean total body water content is about 62%. This method is not used clinically.

Principles of Fluid and Electrolyte Therapy

The most important principle is to prevent or minimize dehydration and electrolyte loss whenever possible. This means the provision of an adequate water supply, adequate drinking space, and a continuous supply of salt and the necessary minerals. The next most important principle is to treat potential losses of fluid and electrolytes as quickly as possible to minimize the degree of dehydration and acid-base imbalance that may occur in animals with diseases in which losses are occurring.

The **major therapeutic objectives** are to **correct the abnormalities** that already exist and to monitor and **provide maintenance therapy** until the animal has recovered. Correction of the abnormalities may require 4 to 6 hours, and maintenance therapy may be necessary for 2 to 4 days, depending on the cause of the disease. Recent studies have identified concerns with bolus fluid resuscitation in septic patients, such as 20 to 40 mL/kg in the first hour.[1-3] These findings suggest that rapid resuscitation should focus on the use of low-volume hypertonic saline, and that traditional high-volume crystalloid solution resuscitation should not use bolus administration. Instead, traditional high-volume crystalloid fluid resuscitation should focus on slower rates of administration (<20 ml/kg/h).

There are at least five possible free water, electrolyte, acid-base, and oncotic pressure abnormalities that could exist at the same time and must be corrected:

- **Fluid volume deficit (free water)**
- **Plasma osmolar deficits**
- **Specific electrolyte imbalances**
- **Acid-base imbalance**
- **Oncotic pressure imbalances**

The two major problems are to determine the nature and degree of the abnormalities present and to decide which fluid and electrolyte replacement solution should be used.

The ideal situation would be to make both a clinical and laboratory evaluation of the animal as described earlier. The history and the diagnosis will suggest the possibility of acidemia or alkalemia and the electrolyte imbalances that are likely to be present. The degree of dehydration can usually be recognized clinically. Severe dehydration and acidemia should be treated as quickly as possible. A summary of the disturbances of fluid and electrolyte balance that occur in some common diseases of cattle and horses, and the suggested fluid therapy, is presented in Table 5-2.

Calculation of Electrolyte Requirements

The electrolyte deficits can be estimated using the serum electrolyte values of the affected animal. The total deficit of the electrolyte in mEq is the product of the deficit of the electrolyte in mEq per liter (ΔmEq/L) and the distribution space for the electrolyte. For sodium, chloride, and bicarbonate, the distribution space is the extracellular fluid volume, which approximates 30% of BW in normally hydrated adults and 50% in normally hydrated neonates. In other words, for sodium, chloride, and bicarbonate, the total milliequivalent deficit = (ΔmEq/L) × (estimated euhydrated BW in kg) × (0.3 or 0.5).

There is much less certainty about the size of the potassium space because potassium is predominantly an intracellular ion.

Types of Intravenous Fluid

Fluids are categorized on the basis of their physical nature (**crystalloid** or **colloid**)

Table 5-2 Summary of disturbances of body water, electrolytes, and acid-base balance in some common diseases of cattle and horses, and suggested fluid therapy

Disease	Major abnormalities and deficits	Flue and electrolyte requirements
Neonatal calf diarrhea (including piglets and lambs)	Metabolic acidosis, low plasma bicarbonate, severe dehydration, loss of sodium, hyperkalemia when acidosis severe	Equal mixtures of isotonic saline and isotonic sodium bicarbonate with 5% dextrose, balanced electrolytes, intravenous and orally
D-lactic acidosis (carbohydrate engorgement of ruminants)	Metabolic acidosis, low plasma bicarbonate, severe dehydration	Sodium bicarbonate initially followed by balanced electrolytes, intravenously
Acute diffuse peritonitis	Dehydration, slight metabolic alkalosis caused by paralytic ileus	Balanced electrolyte solutions in large quantities intravenously for hydration and maintenance
Right-side dilatation/abomasal volvulus of cattle, abomasal impaction (dietary or vagal nerve injury).	Metabolic alkalosis, marked hypochloremia, hypokalemia, severe dehydration	Balanced electrolyte solutions or high-potassium and chloride-acidifying solution, intravenously; may give acidifying solutions orally; can also use mixture of 2 L of isotonic saline (0.9%), 1 L isotonic potassium chloride (1.1%), and 1 L isotonic dextrose (5%)
Peracute coliform mastitis	Severe dehydration, mild electrolyte deficits including mild hypocalcemia, metabolic acidosis if diarrhea present	Balanced electrolyte solutions intravenously in large quantities for hydration and maintenance for 24–48 hours (100–150 mL/kg BW per 24 hours)
Acute diarrhea in the horse (enteric salmonellosis)	Severe dehydration, marked hyponatremia, metabolic acidosis, hypokalemia occurs following bicarbonate therapy.	Hypertonic sodium bicarbonate (5%) 3–5 L/500 kg BW followed by high-sodium, high-potassium alkalinizing solution to correct hypokalemia following bicarbonate therapy, all by the intravenous route
Acute grain engorgement in the horse	Metabolic acidosis, dehydration, and shock	Hypertonic sodium bicarbonate (5%) 3–5 L/500 kg BW followed by balanced electrolytes intravenously
Water and electrolyte deprivation, esophageal obstruction in horses	Moderate dehydration	Balanced electrolytes intravenously, when obstruction relieved, provide electrolyte solution orally
Acute intestinal obstruction	Metabolic acidosis or alkalosis dependent on level of obstruction, severe dehydration in horse, moderate in cow	Isotonic sodium bicarbonate initially, 3–5 L/500 kg BW followed by balanced electrolytes intravenously, horses may develop hypokalemia following bicarbonate therapy and must be given potassium chloride

and osmolarity (**hypotonic**, **isotonic**, or **hypertonic**). Isotonic or slightly hypotonic crystalloid solutions are most commonly administered parenterally, although under specific circumstances hypertonic crystalloid solutions or isotonic colloid solutions are preferred.

Crystalloid Solutions

A crystalloid is a substance that forms a true solution and is capable of being crystallized. Examples of crystalloid solutions are Ringer's solution, lactated Ringer's solution, acetated Ringer's solution, 0.9% NaCl, 7.2% NaCl (hypertonic saline), 1.3% $NaHCO_3$, 8% $NaHCO_3$, calcium gluconate, and 50% dextrose. Sodium chloride is the classic example of a crystalloid solution, as table salt (NaCl) exists as a crystal but dissolves completely when placed in water. Because crystalloids dissolve completely in water, crystalloid solutions containing sodium distribute throughout the entire extracellular fluid space; therefore they are not confined to the intravascular space. Sodium-containing crystalloid solutions are always indicated in hypovolemia (circuit problem) but are contraindicated in congestive heart failure (pump problem) because they provide an additional sodium load, and animals with heart failure have already retained too much sodium. Sodium-containing crystalloid solutions are also contraindicated in the presence of severe hypoalbuminemia because sodium-containing crystalloids will further decrease plasma albumin concentration and oncotic pressure, resulting in the movement of fluid into the interstitial spaces and exacerbating tissue edema.

Crystalloid solutions are characterized in terms of the number of molecules (numerator) per volume of solution (denominator). The number of molecules is expressed in moles (abbreviated as mol), where 1 mol of compound is equivalent to the molecular weight of the compound in grams (formula weights for NaCl, $NaHCO_3$, and KCl are 58.5, 85, and 74 g, respectively). Because body fluids are dilute, moles are expressed as millimoles (mmol = mol/1000) to facilitate readability.

Crystalloid solutions are commonly expressed in terms of the number of charged components (numerator) per volume of solution (denominator). The number of charged components is expressed in equivalents (abbreviated as Eq), where 1 Eq is the number of each charged component that combines with or replaces 1 mol of hydrogen ion (this means that Eq is always a positive number). Because body fluids are dilute, equivalents are expressed as milliequivalents (mEq = Eq/1000) to facilitate readability. To calculate the number of mEq from mmol, simply multiply the number of millimoles by the valence (charge) or mEq/L = (mmol/L) × valence. For instance, 1 mmol of NaCl in solution provides 2 mEq: 1 mEq of Na^+ (1 × 1) and 1 mEq of Cl^- (1 × 1), assuming that NaCl acts as a strong electrolyte in water (i.e., it completely dissociates into Na^+ and Cl^- in water). In comparison, 1 mmol of $CaCl_2$ in solution provides 4 mEq: 2 mEq of Ca^{2+} (1 × 2) and 2 mEq of Cl^- (2 × 1), and 1 mmol of dextrose provides 0 mEq, because dextrose does not dissociate into charged components in water.

The principal reason constituents of plasma are defined in terms of mEq instead of mmol is because electroneutrality must be preserved at all times; the difference between the charge assigned to all strong cations (Na^+, K^+, Ca^{2+}, and Mg^{2+}) and strong anions (Cl^-, lactate, sulfate, ketoacids, nonesterified fatty acids, etc.) in plasma is called the SID, and this factor independently and directly alters blood pH and therefore acid-base status. The normal SID of plasma is approximately 40 mEq/L, although there are species differences in the actual value. Electrolyte solutions with an effective SID greater than 40 mEq/L are therefore alkalinizing because they create a strong ion alkalosis. Electrolyte solutions with an effective SID = 0 are acidifying because they create a strong ion acidosis. Electrolyte solutions of intermediate SID may be alkalinizing or acidifying, depending on the change in plasma SID relative to the decrease in plasma protein concentration (which is alkalinizing; Table 5-3).

Table 5-3 Summary of effective strong ion difference and osmolarity of parenterally administered crystalloid solutions

Solution	Effective SID (mEq/L)	Osmolarity (mOsm/L)
Hypertonic solutions (>312 mOsm/L)		
Alkalinizing		
8.4% $NaHCO_3$	1000	2000
5.0% $NaHCO_3$	595	1190
10% NaH_2PO_4	145	1150
Acidifying		
50% dextrose	0	2500
7.2% NaCl	0	2460
25% magnesium sulfate	0	2028
23% calcium borogluconate	0	1069
Isotonic solutions (300–312 mOsm/L)		
Alkalinizing		
Tromethamine	210	300
1.3% $NaHCO_3$	155	310
Carbicarb	75	300
McSherry's solution	54	312
Darrow's solution	53	312
Acidifying		
Ringer's solution	0	309
0.9% NaCl	0	308
1.15% KCl	0	308
Hypotonic solutions (<300 mOsm/L)		
Alkalinizing		
Acetated Ringer's	27	294
Lactated Ringer's	<14	275
Acidifying		
5% dextrose	0	250

The effective strong ion difference (SID) is the difference between the strong cation and strong anion concentration after metabolizable anions (such as lactate or acetate) have been completely metabolized to produce bicarbonate. Electrolyte solutions with an effective SID of more than 27 mEq/L are alkalinizing because they create a strong ion alkalosis. Electrolyte solutions with an effective SID = 0 are acidifying because they create a strong ion acidosis.

Isotonic, Hypertonic, and Hypotonic Crystalloid Solutions

The tonicity of the solution is an important clinical issue. Complete understanding of the tonicity concept requires differentiation of two terms, **osmolality** and **osmolarity**. Osmolality is the number of dissolved particles per kilogram of solution and is expressed as mOsm/kg of solution. The normal plasma osmolality in large animals is approximately 285 mOsm/kg, and plasma osmolality is aggressively defended by increasing water intake (osmolality >285 mOsm/kg) or promoting free water excretion (osmolality <285 mOsm/kg). The correct term in plasma and extracellular fluid is osmolality, because this factor is measured in the laboratory; however, frequently the term osmolarity is used because 1 L of lactated Ringer's solution closely approximates 1 kg of lactated Ringer's solution and because osmolarity can be easily calculated from the concentration of electrolytes in the fluid solution. Osmolarity is the number of particles per liter of solution and is expressed as mOsm/L of solution.

One kilogram (1 L) of plasma from an adult large animal has two components, 70 g of protein and 930 g of plasma water. Accordingly, the osmolality of normal plasma (285 mOsm/kg) is equivalent to a plasma water osmolarity of 306 mOsm/L ({285 mOsm/kg}/{0.93 L/kg}). Ringer's solution, 0.9% NaCl, and 1.3% $NaHCO_3$ are therefore considered isotonic solutions because they distribute in plasma water and have calculated osmolarities of 309, 308, and 310 mOsm/L, respectively.

The normal plasma osmolarity for solutions to be administered to large animals is approximately 306 mOsm/L; solutions can therefore be defined as isotonic (300–312 mOsm/L), hypertonic (>312 mOsm/L), or hypotonic (<300 mOsm/L). Using this categorization, it is readily apparent that some routinely used crystalloid solutions are hypotonic; in particular, lactated Ringer's solution (275 mOsm/L) is mildly hypotonic and 5% dextrose (250 mOsm/L) is moderately hypotonic, although, as glucose is metabolized, 5% dextrose becomes an increasingly hypotonic solution. Erythrocytes are resistant to increases in plasma osmolarity, whereas they are susceptible to mild decreases in osmolarity; this is the basis of the red blood cell fragility test in which red blood cell suspensions are placed in solutions of decreasing osmolarity. Because of hypotonic-induced hemolysis, parenterally administered fluids should ideally be isotonic or hypertonic.

Hypotonic Crystalloid Solutions

Lactated Ringer's solution is a balanced, polyionic, alkalinizing, and hypotonic (275 mOsm/L) crystalloid solution containing physiologic concentrations of Na^+, K^+, Ca^{2+}, Cl^-, and L- and D-lactate ($CH_3CH(OH)COO^-$). Lactated Ringer's solution alkalinizes because lactate is predominantly metabolized to the bicarbonate ion:

$$CH_3CH(OH)COO^- + 3O_2 \rightarrow 2CO_2 + 2H_2O + HCO_3^-$$

The lactate in lactated Ringer's is a racemic, approximately equimolar mixture of L- and D-lactate. In healthy animals L-lactate is rapidly metabolized; however, animals have negligible D-lactate dehydrogenase activity, leading to slow clearance of D-lactate, which is primarily through the urinary system. DL-lactate solutions, such as lactated Ringer's, therefore have approximately half the alkalinizing ability of L-lactate solutions. The effective SID of lactated Ringer's solution is therefore less than the calculated value of 28 mEq/L. Lactated Ringer's solution is the standard intravenous fluid for neonates and adult horses, because these animals tend to become acidemic when inappetent. However, lactated Ringer's solution is theoretically inferior to acetated Ringer's solution, because critically ill animals may have increased blood L-lactate concentrations and it is incongruous to add L-lactate in this situation.

There has been recent interest in increasing the L-lactate concentration of lactated Ringer's and decreasing the chloride concentration to increase the alkalinizing effect. The inclusion of L-lactate at 56 or 84 mEq/L to an isotonic sodium solution provided a similar alkalinizing effect in healthy calves to the inclusion of bicarbonate at 56 or 84 mEq/L.[4]

Acetated Ringer's solution is a balanced, polyionic, alkalinizing, and hypotonic (294 mOsm/L) crystalloid solution. Commercially available formulations of acetated Ringer's solution contain physiologic concentrations of Na^+, K^+, Mg^{2+}, Cl^-, acetate (CH_3COO^-), and gluconate ($CH_2(OH)\{CH(OH)\}_4COO^-$); the gluconate is problematic because calves (and presumably all large animals) slowly metabolize gluconate.[5] Acetated Ringer's solution alkalinizes because acetate is metabolized to the bicarbonate ion:

$$CH_3COO^- + 2O_2 \rightarrow CO_2 + H_2O + HCO_3^-$$

The strong ion approach to acid-base balance states that acetated Ringer's solution is alkalinizing because it contains a metabolizable strong anion (acetate) that, when metabolized, increases the SID. Two acetated Ringer's solution formulations are commercially available in North America, Plasma-Lyte A and Normosol-R. Both have the same formulation, except Plasma-Lyte has a pH of 7.4 when administered compared with Normosol-R, which has a pH of 6.6 when administered. The difference in solution pH is unlikely to be of clinical significance. The main advantage of acetated Ringer's solution is that the sodium concentration (140 mEq/L) is approximately the same as that of livestock animals, whereas the sodium concentration in lactated Ringer's (130 mEq/L) is appreciably lower.

Five percent dextrose is 250 mOsm/L as administered, but plasma osmolarity decreases below 250 mOsm/L as the glucose is metabolized, leaving free water. Because 5% dextrose has no sodium to expand the extracellular volume and has much less energy content than 50% dextrose on a volume basis, the only application of 5% dextrose is to provide free water or as a vehicle for pharmacologic agents.

Isotonic Crystalloid Solutions

Ringer's solution is a balanced polyionic nonalkalinizing isotonic crystalloid solution that contains physiologic concentrations of Na^+, K^+, Ca^{2+}, and Cl^-. This solution is mildly acidifying because its effective SID = 0 mEq/L. Addition of a fluid with a SID of 0 mEq/L to plasma (normal SID ≈ 40 mEq/L) will decrease plasma SID and therefore directly and independently decrease plasma pH because a 1 mEq/L decrease in SID decreases plasma pH by approximately 0.016. Ringer's solution is the standard intravenous fluid for adult ruminants because these ruminants tend to get alkalemic when inappetent.

Isotonic saline (0.9% NaCl solution) is an isotonic crystalloid solution that has little merit in the routine treatment of sick ruminants, principally because ruminants usually develop hypocalcemia and hypokalemia when inappetent. Accordingly, the use of 0.9% NaCl should be confined to horses, the irrigation of surgical sites and wounds, or as a vehicle for adding other electrolytes and dextrose. Like Ringer's solution, 0.9% NaCl is mildly acidifying because effective SID = 0 mEq/L.

Isotonic sodium bicarbonate (1.3% $NaHCO_3$ solution) is an alkalinizing isotonic crystalloid solution that is used to treat severe acidemia (indicated whenever blood pH <7.20 as a result of metabolic acidosis). This solution is alkalinizing because it buffers hydrogen ion, $HCO_3^- + H^+ \leftrightarrow CO_2 + H_2O$, and increases SID (effective SID = 155 mEq/L). Sodium bicarbonate is superior to sodium L-lactate and sodium acetate for the treatment of metabolic acidosis because it provides an immediate source of bicarbonate. On theoretical grounds, sodium bicarbonate ($NaHCO_3$) should not be used to treat severe respiratory acidosis, because additional CO_2 generated may worsen the respiratory acidosis. However, studies in critically ill large animals have failed to identify a clinically important effect of sodium bicarbonate infusion on increasing arterial P_{CO_2}, inducing respiratory acidosis and further decreasing blood pH. Moreover, concern has been raised that rapid large-volume sodium bicarbonate administration can result in systemic alkalinization but not **paradoxical CSF acidosis**, which may produce adverse neurologic sequelae. An in-depth review of the studies on this topic indicates that paradoxical CSF acidosis has only been observed in anesthetized animals with controlled ventilation. In other words, when sodium bicarbonate is administered to animals that control their own ventilation, even under anesthesia, paradoxical CSF acidosis does not occur because the animal detects the increase in arterial P_{CO_2} and reflexively increases minute volume to combat the bicarbonate-induced respiratory acidosis.[6]

Tromethamine (THAM, Tris-hydroxymethyl aminomethane, 300 mmol/L) is an isotonic solution of an organic amine that is a safe and effective buffer. After administration, 70% of the neutral compound $(CH_2OH)_3C–NH_2$ in tromethamine is immediately protonated to the strong cation $(CH_2OH)_3C–NH_3^+$ in plasma, with the net equation:

$$(CH_2OH)_3C–NH_2 + H^+ \rightleftharpoons (CH_2OH)_3C–NH_3^+$$

The remaining 30% of the administered tromethamine remains unprotonated, and can therefore cross cell membranes and potentially buffer the intracellular compartment. Tromethamine provides an alternative alkalinizing agent to sodium bicarbonate; however, tromethamine does not currently appear to offer any important clinical advantages over sodium bicarbonate in spontaneously breathing animals.

Isotonic formulations are available for intravenous administration with or without electrolytes; administration of tromethamine without electrolytes leads to hyponatremia, and it would appear preferable to administer tromethamine in conjunction with electrolytes.

Carbicarb is an isotonic buffer (300 mOsm/L) made from equimolar disodium carbonate (Na_2CO_3) and sodium bicarbonate; carbonate avoids generation of CO_2 when buffering acidemic blood:

$$CO_3^{2-} + H^+ \rightleftharpoons HCO_3^-$$

Carbicarb was suspected to decrease the incidence and magnitude of hypercapnia when rapid alkalinization was needed in animals with mixed metabolic and respiratory acidosis. Despite numerous studies comparing Carbicarb with sodium bicarbonate, the potential clinical advantages of Carbicarb have only been demonstrated in animals being ventilated or with extremely limited ventilatory ability. Carbicarb has been administered intravenously to diarrheic calves; however, these studies have failed to identify a clinically important advantage over conventional isotonic sodium bicarbonate administration. Accordingly, there does not appear to be a compelling reason to prefer Carbicarb to isotonic sodium bicarbonate when rapid alkalinization of conscious animals is required.

Darrow's solution is an isotonic polyionic solution formulated by Darrow in 1946 for use in human infants; the solution has been administered to calves. Compared with other isoosmotic polyionic solutions, Darrow's solution is hyponatremic, hyperkalemic, and hyperlactatemic and does not contain calcium or magnesium. As such, Darrow's solution is not recommended for administration to large animals.

McSherry's balanced electrolyte solution is an isotonic polyionic solution formulated by McSherry and Grinyer in 1954 for intravenous and intraperitoneal administration to dehydrated diarrheic calves. On theoretical grounds, this is an excellent parenteral fluid for resuscitating dehydrated diarrheic calves that deserves more frequent use. Unfortunately, commercial formulations are currently unavailable.

Hypertonic Crystalloid Solutions

Fifty percent dextrose is 2500 mOsm/L (approximately eight times normal osmolarity). Fifty percent dextrose solutions are commonly administered to ruminants with ketosis or hypoglycemia and produce a transient increase in cardiac contractility. Some commercially available formulations in Europe contain an equimolar mix of dextrose and fructose, although the addition of fructose does not appear to produce a more sustained increase in plasma glucose concentration than that produced by glucose alone.

Table 5-4 Estimated daily energy requirements of fasting cattle

Body weight (kg)	Metabolic body size (kg $W^{0.73}$)	Metabolizable energy requirements (kcal)	Glucose 50% (L/day)
45 (1-month-old calf)	16	1760	7
90	27	2970	1.2
180	45	4950	2.0
360	74	8140	3.3
454	87	9519	3.8
544	100	12100	4.8

The necessity for glucose in fluid therapy has been controversial. Hypoglycemia occurs commonly in septicemic neonates and calves with diarrhea, but is uncommon in most other common diseases in which there is an acute fluid and electrolyte disturbance. Dextrose will promote the movement of extracellular potassium into the cell, will provide metabolic water, and is a source of carbohydrate. If glucose is indicated, large quantities of parenteral glucose are necessary to meet the maintenance energy requirements, and every effort must be made to restore the animal's appetite and to provide the necessary requirements through dietary intake. The energy requirements for maintenance are calculated on the basis of metabolic body size, $kg^{0.73}$, which is a measure of the fasting metabolism in an animal not eating and not doing any muscular work. If 1 g of dextrose given intravenously will provide 5 kcal (2.1 kJ) of energy, the approximate amounts of dextrose solution needed to meet the energy needs for maintenance in cattle are shown in Table 5-4. Table 5-4 provides a rough estimate of the requirements and should be used as a general guideline only. Every effort should be made to supply the energy needs through oral intake of energy-containing foods.

NaCl 7.2% (hypertonic saline) is 2460 mOsm/L (approximately eight times normal osmolarity), and is used for the rapid resuscitation of animals with hypovolemia. Hypertonic saline should be administered at 4 to 5m L/kg BW intravenously over 4 to 5 min (1(mL/kg BW)/min). Faster rates of administration lead to hemodynamic collapse caused by vasodilation and decreased cardiac contractility, whereas slower rates of administration provide no advantages over isotonic crystalloid solutions. Like high-volume 0.9% NaCl, small-volume hypertonic saline consistently induces a mild strong ion acidosis as its effective SID = 0 mEq/L. Generally, the decrease in pH following hypertonic saline administration is less than 0.08 pH units and rapidly dissipates with time. The effect of hypertonic saline on acid-base balance is therefore clinically inconsequential.

The use of small volumes (4–5 mL/kg BW) of hypertonic saline solution, ranging in concentration from 7.0% to 7.5%, has been extensively evaluated for the treatment of various forms of hemorrhagic, septic, and endotoxic shock. Plasma volume is increased by the movement of free water from the intracellular space, increasing cardiac output, mean arterial blood pressure, systemic oxygen delivery, and glomerular filtration rate. Total peripheral vascular resistance and pulmonary vascular resistance decrease, and mean circulatory filling pressure increases. Urine output is restored and acid-base equilibrium returns toward normal in conjunction with improved tissue perfusion.

Hypertonic saline (7.2–7.5%), with or without Dextran 70, has been used successfully in the initial resuscitation of diarrheic calves that have moderate to severe dehydration.[7-9] When used in this manner, resuscitation is optimized if calves receive 3 L of an isotonic oral electrolyte solution by esophageal intubation immediately before hypertonic saline is administered intravenously into the jugular vein through an 18-gauge needle at 4 to 5 mL/kg over 4 to 5 minutes. Combined intravenous hypertonic saline and oral electrolyte solution provides the fastest rate of resuscitation of dehydrated calves, as characterized by cardiac output and mean central venous pressure. It is important to note that the rate of resuscitation with hypertonic saline is even faster than that provided by administration of an equivalent sodium load of lactated Ringer's solution at 80 mL/kg over the first hour. The rapid infusion of small volumes of hypertonic saline should therefore be considered the preferred treatment for the initial resuscitation of severely dehydrated diarrheic calves. Moreover, more of the administered sodium in hypertonic saline is retained by the calf, resulting in more sustained resuscitation, whereas urinary sodium and free water loss is increased in calves administered lactated Ringer's solution or 0.9% NaCl solution.[7,8,10] Although the first studies to

demonstrate efficacy of hypertonic saline in resuscitating dehydrated calves also administered dextran to assist in sustained plasma volume expansion,[7,8] subsequent studies have demonstrated that the addition of dextran is not required for a beneficial response.[9,10]

Hypertonic saline solution is widely used for the treatment of dairy cattle with endotoxic shock and endotoxemia associated with coliform mastitis. Affected cows are given 2 L of hypertonic saline (4–5 mL/kg BW) intravenously, followed by immediate access to drinking water and other supportive therapy. The small volume of hypertonic saline followed by the oral water load increases circulatory volume rapidly, induces slight metabolic acidosis, increases renal perfusion and glomerular filtration rate, and induces homeostatic changes in serum calcium and phosphorus. In experimental endotoxin-induced mastitis of cattle, small volumes of hypertonic saline given intravenously (7.5%, 5 mL/kg BW) resulted in expanded plasma volume and increased the cows' voluntary water intake by about 12 times compared with cows treated with isotonic saline. The rapid intravenous administration of hypertonic saline successfully, but transiently, resuscitates calves in experimental endotoxic shock.[11] Hypertonic saline (7.2% NaCl, 2400 mOsm/L), 4 mL/kg BW intravenously over 4 minutes can be safely administered to endotoxic calves. On a comparative basis, the rapid infusion of large-volume isotonic saline is superior to small-volume hypertonic saline for initial resuscitation of experimentally induced acutely endotoxemic calves.

Hypertonic saline (7.2% NaCl, 2 L intravenously over 10 minutes) has been administered to cattle with RDA, followed by 10 L of 0.9% NaCl intravenously, and the resuscitative effects compared with cattle receiving an equivalent sodium load of 0.9% NaCl (26 L). Hypertonic saline produced a faster rate of initial resuscitation, based on mean central venous pressure and changes in plasma volume.[12] Hypertonic saline (7.5% NaCl, 5 mL/kg intravenously over 15 minutes) has been administered to cattle with experimentally induced acute ruminal acidosis, and the resuscitative effects compared with isotonic saline solution (0.9% NaCl). The response to both fluids appeared equivalent, except for a slighter larger reduction in blood pH in cattle treated with hypertonic saline.[13] It should be noted that hypertonic saline should not be administered to ruminants with acute ruminal acidosis on theoretical grounds. This is because rumen osmolality is markedly increased in acute ruminal acidosis, which minimizes the osmotic gradient that is generated following rapid intravenous small-volume hypertonic saline administration and the volume of free water translocated from the forestomach.

Hypertonic saline solutions have been extensively studied in horses and are widely used for the initial resuscitation of critically ill horses that are undergoing abdominal surgery for colic. Hypertonic saline has been associated with greater and more prolonged improvement in cardiopulmonary function and survival in horses with experimentally induced hemorrhagic and endotoxemic shock and in halothane-induced hypotension in horses. When given intravenously to normal conscious horses at 5 mL/kg BW, there are increases in plasma osmolality and serum sodium and chloride, but clinically normal horses rapidly regulate variable sodium loads. In horses with experimentally induced acute endotoxemia, horses resuscitated with intravenous hypertonic saline (5 mL/kg) and hydroxyethyl starch (10 mL/kg) had a higher cardiac output, lower mean pulmonary artery pressure and mean central venous pressure, higher ionized plasma calcium concentration, and improved respiratory gas exchange and arterial oxygenation than horses resuscitated with high-volume isotonic acetated Ringer's solution.[14,15] These results were consistent with increased interstitial water in the lung and volume overload as a result of conventional rapid high-volume isotonic solution administration.[14] Similar findings were reported earlier in the resuscitation of endotoxemic calves.[11] Hypertonic saline (7.2%) at 4 mL/kg provided a superior resuscitative solution than equivolume isotonic saline (0.9%) in horses eliminated from an endurance event because of dehydration. Dehydrated horses administered hypertonic saline had a greater plasma volume expansion and shorter time to first urination than horses receiving isotonic saline.[16]

Hypertonic solutions of sodium bicarbonate are highly effective for the initial treatment of acidosis associated with D-lactic acidosis in calves, acute diarrhea in calves, and strong ion (metabolic) acidosis in newborn calves. **Sodium bicarbonate 8.4%** is 2000 mOsm/L (approximately seven times normal osmolarity). This solution is used for rapid alkalinization, particularly in the presence of severe acidemia (pH <7.20). The solution osmolarity was selected because it provides 1 mEq of HCO_3^-/mL of solution, which facilitates calculation of the volume to be administered. The speed of intravenous administration of 8.4% sodium bicarbonate should not exceed 1 (mL/kg BW)/min. There is one report of the intravenous administration of 8.4% sodium bicarbonate to normovolemic calves with experimentally induced mixed respiratory and metabolic acidosis; the study found that rapid administration of sodium bicarbonate (5 mL/kg intravenously over 5 min) rapidly corrected the metabolic acidosis, increased blood pH, and improved cardiovascular status without inducing paradoxical CSF acidosis, suggesting that this treatment may be of value in treating dehydrated diarrheic calves.[17] A study in dehydrated calves with naturally acquired diarrhea has been conducted comparing intravenous hypertonic sodium bicarbonate (8.4%, 10 mL/kg over 8 minutes) and hypertonic saline (5.9%, 5 mL/kg over 4 minutes); calves receiving either treatment also received 3 L of an oral electrolyte solution 5 minutes after injection. As expected, the hypertonic sodium bicarbonate solution was more effective in correcting profound acidemia and metabolic acidosis than hypertonic saline.[18] The results of a study that compared the intravenous administration of equivalent sodium loads of 8.4% to 1.3% $NaHCO_3$ to neonatal calves with naturally acquired diarrhea and severe dehydration indicated that isotonic sodium bicarbonate was more effective in rehydrating the calf, whereas the rapid administration of hypertonic sodium bicarbonate was more effective in rapidly correcting the acidemia and strong ion (metabolic) acidosis.[19]

There are recent studies evaluating the effect of hypertonic solutions of **sodium lactate** (11.2% at 5 mL/kg/h administered over 270 minutes); lactate provides an energy substrate that can be used by most cells in the body, while being alkalinizing after metabolism to bicarbonate. In a pig endotoxemia model, infusion of hypertonic sodium lactate increased mean arterial blood pressure and cardiac output and improved oxygenation, relative to hypertonic sodium bicarbonate or 0.9% NaCl solution.[20]

Sodium bicarbonate 5% is 1190 mOsm/L (approximately four times normal osmolarity). This solution is also used for rapid alkalinization in the presence of severe acidemia (pH <7.20). The speed of intravenous administration of 5.0% sodium bicarbonate should not exceed 2 (mL/kg)/min. Three to five liters of 5% sodium bicarbonate may be necessary as initial therapy to correct the severe hyponatremia and strong ion (metabolic) acidosis that occurs in the horse with acute diarrhea. Following this initial treatment, hypokalemia characterized by muscular weakness commonly occurs, which can be treated using a high-sodium, high-potassium, alkalinizing solution.

Calcium gluconate 23% or calcium borogluconate are 1069 mOsm/L (approximately three and a half times normal osmolarity). Calcium borogluconate is the standard treatment for milk fever (hypocalcemia) in cattle. D-gluconate is an aldose sugar produced by oxidation of D-glucose, and is the preferred salt for calcium-containing parenteral solutions because it does not cause tissue necrosis as severe as does $CaCl_2$. Calcium gluconate should not be added to sodium bicarbonate solutions because a white precipitate ($CaCO_3$) forms immediately that interferes with normal fluid administration. Likewise, calcium gluconate should not be administered with tetracycline antibiotics because a yellow precipitate forms.

Colloid Solutions

A colloid is a substance that is too large to pass through a semipermeable membrane. Examples of colloid solutions administered to ruminants are whole blood, stroma-free Hb, plasma, dextrans, hydroxyethyl starches, and gelatins. As a group, colloid solutions are excellent for sustained expansion of plasma volume, which is in marked contrast to the effect of crystalloid solutions. Colloid solutions are contraindicated in congestive heart failure because these animals have increased plasma volume. Colloid solutions are also contraindicated in the presence of oliguric or anuric renal failure because the sustained volume overload may lead to pulmonary edema. Although initial studies using colloid solutions appeared promising, influential studies promoting the use of commercially available solutions have been recently retracted from major journals,[21] and the majority of smaller reviews evaluating the safety and efficacy of colloid solutions were written by investigators that had or have since established ties to the manufacturers of colloid solutions.[22] Moreover, questions are being raised about the relative importance of the difference between plasma oncotic and interstitial oncotic pressures and transcapillary fluid dynamics in patients with normal or decreased capillary pressures. The net result of these recent developments is decreased enthusiasm for the administration of commercially formulated colloid solutions.

Whole blood is the perfect balanced colloid/crystalloid solution, with great O_2-carrying capacity. It has a short shelf-life (<24 hours at 4°C) and is expensive to obtain. Whole blood administration runs the risk of disease transmission and allergic reactions; the latter are extremely rare in ruminants with the first blood transfusion but common enough in horses for blood typing or crossmatching to be required. Descriptions for collecting, storing, and administering blood are available in Chapter 4.

Stroma-free Hb is a blood substitute containing a purified Hb glutamer-200 solution (13 g Hb/dL) derived from cattle blood. A commercially available solution has a 2-year shelf-life at 20°C, an osmolarity of 300 mOsm/L, and an oncotic pressure of 43 mm Hg; the solution is therefore isotonic but hyperoncotic. Stroma-free Hb solutions are excellent at increasing oxygen delivery and carrying capacity while providing similar plasma volume expansion to dextrans and hydroxyethyl starches. The major theoretical concerns regarding administration of stroma-free Hb solutions are potent vasoconstriction and hemoglobinuric nephrosis. Some of the original experimental studies examining the effects of stroma-free Hb administration were completed in sheep, and there are occasional reports of its successful administration to critically ill horses in a clinical situation. It is likely that the high cost of this product will minimize its administration to large animals.

Plasma (fresh or frozen) is an excellent balanced colloid/crystalloid solution. Compared with blood, plasma has a much longer shelf-life (at least 1 year at −20°C) but is more expensive to obtain. Details for collection, harvesting, storing, and administering plasma are available elsewhere, and bovine, equine, and New World camelid plasmas are commercially available. Like blood, administration of plasma runs the risk of disease transmission and allergic reactions, although these risks are less than with blood transfusion.

Plasma is routinely administered to foals with inadequate transfer of passive immunity. Hyperimmune plasma is occasionally administered to neonatal foals and adult horses with gram-negative septicemia and endotoxemia. There appears to be only one report documenting the efficacy of plasma administered to neonatal calves with diarrhea, and these calves were probably colostrum deprived. The 14-day survival rate in diarrheic calves that received 600 to 800 mL of bovine plasma (5 g protein per dL) and electrolytes intravenously was 93% (37/40), which was significantly greater than the survival rate of calves receiving intravenous electrolytes alone (54%, 7/13). Another study failed to identify a beneficial effect of blood transfusion in treating diarrheic calves. Because blood is cheaper to obtain than plasma, whole blood transfusions are usually administered when a neonatal ruminant needs plasma. Human albumin solutions (5% or 25% human albumin in 0.9% NaCl) are available, but are very expensive relative to the use of other colloids such as plasma, blood, or Dextran 70. Consequently, there does not appear to be a persuasive reason for the administration of human albumin solutions to large animals.

Dextran preparations (such as Dextran 70 and Dextran 40) are high molecular weight glucose polymers obtained by bacterial fermentation of sucrose; the fermentation metabolites then undergo acid hydrolysis and fractionation. The molecular weight of dextran can therefore be "selected," and two dextran products, Dextran 70 (mean molecular weight 70,000 g) and Dextran 40 (mean molecular weight 40,000 g), are commercially available. Because the molecular weight of Dextran 70 is similar to albumin (molecular weight 65,000 g), there is limited diffusion of dextran into the interstitial space. Therefore Dextran 70 acts clinically as a plasma volume expander; this is in contrast to isotonic crystalloid solutions, which act as extracellular fluid volume expanders. Dextran 70 has been the most widely used dextran formulation in large animals, and is therefore the recommended product for administration. It is supplied as a 6% concentration in 0.9% NaCl, which provides a hyperoncotic but isotonic solution. Reported administration rates of Dextran 70 are 5 to 40(mL/kg)/h, but it is safer to administer Dextran 70 at less than 20(mL/kg)/h. One milliliter of Dextran 70 expands the plasma volume by 0.8 to 1.2 mL, but 50% of the administered dose is gone by 24 hours. Dextran administration runs the risk of exacerbating preexisting coagulopathies, although the clinical significance of dextran-induced prolongation of activated partial thromboplastin time (APTT) by decreasing factor VIII:C is probably minimal. The risk of coagulopathy is dependent on the administration rate, total dose administered (20 mL/kg is maximum 24-hour dose in humans), and the molecular weight of dextran. The deleterious effects of dextrans are usually associated with large doses or prolonged administration.

The use of **hypertonic saline–dextran solution** (4 mL/kg, 2400 mOsm/L sodium chloride in 6% Dextran 70 administered intravenously once over 4 minutes) combined with an isotonic oral alkalinizing solution containing sodium chloride (3.22 g/L), potassium chloride (1.12 g/L), sodium acetate trihydrate (4.76 g/L), and glucose anhydrous (16.22 g/L), providing 300 mOsm/kg of water and administered at 55 mL/kg BW, was superior to either solution alone for the treatment of experimentally induced hypovolemic diarrhea in calves. The combined treatment resulted in immediate and sustained increases in plasma volume, cardiac output, and stroke volume, improving tissue perfusion. Rapid and sustained rehydration after the combined treatment was indicated by improvement in hydration and clinical depression scores and decreases in hematocrit; blood lactate concentration; and serum creatinine, albumin, and phosphate concentrations. Resuscitation with oral electrolyte solution alone was slower but was complete within 24 hours. Resuscitation with the hypertonic saline–dextran solution alone resulted in only transient benefit.

The administration of hypertonic saline–dextran solution (7.2% NaCl solution with 6% dextran at the rate of 4 mL/kg BW, intravenously during a 4-minute period, combined with oral administration of isotonic electrolyte solution at the rate of 50–60 mL/kg BW) provided a rapid and effective method for resuscitating severely dehydrated calves with experimentally induced diarrhea or with naturally acquired diarrhea.

Hydroxyethyl starch is a high molecular weight glucose polymer (mean molecular weight 450,000 g) that is chemically synthesized from amylopectin, producing a highly branched glucose polymer with a structure similar to that of glycogen. Hydroxyethyl starch is hydrolyzed in blood by α-amylase, and the addition of hydroxyethyl groups slows hydrolysis and prolongs the duration of plasma volume expansion. Hydroxyethyl starch solutions are categorized by the mean molecular weight and a molar substitution ratio (usually stated after a back slash) that

reflects the number of hydroxyethyl substitutions per glucose unit, with a higher number indicating more substitutions and a slower rate of degradation.[23] A variety of hydroxyethyl starch formulations have been developed world wide; Hetastarch (hydroxyethyl starch at 600,000 g/0.75 in 0.9% NaCl solution or 670,000 g/0.75 in lactated Ringer's solution), Pentastarch (200,000 g/0.4 in 0.9% NaCl solution), and Tetrastarch (130,000 g/0.4 or 130,000 g/0.42 in 0.9% NaCl solution). Pentastarch (200,000 g/0.4 in 0.9% NaCl solution), and Tetrastarch (130,000 g/0.4 in 0.9% NaCl solution). Because the molecular weight of hydroxyethyl starch is much greater than that of albumin (65,000 g), hydroxyethyl starch in Hetastarch preparations decreases endothelial permeability by sealing separations of endothelial cells. Hydroxyethyl starch is supplied as a 6% concentration in 0.9% NaCl; this provides a hyperoncotic but approximately isotonic solution. Reported administration rates are 5 to 40(mL/kg BW)/h but, like Dextran 70, it is safer to administer hydroxyethyl starch at less than 20(mL/kg BW)/h. Like Dextran 70, hydroxyethyl starch administration runs the risk of exacerbating preexisting coagulopathies. The risk of coagulopathy is dependent on the administration rate, total dose administered (20 mL/kg BW is the maximum 24-hour dose in humans), and size of the hydroxyethyl starch particles. Administration of 6% hydroxyethyl starch to anesthetized horses at 5 to 15 mL/kg over 90 minutes increased mean central venous pressure and cardiac output but did not correct inhalation anesthetic-induced systemic hypotension.[24] The rapid administration of 6% hydroxyethyl starch to horses with naturally occurring gastrointestinal disease at 10 mL/kg increased colloid osmotic pressure by approximately 20%, but did not return values to within the reference range.[25] High molecular weight hydroxyethyl starch formulations have been recently linked to nephrotoxicity, acute renal failure, and mortality in humans, particularly in septic patients or patients with preexisting renal disease, and the U.S. Food and Drug Administration recommended in 2013 that they not be used in critically ill adults and patients with preexisting renal dysfunction or severe liver disease. Low molecular weight hydroxyethyl starch formulations do not seem to demonstrate similar adverse effects, but are cleared at a faster rate because of their small size, resulting in a shorter duration of action. The relevance of these findings to the use of hydroxyethyl starch formulations in large animals is uncertain, because clinically relevant coagulation abnormalities caused by hydroxyethyl starch were not identified when administered to horses with experimentally induced acute endotoxemia at 10 mL/kg.[15] Hydroxyethyl starch solutions do exert dose-dependent in vitro effects on coagulation in horse blood, as assessed by platelet aggregation and function.[23] The clinical relevance of these in vitro findings has not been determined.

Pentastarch has two important differences to Hetastarch (hydroxyethyl starch) formulations: it appears to have a less exacerbating effect on preexisting coagulopathies and the rate of elimination is faster (elimination half-life of 5.6 hours in healthy horses and possibly 2 hours in critically ill horses); however, similar to hydroxyethyl starch, pentastarch has been associated with an increased incidence of acute kidney injury in humans.[26] Pentastarch has been administered preoperatively to horses with colic at 4 mL/kg, and this infusion produced a higher cardiac output in anesthetized horses for 150 minutes compared with the same volume of hypertonic saline (7.2% NaCl).[27] It should be noted that Pentastarch is considerably more expensive than 7.2% hypertonic saline when compared on a volume basis.

Tetrastarch has been the most recently introduced colloid and, consequently, there are fewer studies examining its efficacy and safety. In vitro studies suggest Tetrastarch produces less impairment of coagulation caused by its lower molecular weight and lower molar substitution formulation. Studies in healthy adult horses indicated Tetrastarch caused plasma volume expansion but a shorter duration of adverse effects on platelet function than a similar dose of Hetastarch.[28] The clinical significance of this difference remains to be determined.

Gelatins (modified bovine collagens) are available for veterinary use. The formulation uses gelatin with a mean molecular weight of 30,000 g and is a 5.6% suspension in NaCl. Compared with dextrans and hydroxyethyl starches, gelatins have a shorter plasma half-life but appear to have less effect on coagulation. Generally, gelatins have not been evaluated as completely as dextrans and hydroxyethyl starches and, on this basis, are not currently preferred.

Practical Administration of Electrolyte Solutions

Under ideal conditions, with laboratory evaluation of the animal, the deficits can be accurately assessed and fluids containing the deficient electrolytes can be formulated. However, under most practice conditions this is not possible and **polyionic crystalloid solutions** are in general use. These usually contain sodium, potassium, chloride, and calcium or magnesium at a concentration similar to the electrolyte composition of extracellular fluid; the solutions may also contain lactate or acetate as bicarbonate precursors. Dextrose may be added to the solution to make an initial mildly hypertonic solution.

Polyionic crystalloid solutions are safe and can be used in large quantities without inducing electrolyte disturbances provided that circulating blood volume and renal function have been restored and are maintained. They can be used for most situations of dehydration and moderate acidemia or alkalemia and moderate electrolyte imbalances. They are not usually adequate for the treatment of severe acidemia or alkalemia, or severe hyponatremia, hypokalemia, or hypochloremia.

For the treatment of severe acidemia or alkalemia, and severe hyponatremia, hypokalemia, and hypochloremia, specific electrolyte solutions are necessary. Generally, they consist of a mixture of the common simple solutions with supplemented electrolytes to correct some major abnormality. These are considered necessary to correct abnormalities quickly that could not be corrected using balanced electrolyte solutions. These solutions are summarized in Tables 5-3 and 5-5. Many intravenous solutions for fluid therapy in calf diarrhea are available, and it is recommended that they should contain 150 mmol/L of sodium, 5 mmol/L of potassium, and about 50 mmol/L of a mixture of bicarbonate and precursors.

When acidemia is not present it is not necessary to use a fluid containing bicarbonate.

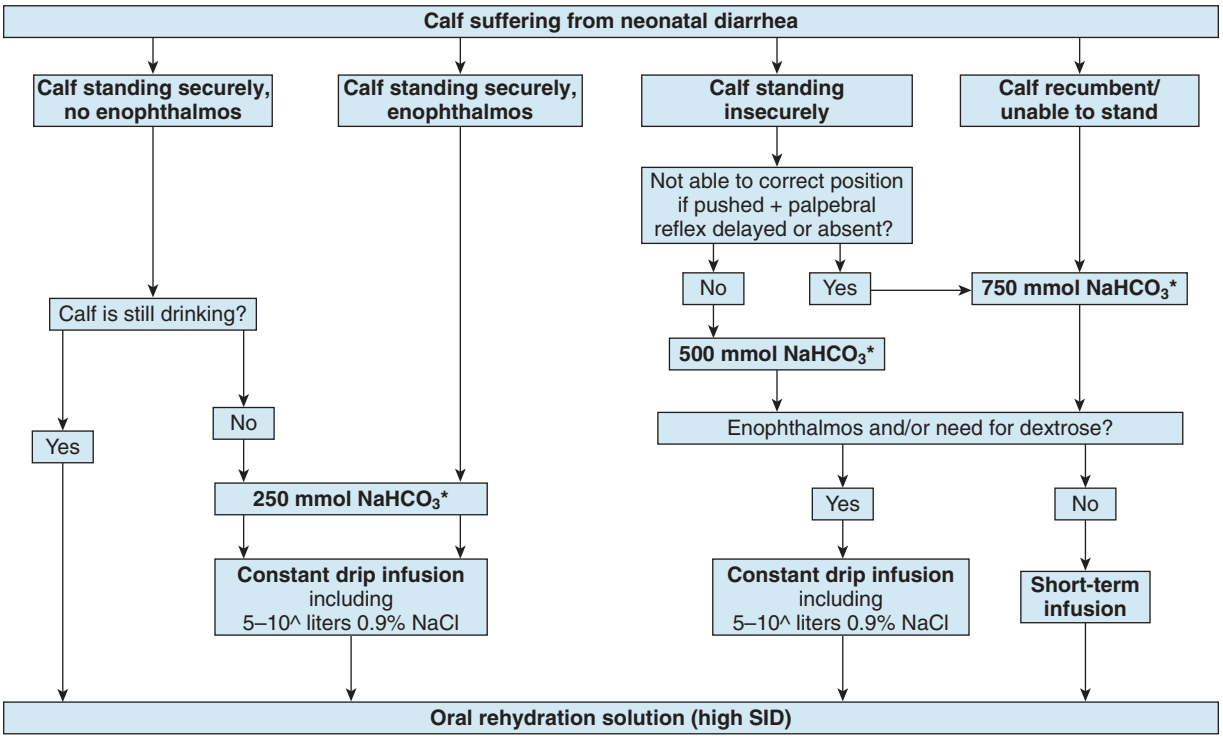
Mature cattle affected with metabolic alkalosis associated with diseases of the abomasum are usually hypokalemic, hypochloremic, and dehydrated. For such cases, a balanced electrolyte solution containing sodium, chloride, and potassium is satisfactory. A solution containing sodium (135–155 mEq/L), chloride (150–170 mEq/L), and potassium (10–20 mEq/L) is effective. In recently calved dairy cattle, calcium borogluconate is commonly added to the mixture.

Solutions containing potassium have been recommended for the treatment of the potassium depletion that occurs in calves with acute diarrhea and in inappetent ruminants and horses. However, in calves with severe acidemia and hyperkalemia, it is important to expand circulating blood volume, restore renal function, and correct the strong ion (metabolic) acidosis before providing additional potassium, which may be toxic. Solutions containing potassium may be indicated following correction of the acidosis and dehydration. However, if the animal's appetite is returned to normal, the oral potassium intake will usually correct any existing deficiencies.

In neonatal calves with dehydration caused by diarrhea, optimized decision trees for treatment have been developed based on clinical signs of hydration status and the presence of varying degrees of acidemia caused by metabolic acidosis (suckling strength, degree of enophthalmos, ability to stand, and presence or absence of palpebral reflex).[3,29] The decision tree is followed to determine the need for oral fluids or intravenous administration of isotonic solutions of sodium bicarbonate containing 250 mmol, 500 mmol, or 750 mmol of sodium bicarbonate, with supplemental glucose added when indicated[30] (Fig. 5-17).

Table 5-5 Composition (mmol/L) and indications for use of electrolyte solutions used in fluid therapy

Solution	Na^+	K^+	Cl^-	Mg^{2+}	Ca^{2+}	HCO_3^-	Lactate or acetate	Dextrose	Gluconate	Major indications
0.9% sodium chloride (isotonic saline)	155		155							Expansion of circulation blood volume
1.3% sodium bicarbonate (isotonic)	155					156				Metabolic acidosis
1.3% sodium bicarbonate in 5% dextrose	155					156		5%		Metabolic acidosis
5% sodium bicarbonate (hypertonic)	600					600				Severe metabolic acidosis
Equal mixture of isotonic saline and isotonic sodium bicarbonate	155		78			78				Metabolic acidosis and dehydration
Balanced electrolyte solution (i.e., McSherry's solution)	138	12	100	5	3		50 (acetate)			Metabolic acidosis electrolyte losses and dehydration
Lactated Ringer's solution	130	4	111		3		28 (lactate)			Metabolic acidosis
Normosol-R	140	5	98				27	23		Metabolic acidosis
Plasma-Lyte A	140	5	98				27	23		Metabolic acidosis
High sodium, alkalinizing solution, lactated Ringer's solution plus sodium bicarbonate (5 g/L)	190	4	111			60	27 (lactate)			Metabolic acidosis and hyponatremia
High-sodium, high-potassium, alkalinizing sodium, lactated Ringer's solution plus 1 g/L potassium chloride and 5 g/L sodium bicarbonate	190	18	125			60	27 (lactate)			Metabolic, acidosis, hyponatremia, hypokalemia
High-potassium acidifying solution, isotonic saline plus 2.5 g potassium, chloride per liter, mixture of 1 L isotonic potassium chloride (1.1%), 2 L isotonic saline (0.9%), and 1 L dextrose 9%	154	35	189							Metabolic alkalosis, hypochloremia, hypokalemia Metabolic alkalosis in cattle with abomasal disease



* Represents the intended amount of sodium bicarbonate
^ An infusion volume of 10 liters is recommended for calves with estimated enophthalmos ≥ 7 mm.

Fig. 5-17 Optimized decision tree for treating neonatal calves with diarrhea in a field setting. Examination of the ability to stand is evaluated by lifting recumbent animals. Enophthalmos reflects a visible gap of 3 to 4 mm between the corneal surface of the eye and the caruncula lacrimalis or normal position of the lower eyelid. (From Trefz FM et al. *BMC Vet Res* 2012;8:238.23).

For the treatment of hypochloremic hypokalemic metabolic alkalosis, acidifying solutions can be used but preferably only if constant laboratory evaluation of the animal is possible. Without laboratory evaluation, the use of Ringer's solution, 0.9% NaCl, or hypertonic saline for correction of strong ion (metabolic) alkalosis in adult cattle is recommended, along with the oral administration of potassium in animals that are inappetent. In experimentally induced hypochloremic hypokalemic metabolic alkalosis in 40 to 50 kg BW sheep, replacement of the chloride deficit using 2 L of hypertonic saline (1.8% sodium chloride) was effective in returning plasma sodium and chloride concentrations to normal within 12 hours, and the plasma potassium concentrations and acid-base balance returned to normal within 36 hours of treatment without providing potassium. Small volumes of hypertonic saline are also effective for the treatment of experimentally induced hypochloremic hypokalemic metabolic alkalosis in sheep.

In summary, five different kinds of solutions are used in large-animal practice:

- **Polyionic crystalloid solutions**, such as lactated Ringer's solution and acetated Ringer's solution, are indicated for dehydration and moderate degrees of acid-base and electrolyte imbalance.
- **Hypertonic saline solution and an oral water load** represent a practical and inexpensive alternative to parenteral administration of large fluid volumes.
- **Hypertonic or isotonic sodium bicarbonates**, such as 8.4, 5.0 (hypertonic), or 1.3% (isotonic) solutions of sodium bicarbonate, are used for severe strong ion (metabolic) acidosis and hyponatremia, particularly in dehydrated depressed calves with diarrhea.
- **Chloride-containing acidifying solutions,** such as Ringer's solution, are used for treatment of strong ion (metabolic) alkalosis.
- **Colloid solutions,** such as plasma or blood, are administered more frequently than Dextran 70 or hydroxyethyl starch solutions.

Because cost is a major consideration in large-animal fluid therapy, it may not be possible to use sterile solutions. Most of the previously mentioned solutions can be formulated using the necessary salts mixed with distilled water, boiled water, or ordinary tap water and are therefore prepared inexpensively.

Quantity of Fluids Required and Routes of Administration

The amount of fluid required depends on the degree of dehydration (an estimate of the volume losses that have already occurred); the continuous losses that occur during treatment; and the maintenance requirements of the animal during treatment presuming its dietary intake of water, electrolytes, and nutrients is minimal. The fluids are usually given in two stages:

- **Hydration therapy** in the first 4 to 6 hours at a rate of 100 to 150 mL/kg BW intravenously.
- **Maintenance therapy** (a combination of **continuous losses** and **maintenance requirements**) in the next 20 to 24 hours, depending on the severity and the course of the disease, at 60 to 80 mL/kg BW per 24 hours intravenously (approximately 3–4 mL/kg BW per hour). In some cases of profuse diarrhea, the continuous losses and maintenance requirements will be about 150 mL/kg BW over a 24-hour period. The daily maintenance water requirements of adult horses range from 54 to 83 mL/kg BW, with a mean of 64 mL/kg BW.

Some examples of the large quantities of fluid required for hydration and maintenance therapy in cases of acute diarrhea are outlined in Table 5-6.

Parenteral Fluid Therapy

The total amount of the estimated necessary hydration therapy should be given intravenously using indwelling intravenous catheters in the first 4 to 6 hours to expand and maintain circulating blood volume. If acidemia or alkalemia is present, it also should be treated immediately. Thus the most important abnormalities—decreased circulating blood volume and acid-base imbalance—are treated first. Restoring circulating blood volume will restore renal function, which will assist in correcting acid-base and electrolyte balance. The immediate correction of acidemia will return the tissues to their normal physiologic activity. The intravenous route is preferred for hydration therapy and for the correction of severe acid-base and electrolyte imbalances. All other routes (intraperitoneal, subcutaneous, and oral) are unsatisfactory in the presence of decreased circulating blood volume.

During the intravenous administration, the animal must be monitored for clinical and laboratory evidence of improvement or deleterious effects. A **favorable response** is indicated by urination within 30 to 60 minutes, an improvement in mental attitude, and some evidence of hydration. **Unfavorable responses** include **dyspnea** because of preexisting pneumonia or pulmonary edema because of too rapid administration, **failure to urinate** because of renal failure or paralysis of the bladder, and **tetany** because of the excessive administration of alkali. Unusual responses such as sweating, trembling, and depression within several hours following the intravenous administration of electrolytes or other substances such as commercial amino acids may occur if the infusion is contaminated during administration. If a laboratory is available, the determination of PCV, bicarbonate, and blood pH will provide an excellent monitoring system during the administration of the fluids.

Rate of Administration

The rate of administration will depend on the size of the animal, the severity of the illness, the type of fluids administered, and the response of the animal to the fluids. In calves, isotonic saline (0.9% NaCl) and sodium bicarbonate solutions can be given at the rate of 1 to 3 L/h; in a mature horse, fluids may be given at the rate of 10 to 12 L/h. Hypertonic solutions such as 5% sodium bicarbonate can be given to a mature horse at the rate of 3 to 5 L/h, followed by balanced electrolytes at 10 to 12 L/h. Solutions containing added potassium should be given cautiously, at the rate of 3 to 5 L/h. In a cow with severe dehydration and acidosis caused by carbohydrate engorgement, fluids may be given at the rate of 10 to 12 L/h.

Adverse reactions to intravenous fluid administration include **sudden muscle weakness** (suggests hypokalemia) and sudden **tachycardia** and **hyperventilation**, which suggest **overhydration**. When these occur the fluids should be stopped and the clinical findings assessed. If laboratory assistance is available, the determination of blood pH and bicarbonate may provide an explanation for the reaction.

Special care is needed when administering intravenous fluids to **hypothermic** animals because intravenous fluid therapy has the potential to further decrease core

Table 5-6 Examples of approximate amounts of fluid required for rehydration and maintenance therapy

Animal	Degree of dehydration (% BW)	FLUID REQUIRED FOR	
		Rehydration (L)	Maintenance (L/24 hours)
Mature horse (500 kg)	8	40	25–50
	12	60	25–50
Newborn calf (50 kg)	8	4	2.5–5
	12	6	2.5–5
Mature cow (700 kg)	8	56	35–70
	12	84	35–70

body temperature. Cooling is inevitable during intravenous fluid therapy whenever animals are housed at temperatures below their core body temperature. It is important to note that fluids initially warmed to 37°C are cooled after going through the fluid administration set. Placing commercially available heaters around the fluid administration line as close as possible to the catheter insertion site is effective in warming intravenous fluids to >36°C at flow rates between 60 and 300 mL/h.[31] When treating hypothermic neonates, many veterinarians place the distal part of the fluid administration set in a bucket of hot water to ensure that the fluid is as warm as possible when administered. The efficacy of this heating approach has not been evaluated, and because of the distance between the bucket and catheter insertion site, it is likely that this approach will not be as effective as use of commercially available heaters around the fluid line.

Intravenous Catheters and Complications

The administration of large quantities of fluids intravenously to farm animals is best done with an indwelling **jugular vein** flexible catheter (10–14 gauge) that is appropriately secured to the animal's neck to prevent withdrawal from the vein (Fig. 5-18). Standard aseptic technique must be used. A plastic, springlike coiled tube and suitable rubber tubing are used to deliver the fluids from large 20- to 25-L plastic containers (Fig. 5-19). The coiled plastic tubing allows the animal to lie down or stand up without disrupting the catheter and tubing. The use of a drip chamber in the rubber tubing system assists in determining the flow rate, which can be adjusted with a clamp. With a 14-gauge catheter, 20 L of fluids can be delivered as hydration therapy to a mature horse or cow over 4 hours.

Auricular Vein of Cattle and Calves

Intravenous fluids are commonly administered to adult cattle and calves in northern Europe using the auricular vein. The short neck, thick skin, and, in some breeds, pendulous dewlap of cattle make it difficult to introduce and secure indwelling jugular catheters for long-term use. The auricular vein of adult cattle can be successfully catheterized with an over-the-needle, 5-cm long, 14-gauge catheter, permitting 20 L of rehydration solution to be delivered over 4 hours. The auricular vein of neonatal calves can be successfully catheterized with an over-the-needle, 2.5-cm long, 22-gauge butterfly catheter, after clipping the external pinna and applying a tourniquet at the base of the ear to facilitate visualization of blood vessels and catheter advancement (Fig. 5-20).

Cecal Catheters in Horses

Percutaneous cecal catheters have been used to deliver fluid solutions in ponies. The advantages include less cost, but complications include peritonitis, diarrhea, laminitis, and hypocalcemia.

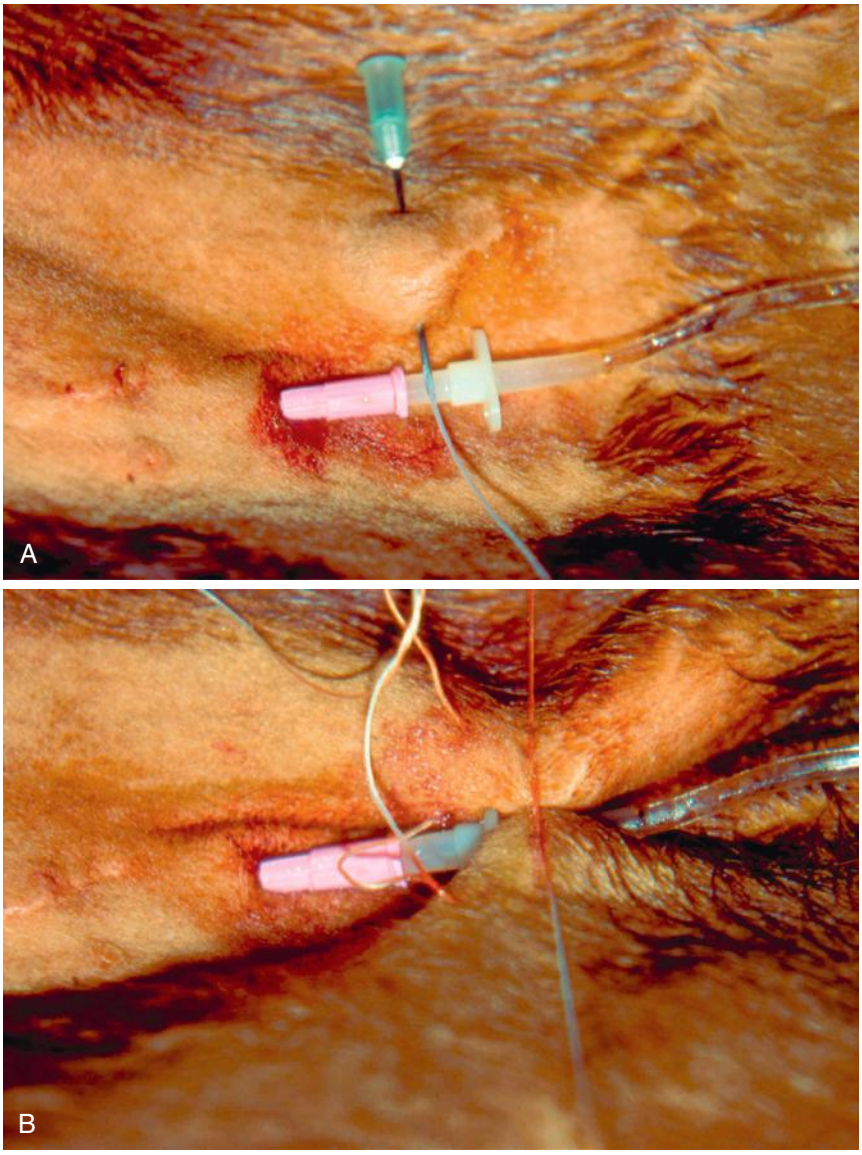


Fig. 5-18 Securing a 14-gauge 14-cm catheter into the jugular vein of a cow. The site of venipuncture is clipped and scrubbed for aseptic placement of a catheter. A 1-mL bleb of 2% lidocaine is placed intradermally at the proposed site of catheter insertion and a 5-mm long stab incision made through the skin, including the dermis. **A,** The catheter is then placed into the lumen of the vein and carefully advanced until the hub of the catheter is level with the skin. The catheter is secured by placing sutures through the skin using an 18-gauge needle and a synthetic multifilament suture material. The suture does a loop around the extension tubing near where it attaches to the hub of the catheter so that the catheter cannot back out. **B,** The 18-gauge needle is then passed through the ventral skin fold adjacent to the catheter, and the suture tightened to create a tunnel.

Thrombophlebitis

Long-term jugular vein catheterization (over a period of a few days) in adult cattle and particularly horses can result in thrombophlebitis, suppurative phlebitis, and catheter sepsis. Inspection of the affected jugular vein reveals swelling, firmness, and moderate pain. Careful digital and visual inspection is necessary to determine the patency of the vein; in about 50% of cases the vein is completely thrombosed and occluded and cannot be used for intravenous administration for 2 to 3 weeks. The extent and severity of the thrombophlebitis can be determined by ultrasonography of the neck, and patency of the vein can be assessed by compressing the vein with the transducer head.

The development of thrombophlebitis is dependent on the method used for skin preparation and the catheterization

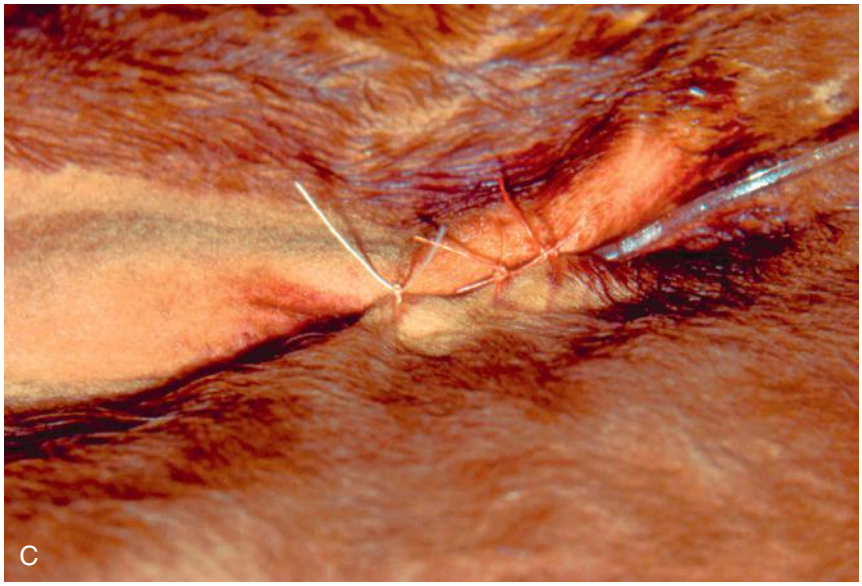

Fig. 5-18, cont'd **C,** Additional sutures are placed through the upper and lower skin folds to lengthen the tunnel and prevent excessive movement at the junction of the catheter with the hub.

Fig. 5-19 Administering large-volume isotonic crystalloid solutions to Holstein–Friesian cows by the jugular vein **(A)** and auricular vein **(B)**.

technique. Careful preparation of the skin and aseptic technique during insertion and placement of the catheter are crucial in preventing this complication. Heparin subcutaneously, 150 IU/kg BW immediately after insertion of the catheter and repeated every 12 hours, has been used prophylactically, but this is not deemed necessary with good technique. Alternating catheters between jugular veins every 48 to 72 hours is standard practice in equine fluid therapy, but despite this precaution complications occur in 20% to 50% of horses whose jugular veins are catheterized for 48 hours. By using catheters made of materials that are less thrombogenic, inserting them in an aseptic manner, and observing simple management practices, the duration of catheter survival increases to about 14 days. The least reactive catheter is Silastic followed by polyurethane; polytetrafluoroethylene causes the most reaction. Catheters that are soft are superior to stiff and rigid ones.

Intravenous fluids for large animals are often stored in a carboy (a Persian and Arabic term meaning *big jug*), which is used to describe a rigid container that can hold 20 to 40 L of fluids. A retrospective study of the risk factors associated with vein thrombosis in horses treated with intravenous fluids in a veterinary teaching hospital found that the use of carboy fluids and diarrhea and fever were related; the incidence was lower in horses that had general anesthesia, surgery, and received antimicrobial agents. A variety of aerobic bacteria were cultured from about 50% of the intravenous catheters removed from horses. Bacteria were isolated from 7% of skin swabs taken from the area around the catheter after surgical preparation with iodine soap and before and after removal of the catheter. However, there was no correlation between bacterial culture and venous thrombophlebitis.

Oral Fluid Therapy

Whenever possible, the oral route can be used to deliver the maintenance requirements. Provided there are no abnormalities of the digestive tract that interfere with oral administration or the absorption of the fluids, the oral route is preferred for maintenance therapy. In ruminants such as adult cattle rumen function must be present for significant absorption of fluids and electrolytes. The oral administration of large quantities of fluid to cattle with rumen atony results in sequestration of the fluid in the rumen and the development of metabolic hypochloremic hypokalemic alkalosis.

Oral Fluid Therapy in Calves and Adult Cattle

A variety of oral electrolyte replacement solutions are available commercially. Most preparations are in the form of powders to be mixed with water or directly with milk. The formulations vary in their composition

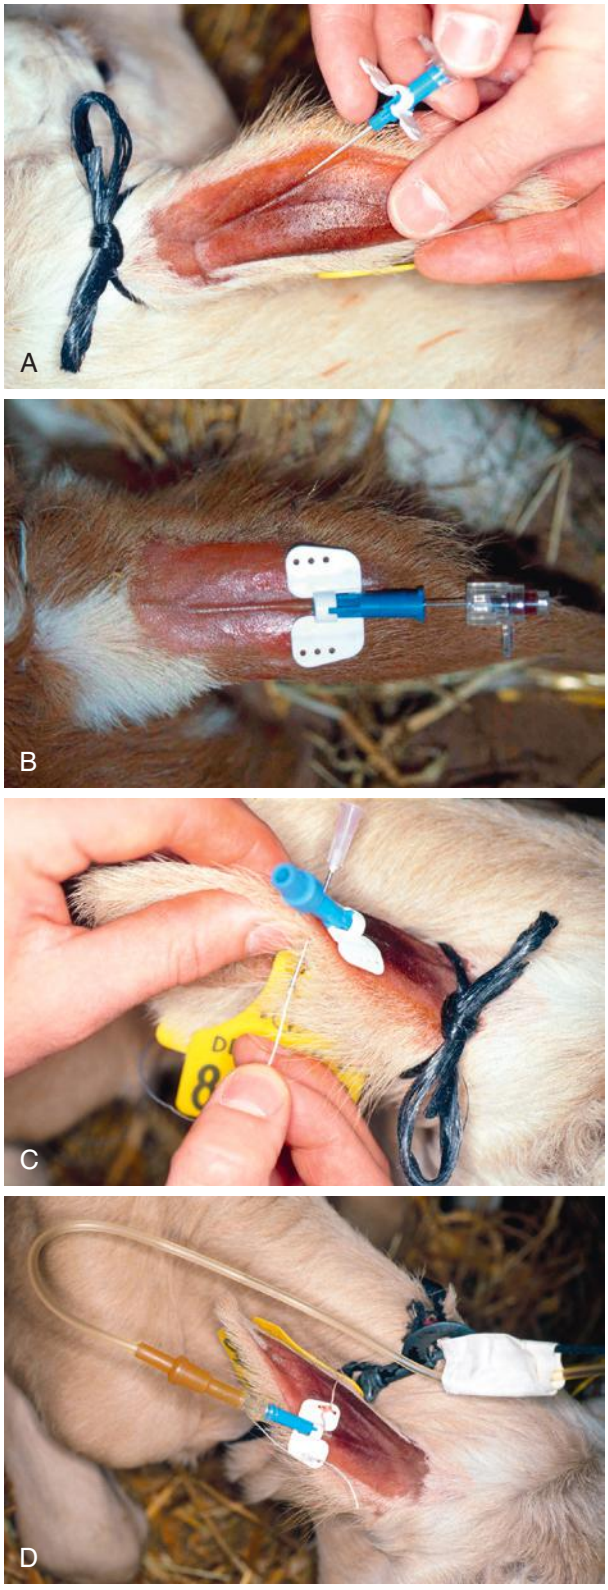

Fig. 5-20 Placement of a 22-gauge 2.5-cm over the stylet butterfly catheter into the auricular vein of a calf. The ear is clipped and scrubbed for aseptic placement of a catheter, and a tourniquet is placed at the base of the ear to facilitate visualization of the auricular veins **(A).** The catheter is then placed into the lumen of the vein and carefully advanced **(B).** The tourniquet is removed and the catheter is secured to pinna by placing a 20-gauge needle though the pinna and butterfly section and tying, taking care not to distort the ear **(C).** Intravenous fluids are then attached and the ear bandaged, taking care not to bandage below the end of the catheter **(D)**. (Pictures generously provided by Dr. Joachim Berchtold, Germany.)

but typically contain sodium, chloride, potassium, glucose, glycine, and bicarbonate or its precursors (acetate, propionate, or citrate). Some formulations contain other agents such as lecithin-coated pectin fiber that is reported to decrease the proliferation of *E. coli* and *Salmonella* spp., or other agents that facilitate normalization of the enteric bacterial population. Knowledge of the requirements for the ideal oral electrolyte solution for diarrheic calves continues to evolve. However, much progress has been made over the last 30 years, and the critical issues in formulating the ideal oral electrolyte solution are osmolality, sodium concentration, source of the alkalinizing agent, and the energy content (which is intimately tied to osmolality). It remains to be determined whether oral electrolyte solutions should contain agents such as glutamine that may facilitate repair of damaged intestinal epithelium. This issue is being actively researched at the moment and a clear consensus has not yet been reached.

Oral electrolyte solutions should be routinely administered to all neonatal calves <21 days of age at the first signs of diarrhea because it cannot be accurately predicted how quickly the calf will become dehydrated. Calves with a 4-mm or greater recession of the eye or calves that are unable to stand should receive intravenous fluids (small-volume hypertonic saline, small-volume sodium bicarbonate, or conventional large-volume isotonic crystalloid solution) in addition to an oral electrolyte solution. The initial treatment of a dehydrated calf should use an oral electrolyte solution that is not added to milk replacer because this provides superior plasma volume expansion.[32] The **osmolality** of the oral electrolyte solution should range from isotonic (300 mosm/kg) to hypertonic (700 mOsm/kg). The effective osmolality at the tip of the intestinal villus is approximately 600 mOsm/kg because of the presence of a countercurrent exchange mechanism. Although markedly hypertonic fluids should be avoided in animals with severe villous damage, it is currently not possible to predict which calves have severe villous damage on the basis of the physical examination findings and measurement of fecal pH or other body parameter. Low osmolality fluids (300 mosm/kg) have inadequate energy content because they have insufficient glucose. For this reason, if milk is withheld, then hypertonic oral electrolyte solutions (~600 mosm/kg) should be administered.[33,34] If milk is fed, then isotonic oral electrolyte solutions (300 mosm/kg) should be administered because inadequate energy content is no longer an issue.[34,35] Ideally fresh milk should be fed to diarrheic calves after 24 hours of treatment; fresh cow's milk is preferred to milk replacer or pasteurized waste milk because fresh milk contains trophic factors that facilitate repair of damaged intestinal

epithelium, and the energy content of milk is required to maintain BW. Generally, milk should not be withheld from diarrheic calves for more than 24 hours.[37]

The **sodium concentration** or the oral electrolyte solution should be between 90 and 130 mmol/L. Adequate sodium absorption is the fundamental determinant of successful expansion of the extracellular space, and is the main reason that oral electrolyte solutions are administered (the sodium concentration of milk is very low with an average value of 28 mmol/L). Sodium concentrations <90 mmol/L provide an inadequate sodium load, whereas sodium concentrations >130 mmol/L can lead to hypernatremia and additional free water loss.

The oral electrolyte solution should also contain **glucose** and either **acetate**, **propionate**, or **glycine** to facilitate sodium absorption and provide energy. There are cotransport mechanisms for sodium and glucose, sodium and volatile fatty acids such as acetate and propionate, sodium and citrate, and sodium and amino acids (such as glycine) in the luminal membrane of villous epithelial cells. Administration of glucose, acetate, propionate, glycine, or citrate therefore facilitates sodium absorption. These transport mechanisms are unimpaired in enterotoxigenic *E. coli* and are at least partially functional in malabsorptive/maldigestive diarrheas. A recent study in healthy normally hydrated neonatal calves raised questions about the relative importance of glucose-coupled sodium transport in rehydrating diarrheic calves with diarrhea, and suggested that the ratio of glucose to sodium (which is thought to range between 1.0 and 3.0 with an optimum ratio of 1.4 based on human infant oral rehydration solutions) may not be an important component of treatment efficacy in neonatal calves.[38] The choice of glycine in oral electrolyte solutions as an amino acid coupled sodium transport was based primarily on its low cost and wide availability, and because glycine was included in early human infant oral rehydration solutions.

The oral electrolyte solution must contain an **alkalinizing agent**, such as acetate, propionate, or bicarbonate, at a concentration range of 40 to 80 mM/L.[39-41] Acetate-containing fluids are as effective as bicarbonate-containing solutions at correcting mild to moderate acidosis: [acetate- = CH_3COO^-] + H^+ + $2O_2$ ↔ $2CO_2$ + $2H_2O$. Acetate must be metabolized to be effective, and metabolism may be impaired in severely dehydrated or acidemic animals, although this has not been proven in severely dehydrated calves. Acetate- or propionate-containing fluids can be fed with milk as acetate and propionate do not raise abomasal pH or inhibit milk clotting. In comparison, bicarbonate containing oral electrolyte solutions, when fed without milk, excessively alkalinize the abomasum and proximal small intestine, decreasing the effectiveness of the "abomasal sterilizer" in killing ingested enteric pathogens, and potentially promoting enterotoxigenic *E. coli* attachment to epithelial cells and STa enterotoxin production. Moreover, bicarbonate does not inhibit growth of *Salmonella i*n the intestinal lumen, whereas acetate and propionate both inhibit *Salmonella* growth. However, it is important to note that bicarbonate-containing oral electrolyte fluids are theoretically more effective at rapidly correcting severe acidemia than acetate and propionate, because bicarbonate reacts directly with H^+ ions (HCO_3^- + H^+ ↔ H_2CO_3 ↔ H_2O + CO_2). The main disadvantage of bicarbonate-containing oral fluids is that the pH of the abomasum (a natural defense mechanism) is increased, raising concerns that bicarbonate may decrease the ability to form a clot in the abomasum. This theoretical disadvantage regarding bicarbonate does not appear to be true, at least when low concentration bicarbonate solutions (25 mmol/L) are fed.[37]

The alkalinizing potential of an oral electrolyte solution can be estimated by calculating the **effective SID** of the formulation as fed. Because electroneutrality must be preserved at all times, the difference between the charge assigned to all strong cations in an oral electrolyte solution (usually only sodium and potassium) and strong anions in an oral electrolyte solution (usually only chloride) is called the effective SID and reflects the concentration of metabolizable strong anions, such as acetate, propionate, and citrate, as well as the concentration of bicarbonate.[39] Oral electrolyte solutions should have an effective SID of approximately 40 to 80 mmol/L. Electrolyte solutions with an effective SID = 0 are acidifying because they create a systemic strong ion acidosis; such solutions are not recommended for the treatment of dehydrated calves with diarrhea.

The **rate of abomasal emptying** influences the rate at which an oral electrolyte solution is delivered to the small intestine, which is the major site of fluid absorption. The rate of abomasal emptying is therefore an important determinant of the rate of rehydration in a dehydrated calf with diarrhea. The volume and caloric content of an ingested fluid meal are the most important determinants of abomasal emptying rate.[40] Other important determinants of emptying rate are the type of protein or fat, osmolality, and duodenal pH, with a solution osmolality of 600 mosm/kg or a luminal pH of <2.0 or >10.0 decreasing the abomasal emptying rate in suckling calves.[40] Studies in healthy calves suggest that oral electrolyte solutions that provide >2.4 g of glucose per kilogram BW may lead to a slower rate of rehydration as a result of a slower delivery of free water, sodium, and glucose to the small intestine, although it has been difficult to detect clinically important differences in the rate of resuscitation when oral electrolyte solutions are fed to calves with naturally acquired diarrhea.

For diarrheic calves, the total 24-hour maintenance requirement is calculated and given orally in divided doses, ideally three times a day. Compared with parenteral therapy, there is less danger from overhydration and electrolyte toxicity, and in acute diarrhea the maintenance of oral fluid and electrolyte intakes will replace continuous losses that occur during the diarrhea. Livestock owners should be informed of the value of providing newborn animals affected with diarrhea associated with dehydration, depression, inactivity, or failure to suck with oral fluids and electrolytes as soon as possible and of the value of continuing this treatment until the animal has returned to normal. Oral electrolyte solutions and water should be made available at all times to animals affected with diarrhea and other diseases in which there is continuous loss of fluid and electrolytes.

The **continued feeding of milk to diarrheic calves** while they are receiving oral fluids and electrolytes has been controversial. In the past, it was conventional to withhold milk from diarrheic calves for 1 to 2 days and then gradually reintroduce milk over the next few days when there is evidence of recovery. An extreme practice was to totally deprive the calf of milk until the diarrhea ceased. The rationale for this practice was that the ability of the calf's intestine to digest milk was impaired, particularly lactose digestion in the rotavirus and coronavirus diarrheas of young calves. It was also thought that the presence of milk in the intestine would provide a substrate for continued growth of enteric pathogens. Recent studies in calves with naturally acquired and experimentally induced diarrhea have demonstrated the benefit of feeding milk to diarrheic calves receiving oral electrolyte solutions[35]; such practice results in more rapid recovery from diarrhea (fewer days of diarrhea), less debilitation, continued weight gain, greater fat stores, faster rate of regeneration of the intestinal mucosa, and less thymic atrophy than calves deprived of milk. Adding the oral electrolyte solution to the milk of calves with diarrhea is effective and practical; this treatment approach requires that water be readily available to treated calves at all times.[36]

In adult ruminants, both water and sodium must be absorbed to produce sustained expansion of the extracellular fluid space. Acetic, propionic, and butyric acids are absorbed rapidly from the forestomach in their nonionized form but are absorbed more slowly in conjunction with a sodium ion in their ionized form. Cattle produce up to 180 L of saliva per day with a sodium concentration of 126 mEq/L, and approximately half of the sodium secreted with saliva is reabsorbed by the forestomach primarily through active transport mechanisms. Based on this physiology, orally administered

sodium is well absorbed in adult ruminants, and sodium absorption is accompanied by the passive movement of water from the rumen into the extracellular space.

Oral sodium bicarbonate administration can be an important part of treating adult ruminants with grain overload. The oral administration of sodium bicarbonate to adult ruminants (2.5 g/kg BW) causes a profound metabolic alkalosis (strong ion alkalosis). Drenching of dairy cows with 700 mL of 40% sodium bicarbonate solution or 46% sodium propionate solution (both markedly hyperosmotic) increases blood pH to an equivalent degree. Oral administration of sodium salts with a high effective SID therefore causes a metabolic alkalosis (strong ion alkalosis) in adult ruminants, as they do in neonatal ruminants.

The vast ruminal capacity for sodium and water absorption can be used by administering hypotonic oral electrolyte solutions to dehydrated adult ruminants. The optimal formulation of an oral electrolyte solution for adult ruminants is unknown, but such a solution should contain sodium, potassium, calcium, magnesium, phosphate, and propionate to facilitate sodium absorption and provide an additional source of energy to the animal. Provided that the osmolality of the rumen contents remains hypotonic to plasma, there will be a slow but sustained absorption of electrolytes and water in an oral electrolyte solution because of the reservoir function of the rumen. An isotonic fluid containing 6.17 g of NaCl, 0.34 g of KCl, and 2.89 g of $NaHCO_3$ (providing 140 mmol/L of sodium, 4.5 mmol/L of potassium, and 110 mmol/L of chloride) was effective in treating dehydrated goats when administered by nasoruminal intubation.[42] Another recommended formulation for adult ruminants, particularly those with **hypochloremic hypokalemia metabolic alkalosis**, contains 7 g of NaCl, 1.5 g of KCl, and 1 g of $CaCl_2$ (providing 120 mmol/L of sodium, 20 mmol/L of potassium, 9 mmol/L of calcium, and 158 mmol/L of chloride).[44] Formulation of a practical, effective, inexpensive, and commercially available oral electrolyte solution for adult ruminants remains an important need in fluid and electrolyte therapy.

Oral Fluid Therapy in Horses

Intravenous fluid and electrolyte therapy has been used extensively for the treatment of dehydration and electrolyte disturbances in the horse with diarrhea. However, oral fluid therapy, as used in calves and adult cattle, has not been used to the same extent. Oral fluid therapy offers may be an effective, practical, and economical method of rehydration of horses with diarrhea that has not yet been fully explored.

In the horse with acute diarrhea, several factors contribute to the nature of the fluid and electrolyte losses. There are increases in fecal sodium and water loss, but the fecal potassium excretion may remain unchanged. The lack of feed intake, which affects primarily the potassium intake, can result in losses of 2500 to 3000 mmol of potassium per day. Although urinary water and potassium losses are reduced, potassium depletion continues; thus potassium losses are very high and need to be replaced, especially in the anorexic horse. The large potassium deficit in diarrheic horses should also be considered when formulating the composition of oral fluids. Administration of 30 to 40 g of potassium chloride or, if chloride administration is inappropriate, 30 to 40 g of potassium bicarbonate in 2 to 4 L of water given by nasogastric tube several times daily to an inappetent horse with diarrhea, can complement intravenous fluid therapy and replace the potassium deficit.

The optimum electrolyte composition of oral fluids and the amount to be used have not yet been determined for the horse. The amount given depends on the degree of dehydration. Dehydration in horses becomes clinically apparent when about 5% of BW has been lost. In a 500-kg horse, assuming 90% water loss, the fluid deficit is about 23 L. Abdominal discomfort may occur following the nasogastric tube administration of a series of 8- to 10-L doses of oral rehydration fluid. The administration of large amounts may result in rapid transit through the stomach and intestines and decreased absorption. A slower rate of administration, such as 8 to 10 L every few hours, may be tolerated more effectively and the transit time in the intestine may be decreased, enhancing absorption. Volumes of 6 to 8 L can be given by nasogastric tube as often as every 15 to 20 minutes by funnel; as much as 20 to 30 L is possible during the first hour and 40 L is possible during a 2-hour period. Oral fluids may also be administered through a small-diameter indwelling nasogastric tube, as is used for prolonged enteral nutrition of horses with dysphagia.

Commercially available **oral electrolyte solutions** are inadequate for horses because the concentrations of sodium and potassium are too low to adequately replace losses. When treating horses with acute diarrhea, the ratio of sodium to chloride ions in the oral solution should be approximately 1.4:1, and the need for glucose in an oral rehydration solution for adult horses has not been clearly demonstrated. One formulation contained 5.27 g of NaCl, 0.37 g of KCl, and 3.78 g $NaHCO_3$ per liter of tap water; this produced a suitable electrolyte composition for oral administration (Na 135 mmol/L, K 5 mmol/L, Cl 95 mmol/L, and HCO_3 45 mmol/L).

Oral administration of bicarbonate will result in a pronounced alkalemia within 3 to 6 hours, with the maximum change in pH occurring at a sodium bicarbonate dose of 1 g/kg BW (which represents 40% of normal extracellular sodium). Doses above this level do not induce additional alkalinization, presumably because of limited absorption of bicarbonate from the intestinal tract. The oral administration of sodium bicarbonate to normal mature resting horses without ad libitum access to water induces metabolic alkalosis, hypernatremia, hypokalemia, and hyperosmolality for at least 8 hours. The oral doses were 0.25, 1, and 1.5 g/kg BW in 3 L of water; the intravenous dose was 0.25 g/kg BW in 3 L of water. The effects were dose dependent: in the horses given the 1 and 1.5 g/kg BW oral doses the hypercapnia persisted for 12 hours, whereas hypercapnia lasted 2 hours in horses given the 0.25 g/kg BW dose orally or intravenously. The effects of these large doses of sodium bicarbonate on the renal function of horses indicated increases in urine flow, fractional clearance of electrolytes and bicarbonate, electrolyte-free water reabsorption, urine concentrations of sodium and bicarbonate, urine excretion, clearance of sodium and bicarbonate, urine pH, and AG.

The temperature or glucose concentration of the fluid does not appear to be important because the rate of fluid absorption was similar in dehydrated horses administered an oral rehydration solution at 5°C, 21°C, or 37°C or containing glucose at 0%, 2.5%, or 3.5%. The tonicity of the oral rehydration solution is of minor clinical importance; however, oral administration of hypertonic solutions (628 mOsm/kg BW) to dehydrated horses caused a transient increase in plasma protein concentration that was attributed to movement of water into the bowel lumen. **Continuous flow administration** of a hypotonic solution at 15 (mL/kg)/h through a **small-diameter nasoesophageal tube** is effective in increasing plasma glucose concentration in healthy adult horses, with maltodextrin (15 g/L) providing a greater glycemic response to that provided by glucose (15 g/L). This treatment protocol appears to provide a useful low-cost method for treating horses that are slightly dehydrated and hypoglycemic, but safety studies using a larger number of horses are required.[43] A practical limitation of oral rehydration solutions in horses is that they should be ingested voluntarily rather than by nasogastric intubation. This limitation has led to recent interest in the oral administration of pastes.

The oral administration of an **electrolyte paste** has been shown to be effective in correcting mild to moderate dehydration in horses, provided animals are monitored to ensure that they drink water. Oral electrolyte pastes may be formulated as follows: 30 g of 1:1 mixture of sodium chloride and potassium chloride, potassium chloride and sodium bicarbonate, or potassium chloride and potassium carbonate, and administered every 6 hours; 120 g of the latter mixture provides 1400 mmol or more of potassium

in a 24-hour period. Administration of higher doses of oral pastes (0.5 g of NaCl/kg BW, 0.5 g of KCl/kg BW, or a mixture of 0.25 g of NaCl/kg BW and 0.25 g of KCl/kg BW) to dehydrated horses induced a transient period of hyperhydration and apparent plasma volume expansion that lasted 12 hours. Although the absorbed electrolytes from an oral paste are subsequently eliminated via the urine, this treatment is potentially of benefit in horses with disease processes associated with ongoing fluid loss, such as diarrhea.

There is no published information on the use of oral fluid therapy in horses that are diarrheic as a result of disease of the small intestine such as enteritis or proximal enteritis (duodenitis). It would seem unlikely that oral fluid therapy would be indicated or effective for anterior duodenitis. In horses with colitis, the small intestinal absorptive capacity is probably intact and oral fluid therapy before transport of the horse to a clinical center for intensive fluid therapy may delay the onset of more serious complications. Horses with mild dehydration can be rehydrated effectively with oral fluid therapy. Horses treated with oral fluid therapy must be monitored clinically, and the hematocrit, total plasma protein concentration, and serum electrolytes should be measured.

Oral fluid therapy provides an effective and inexpensive treatment in horses with impaction of the large colon and dorsal displacement of the colon. An absolute requirement for oral fluid therapy in the horse is that there is no gastric reflux. Generally, although 6 to 8 L of water can be administered by nasogastric tube and funnel (gravity flow) every 15 to 20 minutes, and the administered fluid is rapidly transported to the large intestine, some horses do not tolerate oral fluid administration at 10 L/h and exhibit mild signs of abdominal discomfort. Accordingly, oral fluid rates are more commonly administered at 8 to 10 L every 2 hours using a nasogastric tube and a funnel.[45] Volumes exceeding 10 L should be administered over at least 15 minutes,[46] even though 90% of 10 L of an electrolyte solution is emptied from the stomach within 15 minutes.

It is generally recommended that the osmolality of the fluids should be isotonic, ranging from 280 to 360 mOsm/L; the upper range of tonicity that is safe to administer is unknown. Plain water has been administered at 50 to 150 mL/kg BW over 24 hours in four treatments to horses with experimentally induced dehydration. The administration of water was safe and effective in hydrating the large intestinal luminal contents.[46] One isotonic formulation that was successful in a case series involving 108 horses contained 6 g of sodium chloride and 3 g of potassium chloride per liter of tap water, equivalent to the following electrolyte concentration: 103 mEq/L of Na, 40 mEq/L of K, and 143 mEq/L of Cl.[45] Potassium is an important component of the isotonic formulation in horses with impaction of the large colon or dorsal displacement of the colon. Oral administration of 60 L of lactated Ringer's solution or an isotonic solution over 12 hours was superior in hydrating the contents of the right dorsal colon compared with intravenous administration of an equivalent volume of lactated Ringer's solution or enteral administration of 1g/kg BW of $MgSO_4.7H_2O$ (Epsom salts) or anhydrous Na_2SO_4 as a 1-L solution. Moreover, enteral administration of Epsom salts has been associated with hypermagnesemia, and anhydrous Na_2SO_4 has been associated with hypocalcemia.

Fluid and Electrolyte Therapy in Newborn Piglets and Lambs

The most common cause of fluid and electrolyte imbalance in newborn piglets and lambs is acute neonatal diarrhea. There is severe dehydration, acidemia, hyponatremia and, in some cases, hyperkalemia caused by the acidosis. Balanced electrolyte solutions or isotonic saline and sodium bicarbonate initially followed by balanced electrolytes are indicated and successful. These are given subcutaneously or intraperitoneally at the rate of 15 mL per piglet every 2 hours plus the same amount orally. The safe amount of sterilized porcine serum or saline and 5% dextrose that can be given to piglets is equivalent to about 8% BW intraperitoneally, in two divided doses given 8 hours apart. Lambs are also treated subcutaneously (30–40 mL) and orally (50–100 mL) every 2 hours.

Parenteral Nutrition

Parenteral nutrition is used to provide adequate nutrition intravenously, as long as necessary, when feeding by the gastrointestinal tract is impractical, inadequate, or impossible. The term parenteral nutrition is preferred to total parenteral nutrition because the complete nutritional requirements of large animals are either not completely known or not addressed by intravenous fluid administration. It should be recognized that enteral nutrition represents state-of-the-art medicine because enteral nutrition supports the repair, maintenance, and growth of the gastrointestinal tract to a much greater extent than parenteral nutrition. It should also be recognized that parenteral nutrition should only be contemplated after at least 5 days of inappetence.

The technique is used to supply the nutrient requirements, most importantly protein, of the animal until it returns to normal. In calves affected with persistent diarrhea caused by chronic disease of the alimentary tract, or that cannot or will not eat, total intravenous feeding may be indicated. High concentrations of glucose, protein hydrolysates, lipid emulsions, and electrolytes are given by continuous slow intravenous infusion over a period of several days. Some encouraging results in calves have been published, but the cost-effectiveness of the technique has not been examined.

Parenteral nutrition is an acceptable method of maintaining nutrition in the healthy horse over a period of 10 days. Body weight was maintained at 94% of initial values without clinical evidence of dehydration. No problems were encountered with the long-term intravenous catheterization. The total daily amounts given are calculated on the basis of daily caloric requirement. The intravenous catheter must be inserted down into the cranial vena cava, in which a large volume of blood will dilute the hypertonic concentration of the solution. The potential problems associated with parenteral nutrition include difficulty in the maintenance of a steady intravenous drip, hypertonicity of the solutions used, venous thrombosis, excessive diuresis, catheter sepsis, and bacterial contamination of the solutions.

Parenteral nutrition in foals usually starts with a parenteral daily initial digestible energy of 50 to 55 kcal/kg BW that is designed to address resting energy requirements; the daily energy intake is increased gradually up to a daily target of 120 kcal/kg using a combination of parenteral and enteral nutrition.[47] Because of the cost of components, energy density, and availability of products, there are two philosophical approaches to parenteral nutrition in foals: (1) intravenous dextrose and lipid emulsion with 30% to 40% of the caloric intake provided by lipids or (2) intravenous dextrose, amino acids in a nonelectrolyte solution, and lipid emulsion. The latter formulation has been used for parenteral nutrition in alpacas.[48] B-complex vitamins are usually added to the final parenteral nutrition solution, and there is no clear consensus on the need for concurrent insulin administration. Typical commercially available products administered in North America are designed for use in humans in a critical care setting and include 50% dextrose solution, an 8.5% amino acid solution without electrolytes, and a 20% lipid emulsion solution, with the lipid solution as the most expensive component. In a retrospective study of 53 foals that received parenteral nutrition including lipids, 32% developed hypertriglyceridemia (>200 mg/dL), and this development was significantly associated with nonsurvival.[47] This finding suggests that parenteral nutrition in foals should use limited amounts of lipid for energy, and current recommendations in septic human patients are to provide no more than 5% of the caloric intake from lipid emulsions. Fifteen percent of the 53 foals developed catheter-related complications such as thrombophlebitis or sepsis.[47] This emphasizes the need for strict aseptic technique whenever attaching or flushing fluid administration lines and catheters in animals receiving parenteral nutrition.

A practical and effective parenteral nutrition solution for sheep, goats, and New

World camelids contains the following components and is administered at a rate of 5% of BW per day:[43,44]

- 5 L of a commercial balance electrolyte solution (such as lactated Ringer's solution)
- 1 L of 8.5% amino acids (commercially available)
- 500 mL of 50% dextrose
- 20 mL of B-complex vitamins
- Potassium chloride (20–40 mEq/L) and calcium gluconate 23% (20–50 mL/L) as indicated

The components should be mixed aseptically in this order. Administration is best performed using a centrally located catheter and strict attention should be given to aseptic technique. **Hyperglycemia** is a common finding in neonatal animals undergoing parenteral nutrition, and the occurrence of hyperglycemia (glucose >180 mg/dL, equivalent to >10 mmol/L) has been associated with an increased likelihood of nonsurvival.[49] The widespread availability of low-cost blood glucose point-of-care units has made it much easier to monitor blood glucose concentration every 1 to 2 hours and adjust the fluid administration rate accordingly.

Parenteral nutrition in adult cattle focuses on the administration of 50% dextrose as a continuous rate infusion as part of the treatment of ketosis and hepatic lipidosis and in the supportive treatment in cows that are inappetent or recumbent or have gastrointestinal or infectious diseases.[50] Concentrated (50%) dextrose solutions are administered to keep the infused volume low and minimize plasma volume expansion and diuresis. Cows with hepatic lipidosis or prolonged anorexia sometimes require continuous intravenous infusion of dextrose for several days until they can maintain energy balance. The continuous intravenous infusion of 50% dextrose (0.3 g/kg/h) to healthy lactating dairy cows resulted in hyperglycemia and hyperinsulinemia and a marked reduction in plasma phosphorus concentration. Other effects of intravenous dextrose infusion included decreased plasma potassium concentration, decreased dry matter intake and fecal production, and a transient increase in milk production followed by a sustained decrease. All of these effects were reversed after dextrose infusion was stopped.[50] The results suggest a slower rate of glucose administration (0.1–0.2 g/kg/h) is more appropriate in lactating dairy cattle.

Practical Antimicrobial Therapeutics

6

This chapter is not intended as a treatise on pharmacology, pharmacodynamics, and antibacterial activity of antimicrobial agents. Other textbooks are available that deal with those subjects. However, antimicrobials are the most commonly used group of drugs in large-animal practice, and their use is recommended on many occasions in the following chapters. To avoid repetition, the principles of usage and considerations for dose schedules and for the selection of antibacterial agents for certain circumstances are given here and in the formulary.

Some of the information or opinions presented are based on clinical use rather than experimental evidence. However, this is often unavoidable because, unfortunately, many antimicrobial agents have in the past been released for use in large animals with minimal pharmacologic or clinical evaluation in the species concerned. As a result it has been assumed, often erroneously, that information obtained from studies in laboratory animals, dogs, and humans can be directly applied to the ruminant, horse, and pig.

Principles of Antimicrobial Therapy

The success of antimicrobial therapy depends on **attaining and maintaining**, at the site of infection, a drug concentration that will result, directly or indirectly, in the death or control of the infectious organism with minimal deleterious effect to the host. To achieve these aims the antimicrobial agent must have activity against the organism at its **site of infection** and it must be administered in such a way as to maintain an **effective inhibitory or lethal concentration**. These principles apply to therapy in all species and dictate the choice of antimicrobial agent to be used. However, in farm animal veterinary practice there are also other important considerations:

- **Cost** is critical. This consideration includes not only the primary cost of the drug but also related factors such as the ease and frequency of administration and the duration of treatment.
- **Tissue residue problems** and **withdrawal periods** must also be taken into consideration and are a primary determinant of treatment strategy.
- **Animal welfare** becomes a consideration when a decision is made not to treat an animal because of concerns about cost or the occurrence of residues that would preclude marketing of the animal or its products in the future.
- **Antimicrobial resistance** and the risk of contributing to the emergence and problem of antimicrobial resistance is an increasing concern, not so much with the therapeutic use of antimicrobials but certainly with the prolonged administration of antimicrobials in animal feeds for disease prevention.

In the theoretically ideal situation, the following steps would be taken before selecting an antimicrobial agent for therapy:

- First, the site of infection would be located and the identity of the infecting organism established by culture.
- Second, the minimal inhibitory concentration (MIC) of each antimicrobial agent for the infecting organism would be identified.
- Third, an initial selection would be made based on the susceptibility of the organism and the knowledge of the capacity of the individual antimicrobial agents to penetrate the site of infection and to achieve and exceed these concentrations at nontoxic dose rates.
- Fourth, the dose rates, route of administration, and frequency of administration required to achieve these concentrations for each of the selected antibiotics, in the particular animal species being treated, would then be considered.
- Finally, selection of a particular drug would be based on a consideration of the potential toxicity to the host, on the likely relative efficiency of each drug, on the cost and ease of administration and, in food animals, on costs associated with the relative withholding periods.

For many clinical situations all of these steps cannot be followed before therapy is instituted. It may take several days to establish the identity of the infectious agent unless it can be ascertained by clinical diagnosis. The identification of the organism helps in determining its potential susceptibility, but even without identification the establishment of exact MICs by tube dilution for each antimicrobial agent takes several days, and the results would frequently be historical by the time that they were received. Also, knowledge about each antimicrobial agent and of the varying tissue and organ levels achieved following varying doses given by different routes of administration is not easily remembered and, therefore, not easily available in large-animal field situations. Unfortunately, complete information of this type also is not available for each antimicrobial agent in all large-animal species.

Because of this uncertainty, some expedients are adopted in clinical antimicrobial therapy. One of them is the concept of the **recommended dose** and another is the use of disk susceptibility testing, both of which are discussed later in this chapter. Regardless of these expedients, it should be recognized that rational antimicrobial therapy is based upon the principles outlined earlier. These important principles in antimicrobial therapy are discussed in greater detail individually.

IDENTIFICATION OF THE INFECTION BY CLINICAL EXAMINATION

In infectious disease, clinical examination aims to identify the nature and site of the infection and its cause. The importance of making an accurate clinical diagnosis cannot be overemphasized as the first prerequisite for successful antimicrobial therapy. The establishment of a diagnosis in many instances immediately identifies the pathogen, and previous clinical experience may suggest the specific antibiotic to be used and allow a confident prediction of success of the therapy. Equally, it may indicate the likelihood of unsuccessful or prolonged therapy. For example, the diagnosis of erysipelas in pigs or strangles in horses immediately identifies the etiologic cause of the infection and the type of antimicrobial agent that will be required. It also gives some indication of the likely ease or difficulty of successful therapy and of the duration of therapy that might be required.

The establishment of an accurate diagnosis is also important in animals in which chemotherapeutic control of further disease may be required. Thus in pigs an accurate differentiation between the diarrhea of swine dysentery and that associated with coliform gastroenteritis is essential for effective prophylactic medication.

It is often not possible to establish an exact diagnosis at the first examination; yet in almost every instance it is essential that treatment be instituted at that time, not only for the well-being of the patient but also for the maintenance of good client relationships. The lack of a definitive etiologic diagnosis should never preclude the initiation of therapy during the period when further tests are being performed. Rational therapy in these circumstances depends very much on clinical acumen. A detailed examination leading to a determination of the site and nature of the infection can frequently allow an educated guess at the likely pathogen and allow rational therapy during the period that specific diagnosis is being determined by culture.

This approach is frequently used initially in field situations in large-animal medicine, but it requires good clinical knowledge. Clinicians should be familiar not only with the individual diseases of large animals but also with their **differential diagnosis** and with the **relative prevalence** of each condition in their area. They should also be familiar with the types of organism that may produce infections in various body areas with similar clinical manifestations and the relative prevalence of each of these. Thus peracute mastitis in recently calved cows is most commonly associated with infection by staphylococci but can also be associated with coliform organisms or, more rarely, *Trueperella (Actinomyces* or *Corynebacterium) pyogenes* or *Pasteurella multocida.* Treatment must be initiated immediately if the gland or even the cow is to be saved. There are subtle clinical and epidemiologic differences that may allow some clinical differentiation between these agents, but frequently treatment must begin with no sure knowledge of which agent is involved. There are **two approaches** in this type of situation:

1. Therapy may be directed at the most prevalent or likely agent and, in situations where one particular infectious agent is the most prevalent cause of the condition, this is a rational approach.
2. In other situations, when a disease could be associated with any one of several different organisms, each with a different susceptibility, and when clinical experience suggests that no one organism is the predominant infectious agent, it is more common to initiate therapy with a broad-spectrum antimicrobial agent or a combination that will have activity against all the possibilities. If indicated, the antibacterial agent used for therapy may have to be changed to a more specific one once the actual pathogen and its susceptibility have been determined.

There are also clinical situations in which therapy must begin when there is little knowledge of the site of infection and, consequently, **no knowledge of the identity** of the infecting agent. This occurs when infection, such as abscessation, occurs in deep-seated and clinically inaccessible organs such as the liver or spleen. In these situations it also may not be possible to determine the nature and cause of the disease by laboratory examination, although biochemical examinations and ultrasound may give some indication of the site. In these cases, therapy is generally started with a broad-spectrum antimicrobial agent or a combination of lesser ones, and the accuracy of the selection is determined by subsequent clinical response.

TAKING SAMPLES FOR DIAGNOSIS

In teaching hospitals, there is ready access to bacteriology laboratories, which frequently contain automated and rapid systems for susceptibility testing. However, in practice the taking of samples for this purpose is generally restricted and limited by such factors as the availability of a diagnostic laboratory and by cost. Furthermore, in many cases the results of culture and susceptibility are historical by the time they are received. Nevertheless, information of this type is of value for future similar cases, and it provides prevalence data and data of antimicrobial susceptibility that can be used for background clinical knowledge and justification for extralabel drug use in food-producing animals.

The recognition of when samples should be taken for microbiological examination and susceptibility testing comes with clinical experience. Generally, the approach to dealing with individual sick animals is different from dealing with groups of animals that have a contagious disease. In individual animals, cost and the time for processing usually limit sample taking to valuable stud animals and to horses. They should be taken from **individual sick animals** with life-threatening conditions so that, if a response is not obtained during initial therapy, the subsequent choice of antimicrobial agent can be based on laboratory data. They should also be taken from animals with disease syndromes that may be caused by one of several agents or by an organism that may show **variable resistance patterns**. Examples would be infective arthritis in foals or gram-negative sepsis. The increasing emergence of variable resistance patterns in veterinary pathogens places an increasing importance on sampling and susceptibility testing, and many practices have now established their own laboratories for this purpose.

Samples are also frequently taken from chronic, **poorly responsive conditions** to determine the best course of treatment. In groups of animals where there is **contagious** disease, the taking of samples to establish or confirm the etiologic diagnosis and to determine the best drug for chemotherapy is most important. Where there are **a large number of animals at risk** it is important to confirm the initial choice of therapy as soon as possible so that remedial steps can be taken if the choice was incorrect. It is also important in these situations to have a confirmed accurate etiologic diagnosis so that control measures can be instigated to prevent future problems. Thus an outbreak of diarrhea in postweaned pigs may be caused by coliform gastroenteritis, salmonellosis, or swine dysentery. Clinical and pathologic examination may eliminate swine dysentery but not allow complete differentiation between salmonellosis and coliform gastroenteritis. An aminoglycoside could be used for the initial therapy of the outbreak but, at the same time, samples are taken for culture and susceptibility to determine the exact antimicrobial susceptibility of the infectious agent in case there is resistance to this antibiotic. Also, by this procedure the exact etiologic diagnosis will be determined, which will then determine recommendations for future control of the disease.

Consideration should be given to the **nature of the sample** for examination. In outbreaks of diarrhea there is little point in

taking fecal samples from chronically scouring and runted animals. Samples should be taken from animals at the onset of diarrhea. The site of sampling can also have an influence that may affect the relevance of the results. In animals with pneumonia, the nasal flora may not reflect that in the lung and cultures are best taken as transtracheal aspirates of the lower respiratory system.

Similarly, fecal *Escherichia coli* strains are not always representative of small-intestinal strains in scouring calves.

ANTIMICROBIAL SUSCEPTIBILITY TESTS

Rationale

Antimicrobial susceptibility testing is not required with all infections because many organisms are invariably sensitive to one or more antimicrobial agents, and in most cases these can be used for therapy. The clinician should be familiar not only with the spectrum of each antimicrobial drugs, but also with the spectrum of susceptibility for the common organisms involved in diseases of large animals. **Susceptibility testing** is generally reserved for members of those groups of organisms that show considerable variation in sensitivity to individual antimicrobial agents.

There can be considerable area-to-area variation and spatial and temporal clustering in the susceptibility patterns of individual organisms. It is wise to establish the broad patterns of general susceptibility or resistance for these groups in any practice area, and to monitor any change periodically so that therapy can be guided by this information. This also can provide information justifying the extralabel use of antimicrobials in food-producing animals.

The **purpose of susceptibility testing** is to attempt to determine whether the organism under consideration is likely to be susceptible to the action of an antimicrobial agent at the drug levels that can be achieved using the usual therapeutic dose rates. In clinical terms, organisms are considered to be either **susceptible** or **resistant** to the action of an antimicrobial. However, with many organism–antimicrobial associations, resistance or susceptibility is **not an all-or-none phenomenon;** it is dependent on drug concentration. Organisms that may be resistant to low levels of an antimicrobial agent are frequently susceptible to its action at higher concentrations. Thus an organism that is susceptible to the action of benzylpenicillin at a concentration of 0.1 µg/ml would be considered susceptible because equivalent levels of benzylpenicillin can be easily achieved in the blood and tissues. One that was susceptible only at a concentration above 5 µg/ml might be considered resistant, even though it is possible to achieve and maintain this concentration of benzylpenicillin in the tissues with high and frequent dosing.

Susceptibility Test Methods

Tube Susceptibility Tests

Susceptibility tests may be quantitative or qualitative. **Tube susceptibility tests**, using serial dilutions of the antimicrobial drug against a standard dose of the test organism, provide quantitative information in terms of an exact MIC of the drug being tested. The MIC is the lowest antibiotic concentration that prevents the growth of bacteria within a defined period of time and under the conditions of the test. Tube susceptibility testing is the gold standard. With most antibiotics a mean plasma level two to five times the MIC needs to be sustained through the dosing interval for effective therapy. These tests are laborious and time-consuming and are seldom used in practice situations for these reasons.

Disk Susceptibility Tests

Disk susceptibility tests provide more limited qualitative information. They are generally a valuable adjunct in the choice of an antimicrobial agent for therapy, particularly for systemic diseases. However, the limitations of the usual method of testing and the limitations of interpretation should be recognized by the clinician.

The **Kirby–Bauer** technique is the most commonly used method of disk diffusion susceptibility testing. With this technique, disks are impregnated with a standard amount of antibiotic that diffuses into the media to produce a zone of inhibition of growth. With a standard concentration of antibiotic in the disk and standard antibiotic sensitivity test media and test conditions, the concentration of the diffused antibiotic at any given distance from the disk is relatively predictable and constant. There is a linear relationship between the diameter of the zone of inhibition and the $\log_2$ of the MIC. For each antibiotic MIC, breakpoints have been established and corresponding zone size breakpoints established above or below that which an organism is classified as resistant, susceptible, or of intermediate susceptibility.

Although the Kirby–Bauer disk susceptibility testing system has a quantitative genesis, the results are qualitative, especially as used in most practice laboratories. The MIC breakpoints are specific values used to assign bacteria to one of three classifications: susceptible, intermediate, and resistant.

The MIC breakpoints and thus the published reference zone sizes for resistance and susceptibility are often based on the pharmacokinetic properties of each antimicrobial in humans. These frequently have a limited relationship to their pharmacokinetic properties in animals, particularly ruminants.

Also, a single antimicrobial considered to be representative of its class is used to test susceptibility to that class of antimicrobials, but this representative is not always the antibiotic agent present in commercially available antibiotic treatments for livestock. Further, the use of specific zone diameters to establish resistance and susceptibility assumes a standard test with standard media and under standard conditions. These conditions are frequently not met in veterinary practice laboratories.

Despite these limitations, disk susceptibility tests can be used as a guide to the selection of antimicrobials for therapy in large-animal veterinary practice. They are of particular value in selecting a choice of antibiotic with organisms that exhibit variable patterns of resistance and where this pattern for any one antibiotic is essentially bimodal in distribution. They may have limited value in the testing of organisms in which the sensitivities are clustered around the MIC breakpoint. However, there is a lack of validation for susceptibility testing being predictive for treatment outcome in almost all large-animal diseases because the breakpoints have not been validated. There should not be overreliance on the results of testing for sulfonamide susceptibility because these are frequently misleading and a good clinical response can be achieved with therapy, even though the sensitivity test suggests resistance.

Frequently, with disk susceptibility tests, the organism proves sensitive to a number of different antimicrobial agents. The selection of one of these for therapy is based on such factors as **ease of administration** and **cost**. The relative efficacy of any one of the agents cannot be determined by comparison of the size of the zones of inhibition.

Microtiter Techniques

The development of semiautomated microtiter methodology for direct MIC determinations allows many reference diagnostic laboratories and teaching hospitals to determine MIC concentrations directly in bacterial susceptibility testing. The results are more directly applicable to rational therapy and, in particular, have more relevance than disk diffusion tests for determining the susceptibility of organisms that cluster around the MIC breakpoint for a given antibiotic.

Other Considerations

The antimicrobial susceptibility of an organism can **vary** considerably depending on the **species of animal** from which it is isolated. *E. coli* isolates from pigs generally show a greater degree of antibiotic resistance than those isolated from adult cattle. Similarly, *Campylobacter* spp. isolates from pigs show substantially different antibiotic susceptibility patterns from those isolated from sheep. Isolates from the same species may also vary significantly in susceptibility so that *E. coli* isolated from mastitis in cattle generally have a broader susceptibility pattern than those isolated from enteric disease in calves. In addition, there are area differences and changes with time. Low levels of antibiotic

fed for growth-promoting purposes may influence susceptibility patterns, and in herds where growth promoters are used it is generally wise not to use the same drug or members of the same group for therapeutic purposes without prior testing.

Flaws and Limitations of Culture Susceptibility Testing

Culture and susceptibility data (pharmacodynamics) increasingly are becoming an important tool in the selection of an antimicrobial. Culture and susceptibility testing might identify the target organisms, help to confirm the need for therapy, and confirm the susceptibility of the isolate to drugs of interest. Therefore culture and susceptibility testing is useful; on the other hand, this test represents an in vitro testing system and the results must then be applied to an in vivo situation. As such, culture and susceptibility results must be interpreted in the context of potential host and microbial factors that can alter concentrations achieved at the tissue site. It is extremely important to use proper technique for culture samples because culture data are only as good as the sampling method used for their collection. The following include the limitation of the application of the in vitro data to some patients:

- Time, space, and other limitations exclude testing of all drugs. For some drug classes, one drug serves as a model for other members in the class.
- Many laboratories include model drugs approved for use in humans but not in other animals.
- For any culture and susceptibility method, active metabolites may not be included in the interpretive standards when some metabolites can contribute markedly to activity.
- **Culture and susceptibility testing may fail to represent in vivo behavior of bacterial organism.**
- **The pharmacokinetics contributing to interpretative criteria of culture and susceptibility testing are largely based on total plasma concentrations. Culture and susceptibility testing does not take into account binding of the drug to plasma proteins, which overestimates efficacy of protein bound drugs.** (Box 6-1)

Box 6-1 Pros and cons of empirical therapy versus culture and susceptibility-based antibiotic therapy

Empirical choice	Susceptibility-based choice
Advantages	**Advantages**
• Quicker	• Very likely to have the right antibiotic
• Cheaper	• More likely to have correct dosing regimen
Disadvantages	• Save time and money if wrong antibiotics are chosen empirically
• More likely to have the wrong antibiotics (up to 50% of cases)	**Disadvantages**
• More likely to have the wrong dosing regimen	• Takes 24–48 h
• Potential waste of time	• Cost
• Potential waste of money	• One to two member(s) of each class tested (assumption of similar results with other members)
• Potential for resistance (50% of isolates resistant to antibiotics commonly used empirically)	• Laboratory protocol might not perfectly represent reality

Antibiotic Resistance

Development of antimicrobial resistance by microbial pathogens and commensals represents a major threat to animal health and public health. Current concerns relating to antimicrobial resistance arise principally from the rapid rate of development of resistance relative to the slow rate at which new mechanistic groups of antibiotics are introduced, and the conviction that development of resistance is accelerated by overuse of antibiotics. Antibiotic resistance can be categorized in three types:

1. Natural or intrinsic resistance (predictable resistance)
2. Mutational resistance (unpredictable resistance)
3. Extrachromosomal or acquired resistance

Microorganisms generally resist the actions of antimicrobial agents by (1) interfering with the specific targets necessary for binding of the drug to its target site, such as development of altered receptors or enzyme for antibiotics (altered penicillin binding proteins [PBPs] for β-lactams and DNA gyrase for fluoroquinolones); (2) destroying or altering the conformational integrity of the drug (hydrolysis of the β-lactam ring of penicillins and cephalosporins by β-lactamases); and (3) preventing the drug from attaining an effective concentration at its site of action (alteration of porin channels or induction of efflux of drug).

Antimicrobial resistance is a natural biological phenomenon, and the introduction of antibiotics into clinical use has almost invariably been followed by the emergence of resistance to these drugs in bacterial populations. When a microbial population is exposed to an antibiotic, the more susceptible organisms will succumb, and antimicrobial use in human medicine and in agriculture naturally must result in the selection of antimicrobial-resistant phenotypes. This occurs in nonpathogens as well as pathogens. Resistance is generally slow to reverse or is irreversible.

There are a number of mechanisms in which resistance is engendered. Resistance that results from spontaneous mutation of chromosomal genes encoding a target site is probably of limited importance in clinical settings. It occurs more frequently with certain antibacterials, i.e., rifampin, and may be combated by the inclusion of a second antibacterial in the treatment regimen. Plasmid- and transposon-determined drug resistance is much more important in clinical situations and has led to widespread multiresistance patterns in certain bacterial populations.

Plasmids are extrachromosomal genetic elements that replicate independently of the chromosome. They can be transferred within, and in some cases between, bacterial species and may also act as vectors for transposons. They may encode for single or multiple patterns of antibiotic resistance and, increasingly, multiple patterns of resistance are emerging. With veterinary pathogens, plasmid-determined resistance is particularly important in the Enterobacteriaceae, *Staphylococcus aureus* and to some extent in *Pasteurella* spp.

Virtually all antibiotics given in therapeutic doses cause marked changes in the microflora of sites in the host normally colonized by bacteria. There is suppression of the sensitive flora with subsequent selection and colonization by resistant bacteria. In pigs, there is some evidence that therapeutic use of antibiotics in individual animals does not greatly influence herd flora resistance patterns, but in-feed medication of post-weaned pigs selects for antibiotic resistance that maintains in finisher pigs. The feeding of antibiotics for growth promotion and the feeding of antibiotic-treated milk to calves will select for resistance among organisms within the alimentary tract. These resistant organisms can persist in the animal and in the environment and subsequently form part of the normal colonizing flora of other animals. Thus it is not unusual to isolate organisms, *E. coli*, for example, that are resistant to one or more antibiotics even though the animal from which they were isolated had never received antibiotic medication.

There is a higher prevalence of antibiotic-resistant *E. coli* in the normal intestinal flora of young animals than adults. The prevalence is higher in young animals reared intensively, such as veal calves and pigs, and in

environments in which antibiotic usage has exerted selection pressure. The prevalence falls with increasing age, and the intestinal flora of adults generally shows a broader susceptibility pattern. Although many of these resistant organisms are not pathogens, they contribute a pool of R plasmids that can be transmitted to pathogens, and therapy decisions should take into account what antibiotics are in routine use on the farm as growth-promoting additives. Tetracyclines and neomycin are commonly incorporated in calf milk replacers with the label claim that they are growth promoters and aid in the control of calf diarrhea. However, there are no published studies that support health benefits. There are studies that show improved growth of calves on medicated milk replacers compared with control calves, but this difference is lost after weaning and not of any production benefit.

Feeding antimicrobials to livestock and poultry to reduce disease and promote weight gain has been standard practice in developed countries for several decades but is engendering increasing concern, and the occurrence of antimicrobial resistance is beginning to be considered to be a societal issue. The concern is that antimicrobial use in food-producing animals may affect human health by the presence of drug residues in foods and by promoting the presence of antibiotic-resistant strains in animals that can subsequently infect humans through food or from effluent contamination of the environment. The consequences of this also include an increased risk for resistant pathogens to be transferred to humans by direct contact with animals. Although many of the growth-promoting antibiotics used in animals are not the same as those used for human therapy, antimicrobial exposure can initiate bacterial resistance to compounds of dissimilar structures.

There is a particular risk to farmers, farm workers, and veterinarians from exposure to contamination in the farm environment and a risk from transfer of resistant bacteria through farm food and via environmental contamination from farm effluents.

Public and medical concern about the ways in which antimicrobials are used in agriculture has particularly been aroused by the development of vancomycin-resistant enterococci (VRE) in humans associated with the use of the related drug avoparcin as a growth-promoter in animal feeds. In response to concerns about the emergence of antimicrobial resistance, Sweden banned all growth-promoting antibiotics in 1986. This was followed by a ban on avoparcin and virginiamycin in Denmark in 1995 and 1998, respectively. Finally, the European Union banned the use of avoparcin in 1997 and bacitracin, spiramycin, tylosin, and virginiamycin for growth promotion in 1999. Following the 1995 ban on avoparcin, several investigators reported a decline in animal VRE. In Denmark, frequencies peaked at 73% to 80% and fell to 5% to 6% in poultry. In Italy, VRE prevalence in poultry carcasses and cuts decreased from 15% to 8% within 18 months of the 1997 ban, and in Hungary a 4-year study showed not only a decline in prevalence of VRE among slaughtered cattle, swine, and poultry after removal of avoparcin but also a decrease in vancomycin MICs. Increased virginiamycin use in Danish broilers during the mid-1990s correlated with a rise in resistant *Enterococcus faecium* prevalence, from 27% to approximately 70%. Following the ban, resistance declined to 34% in 2000. Likewise, in Denmark the 1998 ban on the use of tylosin in swine resulted in a decline in erythromycin (a structurally related macrolide) resistance from 66% to 30%. Avilamycin use in 1995 and 1996 increased resistance in broiler *E. faecium* strains, from 64% to 77%, while declining applications after 1996 lowered the prevalence to 5% in 2000. There has been an apparent reduction in vancomycin resistance in fecal enterococci isolated from humans and animals. There has also been an apparent increase in morbidity and mortality among pigs, associated with enteric infections, diarrhea, and chronic infections caused by *Lawsonia intracellularis.* This increase in animal disease since the ban has resulted in a substantial increase in the use of therapeutic antibiotics for food animals in Europe, primarily tetracyclines, trimethoprim/sulfonamides, and macrolides.

With respect to the emergence of antibiotic resistance in zoonotic organisms, a particular concern has been plasmid-determined multiple antibiotic-resistant strains of salmonella that have emerged and caused rapidly spreading epidemics of disease in young calves in England and throughout Europe. These multiple resistance patterns have been associated with particular phage types and biotypes of *Salmonella typhimurium* and *S. dublin.*

Preventing the spread of multiresistant organisms is not easily achieved, and there are examples of spread involving virtually every major pathogenic bacterial group. An example is the emergence and spread of *S. typhimurium* DT104, in which multiple antibiotic resistance is chromosomally determined. A pathogen of a variety of different animal species, including humans, this organism spread globally in the 1990s. Because of the advanced salmonella surveillance system in the United Kingdom, this organism was first recognized as causing outbreaks of disease in cattle and humans in the United Kingdom and its emergence was initially attributed to the use of antimicrobials in cattle. There is, however, no evidence in support of this and its spread was caused by its colonizing ability and not to selection by the feeding of antimicrobials. The history of the emergence and spread of this organism, which was unrelated to the use of antimicrobials in livestock and related more to the colonizing ability of DT104, should act as a brake on proposals to use changing patterns of antimicrobial resistance as a measure of the risk of the use of antimicrobials in livestock.

Plasmid-determined multiple patterns of resistance are likely to increase in organisms in environments in which selection pressure is high as a result of frequent antibiotic usage. The use of antibiotics in agriculture is an obvious target to reduce this selection, and is frequently blamed for the problem of developing antibiotic resistance in human pathogens. Nosocomial infection with antibiotic-resistant animal pathogens is an emerging problem in veterinary hospitals, and procedures for limiting their spread are available.

Although the major concern has been directed at antibiotic use for growth promotion, there are also moves, in some countries, to restrict the use of certain antimicrobials, e.g., fluoroquinolones, from therapeutic use in farm animals. However, a European survey of antimicrobial susceptibility among zoonotic and commensal bacteria from food-producing animals found that, although there was variation among European countries in the resistance of enteric organisms, this largely involved the older antimicrobials, and that resistance to the newer compounds used to treat humans was low. Equally, a study of mastitis pathogens over a 7-year period in the United States showed no trend toward increased resistance and reported a reduction of resistance to β-lactam antimicrobials for several gram-positive mastitis pathogens.

WAYS TO MINIMIZE OR AVOID THE DEVELOPMENT OF ANTIMICROBIAL RESISTANCE

Strategies considered effective in delaying development of resistance involve minimizing the use of antimicrobial agents, and using dosage regimens to achieve drug concentrations at the site of infections that eliminate pathogenic organisms without promoting survival of more resistant microbial subpopulations. The guidelines of antimicrobial usage have been published by a variety of agencies, and these guidelines adhere to the following principles:

- Use antibiotics whenever bacterial infection is confirmed.
- Start treatment early: Logarithmic growth phase of infection
- Dose adequately: Low dose (resistance) and high dose (cost and toxicity)

- Avoid prolonged use of antibiotics.
- When possible, select narrow-spectrum agents, based on definitive identification of the infectious agent, rather than broad-spectrum agents.
- Maintain the dosage: The general rule is to maintain dosing for 7 to 10 days or for 4 to 5 days after resolution of fever. Patients that have compromised host defenses should be treated for 10 to 14 days. Chronic infections may require 4 to 6 weeks of treatment.
- Susceptibility tests: Not practical for each case, periodic testing will help establish a trend for a particular disease or on a particular premise.
- Evaluate clinical effectiveness: Improvement by 4 days after initiation of treatment
- Prevention and good management: As simple as controlling ventilation, humidity, sanitary environment, and avoiding stress

AVOIDING ANTIMICROBIAL RESISTANCE (THREE Ds APPROACH)

- **De-escalate:** No antibiotic usage when alternate therapy is available, limit duration of treatment (shortest course of therapy clinically acceptable), rotate the usage of antibiotics on a regular schedule
- **Design:** Effective dosing regimen, selection of most appropriate antibiotic for the organism while narrowing spectrum of activity
- **Decontaminate:** Reduce bacterial exposure (wearing gloves, hand washing, proper bandaging, strict asepsis during surgery, etc.).

Investigations with fluoroquinolones resulted in the **mutant prevention concentration** (MPC) concept, which represents a novel in vitro measurement of fluoroquinolone potency. The MPC is the concentration of the drug necessary to prevent (inhibit) the emergence of the first-step mutants. In other words, MPC represents the highest MIC of the isolates in patient. It was also reported that the MPC values combined with the pharmacokinetic (PK) profiles could be used to optimize the dosing regimen to prevent the emergence of resistant mutants. When MPC data are applied to achievable and sustainable serum drug concentrations in the body, estimation of the time the serum drug concentration exceeds both MIC and MPC values can be determined. These data, along with kill data, allow for an estimate of the amount of time drug concentration needs to exceed MIC/MPC values to not only result in significant kill, but also to minimize resistance development. On the other hand, there is little correlation between MIC and MPC, and the MIC/MPC ratio is both drug and pathogen specific. Currently, limited data are available to conclude if the MPC concept does or does not apply to other antimicrobial agents.

Antibiotic Metaphylaxis to Control Respiratory Disease

Metaphylaxis (mass medication) to manage respiratory disease in newly received high stress or recently weaned cattle is a common practice. Metaphylaxis is a newer term used to describe the treatment of an entire group of calves with an antibiotic upon arrival at the farm before the onset of overt illness. Several viruses and bacteria have been associated with acute bovine respiratory disease (BRD). This disease syndrome was originally termed *shipping fever,* because signs often occur shortly after arrival in the feedlot. Consistent prevention and control of BRD is costly and difficult. Metaphylaxis can be considered as prevention and a curative treatment because cattle arriving to a stocker or feedlot facility may be at risk for developing BRD as well as currently experiencing various stages of the disease process. Interactions among the respiratory pathogens and compromise of the innate respiratory defense mechanisms, especially as a result of environmental and management stresses such as heat or cold and weaning and transportation, seems to be critical to the development of clinical BRD. This results in considerable economic loss from deleterious effects on cattle health and performance.

The decision to metaphylactically administer any class of pharmaceutical product is based on clinical signs, expected illness rates in the group, and prior evidence of product efficacy. General guidelines that impact the decision to administer metaphylactic treatment for BRD include the following:

- The clinical appearance of the cattle on arrival
- Current (and expected) morbidity/mortality patterns
- Feed consumption
- Elevated body temperature
- Efficacy of products labeled for the control of BRD

Metaphylaxis is most commonly administered within a few days of arrival at the feedlot. Many antimicrobial products are labeled for metaphylactic administration to aid in control of BRD. Many antibiotics are used in metaphylaxis in calves considered *high risk*. When considering metaphylaxis, it is necessary to know that not all antibiotics used in therapy have a beneficial effect in reducing BRD; therefore only approved antibiotics should be used. Antimicrobial drugs currently labeled for metaphylactic administration to cattle for control of BRD include the following:

- Ceftiofur (Excede)
- Chlortetracycline (Aureomycin)
- Chlortetracycline/sulfamethazine (AS-700)
- Florfenicol (Nuflor)
- Oxytetracycline (Tetradure)
- Tilmicosin (Micotil)
- Tulathromycin (Draxxin)

Clinical signs most commonly observed with BRD include high fever, depression, decreased appetite, nasal and ocular discharge, coughing, and varying degrees of dyspnea. The aim of metaphylaxis is to reduce the incidence of acute-onset BRD in highly stressed and newly received calves. An important strategy used to decrease the incidence of BRD is the preventative health program referred to as *preconditioning*, which is a planned management program used before shipment to the feedlot. Generally, preconditioning programs ensure that the animals have been weaned for a predetermined amount of time (usually 30–45 days), vaccinated for various infectious agents (bacterial and viral vaccines), treated with anthelmintics, castrated, dehorned, and acclimated to feed bunks and water troughs before being shipped to feedlots. The cattle health industry should continue to identify means of BRD control though the development of and use of new technologies with the aim of enhancing resistance, reducing risk factors, and decreasing pathogen exposure.

Practical Usage of Antimicrobial Drugs

ANTIBIOTIC DOSAGE: THE RECOMMENDED DOSE

Theoretically, there is no set dose for any antimicrobial agent. The concentration of an antimicrobial drug required for effective activity against different microorganisms varies, and these requirements could be met by varying the dose rate of the drug. However, this is an impractical situation and in practice one works from the **recommended dose,** which will give blood and tissue levels that will be effective against very susceptible organisms with minimal side effects to the host. In this respect the recommended dose

should be considered as a minimum dose. If one is dealing with organisms that require higher concentrations of the drug for therapeutic effectiveness, the recommended dose can be exceeded. With low-toxicity antibacterials this dose may be exceeded severalfold, and with drugs such as benzylpenicillin this is a frequent therapeutic ploy. However, with antibacterials that have toxic potential the recommended dose should only be exceeded with caution and frequently it is wise to search for a different antimicrobial agent to which the organism is more sensitive.

Similarly, the recommended dose may be exceeded in an attempt to increase the concentration gradient in sensitive infections in which necrotic tissue produces long diffusion paths. The recommended dose may also be exceeded for management reasons, as in the case of the treatment of sheep with foot rot or mycotic dermatitis, where only a single treatment is administered for practical purposes.

The **label dose** is the dose stated on the label of the drug and is the legal dose that can be used for that product. The label states the required **withdrawal periods** for avoidance of tissue or milk residues. The recommended doses given in the sections on individual diseases are based on our expectations of therapeutic efficiency, and may exceed the label dose recommendations for certain drugs. The problem of persisting tissue residues should be recognized when label recommendations are exceeded and withdrawal periods should be adjusted accordingly.

Label dose levels and dose intervals for many of the antimicrobial agents used in large animals are frequently too low and too long. In many cases, there are no obvious pharmacologic reasons for these dosing regimens. Unfortunately, pharmacokinetic studies of the earlier antimicrobial agents released for use in large-animal species were limited at the time of their release and it would appear that in many instances the label dose established at that time was inadequate. Some estimate of the dose required for an antimicrobial drug can be obtained by a comparison of the MICs required for activity against various organisms with the blood and tissue levels of the drug obtained at various dose levels. Usually, levels three to five times the MIC are considered necessary for effective therapy, and it is generally considered desirable to maintain these levels over the treatment period, especially with bacteriostatic antimicrobials, although this is probably not essential.

The ultimate proof for dose levels and dose intervals of an antimicrobial is by clinical trials of its efficacy in the treatment of infectious disease. It is apparent that antimicrobial drugs are effective in many diseases in large animals at the dose rates and intervals currently in use. Nevertheless, as the results of pharmacokinetic studies in farm animals become available it is quite probable that they will suggest changes in the dose levels and intervals for several of the antimicrobial drugs in use. This may result in more efficacious therapy and lead to label doses that have a broader spectrum of activity against disease.

ROUTES OF ADMINISTRATION

INTRAVENOUS INJECTION

Intravenously administered antibiotics attain high and immediate blood and tissue levels. This route should be used in the treatment of **septicemia** and other life-threatening diseases. The concentrations obtained are much higher than those obtained with equivalent doses of the same drug given intramuscularly or orally, and, consequently, greater **diffusion concentrations** are achieved at sites of infection. For this reason, this route of administration may also be used in an attempt to increase the drug concentration in areas where the antibiotic normally achieves only low concentrations and where areas of necrosis increase the length of the diffusion pathway. Intravenous (IV) administration may also be indicated in **chronic infections** such as corynebacterial pneumonia in foals, in which diffusion concentrations are required to penetrate the abscess areas and the capsular material of the organism.

An initial IV loading dose (LD) may combat the development of **stepwise resistant mutants**. Because of the initial higher blood and tissue levels, the IV route may also be used for the treatment of infections that are only moderately sensitive to the antibacterial drug being used. This is because effective concentrations may be achieved by repeated IV dosing that would not be achieved by equivalent doses given intramuscularly or orally.

For practical reasons the IV route of administration is used for **low-concentration**, high-volume antimicrobial agents such as sulfamethazine and oxytetracycline. It is also preferred to the intramuscular route in racehorses when there is a need to avoid muscular soreness. The need to avoid **muscle damage** in beef cattle close to marketing may also dictate IV administration.

Administration by this route is not without its dangers. Inadvertent intracarotid injection can occur whenever IV injection is attempted into the jugular vein. Acute **toxic reactions** either to the drug or to its vehicle are more common when intravenous administration is used. Drugs specifically formulated for IV use should be used, or the manufacturer's recommendations on the advisability of the use of this route for any preparation should be followed. Severely toxemic terminal cases may die immediately following injection, and in the owner's mind death may be attributed to the therapy.

Injections should be given **slowly** and not as a bolus. Therapy by repeated IV administration is generally restricted to hospital situations and can be expensive because of the added **cost** of the IV preparations. In field situations an initial **IV LD** followed by sustaining intramuscularly administered doses is frequently indicated in the treatment of infectious diseases and is sound therapeutic policy.

The jugular vein is used in all species except the pig, in which the inaccessibility of superficial veins other than the ear veins makes the jugular route of administration generally impractical. **Perivascular reactions** and intravascular thrombosis are a hazard with this route, especially following the administration of irritant drugs such as sulfonamides and tetracyclines.

INTRAMUSCULAR INJECTION

Intramuscular injection is the most commonly used method for antimicrobial administration in large animals. Where possible this route should be **avoided in meat-producing animals**, especially with irritant preparations. Lesions can be detected at slaughter 12 months after the intramuscular injection of long-acting tetracyclines. If the drug must be given intramuscularly in a meat-producing animal it should be given in the **muscles of the neck**, because scar tissue and blemish are more likely to be detected at this site in the cutting process after slaughter and they can be trimmed. With certain antibiotics, drug residues may persist at these sites for long periods, and the label recommendation for withdrawal or withholding time should be followed.

Irritant drugs should be used with care in **horses**, or avoided, as this species more commonly develops severe reactions at the site of injection. The development of such reactions is usually an indication to change to alternative therapy. Oil-based vehicles frequently produce severe reactions at the site of injection in horses and should not be used.

There is evidence, for some antibiotics at least, that the site of intramuscular administration can influence the rate of absorption, the **bioavailability,** and the subsequent pharmacokinetics of the administered antibiotic. In both cattle and horses, injection in the neck gives more favorable pharmacokinetic parameters than does injection into the gluteal or shoulder muscles. Injection into the dewlap gives the poorest bioavailability. These differences presumably result from differences in the spread of the injected drug within and between the muscles and differences in blood supply. With intermuscular spread there is a greater absorption area and less compromise of capillary and lymphatic structures. Injection into the side of the neck of horses is considered to be malpractice in some countries. When irritant preparations must be given to horses it is wise to inject them into the muscle of the chest between the forelegs, as reactions in this area have less tendency to spread

and are more accessible to drainage and treatment.

At all sites, care should be taken to ensure that the injection is not inadvertently given intravascularly by applying negative pressure to the syringe before injection. In adult animals no more than 10 mL should be given at any injection site. Large injection volumes can result in the formation of encapsulated antibiotic-filled cysts in muscle. Label directions of the maximum amount to be given at any one site should not be exceeded.

With most antimicrobial drugs, excepting the repository forms and drugs of an irritant nature, peak blood concentrations are obtained within 30 to 120 minutes of injection. However, the bioavailability of drugs given by intramuscular injection is markedly influenced by their formulation and irritant nature. This is especially marked with oxytetracycline preparations.

INTRAPERITONEAL INJECTION

Intraperitoneal injection is occasionally used for antimicrobial administration, especially in cattle close to market size, and where IV administration for various reasons may be impractical. It is also occasionally used in pigs with diarrhea, during which the antibacterial drug is combined with fluids for rehydration. In cattle the injection is given in the right flank midway between the last rib and the tuber coxae and at least 10 cm ventral to the lateral processes of the lumbar vertebrae. This is done to avoid retroperitoneal and perirenal deposition of the drug. An aseptic injection technique should be used. Animals with peritonitis are also occasionally additionally treated by this route of injection. In horses with peritonitis the peritoneal cavity can be drained through a cannula inserted in the ventral midline as used for abdominal paracentesis, and the antimicrobial agent is injected via this route. Intraperitoneal injection may also be used for the parenteral administration of the tetracycline group in acutely toxemic animals or in animals with severe respiratory distress when IV injection may result in collapse and even death.

SUBCUTANEOUS INJECTION

Subcutaneous injection has not been commonly used in large-animal practice, but concerns regarding lesions in meat following intramuscular injections are leading to a greater use of this route. Providing the drug is not deposited in a fat depot, this route provides a reasonable alternative to intramuscular injection. With irritant preparations there is a danger of excessive reaction and the occurrence of sterile abscesses. Very small animals (piglets) are often treated by this route. A long-acting formulation of ceftiofur is labeled in North America for subcutaneous administration in the pinna of the ear of cattle. This location was selected because of ease of access and potential for decreased trim of injection site at slaughter. Widespread field use identified rapid death in a very small number of cattle after subcutaneous administration in the ear pinna. Subsequent investigation identified that the cause of sudden death was most likely inadvertent and rapid injection into the auricular artery, with the injection rapidly reaching the cerebral circulation. Recommendations are now available regarding the correct site of the ear pinna to inject to minimize the potential for intraauricular artery injection. One example is subcutaneous injection of the sterile suspension of ceftiofur free acid crystalline (Excede) into the posterior aspect of the ear where it attaches to the head or in the middle third of the posterior aspect of the ear (Fig. 6-1).

ORAL ADMINISTRATION

Oral administration of antimicrobial agents is generally restricted to **preruminant animals**, **young foals,** and **pigs**. The blood and tissue levels achieved following oral administration are considerably less than those achieved by an equivalent dose of the same antimicrobial agent given parenterally, and for this reason the oral dose rate is generally two to five times greater than the parenteral dose. Oral drugs are less reliable because **absorption characteristics** may vary with the volume of ingesta, the presence or absence of gastric and intestinal stasis, or hypermotility and the nature of the ingesta, which variably bind the orally administered drug. For example, oxytetracycline and trimethoprim have a much lower **bioavailability** to calves when administered in milk, rather than in water, because of the high degree of binding to milk. There is some evidence that the oral administration of antibiotics to calves in glucose–glycine–electrolyte solutions is associated with more favorable absorption characteristics. The aminoglycoside and polymyxin groups of antimicrobial agents are not absorbed from the alimentary tract, and benzylpenicillin is largely destroyed within the stomach.

The oral route is the easiest method for administration, and where the cost of revisits is a significant consideration this route is often chosen for **continuing medication**, because it is within the capability of any owner. Generally, however, systemic infections are better treated by parenteral injection and certainly treatment should be initiated by this route. The oral route is the one of choice for the treatment of enteric infections. Experimental studies have shown that the oral administration of antibiotics to healthy neonatal calves may induce villous atrophy within the intestine and malabsorption diarrhea. This occurred particularly with neomycin and to a lesser extent with tetracycline and ampicillin. Although this does not negate the use of antibiotics for specific therapy of enteritis in young calves (when this is indicated), it does suggest that prophylactic use of oral antibiotics has a risk in young calves.

Prolonged oral medication at therapeutic levels may result in **superinfection** in all animal species. Commonly a yeast, staphylococcus, or *Pseudomonas aeruginosa* is involved. It occurs most commonly in calves given courses of differing antimicrobial agents. It is more common following medication involving tetracyclines, and usually a treatment period of at least 2 weeks is required for its development.

Antimicrobial drugs are seldom given orally to ruminant animals. Exceptions are the use of sulfonamides, especially as a sustaining medication following initial parenteral treatment, and low-level antibiotic therapy to feedlot animals to reduce the incidence of liver abscess and respiratory disease. Blood levels following oral administration in ruminants are variable and frequently not achieved until 12 to 18 hours after dosing. Also, many antibacterials are destroyed or inactivated within the rumen. Orally administered antimicrobials cause a significant disruption of the ruminal flora and by itself this

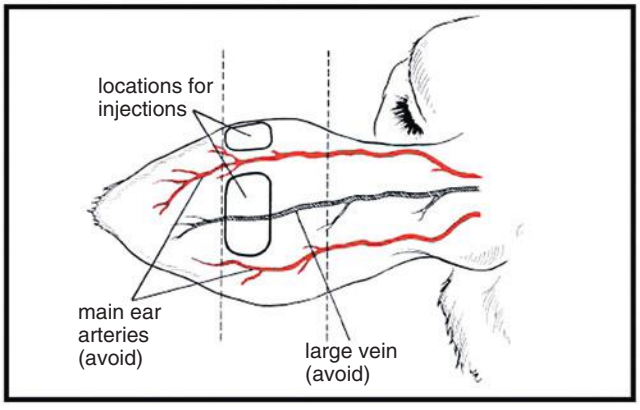

Fig. 6-1 Diagram of the approximate locations of the major arteries of the posterior ear and the recommended needle insertion locations. Administration of Excede Sterile Suspension into ear arteries is likely to be fatal. Excede can also be administered SC at the base of the ear in a rostral direction toward the eye on the same side of the head as the ear, or administered SC at the base of the ear in a ventral direction. (Courtesy of Zoetis, Inc., https://www.zoetisus.com/products/pages/excede_beef/TechnicalResources.aspx Excede® (Ceftiofur Crystalline Free Acid) Sterile Suspension.)

may result in a syndrome of ruminal stasis, anorexia, and depression. If antibacterial agents are given orally to ruminants, the course should be followed by reestablishment of the ruminal flora by cud transfer.

Contamination of Feedstuffs

Antibiotic contamination of rations is a potential problem in feed mills that process medicated and nonmedicated feeds consecutively. The inadvertent feeding of antibiotics to cattle and horses can result in **clinical disease,** and the cause may not be immediately apparent to the investigating clinician. This can occur when cattle and horses are fed medicated pig feed, but may also occur when regular rations become contaminated with antibiotics. Residual carryover of medicated material into other feedstuffs can occur with feed mixers of various types and also via residues in conveyors, hoppers, and trucks. The risk for feedstuffs being contaminated can be quite high, and the most common contaminating drugs are chlortetracycline, sulfonamides, penicillin, and ionophores.

Within 24 hours of being fed medicated feed, dairy cattle show anorexia, rumen stasis, and subsequently pass custard-consistency feces containing undigested fiber. There is a precipitous fall in milk production. Dullness, muscle fasciculation, ketosis, hypocalcemia, and recumbency have also been observed. Affected cattle usually recover when placed on nonmedicated feed, but milk production may be adversely affected for the remainder of the lactation. Feeds contaminated with dimetridazole, lincomycin, and tylosin have been incriminated, although there is debate as to the role of tylosin in this syndrome. The **carryover** of medicated material into other feeds can also create violative **tissue residues** at slaughter. Sulfonamide contamination of swine rations is a particular problem.

The use of orally administered antimicrobial agents in horses over 3 months of age should be approached with great care. Their use can be followed by diarrhea, which is often intractable and results in chronic debilitation or death. Clindamycin and lincomycin carry a high risk and are probably totally contraindicated, and macrolides, tetracyclines, tylosin, and metronidazole are associated with risk in stressed horses.

Water Medication of Pigs

The oral route is the most common and convenient one for group medication of pigs. The antibacterial agent may be incorporated in the water or in the feed. For the treatment of disease in pigs, water medication is preferred as **sick pigs may drink**, whereas they frequently will not eat. Also, water medication can usually be **started immediately**, whereas the mixing of an antibacterial agent with the diet for piggeries purchasing prepared diets may take 1 to 2 days. Antibiotic bioavailability is also less in pelleted feeds.

In outbreaks of contagious disease in pigs, the sick pigs within the group are usually initially treated individually by parenteral injection followed by mass medication of the water supply. Large swine units usually have facilities for in-line medication, and small swine units may not. With pigs using troughs, water medication is no problem. However, with automatic watering systems, medication must be through the header tank, if this can be isolated, or more commonly the water is turned off and medicated water is provided for the pigs via portable 200-L drums with a drinking bowl or nipple drinker inserted in the side.

In determining the **concentration of antibiotic** required in the water, the total daily dose of the drug is computed by multiplying the total weight of the group of pigs in kilograms by the daily dose of the drug in milligrams per kilogram. This dose must then be added to the amount of water that will be consumed in 1 day. It is obvious that this amount will vary according to climatic conditions and to the nature of the disease in the pigs. For example, diarrheic pigs may drink more than normal quantities. In practice, a rule of thumb of 10% body weight water consumption of pigs between weaning and market age has been found to be satisfactory, with estimates of 15% for situations in which high water consumption can be expected. The total daily dose is thus added to the number of liters of water equivalent to 10% to 15% of the estimated total body weight of the group. In pregnant sows, water consumption is usually 5 to 8 L/day, but lactating sows may drink 15 to 20L/day. When there is doubt as to the exact water consumption the medication can be added to the lower estimate and, when consumed, fresh water provided for the remainder of the day. Water medication is generally continued for a period of at least 5 days. Antibiotics may deteriorate rapidly in water, and a fresh mix should be prepared each day. Most drugs for water medication have label directions.

Water Medication in Cattle

There are some major limitations in the mass medication of water supplies of cattle. The daily amount of water consumed is usually directly proportional to the amount of dry matter intake. Anorexia or inappetence will result in a marked decrease in water intake to mere maintenance requirements. Depending on the drug used, the palatability of the medicated water may affect intake. With large drinking water tanks that are replenished on a continuous basis, or even two or three times daily, it is difficult to determine how much drug should be added on a daily basis to maintain a reasonably steady concentration. On a theoretical basis, automatic in-line water medicators should provide a uniform concentration of drug in the water supply. However, some medicators are extremely unreliable and regular surveillance and servicing may be necessary. In countries where below-freezing temperatures occur during the winter months, the medication of water supplies may be difficult and impractical under certain management conditions.

Dietary Medication

This is generally used for long-term disease control. In many countries, the amount of an antimicrobial that can be added to a feed is restricted to the **approved label level** and the veterinarian has no legal right to alter this concentration. The drug is usually added at the feed mill.

Ionophores

Ionophores are feed additives used in cattle diets to increase feed efficiency and body weight gain. They are compounds that alter rumen fermentation patterns. Ionophores have been used widely in the beef and poultry industry for improved feed efficiency and control of coccidiosis. Similar to many other feed additives, ionophores are fed in very small amounts and supplied via another feedstuff as carrier for intake. Some argued that ionophore resistance poses the same public health threat as conventional antibiotics.

Commercially available ionophores include monensin (Coban and Rumensin), lasalocid (Avatec and Bovatec), salinomycin (Bio-cox and Sacox), narasin (Monteban and Maxiban), maduramicin (Cygro), semduramicin (Aviax), and laidlomycin propionate (Cattlyst). Ionophores are classified as carboxylic polyether antibiotics, and they disrupt the ion concentration gradient (Ca^{2+}, K^{+}, H^{+}, and Na^{+}) across microorganisms, causing them to enter a futile ion cycle. Some ionophores (e.g., valinomycin) only move a single ion, but ionophores fed to cattle act as antiporters. The disruption of the ion concentration prevents the microorganism from maintaining normal metabolism and causes the microorganism to expend extra energy. Ionophores function by selecting against or negatively affecting the metabolism of gram-positive bacteria and protozoa in the rumen. The affected bacteria are those that decrease efficient rumen digestive physiology and the energy supplied from the ruminal digestion of feedstuffs. By controlling certain protozoa and bacteria in the rumen, less waste products (methane) are generated. The shift in ruminal bacteria population and metabolism allows beneficial bacteria to be more efficient through an increase in the amount of propionic acid and a decrease in the production of acetic acid and lactic acid. Therefore cattle experience an increase in the overall energy status and use feed resources more efficiently.

Ionophores are classified as an antibiotic, but they are not therapeutic antibiotics. Antibiotic resistance is an increasing concern in public discourse. However, the increase in antibiotic-resistant bacteria as a result of ionophore use is not well supported for a

number of reasons: (1) ionophores have never been (nor are likely to be) used as antimicrobials for humans; (2) ionophores have a very different mode of action from therapeutic antibiotics; (3) ionophore resistance in bacteria seems to be an adaptation rather than a mutation or acquisition of foreign genes; (4) ionophores can translocate across cell membranes of animals, which limits their use as therapeutic antibiotics; and (5) ionophore resistance in targeted bacteria shows complexity and a high degree of specificity.

In vivo and in vitro experiments indicate that only some ruminal bacteria are inhibited by ionophores. Susceptibility and resistance of ruminal bacteria to ionophores are more closely correlated with differences in the cell envelope. Bacteria that produce ionophores are naturally resistant with an unknown mechanism of resistance action. There are few toxicologic reports regarding toxicologic effects of ionophores in target animals and off-target animal species. Ionophores are generally safe and effective if used at recommended doses. However, accidental overdose, misuse, mixing errors, and accidental ingestion in nontarget species could result in toxicity in a number of animals. Horses, cattle, avian species, dogs, cats, and rats are sensitive to ionophore toxicity. Toxic effects of ionophores are thought to be mediated by disrupting the normal ionic gradients of cells leading to mitochondrial damage and lack of cellular energy. A well-known toxic effect of ionophores is cardiac toxicity and muscle degeneration in suspected species; however, the specific tissues affected and resulting clinical signs vary from species to species. However, one less commonly known effect of ionophores is associated with the nervous system, leading to neuropathy, which is manifested with myelin degeneration and ataxia. Cardiac muscles are primarily affected in cattle, and both myocardium and skeletal muscles are damaged in horses. Of the off-target species, the horse appears to be the most sensitive to ionophore toxicosis.

OTHER ROUTES

Other routes of administration may be used to increase the level of antibacterial drug in areas in which diffusion following parenteral administration of the drug may be limited and when high local levels are required. These include intraarticular, intrapleural, and subconjunctival injection. Nonirritant preparations should be used with strict aseptic technique. In most cases these treatments should be supported by parenteral treatment.

Intramammary infusion of drugs is dealt with in Chapter 20. Intratracheal administration of antibiotics has its advocates for the treatment of pneumonia in cattle. In theory, this could result in higher levels of antibiotics at the site of infection, although with many pneumonias diffusion through the affected lung must be minimal. The antibiotics are administered in sterile physiologic saline equivalent to 2 mL/kg body weight. An extensive study has shown variation in absorption and persistence between antibiotics administered by this route, compared with parenteral administration, but has concluded that there is no potentially useful advantage to its use.

The local administration of antibiotics may not always be the preferred route despite historical precedence. For example, in the treatment of the **genital tract**, it has been shown that parenteral administration of antibiotics achieves tissue concentrations of drug in all areas of the genital tract, whereas intrauterine infusion results in comparable concentrations only in the endometrium and uterine secretions. Local and/or parenteral administration may be indicated in different cases of genital tract infection.

DRUG DISTRIBUTION

ABSORPTION

Antibiotics of the aminoglycoside group and polymyxins are not absorbed from the alimentary tract, and if circulating levels of these antibiotics are required they must be given by parenteral injection. Where both intestinal and systemic levels are required, as may be the case in neonatal colibacillosis, these drugs should be given both orally and parenterally. Benzylpenicillin and methicillin are destroyed by acid pH and significant blood levels are not achieved following oral administration, but blood levels are achieved with ampicillin and amoxicillin. Certain sulfonamides (phthalylsulfathiazole, phthalylsulfacetamide, sulfaguanidine, and succinyl sulfathiazole) are not absorbed from the alimentary tract. The remaining antibiotics and sulfonamides are absorbed following oral administration in preruminant calves and lambs and in pigs and horses. However, generally, blood and tissue levels obtained are considerably lower than those achieved with equivalent doses given parenterally. Whey feeding (calcium) will inhibit the absorption of tetracyclines in pigs.

DISTRIBUTION

Factors governing the distribution of antimicrobial agents in the body fluids are complex, and distribution should be considered as involving a multicompartmental system with all body compartments being in contact directly or indirectly with the blood. The occurrence of exchange, and its rate, between the blood and the various tissue compartments is governed by the factors that influence the diffusion of solutes, such as the concentration of the drug and the volume of blood flow through the tissues and the volume of the tissue. It is also considerably influenced by the extent of protein binding of the drug in blood and in the tissues, the ionization constant of the drug, pH differences in the compartments, and the lipid solubility of the drug. Drug distribution is also influenced by age and the disease state of the animal.

In most diseases infection occurs in the extravascular tissue compartments, and it is the concentration of the unbound drug at these sites that determines the efficacy of therapy. The majority of antibiotics diffuse relatively freely in extracellular fluids, but sulfonamides, the chloramphenicol group, tetracyclines, fluoroquinolones, and macrolides have a distribution that more closely approximates total body water, and they can enter cells.

There are several so-called **barriers** to antimicrobial diffusion and these include the brain and cerebrospinal fluid, serous cavities, joints and synovial fluid, the eye, and the placenta and fetus. Generally, sulfonamides, tetracyclines, and chloramphenicol have some ability to penetrate these barriers in the normal state, whereas penicillin may not. Erythromycin has the ability to penetrate intracellularly and across most barriers but will not produce effective levels in the brain or cerebrospinal fluid. Members of the aminoglycoside group of antibiotics generally achieve effective levels in synovial fluid and the pleural and peritoneal fluid but not in the brain or eye. The importance of these barriers, especially those of serous cavities and synovia, in the presence of inflammation is open to doubt and effective therapy can often be achieved by the use of antibiotics that do not in normal situations reach these areas unless they are inflamed. An exception to this rule is infections involving the eyes where, to achieve effective levels, high circulating levels of the antimicrobial agent are required and IV injection to achieve this is usually necessary. Lipophilic drugs diffuse into tears and parenterally administered erythromycin, oxytetracycline, and gentamicin, for example, may achieve bacteriostatic concentrations in tears. In many areas, especially joints and the peritoneal, pleural, and pericardial cavities, high levels of the required antimicrobial agent can be achieved by local administration.

Almost all antimicrobial agents are **excreted** via the kidney, and the urine usually contains high levels of them. This feature is not of great significance in large animals, in which urinary tract infections are comparatively rare, but violative residue levels can

persist in the kidney for long periods with aminoglycosides. Penicillins and tetracyclines have a significant enterohepatic cycle, and erythromycin also may obtain significant levels in bile.

PHARMACOKINETIC PRINCIPLES FOR ANTIMICROBIAL USAGE

A fundamental therapeutic concept is that the right drug must be selected for the right disease. An accurate diagnosis of the disease, knowledge of the clinical situation of the patient, and a sound understanding of the pharmacotherapeutics management of the disease is essential. Recently a second important aspect of therapeutics has emerged emphasizing that clinicians must do more than simply choose the proper drug. They must also select the dose, route of administration, and frequency of administration that will achieve and maintain an appropriate drug concentration at the site of action. Pharmacokinetics is a quantitative study of the time course of drug **absorption, distribution, metabolism, and excretion**. The ultimate goal of pharmacokinetics is to optimize the therapeutic management of individual patients through development of safe and effective drug-dosing regimens. The application of pharmacokinetic principles allows a more rational choice of therapeutic dosage regimen. In many cases, patient characteristics or specific disease states are known to alter the pharmacokinetic properties of a particular drug within the body. If appropriate adjustments in the dosage regimen are made to compensate for these changes, then potential problems of drug ineffectiveness and/or toxicity may be avoided. The following pharmacokinetics parameters are discussed briefly to help clinicians better establish an appropriate dosing regimen for antimicrobial compounds.

Area under the curve (AUC) represents an estimated area under the plasma drug concentration versus time curve. The AUC provides a measure of the extent of drug exposure and has little clinical relevance. Its therapeutic interpretation rests on comparing it with other AUC values or to some other therapeutic measure (such as the MIC of antimicrobial agents). The AUC of an extravascular dose may be compared with the AUC following intravascular administration for the determination of bioavailability. Bioavailability represents the rate and extent of drug absorption following extravascular administration of drugs. The AUC is also used during therapeutic drug monitoring to help identify factors that may affect drug pharmacokinetics, such as disease, food consumption, sex, age, breed, pregnancy, and lactation. It is also used in clinical pharmacology to calculate systemic clearance (systemic clearance [Cl_s] = Dose IV/AUC IV).

Volume of distribution (*V*) is the constant that relates the amount of drug in the body (A) to the plasma drug concentration (C) (i.e., $V = A/C$), but does not necessarily correspond to any actual anatomic volume or compartment. By definition V is the proportionality rate constant between a plasma concentration and the corresponding amount of drug in the body. It is a characteristic of a drug rather than of the biological system, although it may change in the presence of disease, pregnancy, obesity, and other states. Among the antibacterial drugs, β-lactams are ionized at physiologic pH and generally have a low V, whereas macrolides are concentrated in cells and have a high V. Three volumes of distribution are reported in the literature including volume of central compartment (V_c), the volume of distribution during terminal elimination phase (V_{area}), and the steady-state volume of distribution (V_{ss}). In clinical pharmacology, V_c is rarely used, but sometimes this parameter is useful to predict maximum plasma concentration after IV bolus injection. When administering an IV loading dose (LD) to achieve immediate steady-state drug concentrations, the peak concentration associated with the LD can be estimated as how an IV dose/V_c. V_{area} relates the plasma drug concentration during the terminal elimination phase to the corresponding amount of drug remaining in the body. V_{area} is primarily used in clinical pharmacology to estimate the residual amount of drug in the body when drug decreases according to its elimination phase. V_{ss} is useful in clinical pharmacology for calculation of an LD and also for predicting the fluctuation of plasma concentrations during a dosage interval. The V_{ss} provides an estimate of drug distribution that is independent of elimination process. By knowing the value of V_{ss}, it is possible to calculate the dose necessary to obtain a target plasma concentration (i.e., $LD = V_{ss} \cdot C_{ss}/F$), where C_{ss} represents steady-state plasma concentrations and F represents bioavailability. The greater the volume of distribution of a drug, the higher the dose necessary to achieve a desired concentration (e.g., the larger the V_{ss}, the smaller the fluctuation between peak and trough plasma concentrations).

The ***Cl_s*** describes the efficiency of irreversible elimination of a drug from the body (principally by the major organs of biotransformation and elimination, the liver and kidney) and is defined as the volume of blood cleared of drug per unit time. Clearance determines the maintenance dose (MD) rate required to achieve a target plasma concentration at steady state, because at steady state there is an equilibrium in which the rate of drug elimination is matched by the rate and extent of drug absorption (e.g., $MD = Cl_s \times C_{ss}/F$). Cl_s can only be calculated following IV injection of drugs (e.g., Cl_s = IV dose/AUC).

First-pass effect is a type of drug clearance and is defined as the extent to which an enterally administered drug is removed before reaching the systemic circulation by prehepatic and hepatic metabolism. First-pass effects are important as a possible source of variability in clinical response to a drug and in explaining a component of the difference in response between parenteral and enteral administration of the same drug.

Half-life ($t_{1/2}$) is the time taken for the amount of drug in the body (or the plasma concentration) to fall by half. In most cases it is the elimination half-life that is used to distinguish it from the absorption half-life, a parameter that describes the rate of drug absorption and increase in plasma concentration. Half-life is a function of V and Cl_s ($t_{1/2} = 0.693 \times V/Cl_s$) and frequently determines the duration of action after a single dose of a drug, the time taken to reach steady state with repeated dosing (generally three to five half-lives), and the dosing frequency required to avoid large fluctuations in peak and trough plasma concentration during the dosing interval (dosing at intervals of one half-life will lead to plasma concentrations covering a twofold range). The terminal elimination half-life is obtained as $t_{1/2} = 0.693/\lambda_z$, where 0.693 is the natural logarithm of 2 and λ_z is the slope of the terminal phase. Because $t_{1/2}$ is a derived parameter, compounds with similar $t_{1/2}$ values may have markedly different rates of Cl_s and vice versa. For this reason, $t_{1/2}$ is considered a poor indicator of the pharmacokinetics changes that can accompany disease, pregnancy, lactation, and aging.

Time to peak plasma concentration (T_{max}) represents the time after dosing at which the maximum plasma concentration is observed and indicates the time at which the rate of absorption equals the rate of dissipation (distribution and elimination).

Maximum plasma concentration (C_{max}) represents the maximum concentration of the drug observed (or calculated) in plasma after administration and occurs at T_{max}.

Bioavailability (*F*) is defined as the rate and extent to which the active constituent or active moiety of a drug is absorbed from a drug product and reaches the circulation. For systemically active drugs, absolute (100%) bioavailability is assigned to intravenously administered drug (unless the drug is likely to precipitate in blood). The bioavailability of alternative formulations of the same drug administered by other routes is compared with that of the IV route. In this case relative bioavailability is assessed by determining the AUC and comparing it with the AUC following IV administration. For nonsystemically active drugs, bioavailability is frequently determined by nonpharmacokinetic means, often by comparing the time course and degree of clinical response or effect of a test drug with a standard (or reference) drug preparation.

Bioequivalence is a clinical term referring to formulations of a drug with rates and extents of absorption that are sufficiently

similar so that there are not likely to be any clinically important differences with respect to either efficacy or safety. To demonstrate bioequivalence for systemically active drugs, a comparative pharmacokinetic study is generally undertaken, and the similarity (defined by statistical and biological criteria) of C_{max} and AUC of the formulations is assessed. For drugs not acting systemically, comparisons of clinical or other pharmacologic endpoints may be necessary.

DURATION OF TREATMENT

For certain infectious diseases there is an established regimen of therapy that is known from clinical experience to be therapeutically effective. Where such regimens are known they are stated in the treatment section for the individual diseases in subsequent chapters. As a rule of thumb in undifferentiated diseases, therapy should be continued for at least a 3- to 5-day period or longer if there is evidence of chronic infectious disease with localization. An alternative rule of thumb is that treatment should be continued for at least 1 day beyond the return of body temperature to normal, especially if bacteriostatic antibiotics are being used. Chronic pyogenic processes may require treatment for a 2- to 4-week period or even longer.

DRUG COMBINATIONS

Combinations of antimicrobial drugs are frequently used in veterinary practice. Combinations of antimicrobial agents are used either to achieve a **synergistic effect** in the case of a single infection or to achieve a **broad spectrum of activity** in the case of infections involving more than one agent. Combinations may also be of value in combating the **emergence of resistant** mutants during therapy.

The combination of two drugs may result in **indifference**, in which the effect is either that of the single most effective drug or is equal to the sum of the effects of the two individual drugs, or it may result in **synergism** or **antagonism**. There are, however, no hard and fast rules for combinations that will result in any of these effects. Knowledge of these effects results largely from laboratory animal studies and from some human therapeutic trials. From these trials it is evident that the occurrence of **synergism** is very dependent on the type of infectious organism, and to some extent the site of infection, and, whereas two drugs may show a synergistic effect with one type of infection, the effect may be indifferent or even occasionally antagonistic with other infective agents. **Antagonism** is equally not easily predictable, but the drugs that most commonly result in an antagonistic effect when combined with others are the tetracyclines, chloramphenicol, and macrolides.

A traditional approach has been that combinations of bactericidal drugs will generally result in an indifferent effect or in synergism; combinations of bacteriostatic drugs generally give an indifferent effect, whereas combinations of a bactericidal with a bacteriostatic drug may result in antagonism (Box 6-2). This approach is, however, too general for validity, because interactions are specific to individual infections and are dose dependent.

In farm animals, **synergistic activity** between penicillin and streptomycin has been demonstrated in the therapy of mycotic dermatitis and foot rot in sheep.

The synergism between aminoglycoside and β-lactam antimicrobials is widely used in the approach to the therapy of sepsis in neonates. Carbenicillin and gentamicin in combination can be of value in therapy against *P. aeruginosa*, *Klebsiella*, and *Proteus* spp., and tylosin and oxytetracycline can be of value in treating infection with *Mannheimia* and *Pasteurella* spp. Trimethoprim and sulfonamide combinations are of special value in treating several infectious diseases in large animals. Rifampin and erythromycin show in vitro synergism against *Rhodococcus equi,* as does a combination of gentamicin and penicillin. Tiamulin and tetracycline show in vitro synergism against several swine respiratory pathogens, and herd studies show a measured response in the control of respiratory disease greater than that achieved by chlortetracycline alone.

Box 6-2 Mode of action of antimicrobial drugs

Bactericidal antimicrobials
- β-Lactams
  - Penicillin
  - Cephalosporins
- Semisynthetic penicillins
  - Ampicillin
  - Amoxicillin
  - Cloxacillin
  - Methicillin
  - Carbenicillin
- Aminoglycosides
  - Streptomycin
  - Neomycin
  - Gentamicin
  - Paromomycin
  - Tobramycin
- Glycopeptides
  - Vancomycin
- Rifampin
- Bacitracin
- Polymyxins
- Fluoroquinolones

Bacteriostatic antimicrobials
- All sulfonamides
- Trimethoprim
- Methotrexate
- Pyrimethamine
- Tetracyclines
- Macrolides
  - Erythromycin
  - Oleandomycin
  - Spiramycin
  - Tylosin
  - Carbomycin
- Lincomycin
- Chloramphenicol
- Florfenicol

Drug combinations are also used for **broad-spectrum therapy**. An accurate diagnosis with consequent recognition of the likely infectious organism allows specific antibacterial therapy and obviates the need for broad-spectrum antibacterial therapy. However, there are clinical situations in which broad-spectrum therapy, including the possibility of combined drug therapy, is indicated. These include such problems as acute septicemia, in which a number of different organisms, with differing antibacterial sensitivities, can produce identical clinical disease, and those infections associated with organisms that have a varying sensitivity depending on the isolate. The requirement for immediate treatment without knowledge of the bacterial sensitivity dictates the use of antimicrobial drugs designed to obtain a broad spectrum of activity.

The availability of **broad-spectrum drugs,** such as ampicillin or amoxicillin and trimethoprim-potentiated sulfonamides, has lessened the need to use drug combinations, but the latter may still be necessary in certain situations and are fully indicated. Although antagonism has not been demonstrated in clinical veterinary situations, it is wise to avoid bacteriostatic and bactericidal drug combinations.

Fixed-dose combinations are available commercially for some antibiotics, but they **are not recommended** for use and are gradually being withdrawn from the market or being declared not legal for use in food-producing animals. Fixed-dose combinations suffer from the deficiency that the dose level of any one of the drugs in the combination is dictated by the level of the other. Also, the excretion rates of the two drugs may be markedly different. The most common of these, fixed-dose penicillin/streptomycin combinations, suffers from this deficiency.

Where combinations of antibacterial drugs are used they should be given individually and at their respective recommended doses and repeats. Some antibiotics are **physically incompatible** when mixed together. The incompatibility may rest with the drugs or their vehicles and may be visible, as with crystalline benzylpenicillin and neomycin, or it may be inapparent, as with gentamicin and carbenicillin. The two drugs should be given separately at separate sites. Incompatibilities can also occur with antibiotics and intravenous fluid solutions, especially those containing protein hydrolysates.

Antibiotics may influence the **activity of other drugs**. In particular, chloramphenicol

and tetracyclines inhibit liver microsomal metabolism and may significantly increase the half-life of drugs metabolized by this mechanism, such as digitalis or barbiturates, with resultant potential toxicity.

ADDITIONAL FACTORS DETERMINING SELECTION OF AGENTS

In addition to the considerations of bacterial sensitivity to the antimicrobial agent, there are other important factors that dictate the selection of the antimicrobial agent to be used in a particular case. In most clinical situations several agents would be effective and a choice needs to be made among them.

COST

This is a major factor and includes not only the primary cost of the drug but also the ancillary costs that may be associated with its administration. This is a most important factor in agricultural animals but of less importance with pleasure horses. The importance of the primary cost of the drug is obvious. For example, in most countries a 5-day course of treatment with procaine benzylpenicillin will cost considerably less than one with, for example, oxytetracycline. If there is no specific indication for the use of the more expensive drug then the less expensive one should be used. The **ancillary costs** associated with repeat visits to administer the drug may also be important. The practice of dispensing drugs for continuing intramuscular therapy varies between countries and veterinary practices and has an influence on this consideration.

EASE OF ADMINISTRATION

This is a further factor that influences the nature of the drug and treatment used. Generally, one avoids starting a course of therapy with an antibacterial such as tetracycline, which may require daily IV administration, in favor of one that can be administered more simply, unless there are good therapeutic reasons for choosing the former. In situations where facilities are poor, where **mustering or yarding** is difficult, or where mass medication is required, long-acting repository preparations may be indicated. Irritant preparations are avoided where possible.

TOXICITY

This is always a consideration when dealing with infections that may require high dose rates of antimicrobial drugs, or in chronic infections that require a prolonged course of therapy. When a choice is available, antimicrobial agents with a low incidence of toxic side effects at high doses are chosen. As in all clinical situations involving large animals, it is essential to make an assessment of the case and to attempt a **prognosis**. The possible cost and duration of treatment should be estimated and the owner advised of this. When examined in this light the decision may be against treatment and for salvage slaughter.

BACTERICIDAL OR BACTERIOSTATIC ANTIMICROBIALS

Antibiotics are either primarily bactericidal or primarily bacteriostatic in their activity (see Box 6-2). A given antibiotic may be **bactericidal** (i.e., the organisms are killed) and **bacteriostatic** (i.e., the organisms are prevented from growing) depending on the concentration and the target bacteria. Bacteriostatic drugs temporarily inhibit the growth of organisms, but the effect is reversible once the drug is removed. For these drugs to be clinically effective, the drug concentration should be maintained above the MIC throughout the dosing interval. Many bacteriostatic drugs can be bactericidal if drug exposure is sufficiently high or prolonged, and some of the bactericidal groups are bacteriostatic at low concentrations. Both classes rely on intact and **effective body defense mechanisms** for full effect. Although in terms of clinical response little if any difference can be detected between the two groups in most diseases, in certain situations it is probably advisable to choose a bactericidal antibiotic for therapy. This is especially true when dealing with acute septicemic infection, in which there is frequently a significant leukopenia, and a quick maximal bactericidal effect is required and there is also the need to prevent subsequent localization.

Bactericidal drugs cause the death of microbes. These are preferred in infections that cannot be controlled or eradicated by host mechanisms alone because of the nature or site of infection (e.g., bacterial endocarditis) or because of reduced immunocompetence of the host (e.g., patient with immunosuppressive illness or receiving immunosuppressive therapy). Bactericidal antimicrobials are also indicated for antibacterial treatment of secondary infection in **granulocytopenic syndromes** such as bracken fern poisoning or chronic furazolidone poisoning in calves. Bactericidal antibiotics are also preferable in the treatment of heavily **capsulated organisms**, such as *Klebsiella* spp. and *R. equi,* which show antiphagocytic activity. Infections in which significant **intracellular parasitism** occurs are a problem. The majority of antimicrobials that diffuse relatively freely into cells are bacteriostatic in activity and, although the disease may be controlled by their use, infection may still persist in a latent carrier state.

The MIC is the lowest concentration of antibiotic that prevents visible growth after 18- to 24-hour incubation. The minimal bactericidal concentration is the minimal concentration that kills 99.9% of the cells.

Antimicrobial susceptibility is based on these assumptions: MIC > local drug concentration: no effect: resistant (R); MIC = local drug concentration: doubtful: intermediate (I); MIC < local drug concentration: successful therapy: susceptible (S). The S, I, and R designations are assigned by laboratories based on safely achievable plasma concentrations. Breakpoint is an MIC (MIC_{BP}) selected to predict clinical outcome for a specific pathogen, in a specific disease, in a specific species, given a specific regimen (dose, route, duration, and frequency). The MIC_{BP} incorporates pharmacokinetic and pharmacodynamic considerations. Two breakpoints are provided for each drug. An isolate inhibited at a concentration at or below the lower threshold or susceptible MIC breakpoint is designated S, whereas an isolate that is able to grow after in vitro exposure to a drug concentration that equals to the upper threshold or the resistant MIC breakpoint is designated R. The MPC is the concentration of the drug necessary to prevent (or inhibit) the emergence of the first-step mutants. An alternative definition of the MPC is the highest MIC of isolates in the patient (Fig. 6-2).

Postantibiotic Effect

The persistent suppression of bacterial growth following the removal of an antimicrobial agent is called the postantibiotic effect (PAE). Persistence of the antimicrobial effect exists after brief exposure to an antimicrobial agent.

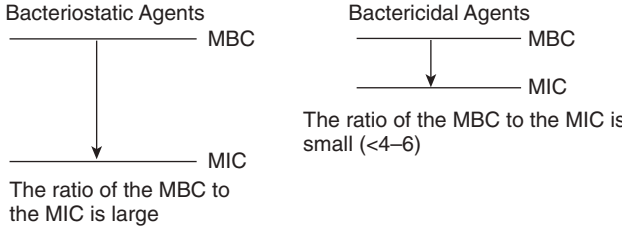

Fig. 6-2 Relationship between minimum bactericidal concentration (MBC) and minimum inhibitory concentration (MIC) for bacteriostatic and bactericidal agents.

Bacterial killing curve studies show that antimicrobial agents exhibit either **concentration-dependent** or **time-dependent** bacterial killing. The relationship among efficacy, MIC, and the magnitude and time course of plasma drug concentration (PDC) is categorized as either concentration dependent (sometimes referred to as dose dependent) or time dependent (sometimes referred to as concentration independent). A third classification has emerged with characteristics from each of these classes (e.g., fluoroquinolones).

Concentration-Dependent Killing

High plasma concentration (C_{max}) relative to the MIC is the major determinant of clinical efficacy. These drugs also have prolonged PAE values, allowing long dosing intervals that maximize clinical efficacy and minimize side effects (e.g., aminoglycosides, fluoroquinolones, metronidazole).

- Rate and extent of killing increase with increasing drug concentrations
- Maximizing peak concentrations increases efficacy and decreases selection of resistant bacteria
- Some can be both time and concentration dependent (AUC is a better predictor of efficacy)
- Ratio of the AUC or C_{max} to the MIC (AUC/MIC or C_{max}/MIC) correlates best with efficacy (ratio of at least 8–10)
- Some antibiotics (e.g. macrolides) can be either time- or concentration dependent based on organism

Time-Dependent Killing

The time that the antimicrobial concentration exceeds the MIC determines the clinical efficacy ($T >$ MIC). Once the MIC of the bacteria has been exceeded, further increases in the plasma concentrations do not increase the activity of these agents. The objective is to keep the average PDC above the MIC of the pathogen for the significant portion (at least 50%) of the dosing interval (e.g., penicillins, cephalosporins, vancomycin, other bacteriostatic agents).

- Increasing concentrations above MIC does not result in proportionate increases in killing, but increasing the dose may be necessary to ensure that PDC > MIC severalfold.
- Antimicrobial action continues as long as concentrations are above MIC and lack PAE.
- PDC should be two to four times the MIC of the pathogen.
- Variable $T >$ MIC: 25% for carbapenems, 50% to 70% extended spectrum penicillins, and 100% for aminopenicillins and penicillins
- For most time-dependent agents, exceeding MIC by 1 to 5 multiples for between 40 and 100% of the interdosing interval is appropriate.

ANTIMICROBIALS PROHIBITED FROM USE IN ANIMALS INTENDED FOR FOOD IN THE UNITED STATES

- Chloramphenicol
- Dimetridazole
- Ipronidazole
- Other nitroimidazoles
- Furazolidone, nitrofurazone, other nitrofurans
- Sulfonamide drugs in lactating dairy cattle (except approved use of sulfadimethoxine, sulfabromomethazine, and sulfamethoxypyridazine)
- Fluoroquinolones
- Glycopeptides (e.g., vancomycin)

DRUG DETERIORATION

Many antibacterials lose their activity rapidly when kept under adverse conditions. **Quality control** in terms of purity, efficacy, and freedom from toxicity costs money, but for these reasons it is preferable to purchase from known reputable companies and follow their recommendations with respect to storage and expiration periods. The use of cheap antibacterial preparations, often purchased in bulk and simply packaged, and distributed with little consideration for factors influencing drug stability, often results in poor therapeutic results. **Crystalline** or dry preparations that require reconstitution to a solution before parenteral administration are frequently presented this way because their activity degenerates rapidly once they are in solution. Therefore once they have been prepared they should be used immediately, or the manufacturer's recommendations should be followed regarding storage. Attention should be paid to the length of activity expected following reconstitution. **Temperature** and exposure to **sunlight** can be important factors in antibiotic stability and become especially important in farm ambulatory practice: car cold boxes should be used to store antibiotic preparations and other sensitive drugs.

UNFAVORABLE RESPONSE TO THERAPY

In clinical cases that do not respond to antimicrobial therapy, the initial consideration should be that the wrong antimicrobial agent has been chosen for therapy. This is especially true of infectious conditions of undetermined etiology in which the drug has been chosen on the basis of an educated guess. In these circumstances adequate time should be given for an evaluation of the efficacy of the treatment before a change is made. Generally, a **3-day period of treatment** is allowed for this evaluation provided there is no marked deterioration in the clinical state or further elevation of temperature during this period. If there is no response to initial therapy then, in the case of conditions of undetermined etiology, it is generally best to change to an entirely different class of antimicrobial agent. However, the possibility of viral or noninfectious etiology should always be considered in these cases, and the case and diagnosis should be reviewed before any change is made.

In any situation in which there is a poor response to therapy the usual causes of this failure should be considered in any further adjustments to therapy or future therapy of similar cases. The first and most obvious of these is that the organism is either **insensitive to the drug** or that it is **not susceptible to the level of the drug** that is being used for therapy. There are two possible approaches. The first is to increase the dose rate and dose frequency and/or to change the route of administration so that higher and possibly effective levels will be achieved, bearing in mind the possible toxic consequences. The second, and safer, approach is to change the antimicrobial agent being used. This problem can be avoided if the organism and its potential **susceptibility** can be identified, either by clinical examination or by appropriate sampling with culture and susceptibility testing. The development of resistance during antimicrobial treatment of an individual animal is not a recognized problem in large-animal medicine.

Another common cause of poor response is that the infection is situated in an area to which the drug is **poorly accessible**. If this is associated with an area behind a barrier to the entry of the antibiotic, such as the joints or the eye, it may be necessary to resort to **higher dose rates** and frequency, or intravenous administration of the drug, or to ancillary local treatment into this area. Alternatively, another drug with **superior penetrability** may be used.

Organisms must be actively metabolizing for antimicrobial agents to exert their effect. This feature can result in poor response to therapy or relapse following discontinuation of therapy in **chronic infections** such as endocarditis or where there is excessive necrotic or fibrotic tissue associated with the infection. In these instances, dormant organisms and the long diffusion tracks make effective cure difficult and high antimicrobial levels sustained over longer periods are required. In **purulent conditions** surgical drainage, where possible, is an essential adjunct to antimicrobial therapy.

The importance of ancillary and **supportive therapy** to counteract the effects of shock, toxemia, and dehydration that may be associated with infection cannot be overemphasized, and frequently such therapy may markedly influence the outcome of a case. It is obvious, for example, that 3 mL of antibiotic will do little to counter the effects of a 4-L fluid deficit in a scouring calf.

DRUG WITHDRAWAL REQUIREMENTS AND RESIDUE AVOIDANCE

In most countries there are requirements for the withdrawal of antimicrobial agents from the feed for specified periods before slaughter, and animals or their milk cannot be marketed for certain periods following antimicrobial therapy.

Antibiotic contamination of food products can be a **public health risk**, although proven risk for toxicity or allergy from antibiotics in humans is minuscule. An example would be allergic reactions to antibiotic residues, particularly penicillin. There are also **commercial considerations** in which residues of antibiotics in milk can cause considerable problems in the manufacture of milk products. Effects on starter cultures for cheese and yogurt can be particularly deleterious and can result in downgrading or total loss of large quantities of manufacturing milk.

The purpose of withdrawal requirements is to ensure that meat and milk for human consumption is wholesome and does not contain violative residues of drugs. The public's concern for the wholesomeness of the food that it consumes will determine the food that it buys. Cooperative quality assurance programs involving both the producer and the veterinarian are a major answer to this concern.

A **withdrawal period** is the time during which the animal must be held free of the drug before it can be marketed. For milk the term **withholding period** is commonly used and defines the period during which milk cannot be sent for human consumption following the treatment of the animal with a drug. A **tolerance** for the pharmacologically active ingredient in tissues is set by regulatory authorities for each drug. The **tolerance level** is the level below which tissue concentrations must fall before they are considered safe for human consumption, and there is a large margin of safety.

The required withdrawal and withholding periods will vary between antimicrobial agents and also with the same antimicrobial agent depending on the amount of drug given; factors such as age and the disease state of the animal are also important. Unfortunately, the required withdrawal and withholding periods to ensure freedom of food products from violative drug residues are not known for the variety of dose concentrations and dose intervals of the various antimicrobials that could be used in clinical practice, and they not likely to be known in the near future. In many countries this has led to regulations that limit the quantity of antibiotics in drug products. **Label instructions explaining product usage and drug withdrawal times are required.** These label instructions include what is generally called the **label dose**.

Label Dose and Extralabel Use

The label dose (and dose interval) is a dose of an antimicrobial for which the specific withdrawal and withholding periods have been established, and these are stated in conjunction with the label dose. The label dose is the officially approved or legal dose rate for that drug.

When an antimicrobial is used, it is incumbent upon the practitioner to notify the owner that the animal cannot be marketed (or milk sent for human consumption) before the accompanying withdrawal (or withholding) period has expired. The practitioner may be legally liable if a violation occurs and this notification has not been given.

In the **United States** the **label dose** of a drug also includes use only in the species of animal for which the drug is labeled, the class of animal (lactating versus nonlactating dairy cow), the disease conditions indicated by the label, the route of injection, the amount of drug to be injected at one site, and the number of repeat treatments that can be given. These **label directions**, and the need to follow them, are directed primarily at lay users of these drugs and lay users may not use the drug in a nonlabel fashion. The label directions should also be followed by the veterinarian whenever possible.

REQUIREMENTS FOR EXTRALABEL USE OF DRUGS IN THE UNITED STATES

- Extralabel use of drugs (ELDU) is permitted only by or under the supervision of a veterinarian.
- ELDU is allowed only for U.S. Food and Drug Administration (FDA)-approved animal and human drugs.
- A valid veterinarian–client–patient relationship is a prerequisite for all ELDU.
- ELDU must be for therapeutic purposes only (animal's health is suffering or threatened), not drugs for production use.
- Rules apply to dosage form drugs and drugs administered in water—ELDU in feed is prohibited.
- ELDU is not permitted if it results in a violative food residue or any residue that may present a risk to public health.
- FDA prohibition of a specific ELDU precludes such use.

Extralabel Use

There are times where **extralabel use** of drugs is necessary and veterinarians can do this where they have established a proper veterinarian–client–patient relationship. It is the intention that the label dose should be one that is therapeutically effective for that drug. However, this is not always the case, and the label dose should not be confused with the term *recommended dose* as used elsewhere in this book. There are also circumstances where, although the label dose may be therapeutically efficient in many cases, it is not for the particular case in hand. Optimal therapeutic dose regimens often require extralabel use of the drug. In these situations, antimicrobial drugs may need to be used at dose concentrations and dose intervals different from the label dose. Extralabel use of the drug may be therapeutically necessary for the successful treatment of the problem, but it is not officially approved and the establishment of the required withdrawal period is entirely incumbent upon the veterinarian. The withdrawal period in these circumstances cannot always be extrapolated from that for the label dose.

DEFINITION OF VALID VETERINARIAN–CLIENT–PATIENT RELATIONSHIP (AMERICAN VETERINARY MEDICAL ASSOCIATION)

An appropriate veterinarian–client–patient relationship will exist when

1. The veterinarian has assumed the responsibility for making medical judgments regarding the health of the animal(s) and the need for medical treatment, and the client (owner or other caretaker) has agreed to follow the instructions of the veterinarian.
2. There is sufficient knowledge of the animal(s) by the veterinarian to initiate at least a general or preliminary diagnosis of the medical condition of the animal(s). This means that the veterinarian has recently seen and is personally acquainted with the keeping and care of the animal(s) by virtue of an examination of the animal(s) and/or by medically appropriate and timely visits to the premises where the animal(s) are kept.
3. The practicing veterinarian is readily available for follow-up in case of adverse reactions or failure of the regimen of therapy.

WITHDRAWAL PERIODS

Label dose withdrawal periods are determined from pharmacokinetic studies of excretion following administration of the label dose. However, the rate of drug elimination from the body can be influenced by drug dose and dose frequency. For example, the metabolism and excretion half-life of sulfonamides in cattle is dose dependent. With repeated dosing of antibiotics, such as tetracycline and the aminoglycosides, there is deposition of the antibiotic in certain tissues, and following cessation of drug administration there is a slow release from these tissues and a long **washout period**. During this washout period there are decreasing concentrations of the drug in tissues and in milk, which, although not of therapeutic importance, are sufficiently high to be violative. This presents a dilemma to the veterinarian trying to establish withdrawal periods. The occurrence of significant washout periods following prolonged therapy with antibiotics

has only recently been recognized, and there are few data on their duration at different dose concentrations and dose frequencies. A further problem is that most pharmacokinetic parameters have been determined in healthy animals, and altered physiology in diseased animals can markedly alter elimination half-lives; there is also considerable animal-to-animal variation. Rather than trying to guess the possible withdrawal period for an extralabel use, computer-based data information banks with easy access are established to provide this information. One of these is the Food Animal Residue Avoidance Databank (www.farad.org), which provides recommendations for withdrawal intervals for extralabel drug use based on analysis of published pharmacokinetic data, foreign and domestic label drug withdrawal intervals, and established maximum residue limits.

RESIDUE TESTING

Currently, the only way to attempt to ensure nonviolation with extralabel use of antimicrobials is to test for residues. There are a very large number of testing systems becoming available that vary in their method of detection of the presence of antibiotics. Tests such as the Swab Test on Premises (STOP), Calf Antibiotic and Sulfa Test (CAST), Live Animal Swab Test (LAST), Fast Antimicrobial Screen Test (FAST) (which has a higher sensitivity and shorter analytical time and has largely replaced the use of STOP and CAST), the Delvotest P, the Charm Inhibition Assay, and the Charm Farm and Disk Assays are based on the inhibition of growth of *Bacillus stearothermophilus* var. *calidolactis* or *B. stearothermophilus.* Although relatively cheap and easy to perform, they have a risk for false-positive results due to inhibition of growth by inhibitory substances other than antibiotics in milk, particularly substances in milk from inflamed mammary glands. They are sensitive for detecting penicillin and its derivative compounds but less sensitive to other classes of antibiotic. Other commercially available tests use a variety of different immunologic detection methods and test for a single antibiotic or class of antibiotics.

TESTING FOR COMPLIANCE

Most countries have a monitoring program to detect the occurrence of residues in meat. In the United States, sampling provides a 95% probability of finding a violative residue when 1% of the population is violative. The occurrence of violative residues in red meat is very low because the prevalence of infectious disease is low in the period before slaughter. Feedlot cattle can have a high prevalence of disease in the early feeding period, but there is a substantial subsequent period on-feed before the animals are slaughtered, which exceeds the withholding period of most drugs used for treatment of disease occurring during the early feeding period. Violative drug residues occur predominantly in cull dairy cows and in bob veal calves.

The concentrations for the various antibiotics that are violative are not stated in this chapter for two reasons: they vary from country to country and the violative concentrations tend to be set by the sensitivity of the detection assay used by the regulatory authority and, as assay technology improves, legally acceptable minimal concentrations will be lowered. Local regulatory publications should be consulted for current requirements.

Assay techniques can be remarkably sensitive. An example is the occurrence of violative residues of chloramphenicol in the milk, blood, and urine of cows that had teat or skin lesions sprayed with a 5% chloramphenicol solution, which is an illegal drug for use in animals for food in most countries.

CAUSES OF RESIDUE VIOLATIONS IN MILK

In a retrospective study of reasons for the presence of violative antibiotic residues in milk, **failure to withhold milk** for the full withdrawal period and **accidental inclusion of treated milk** in the shipment were the most common. Accidental inclusion of treated milk can occur when there is **inadequate identification** of treated cows. The veterinarian should work with the producer to establish a system that easily identifies cows whose milk is subject to a withholding period. Colored leg markers are one system and are immediately visible to the milker.

Contamination of recorder jars and milking equipment with the high concentration of antibiotic secreted in milk in the first milking after treatment is a further reason for residue violations. Treated cows should be **milked last** in large dairies, or milked with separate equipment, and are preferably kept separate as a hospital string.

COMMON CAUSES OF ANTIBIOTIC RESIDUES IN MILK

- Extended usage or excessive dosage
- Failure to observe withdrawal times
- Poor records of treatment
- Prolonged drug clearance
- Failure to identify treated animals
- Contaminated milking equipment
- Milker or producer mistakes
- Products not used according to label directions
- Lack of advice on withdrawal period
- Withholding milk from treated quarters only
- Early calving or short dry periods
- Purchase of treated cows
- Use of dry cow therapy for lactating cows
- Milking dry cows

Other reasons for residue violations include **short dry periods**, in which dry cow therapy has been used but the cow has calved earlier than expected. The infusion of **dry cow treatments** into the udder of heifers before calving for the prevention of summer mastitis has also been followed by the presence of violative residues for as long as 26 days. A less common cause is the **accidental milking of dry cows**, in which the latter are not kept as a separate group, and the withholding of milk from only treated quarters. The use of dry cow infusion preparations for treatments during lactation can occur by mistake if drugs intended for the treatment of lactating cows are not kept in a **separate storage area** from other drugs.

The **risk** for residues is higher for farms that have higher frequency of antibiotic usage and for those that use part-time labor. The use of **records** to document treatments and the day of exit from the withholding period is an important preventive measure. Sulfonamides, tetracyclines, penicillins, aminoglycosides, cephalosporin, and chloramphenicol have been found in milk in the United States.

CAUSES OF RESIDUE VIOLATIONS IN BEEF CATTLE

Violative drug residues occur predominantly in cull dairy cows and in bob veal calves. In one study the primary reasons for violations in this group were as follows:

- Failure to observe the withdrawal periods (61%)
- Use of an unapproved drug (10%)
- Feeding calves milk or colostrum from a treated cow (9%); a greater risk for residues occurs in herds that feed larger volumes of colostrum, possibly reflecting contamination from dry cow therapy; waste milk, discarded from treated cows and fed to calves, is also a risk especially if extralabel doses of antimicrobials are used for udder infusions
- Exceeding the label dose (6%)

The major drugs involved with residues in meat are neomycin, streptomycin, penicillin, oxytetracycline, gentamicin, and sulfamethazine. Intramuscular injection is the route of administration in 60% of the residue cases, oral administration in 28%, and intramammary infusion in 9%. The use of orally administered antimicrobial boluses in calves that were subsequently slaughtered as bob veal calves is also a problem.

CAUSES OF RESIDUE VIOLATIONS IN SWINE

Similar causes are recorded for the occurrence of violative residues in pigs, but an additional problem in pigs is the tissue residues resulting from **antibiotic inclusions in feeds** for growth promotion and disease control. Sulfonamides are a particular problem. Nonobservance of the required

withdrawal period can result in the rejection of market batches of animals with a substantial financial loss to producers. If feed inclusions have been for the purposes of medication, the prescribing veterinarian may be liable if adequate information on withdrawal periods has not been given.

There is also a problem with **sulfonamide residues** resulting from carryover of sulfonamides from medicated to nonmedicated feeds at the feed mill or on the farm. Mistakes in feed **delivery**, feed-**mixing** sequences, ingredient **contamination** and contamination within the bulk feed **distribution system**, and **delivery augers** can cause residual contamination. **Carryover concentrations** of sulfamethazine (sulfadimidine) of greater than 2 g/t in the finisher ration can result in violative residues in the liver at slaughter. The use of granular forms of sulfamethazine markedly reduces the potential for carryover.

A further source of contamination in the piggery is **environmental contamination**. Manure and pooled urine from swine fed 100 g/t of sulfamethazine contain sufficient drug to contaminate swine to violative levels when contact with the material is maintained, and this can continue for 6 to 7 weeks when pens are not cleaned after a drug is withdrawn from the feed. **Dried urine** has the potential for airborne contamination of pigs. Sulfamethazine is stable in manure and flush water for long periods and **coprophagy** by pigs can lead to significant intake of the drug. To avoid the risk of this occurring, it is recommended that 3 days after the medicated feed has been withdrawn, the pens should be thoroughly cleaned or the pigs moved to new housing. Water medication can also lead to buildup of residues in the water delivery system, so the watering systems should be flushed. Pigs destined for slaughter can be tested on the farm before shipping using commercially available testing systems, which can also be used for detection of the occurrence of sulfonamides in feed and water.

TYPE OF THERAPY

In the United States veterinarians are responsible for a very minor proportion of detected residue violations. Possible causes of violations resulting from veterinary therapy include the selection of an inadequate withdrawal period following extralabel use of an antimicrobial and treatment modalities that may not be considered a risk. The local infusion of antibiotic solutions into the uterus of cows may result in circulating concentrations of antibiotic and residues in body tissues and in milk. This results from the absorption of the antibiotic through the endometrium and from the peritoneal cavity following passage through the fallopian tubes. Similarly, following infusion of antibiotic solutions into one quarter of the udder, low concentrations of the antibiotic can occur in milk secreted from the remaining quarters. Gentamicin is generally considered not to be absorbed from the mammary gland, but more than 87% of an intramammary dose of gentamicin is absorbed from the *inflamed* udder.

APPROVED DRUGS

Whenever possible, approved antimicrobials should be used for therapy at label dose and a known withdrawal time to comply with regulatory requirements and to minimize the possibility of antibiotic residues in meat and milk. It may be necessary to use nonapproved antimicrobial drugs in certain circumstances and in minor species. The use of an approved antibiotic in a minor species for which it is not approved constitutes an extralabel use of the drug. The legality of the use of unapproved drugs, or of approved drugs in minor species for which they are not approved, is questionable. If such use is contemplated, it is probably wise to have culture and sensitivity data indicating that the use of the unapproved drug is therapeutically necessary. Certain nonapproved antibiotics are **totally banned** for use in food-producing animals in some countries (e.g., in the United States chloramphenicol, nitroimidazoles, sulfamethazine in dairy cattle over 20 months of age, furazolidone, the use of fluoroquinolones in an extralabel fashion) and local regulations should be followed. The use of sulfamethazine in food-producing animals may be banned in some countries. The American Association of Bovine Practitioners has passed a voluntary moratorium on the use of aminoglycosides in cattle.

Classification of Antimicrobial Agents: Mechanisms of Action and Major Side Effects

AMINOGLYCOSIDES AND AMINOCYCLITOLS

Aminoglycosides are a class of bactericidal antimicrobial compounds (e.g., amikacin, tobramycin, apramycin, streptomycin, gentamicin, neomycin, kanamycin, dihydrostreptomycin, spectinomycin) produced from strains of *Streptomyces* spp., *Micromonospora* spp., and *Bacillus* spp. They are the drugs of choice for the treatment of serious aerobic gram-negative infections in animals.

MECHANISM OF ACTION

Aminoglycosides exert a bactericidal action by entering the bacterial cell and inhibiting protein synthesis. They are transported into bacteria based on an ionic association between cationic aminoglycosides and the anionic surface of the cell. Aminoglycosides penetrate through aqueous channels (porins) of gram-negative bacteria or the water-filled peptidoglycan wall of gram-positive bacteria into the periplasmic space. Transport across the cytoplasmic membrane (inner) is caused by an electrical potential gradient generated by an oxygen-requiring transport process linked to an electron transport system, which causes the bacterial cytoplasm to be negatively charged. This transport process is an energy-requiring aerobic step that does not occur in an anaerobic environment. The efficacy of aminoglycosides therefore depends on a high oxygen tension in the environment, and, consequently, anaerobic bacteria are resistant to aminoglycosides. The transport mechanism can also be inhibited by divalent cations (i.e., Ca^{2+}, Mg^{2+}).

Aminoglycosides bind to one or more receptor proteins on the 30S subunit of bacterial ribosome. This binding interferes with protein synthesis via restricting polysome formation and causing disaggregation to monosomes, misreading mRNA, nonsense and frameshift mutations of proteins, and cell death.

TOXICITY

Ototoxicity and nephrotoxicity are common side effects of aminoglycoside administration because cellular matrixes in these organs contain large amounts of phospholipids (anionic aminoglycoside receptors) compared with other tissues of the body. As a result, aminoglycosides should not be used with other ototoxic or nephrotoxic drugs (i.e., furosemide, amphotericin B).

Ototoxicity results from progressive damage to cochlear cells (more common with amikacin and neomycin) and can result in deafness in dogs, as well as damage to vestibular cells (more common with streptomycin and gentamicin) and can cause ataxia in cats. Ototoxicity is largely irreversible but has rarely been documented in large animals administered aminoglycosides.

Nephrotoxicity (occurring most commonly during prolonged therapy, longer than 10 days) is caused by the damage of the membranes of proximal tubular cells that have a high metabolic rate, resulting in a loss of brush border enzymes, proteinuria, decreased glomerular filtration rate, and azotemia. The mechanism of renal toxicity is not fully understood. Risk factors for nephrotoxicity include high doses, long duration of treatment, preexisting renal dysfunction or dehydration, concurrent administration of nephrotoxic drugs or diuretics, persistently elevated trough concentrations, and very young or old age.

Renal toxicity is largely reversible because of regeneration of tubules after the drug is cleared. Metabolic acidosis and electrolyte disturbances (e.g., hyponatremia, hypokalemia) increase renal toxicity of aminoglycosides. High-protein diets increase the glomerular filtration rate and renal blood

flow, promoting aminoglycoside excretion and protecting against nephrotoxicity.

Aminoglycosides cross the placental barrier and can produce nephrotoxicity and ototoxicity in a pregnant animal and its developing fetus. All aminoglycosides given rapidly IV cause bradycardia, decreased cardiac output, and lower blood pressure through an effect on calcium metabolism. Neuromuscular blockade is uncommon following administration of aminoglycosides and is caused by prejunctional blockage of acetylcholine release caused by impaired calcium release at myoneural junctions (muscle paralysis and apnea). The IV administration of calcium salt is used as a treatment for this toxicity. Because of this potential toxicity, it is best not to administer an aminoglycoside when neuromuscular blocker administration is considered.

Spectinomycin is much less toxic than the aminoglycosides; as much as 400 mg/kg IV can be tolerated. There are few important side effects of spectinomycin administration including no ototoxicity or nephrotoxicity. However, pain at the injection site; dizziness, nausea, and insomnia; and urticaria, chills, and fever have been reported. Administration of lincomycin-spectinomycin oral preparations, by parenteral injection to cattle, has produced heavy losses associated with severe pulmonary edema.

β-LACTAM ANTIBIOTICS: PENICILLINS, CEPHALOSPORINS, AND β-LACTAMASE INHIBITORS

β-Lactam antibiotics are **bactericidal.** There are many congeners in this group of drugs. Members of this group differ in the

- Organisms against which they can be used (spectrum of activity)
- Pharmacokinetics, stability, and suitable route of administration
- Type and extent of bacterial resistance encountered

There are four major groups of penicillins: narrow spectrum, broad spectrum (aminopenicillins), extended spectrum, and penicillinase resistant (Table 6-1). Penicillin-β-lactamase inhibitor combinations (potentiated penicillins) include amoxicillin-clavulanate (orally, PO), ampicillin-sulbactam (IV), ticarcillin-clavulanate (IV), and piperacillin-tazobactam (IV).

Mechanism of Action

Penicillins and cephalosporins induce their mechanism of action by inhibiting bacterial cell wall synthesis by interfering with the final stage of peptidoglycan synthesis. The peptidoglycan component of the cell wall is essential to the integrity of the bacterial envelope. The peptidoglycan is composed of glycan chains, which are linear strands of two amino sugars (*N*-acetyl glucosamine and *N*-acetylmuramic acid) and pentapeptides that are cross-linked by peptide chains. Formation of a rigid cell wall is through cross-linking between chains of peptidoglycan catalyzed by transpeptidase enzymes (PBPs in cell membrane). Penicillin occupies the D-alanyl-D-alanine substrate site of transpeptidase and becomes linked to the enzymes by a covalent bond, inhibiting transpeptidation or cross-linkage. Penicillin is most effective against actively dividing bacterial colonies and should not be used with bacteriostatic agents. Differences in susceptibility of gram-positive and gram-negative bacteria to penicillins results from structural differences in cell walls, differences in receptor sites (PBPs) and binding affinity for the target PBP, the relative amount of peptidoglycan present, and to different types of β-lactamase produced by bacteria. The composition of cell wall differs between gram-positive and gram-negative bacteria. The gram-positive cell wall is between 50 and 100 molecules thick, whereas the gram-negative cell wall is one to two molecules thick. The lipopolysaccharide outer membrane forms a barrier to water-soluble penicillins, but porins inserted in this layer permit entry to some extended-spectrum penicillins, depending on size, charge, and hydrophobicity of R groups. As a result, many gram-negative bacteria are resistant to penicillins.

Toxicity and Clinical Considerations

Allergic reactions to penicillin and its metabolites (penicilloic acid) occur when penicillin acts as a hapten to evoke antibody reactions, including hypersensitivity skin eruptions, hemolytic anemia, and anaphylaxis. As a result, penicillin residues in food-producing animals constitute a public health risk.

Superinfection can be a clinical problem during penicillin administration, reflecting the appearance of bacteriologic and clinical evidence of a new infection during the chemotherapy of a primary one. Penicillins can promote a single resistant microorganism to become dominant, invading the host and producing infection. Penicillins can alter normal intestinal flora and bowel function (anorexia, vomiting, and diarrhea) and can result in death in some species such as guinea pigs, hamsters, and rabbits.

Central nervous system seizures and cardiac arrest can occur in humans with epileptogenic foci that receive large doses of penicillin G. To avoid the induction of fatal ventricular arrhythmias, care should be taken with the rate at which potassium penicillin G is injected IV because of the potassium content of the injection.

Cephalosporins are β-lactam antimicrobials that have a mechanism of action similar to that of the penicillins (inhibition of bacterial cell wall synthesis). Different side chains exist in cephalosporins to create individual drugs (four generations of cephalosporins now exist). Unlike penicillins, cephalosporins contain a dihydrothiazine ring instead of a thiazolidine ring.

TOXICITY

Cephalosporins cause fewer hypersensitivity reactions than penicillins. Cephalosporins should not be used in animals with a known sensitivity to penicillins (cross-reactivity). Cephalosporins are potentially nephrotoxic and, consequently, caution should be used when administered with other nephrotoxic drugs such as aminoglycosides (e.g., gentamicin, amikacin, neomycin) and amphotericin B. Cephalosporins in the urine can cause a false-positive reaction for glucosuria (copper-reduction technique) and proteinuria (sulfosalicylic turbidimetric test).

Superinfection has been associated with oral administration of first-generation

Table 6-1 The four major categories of penicillin: Narrow spectrum, broad spectrum, penicillinase resistant, and extended spectrum

Narrow-spectrum penicillins	Aminopenicillins (broad spectrum)	Penicillinase-resistant penicillins (antistaphylococcal penicillins)	Extended-spectrum penicillins (antipseudomonal penicillins)
Crystalline penicillin G (IV) Penicillin V (PO) Aqueous penicillin G (IM)	Amoxicillin (PO) Ampicillin (IV or PO) Hetacillin	Methicillin (IV) Nafcillin (IV) Isoxazolyl penicillins (IV or PO) Cloxacillin Dicloxacillin Oxacillin Flucloxacillin	Ureidopenicillins Piperacillin (IV) Azlocillin (IV) Mezlocillin (IV) Carboxypenicillins Ticarcillin (IV) Carbenicillin (IV)

IV, intravenous; PO, orally; IM, intramuscular.

cephalosporins. Orally administered cephalosporins may cause anorexia, vomiting, and diarrhea.

CHLORAMPHENICOL

Chloramphenicol inhibits protein synthesis by binding to the 50S ribosomal subunit near the site of action of macrolides and lincosamides; antimicrobials in the latter two classes interfere with the binding of chloramphenicol and may therefore interfere with each other's actions if given concurrently. Chloramphenicol is usually bacteriostatic with a broad-spectrum activity (gram-positive, gram-negative, aerobic, and anaerobic bacteria).

MECHANISM OF ACTION

Chloramphenicol binding to the 50S bacterial ribosomal subunit inhibits peptide bond formation and protein synthesis by interfering with peptidyl transferase enzyme activity. This may affect mammalian mitochondrial protein synthesis, because mammalian mitochondrial ribosomes have a strong resemblance to bacterial ribosomes.

TOXICITY

Dose-dependent anemia can occur in animals (especially in cats) and humans and is reversible. The anemia is caused by inhibition of mitochondrial protein synthesis in bone marrow, as well as inhibition of iron uptake by erythrocytes, which slows the rate of maturation of erythrocytes in bone marrow. **Dose-independent anemia (aplastic anemia)** occurs in humans and is independent of treatment duration. The mechanism of toxicity is thought to involve nitroreduction of a para-nitro group, leading to the production of nitrosochloramphenicol and other toxic metabolites that trigger stem cell damage. Because of the occurrence of rare but fatal aplastic anemia in humans, **the use of chloramphenicol in food-producing animals is banned by the Food and Drug Administration (FDA).** As a result, humans should use gloves and eye protection when administering chloramphenicol and avoid repeated contact with or inhalation of the powder.

Other side effects are uncommon but occur mainly in young animals because of impaired glucuronidation pathways. Depression, dehydration, reduced fluid intake, weight loss, emesis, diarrhea, and anorexia have been reported with high or prolonged dosages of chloramphenicol. Administration is not recommended in lactating animals because of excretion in milk and possible toxicity risk in offspring (liver is not fully functioning in neonates and fetus). Drug interactions can occur, usually caused by inhibiting the activity of cytochrome P-450 enzymes in the liver, resulting in impaired hepatic metabolism of drugs such as phenobarbital, pentobarbital, primidone, and phenytoin.

CHLORAMPHENICOL ANALOGS

Florfenicol and **thiamphenicol** are chloramphenicol derivatives. They were synthesized because of the rare occurrence of chloramphenicol-induced aplastic anemia in people and also the ban on the use of chloramphenicol in food-producing animals. Attempts were made to synthesize chloramphenicol analogs to maintain broad-spectrum antimicrobial activity and eliminate the induction of aplastic anemia in people**.** The mechanism of the antimicrobial activity and antimicrobial spectrum are similar to that of chloramphenicol.

TOXICITY

Signs of toxicity are varied and include diarrhea and hyperbilirubinemia in horses, diarrhea and decreased feed consumption and rumen activity in cattle, local tissue reaction following intramuscular and subcutaneous administration, and perianal inflammation and rectal eversion/prolapse in swine. Fatal bone marrow suppression with overdose or prolonged florfenicol administration has been reported.

FLUOROQUINOLONES

Fluoroquinolones are a class of synthetic antimicrobial compounds with broad-spectrum antimicrobial activity (enrofloxacin, orbifloxacin, difloxacin, ciprofloxacin, marbofloxacin, danofloxacin, etc.). Fluoroquinolones exhibit good activity against many gram-negative bacteria (e.g., *E. coli, Enterobacter* species, *Klebsiella* species, *Pasteurella* species, *Proteus* species, *Salmonella* species). Some gram-positive bacteria are also susceptible to fluoroquinolones (primarily *Staphylococcus intermedius* and *S. aureus,* including β-lactamase producing gram-positive bacteria; however, the MIC values for staphylococci are typically higher than those for gram-negative bacteria. Poor activity in general against anaerobes and fluoroquinolones should not be used to treat anaerobic infections. *Chlamydia, Rickettsia, Mycoplasma, Mycobacteria, Ehrlichia, Coxiella,* and *Ureaplasma* sp. can also be susceptible to fluoroquinolones. New-generation fluoroquinolones, such as grepafloxacin, trovafloxacin, and premafloxacin, have increased activity against gram-positive cocci and anaerobic bacteria. They are bactericidal, potent, and are well tolerated by animals and can be administered with a variety of routes (orally, subcutaneously, intramuscularly, and intravenously).

MECHANISM OF ACTION

Fluoroquinolones are bactericidal and exhibit good antibacterial activity, especially against gram-negative bacteria. They inhibit bacterial **DNA gyrase** or **topoisomerase IV enzyme** activity, which is necessary for the DNA supercoiling, because the replicating strands separate inhibiting bacterial DNA replication and transcription. Mammalian cells are resistant to the killing effects because topoisomerase II activity is only inhibited at much higher concentrations.

TOXICITY

Fluoroquinolones are relatively safe with no allergic and teratogenic activity in animals. They do not alter the anaerobic flora of the gastrointestinal (GI) tract, but high doses might generate reversible GI tract disturbances (e.g., nausea, vomiting, diarrhea). Central nervous system toxicity (e.g., convulsion, seizure) caused by inhibition of the GABA neurotransmitter has been reported primarily in humans but has also been reported in horses.

Arthropathy, characterized by formation of vesicles on the articular surface of the chondrocyte, has been reported to occur at recommended dosages in young dogs and foals, with other domestic animals appearing to be more resistant. This toxicity is thought to be caused by the ability of drugs to bind magnesium ions, which are necessary for the proper development of the cartilage matrix (loss of proteoglycan in the articular cartilage). No effect on pregnancy has been observed, but it is better to avoid using fluoroquinolones in pregnant animals unless no other antimicrobials are effective. Although enrofloxacin and orbifloxacin have been used in horses (in an unapproved manner), these drugs should not be used in young horses because of potential cartilage damage (enrofloxacin and orbifloxacin should not be administered to horses less than 3 years of age, except as a last resort for severe infections not treatable with other medications).

Inhibition of the activity of hepatic microsomal enzymes can alter the metabolism of certain drugs such as theophylline. Crystalluria has been reported in humans (primarily with ciprofloxacin) but not in animals.

LINCOSAMIDES

There are three antibiotics in the lincosamide group: lincomycin, pirlimycin and clindamycin. Like the macrolides, lincosamides are primarily used to treat gram-positive bacterial infections (including β-lactamase-producing gram-positive bacteria, *Staphylococcus* spp., and *Streptococcus* spp.), in which there is resistance or intolerance to penicillins. Lincosamides are highly effective against anaerobes with poor activity against gram-negative aerobes.

MECHANISM OF ACTION

Lincosamides bind to the 50S ribosome in which they inhibit protein synthesis. Because this binding site is similar to that of

chloramphenicol and the macrolides, concurrent use of these antimicrobials decreases overall efficacy; therefore combination therapy should be avoided.

TOXICITY

Severe side effects in humans include pseudomembranous colitis, and this has also been reported in animals with fermenting GI tracts (horses, ponies, ruminants, hamsters, rabbits, guinea pigs, and chinchillas). Oral administration is contraindicated because of severe, often fatal, diarrhea. In cattle, oral administration of lincomycin at concentrations as low as 7.5 parts per million in feed has resulted in inappetence, diarrhea, ketosis, and decreased milk production. Intramuscular clindamycin injection is very painful. No serious side effects have been observed following intramammary injection of pirlimycin in dairy cows.

MACROLIDES

Erythromycin is one of the macrolide antibiotics (tylosin, spiramycin, tilmicosin, tulathromycin, gamithromycin, tildipirosin, azithromycin, clarithromycin, etc.). Macrolides are usually regarded as being bacteriostatic, but they can be bactericidal in high concentrations against susceptible organisms. Macrolides are highly effective against aerobic gram-positive cocci and bacilli and also against gram-positive anaerobes and *Mycoplasma* species.

MECHANISM OF ACTION

Macrolides bind to the 50S ribosomal subunit interfering with the binding of aminoacyl-tRNA-to 50S and block peptide bond formation. This inhibits the translocation of a newly synthesized peptidyl tRNA molecule from the acceptor site to the peptidyl site.

TOXICITY

Macrolides are relatively safe, with toxicity most often reported in humans. Studies have been conducted documenting the prokinetic effects of erythromycin, spiramycin, tilmicosin, tulathromycin, and tylosin in cattle.

There can be **pain and irritation** following intramuscular injection that is formulation dependent. Macrolides and lincosamides such as tylosin are associated with causing colitis and fatal diarrhea in horses, so their use is usually restricted to oral erythromycin for the treatment of *R. equi* infections in foals. Erythromycin has been associated with hyperthermia in foals; treated foals that are turned out on hot, sunny, humid days develop fever, tachypnea, and distress, which may result in fatal heat stroke. Diarrhea has been reported in horses and cattle.

Cardiovascular toxicity has been reported in animals other than cattle, and has been particularly associated with tilmicosin. Deaths have been reported in humans related to accidental tilmicosin exposure. Tylosin and spiramycin may induce contact dermatitis in veterinarians. The intravenous administration of tylosin in cattle can cause shock, dyspnea, and depression, and fatal adverse events have been reported following the use of tildipirosin in swine.

SULFONAMIDES

The sulfonamides are synthetic antimicrobial agents with a wide spectrum encompassing most gram-positive and many gram-negative organisms. Sulfonamides are the oldest group of antibiotics used therapeutically. These drugs were the first efficient treatment to be used systematically for the prevention and cure of bacterial infections. Sulfonamides are derived from the first sulfonamide, sulfanilamide. The long-term use of these drugs may have resulted in resistance that now limits their use. **To increase the efficacy of sulfonamides and convert them from bacteriostatic to bactericidal drugs (most of the time they function as bacteriostatic antimicrobials), they are sometimes combined with other compounds such as trimethoprim and ormetoprim (also pyrimethamine) to potentiate their antibacterial effects.**

MECHANISM OF ACTION

Folic acid is an essential nutrient necessary for protein and nucleic acid synthesis (DNA and RNA). Folic acid is synthesized by bacteria from the substrate, para-amino-benzoic acid (PABA), and all cells require folic acid for growth. Folic acid (as a vitamin in food) diffuses or is transported into mammalian cells. However, folic acid cannot cross bacterial cell walls by diffusion or active transport. For this reason, bacteria must synthesize folic acid from PABA. Sulfonamides act by competing with PABA as a substrate for the enzyme dihydropteroate synthase, which incorporates PABA into dihydropteroic acid, the immediate precursor of folic acid.

Sulfonamides are bacteriostatic. Trimethoprim, ormetoprim, and pyrimethamine are bacteriostatic, inhibiting dihydrofolate reductase activity necessary for purine and pyrimidine nucleotide synthesis. They also inhibit folic acid synthesis but at a different point in the metabolic pathway from sulfonamides. Dihydropteroate synthase is not present in mammalian cells, whereas pyrimethamine and trimethoprim are more active against the parasite's dihydrofolate reductase than against the mammalian enzyme.

TOXICITY AND CLINICAL CONSIDERATIONS

Sulfonamides can cause toxicity of multiple organs, including the liver, but there is no difference among the various sulfonamides in the risk of toxicity. Use can be limited in a small number of patients because of hypersensitivity drug reactions (Type II and III hypersensitivity reactions). Idiosyncratic reactions, including immune-mediated reactions such as drug fever, urticaria, skin rashes, anemia, leukopenia, thrombocytopenia, nonseptic polyarthritis, focal retinitis, and hepatitis, are reported in some species.

Immune-mediated diseases of skin, kidney, liver, and eye (keratoconjunctivitis sicca) are not dose dependent and occur in response to any of the sulfonamides. Fortunately, these adverse reactions are rare when sulfonamides are used at recommended doses and for less than 2 weeks.

High doses of sulfonamides (30 mg/kg twice a day) can alter thyroid function, especially in dogs, causing decreased levels of thyroxin and thyronine (hypothyroidism). Decreases are clinically significant after 3 weeks of administration and will return to normal by 3 weeks after the drug is discontinued.

Renal crystalluria has been reported when administering high doses, and as a consequence it is important to ensure that the animal is well hydrated to avoid renal damage caused by precipitation of the sulfonamide (crystalluria). Because herbivores generally have alkaline urine, crystallization is not as much a concern in herbivores as in carnivores with their acidic urine.

Congenital defects are possible in foals born to mares treated for equine protozoal myeloencephalitis during pregnancy.

Precautions and Contraindications

As a general rule, sulfonamides should be used with caution or avoided in animals with liver disease, kidney disease, blood dyscrasia, or a history of hypersensitivity to sulfonamides.

Although commonly administered orally to horses, potentiated sulfonamides are not for use in horses intended for food. Potentiated sulfonamides have been associated with inducing diarrhea in horses. The injectable formulations of potentiated sulfonamides are suspensions; rapid IV administration causes hypotension and collapse.

TETRACYCLINES

Tetracyclines (tetracycline, chlortetracycline, oxytetracycline, doxycycline, minocycline, etc.) possess a broad-spectrum bacteriostatic activity against aerobic and anaerobic gram-positive (not β-lactamase-producing gram-positive bacteria) and gram-negative bacteria. They are also effective against microorganisms that are resistant to other antibiotics, such as several *Rickettsiae (Anaplasma, Ehrlichia* and *Haemobartonella), Spirochetes* (including Lyme disease), *Mycoplasma pneumoniae, Chlamydia* spp., and *Plasmodium* spp. Superinfections are rare with prolonged tetracycline administration.

MECHANISM OF ACTION

Tetracyclines cross the outer bacterial cell membrane by diffusion through aqueous channels (porins). They enter the cytoplasm by a protein carrier system in gram-negative bacteria and by an energy-dependent process in gram-positive bacteria. Tetracyclines then bind to the 30S ribosomal subunit of bacteria; binding interferes with bacterial protein synthesis in growing or multiplying organisms. This binding prevents the attachment of the aminoacyl-tRNA to the acceptor site on the mRNA ribosomal complex.

TOXICITY

Tetracyclines are considered relatively safe. The clinically most important toxicity occurs in animals administered high doses or animals administered with impaired renal function that are administered typical therapeutic doses (except for doxycycline and minocycline). In addition, expired tetracycline and oxytetracycline can decompose to form a nephrotoxic compound that results in Fanconi syndrome and glucosuria because reabsorption of glucose from the glomerular filtrate is impaired.

Most tetracyclines, except oxytetracycline, are too irritating to be administered intramuscularly or subcutaneously (sterile abscess), and great care is applied in the formulation of intramuscular products to minimize tissue damage. As a result, tetracyclines are often administered intravenously or orally. Rapid IV administration can cause the animal to collapse; to avoid this, the tetracycline should be injected slowly over a period of several minutes or administered diluted in normal saline solution free of polyvalent cations (as they bind tetracyclines and result in precipitation). Collapse is attributed to transient cardiovascular dysfunction such as atrioventricular block, ventricular bradycardia, and hypotension. The IV use of doxycycline in horses is associated with deleterious side effects on the cardiovascular system, which may result in fatalities. Undiluted propylene glycol–based oxytetracycline products can cause intravascular hemolysis and hemoglobinuria when administered by rapid IV injection.

Impaired bone development in fetus and young animals (tetracyclines pass the placental barrier readily and are administered for research purposes to monitor the rate of bone growth). As a result, tetracyclines should not be used in pregnant animals during the last half of gestation. Tooth mottling (discoloration of tooth enamel) also occurs if tetracyclines are administered during pregnancy (especially the last 2–3 weeks of pregnancy) and during the first postnatal month when tooth development is occurring. This effect is caused by chelation of tetracyclines to the calcium deposits in the developing teeth. Tetracyclines are antianabolic because they decrease protein synthesis at high concentrations.

MISCELLANEOUS ANTIBIOTICS

Bacitracin

Bacitracin is a complex labile polypeptide produced by *Bacillus subtilis.* It inhibits peptidoglycan synthesis during the second step of bacterial cell wall synthesis by interfering with the activity of phosphorylase and is bactericidal.

Bacitracin has activity against gram-positive bacteria and is often combined with antibiotics that have gram-negative spectrum of activity (such as polymyxin B, neomycin, or both). Bacitracin is not absorbed orally; systemic usage is associated with the development of nephrotoxicity in addition to pain, induration, and petechiae at the site of injection. As a result, bacitracin is most commonly applied topically in ointments.

Carbadox

Carbadox is a newer synthetic antibiotic agent that is primarily effective against gram-positive bacteria with little efficacy against some gram-negative bacteria. The mechanism of antimicrobial action is not known, but carbadox is bactericidal.

Carbadox is most commonly used as a feed additive to promote growth in swine and also to control swine dysentery (*Serpulina hyodysenteriae,* formerly known as *Treponema hyodysenteriae*), bacterial enteritis (particularly *Salmonella* spp.), and nasal infections (*Bordetella bronchiseptica*). It is carcinogenic and genotoxic in rodents and, consequently, the usage of carbadox is prohibited in Europe and Canada.

Carbadox stimulates the renin-angiotensin system and suppresses aldosterone production by inducing morphologic changes in adrenal cortex (plasma $Na\downarrow$ and $K\uparrow$). Clinical signs of reduced aldosterone production in pigs include growth retardation, dry feces, wasting, dehydration, urine drinking, and a strong interest in salt-containing products.

Dapsone

Dapsone is a chemical class different from sulfonamides but its mechanism of action is similar to sulfonamides via inhibition of bacterial synthesis of dihydrofolic acid by competing with para-aminobenzoate for the active site of dihydropteroate synthase. Dapsone is rapidly and well absorbed following oral administration and is primarily eliminated via the urine as conjugates and unidentified metabolites.

There is no veterinary approved form of dapsone. It is potentially useful for the oral treatment of some protozoal infections in horses. Dapsone is carcinogenic and should be used with caution in pregnant and nursing animals. Toxic effects include hepatotoxicity, anemia, thrombocytopenia, neutropenia, and GI effects.

Metronidazole

Metronidazole is a bactericidal agent that is also effective against protozoa that cause intestinal disease such as *Giardia* organisms, *Entamoeba histolytica, Trichomonas* organisms, and *Balantidium coli.* It is effective against most obligate anaerobes including *Bacteroides* spp., *Fusobacterium, Veillonella, Clostridium* spp., *Peptococcus,* and *Peptostreptococcus.* Metronidazole is primarily used as part of the treatment of anaerobic bacterial infections. It is taken up by anaerobic bacteria and protozoa and reduced to a cytotoxic metabolite that disrupts DNA synthesis, which results in bacterial cell death.

There is no veterinary-approved form of metronidazole, and its use is prohibited in food-producing animals in many countries because laboratory studies have demonstrated mutagenicity and carcinotoxicity. Human formulations are used for treatment of enteric bacterial infections caused by anaerobic bacteria in horses such as giardiasis and clostridiosis. Metronidazole may be teratogenic; therefore the drug should be avoided if possible in pregnant animals, especially during the first few weeks of gestation, and also in nursing animals. Metronidazole should not be used in debilitated animals.

The most severe adverse effect is dose-related central nervous system toxicity including loss of balance, head tilt, nystagmus, disorientation, tremors, and seizures with high doses of metronidazole in horses.

Nitrofurans (e.g., Nitrofurantoin, Nitrofurazone, Furazolidone)

Nitrofurans are derived from 5-nitrofuran, and more than 3500 nitrofurans have been synthesized. The use of nitrofurans in food-producing animals is banned in many countries because of potential carcinogenic effects in laboratory animals. Nitrofurans are broad-spectrum antibiotics that are highly effective against gram-negative bacteria, with some activity against gram-positive bacteria. Furazolidone also has activity against protozoa, *Giardia, Trichomonas,* and coccidia.

Nitrofurans are bacteriostatic and inhibit bacterial carbohydrate synthesis by interfering with the conversion of pyruvate to acetyl coenzyme A. They have been administered orally and topically, with oral bioavailability improved when administered with feed. Nitrofurans are no longer commonly used for the treatment of systemic infections because the effective MIC often approximates the toxic concentration. Nitrofurans are also rapidly eliminated so it is difficult to achieve and sustain therapeutic concentrations in tissues. Nitrofurans (primarily nitrofurantoin) are very occasionally used in horses for the treatment of lower urinary tract infections because they are highly concentrated in urine.

The most common use of nitrofurans is in topical preparations for the eye, ear, mucous membrane, and skin.

Novobiocin

Novobiocin is a dibasic acid derived from coumarin and is clinically used as a mono- (Na^+) or dibasic (Ca^{2+}) salt form. The mechanism of antibacterial activity is not known but is bactericidal. Several mechanisms of action have been proposed including nonspecific inhibition of bacterial wall synthesis; inhibition of DNA, RNA, and protein synthesis; inhibition of respiration and oxidative phosphorylation; and induction of intracellular magnesium deficiency.

Novobiocin has activity against gram-positive and gram-negative bacteria with higher efficacy against the gram-positive bacteria (most gram-negative bacteria are resistant), especially *S. aureus.* Other susceptible organisms include *Neisseria* spp., *Haemophilus* spp., *Brucella* spp., and some strains of *Proteus* spp. Novobiocin is used occasionally as an alternative to penicillins against penicillin-resistant *Staphylococcus* spp. It has synergistic activity with tetracyclines, and combination novobiocin–tetracycline therapy has been used in an attempt to broaden the spectrum of activity and decrease the development of resistance.

Toxic reactions to novobiocin include skin rashes, leukopenia, thrombocytopenia, agranulocytosis, anemia, nausea, vomiting, and diarrhea. Novobiocin is less toxic when used topically; its use in large animals is limited to topical application and intramammary administration in lactating dairy cattle.

Polymyxins

Polymyxin A, B, C, D, E, and M represent a group of *N*-monoacetylated decapeptide antimicrobial agents produced by *Bacillus polymyxa.* Sulfate salt forms of polymyxin B (mixture of polymyxin B_1 and B_2) and E (also called Colistin) are used clinically. The usage is primarily limited to oral (Colistin) or topical (polymyxin B) use because of their systemic toxicity, although short-term IV administration of polymyxin B has been used as part of the initial treatment of endotoxemia in horses.

Polymyxins are surface-active cationic detergents and are bactericidal by interfering with bacterial cell membrane phospholipids and disrupting their structure. Development of bacterial resistance is rare for susceptible bacteria.

Polymyxins and Colistin are primarily used in topical skin, mucous membrane, eye, and ear preparations and intramammary formulations for lactating dairy cattle. Antimicrobial activity is markedly reduced in the presence of pus, in tissues containing acidic phospholipids, and in the presence of anionic detergents. Polymyxins have been used orally in cattle and swine for the treatment of gram-negative enteric infections, but they have a narrow safety margin. Toxic effects include nephrotoxicity, respiratory paralysis (rapid IV injection), and central nervous system dysfunction including anorexia, pyrexia, and depression.

Rifampin

Rifampin is a complex macrocyclic semisynthetic antibiotic derived from rifamycin B. It is highly active against gram-positive bacteria (*Staphylococcus* spp.), *Mycobacterium* spp., *Haemophilus* spp., *Neisseria* spp., and *Chlamydia* spp., but has limited activity against gram-negative bacteria because of differences in the ability of the antibiotic to pass through the bacterial cell wall. Rifampin also has some antifungal and antiviral (poxviruses and adenoviruses) activity. In large animals, rifampin is most commonly administered orally in conjunction with other antibiotics to treat deep-seated abscesses such as liver abscesses in sheep caused by *Corynebacterium pseudotuberculosis* (caseous lymphadenitis) or pulmonary abscesses in foals caused by *R. equi.* Rifampin has also been used to treat individual valuable cattle with Johne's disease. Combined administration with another antibiotic is strongly advised because coadministration slows the development of resistance to rifampin.

Rifampin is bactericidal and inhibits the activity of DNA-dependent RNA polymerase, preventing the initiation of RNA synthesis by interfering with the activity of the β-subunit of DNA-dependent RNA polymerase. Rifampin metabolites may impart a red-orange color to the urine, feces, saliva, and tears.

Rifampin is a potent inducer of hepatic microsomal enzymes (hepatotoxicity) and is also teratogenic, so the use in pregnant animals should be restricted. Rifampin administration accelerates the metabolism of chloramphenicol and corticosteroids (prednisone and dexamethasone). The most common toxic effect is hepatotoxicity, and animals on long-term administration should have a periodic serum biochemical analysis performed to monitor for signs of hepatic injury and dysfunction.

Vancomycin

Vancomycin is a glycopeptide bactericidal antibiotic that inhibits peptidoglycan synthesis in the bacterial cell wall during replication. A variety of *n*-alkyl vancomycin forms have been synthesized with some forms being more active and with some having longer elimination half-lives than that of vancomycin. Vancomycin is primarily effective against gram-positive bacteria (in particular, *Staphylococcus* spp. and streptococci), enterococci (*E. faecium* and *E. faecalis*), and *Neisseria* spp. It is also effective against gram-positive anaerobic cocci with no activity against anaerobic gram-negative bacteria. Its most important use in veterinary medicine is for the treatment of life-threatening methicillin-resistant *S. aureus* infections.

Extralabel usage of vancomycin in food-producing animals is prohibited by the FDA. Vancomycin is not absorbed orally, intramuscular and subcutaneous injections are painful and irritating, and, consequently, vancomycin must be administered with slow IV infusion over at least 30 minutes as a dilute solution. Rapid IV administration has been associated with flushing of the skin, pruritus, tachycardia, severe hypotension, cardiac arrest, and other signs associated with histamine release. Nephrotoxicity and ototoxicity are possible. Newer formulations are safer but might be associated with histamine release following IV injection.

Virginiamycin

Virginiamycin is a peptolide antibiotic consisting of a predominant M fraction ($C_{28}H_{35}N_3O_7$) and the lesser S fraction ($C_{43}H_{49}NO_{10}$). The S and M fractions have bacteriostatic and bactericidal activities when they are used separately and together, respectively. Virginiamycin is not known to have synergistic activity with other classes of antibiotics.

Virginiamycin inhibits protein synthesis by binding to the 23S ribosomal subunit and blocking the translation process, with no effect on transcription. It is not commonly used to treat bacterial infections in domestic animals despite possessing a broad-spectrum antimicrobial activity. Most often it is used as a feed-additive formulation for growth promotion in animals such as swine, turkey, and broiler chickens.

Diseases of the Alimentary Tract: Nonruminant

7

Principles of Alimentary Tract Dysfunction

The primary functions of the alimentary tract are the **prehension**, **digestion** and **absorption of food and water,** and the **maintenance of the internal environment** by modification of the amount and nature of the materials absorbed.

The primary functions can be divided into four major modes and, correspondingly, there are four major modes of alimentary dysfunction. There may be abnormality of **motility**, **secretion**, **digestion,** or **absorption.** The procedure in diagnosis of alimentary tract dysfunction should be to determine which mode or modes of function are disturbed before proceeding to the determination of the site and nature of the lesion and ultimately of the specific cause.

MOTOR FUNCTION

NORMAL GASTROINTESTINAL MOTILITY

The form and function of the small intestine of farm animals are similar between species, but the stomachs and large intestines vary considerably. The motility patterns in both the small and large intestine are similar among the species. In the small intestine, the fundamental unit of electrical activity is the slow wave, which is a subthreshold fluctuation in membrane potential. Slow waves are constantly propagated from the stomach to the rectum. When an additional stimulus causes the membrane potential to exceed the excitation threshold, a spike or electrical response activity occurs, which is usually accompanied by contraction. Almost all spike activity in the intestine is superimposed on slow waves, which are important in controlling frequency and velocity at which spiking events occur. The spiking activity, also known as the migrating myoelectric complex, is the myoelectric pattern in the stomach and small intestine of fasted nonruminants, fed and fasted ruminants, and pigs and horses fed ad libitum.[1] There are three phases of the migrating myoelectric complex:

- **Quiescent phase**, in which very little spike activity occurs
- **Irregular phase**, characterized by intermittent spike activity
- **Activity front**, characterized by intense, continuous spike activity

There is very little muscle contraction or transit of gut contents during the quiescent phase. During the irregular phase, contractions mix the intestinal contents and propel them in an aboral direction. The activity front is accompanied by intense muscular contraction that obliterates the lumen, preventing backflow of content as it propagates, or migrates, down the intestine.

In nonruminants, and pigs and horses fed periodically, feeding abolishes the migrating myoelectric complex for several hours. It is replaced by the fed pattern, characterized by intermittent spike activity resembling the irregular phase.

Normal cecal and colonic myoelectric activities, like those of the small intestine, are characterized by slow waves and spikes. However, unlike the small intestine, the patterns of spikes vary greatly with the species and the area of the large intestine.

Abnormalities of stomach and intestinal motility represent the most common consequence of gastrointestinal tract disease. Disruption in gastrointestinal tract motility can result in the following:

- Hypermotility or hypomotility
- Distension of segments of the tract
- Abdominal pain
- Dehydration and shock

HYPERMOTILITY AND HYPOMOTILITY

The most important functions of alimentary tract motility are the peristaltic movements that move ingesta from the esophagus to the rectum, the segmentation movements that churn and mix the ingesta, and the tone of the sphincters. In ruminants these movements are of major importance in the forestomach. Prehension, mastication, and swallowing are the other functions of alimentary tract motility that are essential for normal function. Eructation of ruminal gases is an additional crucial function of motility in ruminants.

Abnormal motor function can take the form of **increased or decreased motility.** Peristalsis and segmenting movements are usually affected equally and in the same manner. Motility depends on stimulation via the sympathetic and parasympathetic nervous systems, and is thus dependent on the activity of the central and peripheral parts of these systems and on the intestinal musculature and its intrinsic nervous plexuses. Autonomic imbalance, resulting in a relative dominance of one or other system, is manifested by hypermotility or hypomotility, and can arise as a result of stimulation or destruction of hypothalamic centers, the ganglia, or the efferent or afferent peripheral branches of the system. Debility, accompanied by weakness of the musculature, or severe inflammation, such as occurs in acute peritonitis or after trauma, or infarction, results in atony of the intestinal wall. Less severe inflammation, such as occurs in mild gastritis and enteritis, can result in an increase in muscular activity and increased propulsive activity. Abnormalities in intestinal motility can result in diarrhea or constipation and adversely affect digestion and absorption of ingesta.

Increased irritability at a particular intestinal segment increases its activity, and disturbs the normal downward gradient of activity that ensures the ingesta are passed from the esophagus to the rectum. Not only is the gradient toward the rectum made steeper, increasing the rate of passage of ingesta in that direction, but the increased potential activity of an irritated segment may be sufficiently high to produce a reverse gradient to the oral segments so that the directions of the peristaltic waves are reversed orally to the irritated segments.

DISTENSION

One of the major results of abnormality of motility is distension of one or more segments of the gastrointestinal tract. Distension can be the result of accumulation of gas, fluid, or ingesta. Much of the accumulated fluid represents saliva and gastric and intestinal juices secreted during normal digestion. Gas distension occurs as a result of failure to expel gas, by eructation or as flatulence, which is produced either as a result of normal digestive processes or abnormal fermentation.

Distension causes pain and, reflexively, increased spasm and motility of adjoining gut segments. Distension also stimulates further secretion of fluid into the lumen of the intestine, and this exaggerates the distension. When the distension passes a critical point, the ability of the musculature of the wall to respond diminishes, the initial pain disappears, and a state of paralytic ileus develops in which much muscle tone is lost.

ABDOMINAL PAIN

Visceral pain can arise in any abdominal viscus or organ, but the mode of its development is always the same, and alimentary tract disease is the major cause of visceral and, more specifically, of abdominal pain. The **most important mechanism is stretching of the wall of the viscus**, which stimulates free pain endings of the autonomic nerves in the wall. Contraction does not itself cause pain but does so by causing direct and reflex distension of neighboring segments. Thus spasm, an exaggerated segmenting contraction of one section of intestine, will result in distension of the immediately oral segment of intestine when a peristaltic wave arrives. When there is increased motility for any reason, excessive segmentation and peristalsis cause abdominal pain, and the frequent occurrence of intermittent bouts of pain depends on the periodic increases in muscle tone that are typical of the alimentary tract wall. Other factors that have some stimulating effect on the pain of end organs are edema and failure of local blood supply, such as occurs in local embolism or in intestinal accidents accompanied by twisting of the mesentery. A secondary mechanism in the production of abdominal pain is the stretching and inflammation of serous membranes.

Clinically, abdominal pain can be detected by palpation and the eliciting of pain responses. However, it is unknown if the response elicited is caused by involvement of underlying organs or by referred pain. It is difficult to decide if referred pain occurs in animals. In humans it is largely a subjective sensation, although often accompanied by local hyperalgesia. There are no known examples of referred pain that are of diagnostic importance in animals, and a local pain response on palpation of the abdomen is accepted as evidence of pain in the serous membranes or viscera that underlie the point of palpation.

DEHYDRATION AND SHOCK

An immediate effect of distension of the stomach or small intestine by the accumulation of saliva and normal gastric and intestinal secretions is the stimulation of further secretion of fluid and electrolytes into the oral segments. The stimulation is self-perpetuating, and creates a vicious cycle resulting in loss of fluid and electrolytes to the point where fatal dehydration can occur. The dehydration is accompanied by acidosis or alkalosis, depending on whether the obstruction is in the intestine and accompanied by loss of alkali, or in the stomach and accompanied by a large loss of acid radicals. The net effect is the same whether the fluid is lost by vomiting or is retained in the gut.

The same cycle of events occurs in ruminants that gorge on grain, but here the precipitating mechanism is not distension but a gross increase in osmotic pressure of the ingesta caused by the accumulation of osmotically active compounds, including lactic acid. Dehydration is also of major importance in diarrhea, irrespective of the cause. An important additional factor in the production of shock, when there is distension of alimentary segments, is a marked reflex depression of vasomotor, cardiovascular, and respiratory functions. In diarrhea in calves in which there is no septicemia or toxemia associated with bacteria, the endpoint in the phase of dehydration can be cardiac failure caused by severe metabolic acidosis and electrolyte abnormalities. Renal ischemia leading to azotemia or uremia can result from decreased circulating blood volume and also contribute to a fatal outcome. These matters are discussed in detail in Chapters 5 and 6.

SECRETORY FUNCTION

Diseases caused by abnormalities of secretion of digestive enzymes are not generally recognized in farm animals. In humans, and to a lesser extent in small animals, defects of gastric and pancreatic secretion produce syndromes that are readily recognized, but they depend on clinical pathologic examination for diagnosis. If they do occur in farm animals, they have so far only been recognized as aberrations of motility caused by the defects of secretion. However, it is reasonable to assume that some neonates are deficient

in lactase activity, which results in dietetic diarrhea. Undigested lactose causes diarrhea by its hyperosmotic effect, and some of the lactose can be fermented in the large intestine, the products of which fermentation exaggerates the diarrhea. A deficiency of lactase activity has been suspected in foals affected with diarrhea of undetermined origin when the definitive diagnosis has not been made. The intestinal lactase activity of foals is at its highest level at birth, gradually declines until the fourth month of age, and then disappears from adults before their fourth year.

DIGESTIVE FUNCTION

The ability of the alimentary tract to digest food depends on its motor and secretory functions and, in herbivores, on the activity of the microflora that inhabits the forestomachs of ruminants or cecum and colon of Equidae. The flora of the forestomachs of ruminants is capable of digesting cellulose, of fermenting the end products of other carbohydrates to volatile fatty acids, and of converting nitrogenous substances to ammonia and protein. In a number of circumstances, the activity of the flora can be modified so that digestion is abnormal or ceases. Failure to provide the correct diet, prolonged starvation or inappetence, and hyperacidity such as occurs in engorgement on grain all result in impairment of microbial digestion. The bacteria, yeasts, and protozoa may also be adversely affected by the oral administration of antibiotic and sulfonamide drugs or drugs that drastically alter the pH of the rumen content.

Diseases of the stomach of ruminants are presented in Chapter 8. Information about the digestive and absorptive capacities of the equine gut is not exhaustive, but some basic data are available. The rate of passage of ingesta through the stomach and intestines is rapid but varies widely depending on the physical characteristics of the ingesta and dissolved material passaging more rapidly than particulate material; 75% of a liquid marker can be emptied from the stomach in 30 minutes and be in the cecum in 2 hours. Passage through the large bowel is much slower, especially in the latter part of the colon in which much of the fluid is absorbed. There is an obvious relationship between the great activity of the small intestine and the effect of a complete obstruction of it: the pain is very severe and often uncontrollable with standard analgesics; fluid loss into the obstructed parts is rapid; and dehydration, loss of electrolytes, and disturbances of acid-base balance are acute, severe, and life-threatening.

ABSORPTIVE FUNCTION

Absorption of fluids and the dissolved end products of digestion can be adversely affected by increased motility or by disease of the intestinal mucosa. In most instances, the two occur together but, occasionally, as with some helminth infestations, lesions occur in the intestinal wall without accompanying changes in motility.

Manifestations of Alimentary Tract Dysfunction

Inanition is the major physiologic effect of alimentary dysfunction when the disease is chronic, dehydration is the major effect in acute diseases, and shock is the important physiologic disturbance in hyperacute diseases. Some degree of abdominal pain is usual in most diseases of the alimentary tract, with the severity varying with the nature of the lesion. Other manifestations include abnormalities of prehension, mastication, and swallowing; and vomiting, diarrhea, hemorrhage, constipation, and scant feces.

ABNORMALITIES OF PREHENSION, MASTICATION, AND SWALLOWING

Prehension is the act of grasping for food with the mouth (lips, tongue, and teeth). It includes the ability to drink. Causes of faulty prehension include:

Paralysis of the muscles of the jaw or tongue

Malposition of incisor teeth caused by the following:
- Inherited skeletal defect (inherited displaced molar teeth, inherited mandibular prognathism, inherited congenital osteopetrosis)
- Rickets

Absence of some incisor teeth

Pain in the mouth caused by the following:
- Stomatitis, glossitis
- Foreign body in mouth
- Decayed teeth, e.g., fluorosis

Congenital abnormalities of tongue and lips:
- Inherited harelip
- Inherited smooth tongue of cattle

A simple examination of the mouth usually reveals the causative lesion. Paralysis is indicated by the behavior of the animal as it attempts to ingest feed without success. In all cases, unless there is anorexia caused by systemic disease, the animal is hungry and attempts to feed but cannot do so.

Mastication may be painful and is manifested by slow jaw movements interrupted by pauses and expressions of pain if the cause is a bad tooth, but in a painful stomatitis there is usually complete refusal to chew. Incomplete mastication is evidenced by the dropping of food from the mouth while eating and the passage of large quantities of undigested material in the feces.

Swallowing is a complex act governed by reflexes mediated through the glossopharyngeal, trigeminal, hypoglossal, and vagal nerves. It has been described endoscopically and fluoroscopically in the horse. The mechanism of the act includes closure of all exits from the pharynx, the creation of pressure to force the bolus into the esophagus, and involuntary movements of the musculature of the esophageal wall to carry the bolus to the stomach. A defect in nervous control of the reflex or a narrowing of the lumen of the pharynx or esophagus may interfere with swallowing. It is difficult to differentiate clinically between physical and functional causes of dysphagia (difficulty in eating/swallowing).

Dysphagia is manifested by forceful attempts to swallow accompanied initially by extension of the head, followed by forceful flexion and violent contractions of the muscles of the neck and abdomen. Inability to swallow is usually caused by the same lesions as dysphagia, but to a greater degree. If the animal attempts to swallow, the results depend on the site of the obstruction. Lesions in the pharynx cause regurgitation through the nostrils or coughing up of the material. In the latter instance, there is danger that some of the material is aspirated into the lungs and could cause acute respiratory and cardiac failure or aspiration pneumonia. When the obstruction is at a low level in the esophagus, a large amount of material can be swallowed and then regurgitated. It is necessary to differentiate between material regurgitated from the esophagus and vomitus: the former is usually slightly alkaline and the latter is acid.

CAUSES OF DYSPHAGIA AND INABILITY TO SWALLOW

- Foreign body, tumor, or inflammatory swelling in pharynx or esophagus
- Painful condition of pharynx or esophagus
- Esophageal obstruction by impacted feed material
- Esophageal dilatation caused by paralysis
- Esophageal diverticulum
- Esophageal spasm at site of mucosal erosion (achalasia of cardia not encountered)

DROOLING OF SALIVA AND EXCESSIVE SALIVATION

Drooling saliva from the mouth, distinct from frothing such as occurs during convulsions, can be caused by pain in the mouth and by an inability to swallow. Excessive salivation is caused by stimulation of saliva production by systemic toxins, especially fungal toxins, or by hyperthermia. With systemic poisonings the increased salivation is often accompanied by lacrimation.

LOCAL CAUSES OF DROOLING

- Foreign body in mouth or pharynx
- Ulceration, deep erosion or vesicular eruption of the oral mucosa
- Inability to swallow (esophageal abnormality)

SYSTEMIC CAUSES OF EXCESSIVE SALIVATION

- Poisonous trees: *Oleander* spp., *Andromeda* spp. (rhododendron)
- Other poisonous plants: kikuyu grass (or an attendant fungus)
- Fungal toxins, e.g., slaframine and those causing hyperthermia, e.g., *Claviceps purpurea* and *Acremonium coenophialum*
- Iodism
- Watery mouth of lambs
- Sweating sickness
- Methiocarb poisoning

VOMITING AND REGURGITATION

VOMITING

Vomiting is the forceful ejection of contents of the stomach and the proximal small intestine through the mouth, and is a complex motor disturbance of the alimentary tract. It is a vigorously active motion signaled by hypersalivation, retching, and forceful contractions of the abdominal muscles and diaphragm. Vomiting is essentially a protective mechanism with the function of removing excessive quantities of ingesta or toxic materials from the stomach. Note that vomition is exceedingly rare in horses and is usually a terminal event. Vomition occurs in two forms: **projectile** and **true vomiting**.

Projectile Vomiting

This is not accompanied by retching movements, and large amounts of fluid material are ejected with little effort. It is almost always as a result of overloading of the stomach or forestomach with feed or fluid.

True Vomiting

As it occurs in monogastric animals like the dog and cat, true vomiting is accompanied by retching movements including contraction of the abdominal wall and of the neck muscles and extension of the head. The movements are commonly prolonged and repeated, and the vomitus is usually small in amount and of porridge-like or pasty consistency. It is usually a result of irritation of the gastric mucosa. Vomiting is commonly designated as being either peripheral or central in origin depending on whether the stimulation arises centrally at the vomiting center or peripherally by overloading of the stomach or inflammation of the gastric mucosa, or by the presence of foreign bodies in the pharynx, esophagus, or esophageal groove. Central stimulation of vomiting by apomorphine and in nephritis and hepatitis are typical examples, but vomiting occurs rarely, if at all, in these diseases in farm animals.

Vomiting can have serious effects on fluid and electrolyte balance because of the losses of gastric and intestinal contents. Aspiration pneumonia and laryngeal obstruction are potentially serious consequences of vomiting. Examination of any suspected vomitus to determine its site of origin should always be performed.

True vomiting is rare in farm animals except in pigs with gastroenteritis and some systemic diseases. True vomiting does not occur in ruminants but abnormal regurgitation does (see later). **True vomiting is not a feature of gastric disease in the horse for two reasons.** First, the strong cardiac sphincter inhibits the release of stomach contents; in horses rupture of the stomach is more likely to occur before vomiting takes place. Second, the soft palate and epiglottis combine to affect a seal between the oral and nasal parts of the pharynx so that any vomited stomach contents must be discharged through the nasal cavities and not through the mouth. Spontaneous nasal regurgitation or vomiting does occur occasionally, as manifested by the production of green stomach contents at the nostrils. This suggests extreme gastric distension or a dilated esophagus and cardiac sphincter and perhaps some underlying neurologic deficit. Thus vomiting of large quantities of material in the horse is usually a terminal event and suggests gastric rupture.

REGURGITATION

Regurgitation is the expulsion through the mouth or nasal cavities of feed, saliva, and other substances that have not yet reached the stomach. In most cases it is caused by abnormalities of the esophagus that interfere with swallowing. A common example in large animals is the regurgitation of feed, saliva, and perhaps bloodstained fluid from the esophagus of the horse with esophageal obstruction. Esophagitis is also a common cause of regurgitation.

Ruminants regurgitate rumen contents as part of rumination, but the material is not expelled from the mouth or into the nasal cavities. The regurgitation of rumen contents through the mouth does occur in cattle occasionally, is abnormal, and is a dramatic event. It is usually associated with loss of tone of the cardia or inflammation of the cardia (see examples in the following sections).

Nasogastric regurgitation or gastric reflux occurs in the horse. Stomach contents flow into the esophagus, and usually into the nasopharynx and nasal cavities, as a result of distension of the stomach with fluid (which usually originates in the small intestine). This involuntary process is usually slow and gradual, unlike true vomiting. Gastric reflux in the horse can be elicited by nasogastric intubation. Spontaneous efflux of stomach contents is indicative of high-volume and high-pressure fluid distension of the stomach. On other occasions the presence of sequestrated gastric fluids can be confirmed only by the creation of a siphon, using the nasogastric tube to infuse a volume of fluid then disconnecting its supply to retrieve the **nasogastric reflux.**

Causes of vomiting and regurgitation include the following:

- Terminal vomiting in horses with acute gastric dilatation
- "Vomiting" in cattle is really *regurgitation* of large quantities of rumen contents through the mouth. Causes include the following:
  - Third-stage milk fever (loss of tone in the cardia)
  - Arsenic poisoning (acute inflammation of the cardia)
  - Poisoning by plants including *Eupatorium rugosum, Geigeria* spp., *Hymenoxys* spp., *Andromeda* spp., *Oleander* spp., and *Conium maculatum*
  - Veterinary administration of large quantities of fluids into the rumen (regurgitation occurs while the stomach tube is in place)
  - Use of a large-bore stomach tube
  - Cud-dropping: a special case of regurgitation usually associated with abnormality of the cardia
- Vomiting in pigs may be caused by the following:
  - Transmissible gastroenteritis (TGE)
  - Acute chemical intoxications
  - Poisoning by the fungus *Fusarium* spp., which also causes off-feed effects suspected to be analogous to nausea in humans
- Regurgitation in all diseases causing dysphagia or paralysis of swallowing

DIARRHEA, CONSTIPATION, AND SCANT FECES

Diarrhea and constipation are the most commonly observed abnormalities in **fecal consistency**, **composition,** and **frequency of defecation**.

DIARRHEA

Diarrhea is the increased frequency of defecation accompanied by feces that contain an increased concentration n of water and decrease in dry matter content. The consistency of the feces varies from soft to liquid.

Abnormalities of peristalsis and segmentation usually occur together, and when there is a general increase in peristaltic activity there is increased caudal flow, resulting in a decrease in intestinal transit time and diarrhea. Because of a lack of absorption of fluid the feces are usually softer than normal, the dry matter content is below the normal range, and the total amount of feces passed per day is increased. The frequency of

defecation is usually also increased. Common causes of diarrhea are

- Enteritis, including secretory enteropathy
- Malabsorption, e.g., caused by villous atrophy and in hypocuprosis (caused by molybdenum excess)
- Neurogenic diarrhea as in excitement
- Local structural lesions of the stomach or intestine, including the following:
  - Ulcer, e.g., of the abomasum or stomach
  - Tumor, e.g., intestinal adenocarcinoma
- Indigestible diet, e.g., lactose intolerance in foals
- Carbohydrate engorgement in cattle
- In some cases of ileal hypertrophy, ileitis, diverticulitis, and adenomatosis
- Terminal stages of congestive heart failure (visceral edema)
- Endotoxic mastitis in cattle (splanchnic congestion)
  - Small colon impaction in horses
  - Sand colic in horses
- Chronic and acute undifferentiated diarrhea in horses
- Vagus indigestion in cows causes pasty feces but bulk is reduced; these cases may be mistaken initially for other causes of diarrhea

Malabsorption Syndromes

Malabsorption syndromes are being recognized with increased frequency in monogastric farm animals. For example, in recently weaned pigs, there is villous atrophy with a resulting loss in secretory and absorptive function. Inefficient digestion originating in this way may or may not be manifested by diarrhea, but in malabsorption there is usually diarrhea. There is always failure to grow or maintain body weight (BW), in spite of an apparently normal appetite and an adequate diet. In horses, the lesions associated with malabsorption, which can be with or without diarrhea, include villous atrophy, edema and/or necrosis of the lamina propria of the gut wall, and nodular tracts and aggregations of eosinophils indicating damage by migrating strongyle larvae. Special tests are now detailed for the examination of digestive efficiency in the horse. These are listed in the next section. Increased venous pressure in the portal circuit caused by congestive heart failure or hepatic fibrosis also causes diarrhea.

The question of whether or not enteritis in animals causes intestinal hypermotility and increased peristalsis, resulting in diarrhea, remains unresolved. If hypermotility and increased peristalsis cause diarrhea, antimotility drugs may be indicated in some causes of acute infectious diarrhea. Current concepts on the pathophysiology of the common diarrheas associated with infectious agents (such as enterotoxigenic *Escherichia coli*) indicate that there is a net increase in the flow of intestinal fluid into the lumen and a decrease in outflow back into the systemic circulation, which causes distension of the intestine with fluid. The hydraulic effect of the distension can cause diarrhea, and hypermotility is probably not necessary. In addition, because of the temporary malabsorption that exists in infectious enteritides, and the presence of infectious agents and enterotoxins in the lumen of the intestine, the emphasis should be on evacuation of the intestinal contents and not on the use of anticholinergic drugs to inhibit evacuation. Furthermore, it is unlikely that the anticholinergics will have any significant effect on the secretory-absorptive mechanisms that have been altered by an enteropathogen.

CONSTIPATION

Constipation is the **decreased frequency of defecation** accompanied by feces that contain a decreased concentration of water. The feces vary in consistency from being hard to dry and of small bulk. True constipation, as it occurs in humans, is usually characterized by failure to defecate and impaction of the rectum with feces. When the motility of the intestine is reduced, the alimentary transit time is prolonged and constipation or scant feces occurs. Because of the increased time afforded for fluid absorption, the feces are dry, hard, of small bulk, and are passed at infrequent intervals. Constipation may also occur when defecation is painful, such as in cattle with acute traumatic reticuloperitonitis.

SCANT FECES

Scant feces are small quantities of feces, which may be dry or soft. Scant feces are most common in cattle with abnormalities of the forestomach or abomasum resulting in the movement of only small quantities of ingesta into the small and large intestines (**an outflow abnormality**). The details are available in Chapter 8. When there is complete intestinal stasis the rectum may be empty except for blood-tinged, thick, pasty material.

Common causes of constipation or scant feces are as follows:

- Diseases of the forestomach and abomasum causing failure of outflow
- Impaction of the large intestine in the horse and the sow
- Severe debility, as in old age
- Deficient dietary bulk, usually fiber
- Chronic dehydration
- Partial obstruction of large intestine
- Painful conditions of the anus
- Paralytic ileus
- Grass sickness in horses
  - Cauda equina syndrome in any species
  - Polyneuritis equi
- Chronic zinc poisoning in cattle
- Terminal stages of pregnancy in cows.

ILEUS (ADYNAMIC AND DYNAMIC ILEUS)

Ileus is a state of **functional obstruction** of the intestines or failure of peristalsis. It is also known as **paralytic ileus** or **adynamic ileus. Dynamic or mechanical ileus** is a state of physical obstruction. In paralytic ileus there is loss of intestinal tone and motility as a result of reflex inhibition. This can occur in acute peritonitis, excessive handling of viscera during surgery, and prolonged and severe distension of the intestines as in intestinal obstruction or enteritis. Ileus can also be caused by acid-base imbalance, dehydration, electrolyte imbalances such as hypocalcemia and hypokalemia, and toxemia. Ileus can affect the stomach, causing delayed gastric emptying and subsequent dilatation with fluid and gas. The effect of ileus on the intestines is to cause failure of orocaudal movement of fluid, gas, and ingesta and accumulation of these substances, which results in intestinal distension and varying degrees of abdominal pain, dehydration, and a marked reduction in the amount of feces. Distension of the abdomen, fluid-tinkling, fluid-splashing sounds, and pings on percussion of the abdomen are common clinical findings. Impaction of the large intestine of horses is a form of ileus.

Postoperative ileus of the small and large intestines is a common complication of surgical treatment for colic in the horse.[2-5] The clinical findings include gastric reflux because of gastric distension with fluid, absence of or minimal intestinal peristaltic sounds, an absence of feces, abdominal pain, distended loops of intestine palpable per rectum, and varying degrees of shock and dehydration as a result of intestinal fluid sequestration and a decrease in fluid absorption. **Infarction of the intestinal wall** associated with an acute mechanical obstruction of the intestine also results in ileus. In thromboembolic colic caused by verminous mesenteric arteritis in the horse, large segments of the large colon and cecum can become infarcted, resulting in irreversible ileus.

The etiology and pathogenesis of ileus in farm animals are not well understood. Sympathetic hyperactivity is thought to be a factor. The gastroileal reflex is one example of the influence of the activity of one part of the digestive tract on that of another; inhibition of gastric motility when the ileum is distended is called ileogastric reflex. Immediate cessation of all intestinal movement (adynamic ileus) follows distension of an intestinal segment, rough handling of the intestine during abdominal surgery, or peritoneal irritation. Adynamic ileus operates through three pathways: general sympathetic discharge of the peripheral reflex pathway through the iliac and mesenteric plexuses and the intramural plexuses. The treatment of ileus depends on the original

Table 7-1 Medications with potential prokinetic actions in horses (see text for references)

Drug	Mechanism of action	Proposed dose	Potential indications
Parasympathomimetics			
Bethanechol	Direct acting muscarinic receptor agonist	0.025 mg/kg BW, IV or SC every 4–6 h	Disorders requiring promotion of gastric or cecal emptying. Postoperative ileus, gastroesophageal reflux in foals
Neostigmine	Indirect acting cholinesterase	0.0044–0.022 mg/kg BW, IV, IM or SC; 4 mg SC every 6 h; 2 mg SC every 2 h	Caecal and large colon impactions inhibitor
Benzamides			
Metoclopramide	5-HT4 agonist, 5-HT3 and D2 antagonist	0.04 mg/kg BW/h, IV CRI	Disorders requiring promotion of gastric and small intestinal motility, post-operative ileus, anterior enteritis
Cisapride	5-HT4 agonist, 5-HT1 antagonist	0.1–0.25 mg/kg BW/h, IV over 60 min; 0.1 mg/kg BW, IM	Disorders requiring promotion of gastric and small intestinal motility, post-operative ileus, anterior enteritis
Mosapride	5-HT4 agonist	1–2 mg/kg BW, PO, every 24 h	Gastric impactions, small intestinal ileus, cecal impactions
Tegaserod	5-HT agonist	0.27 mg/kg BW, PO every 12 h	Large colon impactions
Sodium channel blockers			
Lidocaine	Unknown	1.3 mg/kg BW, IV (loading dose) followed by 0.05 mg/kg BW/min CRI	Post-operative ileus, anterior enteritis
Macrolide antimicrobials			
Erythromycin	Stimulation of motilin receptors	0.5–1 mg/kg BW in saline, IV over 60 min	Disorders requiring promotion of gastric and small intestinal motility, post-operative ileus, cecal impactions
Dopamine antagonists			
Domperidone	D2-receptor antagonist	0.2 mg/kg BW, IV	Disorders requiring promotion of gastric and small intestinal motility, post-operative ileus
α-Adrenergic antagonists			
Yohimbine	α_2-Adrenergic receptors antagonist	0.15 mg/kg BW, IV every 3 h 0.25 mg/kg BW in saline, IV over 60 min	Post-operative ileus
Tolazoline	α_2-Adrenergic receptors antagonist	1 mg/kg BW in saline, IV	Unknown over 60 min
Atipamezole	α_2-Adrenergic receptors antagonist	0.03–0.06 mg/kg BW, IM	Unknown; possible prevention of α-adrenergic–induced ileus
Acepromazine	Nonspecific α-adrenergic receptors antagonist	0.01 mg/kg BW, IV or IM 4 h	Post-operative ileus
Opioid antagonists			
Naloxone	Opioid antagonist	0.05 mg/kg BW, IV	Unknown, possible large colon impactions, opioid-induced ileus
N-methylnaltrexone	Opioid antagonist	0.75 mg/kg BW, IV every 12 h	Unknown, possible large colon impactions, opioid-induced ileus

BW, body weight; IM, intramuscularly; IV, intravenously; PO, orally; SC, subcutaneously; CRI, constant rate infusion.

cause. Physical obstruction of the intestines and torsion of the stomach must be corrected surgically.

Management of postoperative ileus and ileus associated with proximal duodenitis–jejunitis (anterior enteritis) includes correction of fluid and electrolyte abnormalities, relief of gastric distension, and administration of prokinetic drugs. Lidocaine (lignocaine, loading dose 1.5 mg/kg followed by 0.033 mg/kg/min intravenously) administered prophylactically to horses undergoing exploratory laparotomy because of abdominal pain reduces the severity and duration of postoperative ileus.[4,6]

Motility of the gastrointestinal tract can be modified by administration of a number of compounds (Table 7-1).[7-11] Clinical utility is documented for administration of lidocaine to horses with postoperative ileus (see earlier information) and for erythromycin in cattle following surgery for abomasal disease.[7,8]

ALIMENTARY TRACT HEMORRHAGE

Hemorrhage into the stomach or intestine is a common occurrence in farm animals. The main causes include the following:

- Gastric or abomasal (rarely duodenal) ulcers
- Severe hemorrhagic enteritis
- Structural lesions of the intestinal wall, e.g., adenomatosis, neoplasia
- Infestation with blood-sucking nematodes, e.g., bunostomiasis,
- Local vascular engorgement or obstruction as in intussusception and verminous thrombosis

Hemorrhage into the stomach results in the formation of **acid hematin,** which makes vomitus a dark brown color like coffee grounds, and feces have a black or very dark brown, tarry appearance (**melena**). The change in appearance of the feces caused by hemorrhage into the intestine varies with the level at which the hemorrhage occurs. If the blood originates in the **small intestine,** the feces may be **brown-black**, but if it originates in the **colon or cecum**, the blood is unchanged and gives the feces an **even red**

color. Hemorrhage into the **lower colon and rectum** may cause the voiding of feces containing or consisting entirely of **clots of whole blood (hematochezia)**.

If there is any doubt about the presence of blood in the feces or vomitus, biochemical tests should be performed. The hemorrhage may be sufficiently severe to cause anemia and, in particularly severe cases, acute peripheral circulatory failure. In cattle the most sensitive test is one using a dilute alcoholic solution of guaiac as the test reagent. It is capable of detecting a daily blood loss into the abomasum of as small a volume as 70 mL. Transit time of blood from abomasum to rectum in normal cows varies from 7 to 19 hours.

ABDOMINAL PAIN

The pain associated with diseases of the abdominal viscera causes similar signs regardless of the viscus or organ involved and careful clinical examination is necessary to locate the site of the lesion. The manifestations of abdominal pain vary with the species, with horses being particularly sensitive, but they are comprised largely of abnormalities of behavior and posture. Pain as a systemic state is presented in general terms in Chapter 5, including its effects on body systems and methods for its detection.

Readily identifiable syndromes of abdominal pain referable to the alimentary tract include the following.

Horses

- Acute pain: Pawing, flank-watching, rolling
- Subacute pain: Lesser degree of flank-watching, often excessive pawing, lying down frequently without rolling, stretching out as if to urinate, males may extrude the penis, walking backward, dog-sitting posture, lying on back, impulsive walking
- Peritoneal pain: Rigidity of the abdominal wall, pain on palpation.

Cattle

- Acute pain: Downward arching of back with treading of the hind feet, lying down (rolling is uncommon), calves will lie down and bellow with severe abdominal pain, as in abomasal torsion
- Subacute pain, including peritoneal pain: Back arched upward, grunting on walking or lying down, grunting on deep palpation of the abdomen, immobility

DIFFERENTIAL DIAGNOSIS

The disease states likely to be mistaken for the above categories of alimentary tract pain are

- Acute pain: Paresthesia, e.g., in photosensitive dermatitis of cows; pleuropneumonia in the horse; uterine torsion in the mare and cow; urticaria as in milk allergy in cows; renal and urethral colic; compulsive walking, e.g., in hepatic disease; lead poisoning; dysuria or obstruction of urinary tract generally; laminitis; and lactation tetany in mares
- Subacute pain: Encephalopathy, possibly hepatic insufficiency

COMMON CAUSES OF ALIMENTARY TRACT PAIN

Horses

- Acute pain: All causes of intestinal obstruction, gastric dilatation, enteritis generally, acute colitis, rarely salmonellosis
- Subacute pain: Thromboembolic colic, impaction of the large intestine, ileal hypertrophy

Cattle

- Acute pain: Intestinal obstruction, especially by phytobezoars; poisoning by kikuyu grass, *Andromeda* sp., *Oleander* sp., and water hemlock (*Cicuta* sp.)
- Subacute pain: Traumatic reticuloperitonitis and peritonitis generally, abomasal volvulus

TENESMUS

Tenesmus, or persistent straining, is common in many diseases of the organs of the pelvic cavity; therefore, it is not necessarily a diagnostic sign of disease in the lower alimentary tract. It is sometimes associated with frequent defecation caused by neurologic stimulation of peristalsis. Common causes of tenesmus are listed by species in the following sections.

Cattle

- Lower alimentary tract disease, e.g., colitis and proctitis caused by coccidiosis
- Genital tract disease, e.g., severe vaginitis, retained placenta
- Estrogen toxicity in steers, e.g., estrogen implantation, fusariotoxicosis
- 4-Aminopyridine poisoning, methiocarb poisoning
- Lower spinal cord lesions: spinal cord abscess, rabies
- Idiopathic

Horses

- Tenesmus does not usually occur except during parturition.

Pigs

- Constipation in parturient sows; also dystocia

SHOCK AND DEHYDRATION

Acute rapid distension of the intestine or stomach causes reflex effects on the heart, lungs, and blood vessels. The blood pressure falls abruptly, the temperature falls below normal, and there is a marked increase in heart rate. In acute intestinal accidents in horses that terminate fatally in 6 to 12 hours, shock is the major cause of death. There appears to be some species difference in the susceptibility to shock because similar accidents in cattle rarely cause death in less than 3 to 4 days; acute ruminal tympany is an exception and may exert its effects rapidly, causing death in a very short time after its onset. Less severe distension, vomiting, and diarrhea cause clinically recognizable dehydration and abnormalities of electrolyte concentration and acid-base balance. Determination of the relative importance of shock and dehydration in a particular case at a particular time is one of the challenges in gastroenterology. The subject is considered in detail in a later section.

ABDOMINAL DISTENSION

Distension of the abdomen is a common manifestation of disease of the alimentary tract. Generally, abdominal distension associated with the alimentary tract is caused by **distension of viscera** with **gas** or **fluid**. The degree of abdominal distension depends on the viscera that are distended, the species involved, and the age of the animal. Abdominal distension is most pronounced when large viscera of adult cattle and horses are distended. Distension of the small intestines in adult cattle and horses is not reliably detected on rectal examination but can be detected by percutaneous ultrasound examination of the abdomen.[12-14]

Occasional cases of abdominal distension are caused by **pneumoperitoneum**, which usually follows abdominal surgery. In ruminants the most common causes are distension of the rumen, abomasum, cecum, and large intestine, and the details of which are presented in Chapter 8. Abdominal distension in horses and pigs is usually caused by distension of the large intestine. Gastric dilatation of the horse does not cause abdominal distension. Ascites is a cause of abdominal distension in all species but can be difficult to detect in horses.

Abdominal distension can be symmetric, asymmetric, or more pronounced dorsally or ventrally on one or both sides. The severity can vary from mild and barely detectable to so severe that the skin over the abdominal wall has sufficient tension that it cannot be picked up or "tented." Determination of the cause of the distension requires careful examination of the abdomen by inspection, palpation, percussion, and simultaneous auscultation. Rectal palpation is used to determine the location and nature of

distended viscera. Diseases of other body systems that cause abdominal distension and must be considered in the differential diagnosis include advanced pregnancy and hydrops allantois.

The alimentary tract diseases of simple-stomached animals in which abdominal distension can be a manifestation include the following:

- Intestinal tympany: Caused by excessive gas production caused by abnormal fermentation in the large intestine of horses and pigs
- Obstruction of the large intestine: In horses and pigs as a result of their torsion or miscellaneous constrictions caused by adhesions, usually as a result of peritonitis
- Retention of the meconium: In foals this is often accompanied by severe distension of the colon and abdomen

Obstruction of the small intestine may cause abdominal distension but not to the degree that occurs in distension of the large intestine. In all the previously mentioned diseases, acute abdominal pain is common.

ABNORMAL NUTRITION

Failure of normal motor, secretory, digestive, or absorptive functions causes impairment of the nutrient supply to body tissues. Inanition or partial starvation results, and the animal fails to grow, loses BW, or shows other signs of specific nutritional deficiencies. Ancillary effects include decreased appetite when gut motility is decreased; in many cases in which motility is increased and there is no toxemia, the appetite is increased and may be voracious.

Special Examination

The general aspects of the clinical examination of the alimentary tract and abdomen of farm animals are described in Chapter 1. Some additional or special examination techniques and procedures are included in the following sections.

NASOGASTRIC INTUBATION

RUMEN OF CATTLE

Examination of the rumen contents is often essential to assist in determination of the state of the rumen environment and digesta. Passage of a stomach tube into the rumen will determine the patency of the esophagus and if there is increased intraruminal pressure associated with a frothy or free-gas bloat. In a free-gas bloat, large quantities of gas are usually released within a minute. In a frothy bloat, the ruminal end of the tube may become occluded by the froth and very little if any gas is released. Moving the tube back and forth within the rumen and blowing air into the tube to clear the ruminal end may result in the release of some gas.

When the tube is in the rumen, some **rumen juice** can be siphoned or pumped out and collected in an open beaker for field and laboratory analysis. The **color**, depending on the feed to a limited extent, will be green, olive-green or brown-green. In cattle on **pasture** or being fed good quality hay, the color is **dark green**. When **silage or straw** is the diet the color is **yellow-brown**. In grain overload the color is **milky gray**, and in rumen stasis of long duration with putrefaction, the color is **greenish-black**. The **consistency of the rumen contents** is normally slightly viscid, and watery rumen content is indicative of inactive bacteria and protozoa. **Excess froth** is associated with frothy bloat as in primary ruminal tympany or vagus indigestion. The **odor** of the rumen contents is normally aromatic and, although somewhat pungent, not objectionable to the nose. A **moldy, rotting odor** usually indicates protein putrefaction, and an intensely sour odor indicates an excess of lactic acid formation caused by grain or carbohydrate engorgement. The **pH of the rumen juice** varies according to the type of feed and the time interval between the last feeding and taking a sample for pH examination. The normal range, however, is between 6.2 and 7.2. The pH of rumen juice should be examined immediately after the sample is obtained, using a wide range pH (1–11) paper. **High pH values** (**8–10**) will be observed when putrefaction of protein is occurring in the rumen or if the sample is mixed with saliva. Low pH values (4–5) are found after the feeding of carbohydrates. Generally, a **pH below 5** indicates **carbohydrate engorgement**; this pH level will be maintained between 6 and 24 hours after the animal has actually consumed the carbohydrate diet. Microscopic examination of a few drops of rumen fluid on a glass slide with a low-power field will reveal the level of protozoon activity. Normally five to seven protozoans are active per low-power field. In lactic acidosis the protozoa are usually absent or a few dead ones are visible.

DECOMPRESSION OF DISTENDED RUMEN

In adult cattle with severe abdominal distension caused by gross distension of the rumen it is difficult, if not impossible, to assess the status of the abdomen. To determine whether the rumen is distended and/or to relieve the pressure a large-bore stomach tube should be passed (Colorado Kingman tube: 2 m long and 3-cm inside diameter). In vagus indigestion, the rumen may be grossly distended with fluid contents, which will gush out through a large-bore tube. In some cases 100 to 150 L of rumen contents may be released. If no contents are released the contents may be frothy or mushy and the rumen end of the tube will plug almost instantly. Rumen lavage may then be attempted using a water hose to deliver 20 to 40 L of water at a time followed by back drainage using gravity flow. After the rumen is partially emptied it is usually possible to more accurately assess the rumen and the abdomen.

DECOMPRESSION OF THE HORSE'S STOMACH

Attempts to pass a nasogastric tube in the horse will usually detect complete or partial obstruction of the esophagus. In gross distension of the stomach in the horse, there is an immediate rush of fluid contents as soon as the cardia is passed (**gastric reflux**). The technique of gastric decompression is therapeutic and diagnostic. Gastric distension is a highly painful feature of some colic cases, and the mere pain relief of gastric decompression facilitates the clinical examination. The retrieval of significant volumes (2 L or more) of sequestrated gastric fluid is also an extremely specific indicator of intestinal obstruction, especially small-intestinal obstruction, and a reasonably specific indicator that surgical intervention is necessary.

MEDICAL IMAGING

RADIOGRAPHY

Because of their large size, and the presence of substantial amounts of gas in the large intestine, abdominal radiography has not been used routinely as a diagnostic aid in mature horses with abdominal pain. Similarly, in mature cattle the sheer size of the abdomen and the gas in the rumen has not favored abdominal radiography except for identifying the presence of metal objects in the reticulum. **Esophageal radiography** is, however, useful for the diagnosis of disorders of swallowing in horses.

Foals, calves, and small horses are too small to be palpated per rectum, and abdominal radiography, with and without contrast media, has been used diagnostically in colic of foals. A standard lateral abdominal radiography is a valuable diagnostic aid in the foal with colic. The site of the lesion, whether gastric, small, or large intestinal, or a combination of all three, can be determined from the radiographs. The **sensitivity of radiography** in detecting gastrointestinal lesions in neonatal foals was found to be 96%, and the specificity was 71%.

Knowledge of the radiographic appearance of the normal neonatal abdomen is important before lesions can be reliably detected. The standing lateral radiographic of the normal abdomen of the neonatal foal is characterized by the following:

- A gas cap over fluid and ingesta in the stomach
- Small collections of gas in the small intestine in the cranial and midcentral abdomen

- Gas caps over fluid and ingesta in the cecum and large colon, seen in the caudodorsal abdomen
- Small amounts of gas in the small colon and inconsistent gas in the rectum, seen at the pelvic inlet

Abdominal radiography has also been used for the diagnosis of enterolithiasis and sand accumulation as causes of colic.[15-18] The technique provides a high positive predictive value and is cost-effective in high-prevalence areas.

ABDOMINAL ULTRASONOGRAPHY

Abdominal ultrasonography has been used to identify small intestine intussusceptions, large-colon displacements, abdominal viscera, and neoplasms. The technique requires only several minutes in the hands of an experienced clinician.[14]

Horse

Abdominal ultrasonography is a diagnostic aid that is used for evaluation of equine colic and to assist in differentiation of medical from surgical colics.[19-21]

It is accurate in identifying horses with abnormal small intestines. Completely distended small intestine is associated with an increased risk of strangulating obstruction (odds ratio [OR] 6.3), inability to visualize the left kidney (OR 31 for left dorsal displacement), and thickened large colon (OR 12 for large-colon strangulating volvulus).[22] Detecting increased thickness of the wall of the large intestine during ultrasonography is a reproducible and accurate preoperative test for large-colon torsion in horses with surgical colic localized to the large colon.[20] The duodenum of the horse can be evaluated by ultrasonography. The technique has been used to detect large-intestinal sand accumulations.[23] Gastrointestinal activity patterns have been evaluated in healthy horses using B-mode and Doppler ultrasonography.[24] The anatomy and biometric analysis of the thoracic and abdominal organs in healthy foals from birth to age 6 months have been evaluated with ultrasonography.[25]

Cattle

Abdominal ultrasonography is an ideal diagnostic aid for the investigation of gastrointestinal diseases, the most common of which include traumatic reticuloperitonitis, left and right displacement of the abomasum, duodenal obstruction, hemorrhagic bowel syndrome, omasal disease, ileus of the small intestine, and dilatation and displacement of the cecum.[12,13,26] The various divisions of the small intestine can be differentiated from one another with the exception that the ileum cannot be differentiated from the jejunum. In normal cows, in which the intestine is full of ingesta, all parts of the intestine have a relatively large diameter. In cows with ileus, the loops of intestine proximal to the ileus are distended, and those distal to the ileus are empty.

ENDOSCOPY

Gastroscopic examination is limited to monogastric animals and has particular utility in horses and foals. It is useful in confirming the presence or absence of gastric ulcers, impaction, neoplasia, and inflammatory disease. The procedure involves passage of a flexible endoscope of at least 3 m in length for the adult horse and approximately 13 mm in diameter.[27] Case preparation is important to ensure that the stomach and proximal duodenum can be completely visualized. Feed should be withheld for approximately 16 hours and water for no less than 1 hour. Horses are usually sedated before commencing the examination. Insufflation of the stomach is essential for a thorough examination, although it has been associated with segmental volvulus in a small number of cases.[28]

A complete examination of the stomach is important, and the presence or absence of squamous ulceration cannot be used as a predictor for the presence or absence of glandular ulceration.[27] Observation of the squamous mucosa is relatively easy, whereas passage through to the pyloric antrum is more technically demanding. However, observation of the pyloric antrum is critical because the majority of glandular ulceration occurs in this region.[29-31] Observation of the most ventral portion of the fundus is typically not possible because of the presence of fluid. The fluid can be suctioned out via the biopsy channel of the gastroscope; however, this is usually not necessary because ulceration in this region is rare.[27]

LAPAROSCOPY

In this procedure a laparoscope is passed through an incision in the abdominal wall of either the left or right paralumbar fossa. Feed must be withheld for 36 hours, analgesia is provided during the procedure, and abdominal insufflation with carbon dioxide is required to separate the viscera for viewing. Laparoscopy in standing horses is a valuable diagnostic aid for examination of the structures in the dorsal regions of the abdomen. In the standing horse, the anatomic structures of importance that can be viewed in the left half of the abdomen are the hepatic duct, left lateral and quadrate lobes of the liver, stomach, left kidney with associated nephrosplenic ligament, segments of the jejunum, descending colon and ascending colon, left side of the male and female reproductive tracts, urinary bladder, vaginal ring, and mesorchium. The important structures observable in the right side of the abdomen are the common hepatic duct, left lateral, quadrate and right lobes of the liver, caudate process of the liver, stomach, duodenum, right dorsal colon, epiploic foramen, omental bursa, right kidney, base of the cecum, segments of jejunum, descending colon and ascending colon, urinary bladder, right half of the male and female reproductive tracts, and rectum.

In the dorsally recumbent horse under general anesthesia, with laparoscopy the main structures of diagnostic relevance in the caudal region of the abdomen are the urinary bladder, mesorchium, ductus deferens (left and right), left and right vaginal rings, insertion of the prepubic tendon, random segments of jejunum and descending colon, the pelvic flexure of the ascending colon, body of the cecum, and cecocolic fold. The main structures observed in the cranial region of the abdomen are the ventral surface of the diaphragm; falciform ligament and round ligaments of the liver; ventral portion of the left lateral, left medial, quadrate, and right lateral lobes of the liver; spleen; right and left ventral colons; sternal flexure of the ascending colon; apex of the cecum; and stomach. Alterations in cardiovascular and respiratory functions in response to the pneumoperitoneum and various positional changes indicated a need for continuous and thorough anesthetic monitoring and support.

EXPLORATORY LAPAROTOMY (CELIOTOMY)

An exploratory laparotomy is useful for palpating and inspecting the abdominal viscera as a diagnostic aid in cattle, sheep, and horses of all ages. Cost and time are important factors, but if abdominal disease is suspected and other diagnostic techniques cannot identify the location and nature of the abnormality, a laparotomy is highly desirable.

TESTS OF DIGESTION AND ABSORPTION

Digestion and absorption of nutrients are complex, interrelated functions of the gastrointestinal tract. Failure in one or more of normal motility and enzymatic digestion of food and absorption of simple sugars, fat, and protein by the small intestine can result in inadequate assimilation of nutrients from the gastrointestinal tract. Tests of small-intestinal digestion, absorption, or both have been devised for use in monogastrics. These tests take advantage of the rapid appearance in blood of products of digestion, or of compounds that are readily absorbed without digestion.

Indications for these tests include the following:

- Weight loss of undetermined cause suspected to be from failure of absorption of food by the small intestine
- Diarrhea of suckling foals suspected to be from failure of the foal to digest lactose (lactase deficiency)

- Suspected protein-losing enteropathy of older foals and adult horses

Low serum protein and albumin concentrations with small-intestinal disease can be caused by failure of digestion of proteins and absorption of amino acids or leakage of plasma proteins into the intestine. Some horses with protein-losing enteropathy have abnormal tests of intestinal digestion and absorption of sugars. **Contraindications** include the presence of obstructive lesions of the gastrointestinal tract, risk of worsening the disease process by the period of fasting required for most of the tests (such as in ponies with hyperlipemia), or known adverse reactions of the animal to any of the test substances.

Interpretation of the test is based on the concentration of the variable of interest (usually glucose or xylose) in blood over a period of time after administration of the test meal (usually by nasogastric intubation). Concentration of the metabolite or marker of interest in blood is plotted against time, and the shape of the curve, highest concentration attained, time to attain the highest concentration, and elevation over baseline values (i.e., those measured immediately before administration of the test meal) are compared against values obtained from clinically normal horses or foals. Blood concentrations of glucose or xylose that are lower than expected (so called "flat curve") can be indicative of alterations in gastrointestinal function that hinder propulsion, digestion, or absorption of nutrients. Thus tests of digestion and absorption alone rarely provided sufficient information to make a definitive diagnosis of the functional disorder. The exception to this rule is the modified lactose tolerance test in foals (see later). Interpretation of the results of oral tests of absorption is often confounded by factors that alter gastrointestinal function, such as feed withholding or enteritis or conditions that alter removal of the test compound from blood like reduced insulin sensitivity. This is particularly the case for tests that depend on measurement of blood glucose concentration. Blood glucose concentrations are determined in the absorptive state by the difference in rates of absorption of glucose from the small intestine into blood and removal of glucose from blood by uptake into muscle, adipose tissue, and metabolically active tissues. Conditions that enhance glucose uptake from the blood can result in low peak blood glucose concentrations, and conditions that decrease insulin sensitivity (as is seen in fat horses) can result in high blood glucose concentrations. The use of D-xylose as an indicator of small-intestinal absorption is intended to avoid these effects of variable glucose disposal. Therefore the values obtained with oral tests of absorption and digestion should be interpreted with caution and should be considered in light of all clinical and laboratory data available for the animal. Sedation does not affect D-xylose uptake in horses.[32]

GLUCOSE ABSORPTION TEST

The oral glucose tolerance test is one of the simplest tests of small-intestinal absorptive capacity to perform. However, because of the many factors that affect blood glucose concentration, including factors not related to small-intestinal absorptive capacity, results of the test can on occasion be difficult to interpret. Oral glucose tolerance testing can produce abnormal results in horses with diseases that do not involve the small intestine, such as lower motor neuron disease or polysaccharide storage myopathy. On the other hand, the oral glucose tolerance test is often used because of the ready availability of glucose for oral administration and routine nature of measurement of blood glucose concentrations.

The main indications for performing oral glucose tolerance testing include unexplained weight loss believed to be associated with gastrointestinal disease and suspected protein-losing enteropathy. Contraindications are those listed previously. In addition, care should be exercised in performing the test in horses at increased risk of laminitis, because rapid passage of unabsorbed glucose into the large colon and cecum can cause laminitis.

Horses undergoing oral glucose tolerance testing are first fasted for 12 to 18 hours. Access to water should be provided. Glucose is given by stomach tube at 1 g/kg BW of anhydrous glucose (or comparable) as a 10% to 20% solution in water. Blood for measurement of glucose concentration is collected immediately before and every 30 minutes for 4 to 6 hours after glucose administration. Some protocols involve less frequent (hourly) collection of blood. One protocol requires collection of blood samples before and 120 minutes after administration of glucose. This last protocol is not recommended because early or delayed peaks in blood concentration are not detected. The blood glucose concentration in the normal horse increases by at least 85% (from 90 up to 180 mg/dL [5.0–10.0 mmol/L]) with peak blood concentrations attained 90 to 150 minutes after administration of glucose. Horses with partial malabsorption have increases in blood glucose concentration of 15% to 85% of baseline values, and horses with complete malabsorption have no increase or less than 15% increase in blood glucose concentration by 2 hours. Blood concentrations of glucose in normal horses return to resting values in approximately 6 hours. The shape of the curve is affected by the horse's previous diet, and the curve is much lower in horses fed on stored feeds such as hay and grain compared with horses eating pasture of clover and grass.

Horses with weight loss and complete failure of absorption of glucose are likely to have extensive infiltrative disease of the small intestine such as lymphosarcoma or granulomatous enteritis. Of 25 horses with partial failure of glucose absorption, 18 (62%) had structural abnormalities of the small intestine. Clearly abnormal results of the oral glucose tolerance test appear to be fairly specific for severe and widespread small-intestinal disease. Care should be taken when interpreting results that deviate only marginally from normal values.

STARCH DIGESTION TEST

A suitable test for the evaluation of gastric, small-intestinal, and pancreatic function is the starch digestion test. The test relies on the presence of amylase in the small intestine with subsequent cleavage of starch into glucose, which is then absorbed into the blood. The horse is fasted for 18 hours and then given corn starch (1 kg in 4 L of water or 2 g/kg BW) by stomach tube. A pretreatment blood sample is matched with others taken at 15, 30, 60, 90, and 120 minutes and then hourly to 6 hours.

In the normal horse there is an increase in blood glucose levels of about 30 mg/dL (1.7 mmol/L; from 90 up to 120 mg/dL [5.0–6.7 mmol/L]), with the peak occurring at 1 to 2 hours and the curve returned to pretreatment level at 3 hours. The test can be affected by the diet of the horse before testing.

LACTOSE DIGESTION TEST

Newborn animals rely on ingestion of milk sugar (lactose) as an important source of energy until weaning. Lactose is digested in the proximal small intestine by lactase, a disaccharidase present in the brush border of intestinal epithelial cells that cleaves lactose into glucose and galactose. Loss of small-intestinal production of lactase, such as occurs in some bacterial and viral enteritides including rotavirus infection, results in failure to cleave lactose and passage of the sugar to the hind gut. Fermentation of lactose in the hind gut causes acute and sometimes severe osmotic diarrhea. A prime indication for the oral lactose tolerance test is therefore acute diarrhea in neonates being fed milk. The test is also important because a positive test (i.e., demonstration of lactose intolerance) provides a clear indication for feeding lactose-free milk or providing supplemental lactase in the animal's diet.

An oral lactose digestion test has been devised for foals. Lactose (1 g/kg BW) is given by stomach tube in a 20% solution to a foal that has been fasted for 2 to 4 hours. In foals and young horses up to 3 years of age there is a rise in blood glucose levels from 86 ± 11 mg/dL (4.8 ± 0.1 mmol/L) up to 153 ± 24 mg/dL (8.5 ± 1.3 mmol/L), with a peak achieved in 90 minutes, and the level returns to pretreatment levels in 5 hours. In foals of 1 to 12 weeks of age the plasma glucose concentration should rise by at least 35 mg/dL

(1.9 mmol/L) and peak within 40 minutes of the administration of the lactose. With this test no changes in blood sugar levels occur in horses over 4 years of age. Instead there is abdominal discomfort followed by diarrhea, with feces the consistency of cow feces for the next 24 hours. Sucrose and maltose are readily digested by the intestine of the adult horse, but not by newborn foals. Maximum levels of the relevant intestinal disaccharidases (sucrase and maltase) are not achieved until 7 months of age. The oral lactose digestion test is likely to be of value as a monitor of epithelial damage in young horses. In humans the ability to hydrolyze lactose is one of the first functions of the intestinal mucosa to be lost in which there is epithelial damage in the gut. It is also one of the last functions to return in the recovering patient. The loss of intestinal lactase may be the pathogenetic basis of the diarrhea that occurs in rotavirus infections in neonates. Lactase digestion is impaired in calves with mild diarrhea. Calves with acute diarrhea are in a catabolic state and respond with a larger increase in plasma glucose concentration to a given amount of glucose than do healthy calves.

A modification of the oral lactose tolerance test in foals includes a second evaluation in foals in which there is failure of blood glucose concentrations to increase by the appropriate amount after oral administration of lactose. At least 8 hours after the first test, foals are fed a meal of lactose-free milk, or of milk to which lactase has been added. Blood glucose concentrations are measured, and an increase of at least 35 mg/dL (1.9 mmol/L) is interpreted as evidence of lactase deficiency. Such animals can then be maintained on a diet of lactose-free milk. Diarrhea usually resolves in 24 hours but returns within hours of feeding milk containing lactose.

An alternative to the lactose tolerance tests described earlier is to simply feed the foal lactose free milk for several days. The foal must not have access to mare's milk or milk-based feed supplements during this time. Some foals have prompt resolution of diarrhea when fed only lactose-free milk.

XYLOSE ABSORPTION TEST

D-Xylose is used to evaluate small-intestinal absorptive function because it is not metabolized by tissues, which is an advantage over the oral glucose tolerance test. D-xylose absorbed from the intestinal tract is excreted unchanged in the urine within 15 hours of dosing. Concentrations of D-xylose in blood are therefore dependent only on the rate of absorption from the intestine and rate of excretion into the urine. However, the compound is more expensive than glucose, and measurement of D-xylose in blood requires a particular analysis that might not be readily available. Indications for the test are the same as those for the oral glucose tolerance test described earlier.

D-Xylose, at a dose rate of 0.5 g/kg BW as a 10% solution, is administered by stomach tube after a starve of 18 hours. A maximum blood xylose level of 30 mg/dL (2.0 mmol/L) at 1.5 hours is a normal result in adult horses. In normal foals the peak blood concentration of xylose is reached in 30 to 60 minutes, and the level attained varies with age, being highest (47 mg/dL [3.14 mmol/L]) at 1 month of age and lowest (19 mg/dL [1.25 mmol/L]) at 3 months (the pretreatment reading should be zero). In abnormal horses the xylose curve is flat (a peak of 7–13 mg/dL [0.5 mmol/L] at 60 to 210 minutes) contrasted with a peak of 20 mg/dL [1.3 mmol/L] at 60 minutes in normal horses. As an initial checking test, one postdosing sample at 2 hours is recommended.

Interpretation of the test is influenced by the customary diet of tested animals and feed deprivation. Horses receiving a high-energy diet have a lower absorption curve than horses on a low-energy diet. The test is also affected by the duration of deprivation of feed. In mares deprived of feed for 72 and 96 hours, the rate of D-xylose absorption and the maximum concentrations of D-xylose in plasma were reduced. For example, apparent low absorption can be caused by increased transit time through the gut, perhaps from to excitement.

Low blood concentrations of xylose occur in horses with small-intestinal infiltrative disease, such as lymphosarcoma or granulomatous enteritis. The test appears to be quite specific (low false-positive rate) for small-intestinal disease, but the sensitivity (false-negative rate) is unknown. Peak xylose concentration is significantly ($P = 0.048$) higher in horses with suspected inflammatory bowel disease that survive (1.36 ± 0.44 mmol/L) than nonsurvivors (0.94 ± 0.36 mmol/L).[33]

A D-xylose absorption curve has been determined for cattle. The xylose (0.5 g/kg BW) is deposited in the abomasum by abomasocentesis, and a peak of blood glucose is attained in about 90 minutes.

SUCROSE ABSORPTION TEST

The sucrose absorption test differs from the other tests in this section in that abnormal results are associated with detection of sucrose in blood or urine of horses. Sucrose is not normally absorbed intact; it is usually cleaved by disaccharidases in the small intestine into glucose and fructose, which are then absorbed. Intact sucrose is absorbed across compromised gastric mucosa, and detection of sucrose in blood or urine indicates the presence of gastric ulceration, because mammals neither synthesize nor metabolize sucrose. The sucrose absorption test involves administration of 250 g of sucrose to an adult horse that has been fasted overnight. Blood samples for measurement of serum sucrose concentration are collected at 0, 15, 30, 45, 60, and 90 minutes after dosing. Alternatively, a urine sample is collected 2 hours after dosing (the bladder must be emptied immediately before dosing). Peak serum sucrose concentrations occur 45 minutes after administration, and peak values correlate with the severity of gastric ulceration. Horses with minimal lesions have serum sucrose concentrations of 103 pg/μL, whereas horses with the most severe lesions have concentrations of 3400 pg/μL.

RADIOACTIVE ISOTOPES

A technique used for determining whether a protein-losing enteropathy is present is based on the examination of feces for radioactivity after the intravenous administration of a radioactive agent. ^{51}Cr ^{13}C-labeled plasma protein has been used for this purpose. Similarly, administration of radioactively labeled leukocytes reveals the presence of small-intestinal inflammatory disease in horses. The test is quite specific, in that false-positive tests are uncommon, but not very sensitive.

ABDOMINOCENTESIS FOR PERITONEAL FLUID

Peritoneal fluid reflects the pathophysiological state of the parietal and visceral mesothelial surfaces of the peritoneum. Collecting a sample of peritoneal fluid is useful in the diagnosis of diseases of the peritoneum and the abdominal segment of the alimentary tract. It is of vital importance in horses in the differential diagnosis and prognosis of colic and in cattle in the diagnosis of peritonitis.

EQUINE AND BOVINE PERITONEAL FLUID

Normal peritoneal fluid is a transudate with properties as summarized in Tables 7-2 and 7-3. It has functions similar to those of other tissue fluids. It contains mesothelial cells, lymphocytes, neutrophils, a few erythrocytes, and occasional monocytes and eosinophils. The following general comments apply:

- It can be examined in terms of physical characteristics, especially color, translucence, specific gravity, clotting time, biochemical composition, cell volume, cell morphology, and cell type.
- Examination of the fluid may help determine the presence in the peritoneal cavity of
  - Peritonitis (chemical or infectious)
  - Infarction of a segment of gut wall
  - Perforation of the alimentary tract wall
  - Rupture of the urinary bladder
  - Leakage from the biliary system
  - Intraperitoneal hemorrhage
  - Peritoneal neoplasia
- The reaction of the peritoneum varies with time, and a single examination can be dangerously misleading. A series of examinations may be necessary, for example, in acute cases at intervals of as short as an hour.

Table 7-2 Guidelines for the classification and interpretation of bovine peritoneal fluid

Classification of fluid	Physical appearance	Total protein (g/dL)	Specific gravity	Total RBC × 10^6/μL	Total WBC × 10^6/μL	Differential WBC count	Bacteria	Particulate matter (plant fiber)	Interpretation
Normal	Amber, crystal clear 1–5 mL per sample	0.1–3.1 (1.6) Does not clot	1.005–1.015	Few from puncture of capillaries during sampling	0.3–5.3	Polymorphonuclear and mononuclear cells, ratio 1 : 1	None	None	Increased amounts in late gestation, congestive heart failure
Moderate inflammation	Amber to pink, slightly turbid	2.8–7.3 (4.5) May clot	1.016–1.025	0.1–0.2	2.7–40.7 (8.7)	Nontoxic neutrophils, 50%–90%; macrophages may predominate in chronic peritonitis	None	None	Early stages of strangulation, destruction of intestine; traumatic reticuloperitonitis; ruptured bladder; chronic peritonitis
Severe inflammation	Serosanguineous, turbid, viscous 10–20 mL per sample	3.1–5.8 (4.2) Commonly clots	1.026–1.040	0.3–0.5	2.0–31.1 (8.0)	Segmented neutrophils, 70%–90%; presence of (toxic) degenerate neutrophils containing bacteria	Usually present	May be present	Advanced stages of strangulation obstruction; acute diffuse peritonitis; perforation of abomasal ulcer; rupture of uterus, stomachs, or intestine

RBC, red blood cell; WBC, white blood cell.

Table 7-3 Characteristics of equine peritoneal fluid in selected diseases of horses

Disease	Protein concentration	Total nucleated cell count	Cytological comments	Other variables	Comments
Normal horse	<2.1 g/dL <21 g/L	<9 × 10^9 cells/L <9 × 10^3 cells/μL (TNCC is usually substantially lower in clinically normal horses)	Approximately 50% each of nondegenerate neutrophils and mononuclear cells	Lactate <1 mmol/L (always < plasma (lactate)); Glucose <2.0 mmol/L different from blood glucose; pH > 7.45; fibrinogen < 300 mg/dL (3 g/L) Creatinine = serum creatinine No red blood cells	Clear and slightly yellow Not malodorous Culture does not yield growth
Normal late gestation mare	<2.5 g/dL <25 g/L	<0.9 × 10^9 cells/L <900 cells/μL	<40% neutrophils; no degenerative changes. <20% lymphocytes	Fluid usually readily obtained; clear and slightly yellow	
Normal postpartum (<7 days) mare	<2.5 g/dL <25 g/L	<5.0 × 10^9 cells/L <5.0 × 10^3 cells/μL	<50% neutrophils; no degenerative changes <10% lymphocytes	Fluid usually readily obtained; clear and slightly yellow	
Dystocia but clinically normal mare (1 day)	<2.5 g/dL <25 g/L	2.7 × 10^9 (3.9) cells/L* 2.7 × 10^3 (3.9) cells/μL	50%–90% nondegenerate neutrophils; 40% mononuclear cells and 10% lymphocytes	Fluid clear and yellow Essentially normal fluid with small increases in TNCC and protein concentration	
Dystocia and clinically abnormal mare (uterine rupture, vaginal tear)	4.4 (1.3) g/dL* 44 (13) g/L	27 × 10^9 (35) cells/L* 27 × 10^3 (35) cells/μL	70%–100% neutrophils, some of which are degenerate, <10% mononuclear cells and <10% lymphocytes	Increased red blood cell count	Fluid yellow or serosanguinous and cloudy; can be malodorous; culture can yield variety of bacteria; red cell count in mares with middle uterine artery rupture is high with normal TNCC

Continued

Table 7-3 Characteristics of equine peritoneal fluid in selected diseases of horses—cont'd

Disease	Protein concentration	Total nucleated cell count	Cytological comments	Other variables	Comments
Peritonitis, septic	5.2 (4.0–6.0) g/dL† 50 (40–60) g/L	131 (7–700) × 10^9 cells/L† 131 (7–700) × 10^3 cells/μL	Almost all neutrophils, many of which have degenerative changes Some neutrophils contain bacteria in many cases; plant material with rupture of intestine	pH < that of blood; glucose < blood (difference < 2.0 mmol/L or 50 mg/dL); peritoneal glucose < 30 mg/dL (1.5 mmol/L); fibrinogen > 200 mg/dL (2.0 g/L)	Fluid usually dark yellow, brown, or serosanguinous Can be green if severe rupture of intestine or stomach; cloudy. Malodorous; culture yields bacteria
Peritonitis, nonseptic (e.g., nonstrangulating, nonischemic obstructive lesion of the bowel)	2.7 (0.7–4.9) g/dL† 27 (7–49) g/L	13 (0.4–516) × 10^9 cells/L† 13 (0.4–516) × 10^3 cells/μL	Mostly neutrophils (>50%) Nondegenerate No bacteria detected No plant or foreign material	No abnormalities pH ≥ that of blood	Fluid yellow and clear Not malodorous; no bacteria isolated on culture
Strangulating intestinal lesion or ruptured intraabdominal viscus	5.2 (4.0–6.0) g/dL† 50 (40–60) g/L	131 (7–700) × 10^9 cells/L† 131 (7–700) × 10^3 cells/μL	Almost all neutrophils, many of which have degenerative changes Some neutrophils contain bacteria in many cases; plant material with rupture of intestine	Lactate 8.5 ± 5.5 mmol/L	Serosanguinous fluid Cloudy if ruptured
Nonstrangulating obstruction				Lactate 2.1 ± 2.1 mmol/L	
Peritonitis caused by *Actinobacillus equuli*	2.5–8.4 g/dL 25–84 g/L	46–810 × 10^9 cells/L 46–810 × 10^3 cells/μL	>80% neutrophils, most of which do not have signs of degeneration Low numbers of gram-negative pleomorphic rods, both intracellular and extracellular		Cream, orange, brown or red fluid; turbid; not malodorous; growth of *Actinobacillus equuli* on culture
Intraabdominal abscess	>2.5 g/dL >25 g/L	>10 × 10^9 cells/L >10 × 10^3 cells/μL	>80% nondegenerate neutrophils; usually no bacteria detected on Gram stain		Yellow to white; slightly cloudy; culture will occasionally yield × causative bacteria (usually *Streptococcus equi*)
Hemoperitoneum	3.2–6.3 g/dL 32–63 g/L	<10 × 10^9 cells/L <10 × 10^3 cells/μL	Differential similar to blood Mostly nondegenerate neutrophils, erythrophages, and hemosiderophages as hemorrhage resolves	High red cell count (2.4–8.6 × 10^{12} cells/L, 2.4–8.6 × 10^6 cells/μL)	Serosanguinous to frankly bloody
Intraabdominal neoplasia (lymphosarcoma, gastric squamous cell carcinoma)	<2.5 g/dL <25 g/L	<10 × 10^9 cells/L <10 × 10^3 cells/μL	Abnormal cells not detected in most cases Care should be taken not to mistake reactive lymphocytes for neoplastic lymphocytes		Clear and yellow; often subjective assessment of increased quantity (increased ease of collection of a large quantity of fluid)
Uroperitoneum	<2.5 g/dL <25 g/L	<10 × 10^9 cells/L <10 × 10^3 cells/μL	Normal differential, might see calcium carbonate crystals in adult horses with uroperitoneum	Creatinine > serum creatinine concentration Urea nitrogen > serum urea nitrogen concentration Potassium > serum potassium concentration	Large amount of fluid Clear to very pale yellow Uriniferous odor

TNCC, Total nucleated cell count.
**Mean (standard deviation [SD]).*
†*Median (range).*

- A significant reaction in the peritoneal cavity may be quite localized, so a normal sample of fluid collected at one point in the cavity may not be representative of the entire cavity.
- Changes in peritoneal fluid, especially its chemical composition, e.g., lactate level, may be a reflection of a systemic change. The examination of a concurrently collected peripheral blood sample will make it possible to determine whether the changes are in fact restricted to the peritoneal cavity.
- As in any clinicopathologic examination the results must be interpreted with caution and only in conjunction with the history and clinical findings.

Specific Properties of Peritoneal Fluid (Normal and Abnormal)

Color

Normal fluid is crystal clear, straw-colored to yellow. Turbidity indicates the presence of increased leukocytes and protein, which may include fine strands of fibrin.

A **green color** suggests food material; intense orange-green indicates rupture of the biliary system. A **pink-red color** indicates presence of hemoglobin; degenerated erythrocytes; entire erythrocytes; and damage to the vascular system by infarction, perforation, or hydrostatic pressure. A **red-brown color** indicates the late stages of necrosis of the gut wall, the presence of degenerated blood and hemoglobin, and damage to gut wall with hemorrhage.

Whole blood, clear fluid streaked with blood, or heavily bloodstained fluid indicates that the sample has been collected from the spleen or a blood vessel or that there is hemoperitoneum. Rupture of the uterus or bladder or dicoumarol poisoning are also possibilities.

A dark green sample containing motile protozoa with very few leukocytes and no mesothelial cells indicates that the sample has been collected from the gut lumen. Enterocentesis has little apparent clinical affect in normal horses, although an occasional horse will show a transient fever. However, puncture of a devitalized loop of intestine may lead to extensive leakage of gut contents and fatal peritonitis. The effect of enterocentesis of normal gut on peritoneal fluid is consistently to increase the neutrophilic count, which persists for several days.

Cellular and Other Properties

Surgical manipulation of the intestinal tract during exploratory laparotomy or intestinal resection and anastomosis in the horse results in a significant and rapid postoperative peritoneal inflammatory reaction. Manipulation of the viscera causes injury to the mesothelial surfaces. Total and differential nucleated cell counts, red blood cell numbers, and total protein and fibrinogen concentrations were all elevated on the first day after the surgery and remained elevated for up to 7 days in a study of this phenomenon.

In cattle, exploratory celiotomy and omentopexy result in an increase in the total nucleated cell count by a factor of 5 to 8, minor increases in specific gravity, and increases in total protein concentration by a factor of up to 2. These changes appear by 2 days after surgery and continue to increase through to day 6.

Particulate matter in peritoneal fluid suggests either fibrin clots/strands or gut contents caused by leakage from a perforated or ruptured gut wall.

High specific gravity and **high protein content** are indicative of vascular damage and leakage of plasma protein, as in peritonitis or mural infarction.

The **volume** and viscosity of fluid varies. A normal flow is 1 to 5 mL per sample. A continuous flow with 10 to 20 mL per sample indicates excess fluid caused by a ruptured bladder or ascites (clear yellow), acute diffuse peritonitis (yellow, turbid), and infarction or necrosis of gut wall (thin, red-tinged). The higher the protein content, as the peritoneal fluid shifts from being a transudate to an inflammatory exudate, the higher the viscosity becomes. Highly viscous fluid may clot.

Cells

A rapid staining method, using a modified Wright's stain, makes a stained slide ready for examination within 5 minutes. The value of the technique is in indicating the number of leukocytes and other cells present, and in differentiating the types of cell.

An **increase in total white cell count** of the fluid including a disproportionate number of polymorphonuclear cells indicates acute inflammation, which may have an infectious origin or else be sterile. An increase in mononuclear phagocytes from the peritoneum is an indication of chronic peritonitis. **Degenerate and toxic neutrophils** suggest the probability of infection being present. An increase in the number of **mesothelial cells** with the distinctive presence of actively dividing mitotic figures suggests neoplasia.

Bacteria found as **phagocytosed inclusions in leukocytes,** or by culture of fluid, indicate an infective peritonitis, which may arise by hematogenous spread, in which case the infection is likely to be a specific one. If there has been leakage from a peritoneal abscess the same comment applies, but if there is leakage through a segment of devitalized or perforated bowel wall there is likely to be a mixed infection and possibly particulate matter from bowel contents.

Entire erythrocytes, often accompanied by some hemoglobin, indicate either hemoperitoneum, in which case there should be active phagocytosis of erythrocytes, or that the sample has been inadvertently collected from the spleen. The blood is likely to be concentrated if there has been sufficient time for fluid resorption across the peritoneum. Splenic blood has a higher packed cell volume (PCV) also, but there is no erythrophagocytosis evident in the sample. A **PCV of less than 5%** in peritoneal fluid suggests extravasation of blood from an infarcted or inflamed gut wall; a PCV of more than 20% suggests a significant hemorrhage.

Abdominocentesis in Horses

In the horse the recommended site for paracentesis is on the ventral midline, 25 cm caudal to the xiphoid (or midway between the xiphoid and the umbilicus). Following surgical preparation and subcutaneous infiltration of an anesthetic, a stab incision is made through the skin and subcutaneous tissues and into the linea alba. A 9-cm long blunt-pointed bovine teat cannula, or similar metal catheter, with the tip wrapped in a sterile swab to avoid blood and skin contamination, is inserted into the wound and manipulated until the incision into the linea alba can be felt. With a quick thrust the cannula is pushed through the linea alba into the peritoneal cavity. A "pop" is often heard on entry into the peritoneal cavity. Failure to incise into the linea alba first will cause many cannulas to bend and break.

In most horses (about 75%) a sample of fluid is readily obtained. In others it takes a moment or two before the fluid runs out, usually spurting synchronously with the respiratory movements. Applying suction with a syringe may yield some fluid if there is no spontaneous flow. Normal fluid is clear, yellow, and flows easily through an 18-gauge needle. Two samples are collected, one in a plain tube and one in a tube with an anticoagulant. If the fluid clots readily a few drops should be placed and smeared out on a glass slide and allowed to dry for staining purposes.

In peritonitis, the total leukocyte count will increase markedly, but wide variation in the total count can occur between horses with similar conditions, and in the same horse within a period of hours. Variations are caused by the nature and stage of the lesion and by the total amount of exudate in the peritoneal cavity, which has a diluting effect on the total count. Total leukocyte counts ranging from 10,000 to 150,000 µL have been recorded in peritonitis and in infarction of the intestine in horses. Experimentally, the intravenous injection of endotoxin into horses causes marked changes in the peripheral blood cellular components, but there are no changes in the total white cell count of the peritoneal fluid.

In **healthy foals** the reference values for peritoneal fluid are different from adult horses. The maximum peritoneal fluid nucleated cell counts in foals are much lower than in adult horses (1.5×10 /L versus 5.0×10 /L). Nucleated cell counts greater than 1.5×10 /L should be interpreted as elevated.

Peritoneal fluid abnormalities in mares within a week of foaling should be attributed to a systemic or gastrointestinal abnormality and not to the foaling event. The nucleated cell count, protein concentration, fibrinogen concentration, and specific gravity of peritoneal fluid from recently foaled mares should be normal; however, differential cell counts may be abnormal for up to 1 week after foaling.

Risks

Abdominocentesis is not without some danger, especially the risk of introducing fecal contents into the peritoneal cavity and causing peritonitis. This appears to be of major importance only if there are loops of distended atonic intestine situated on the ventral abdominal wall. This is a common occurrence in the later stages of intestinal obstruction that is still amenable to surgery. Puncture of a devitalized loop of intestine may cause a leakage of intestinal contents and acute diffuse peritonitis, which is rapidly fatal. Penetration of a normal loop of intestine occurs often enough to lead to the conclusion that it appears to have no ill effects. If a sample of peritoneal fluid is an important diagnostic need in a particular case, and the first attempt at paracentesis causes penetration of the gut, it is recommended that the attempt be repeated, if necessary two or three times, at more posterior sites. Repeated abdominocentesis does not cause alterations in peritoneal fluid constituents, and any significant changes are likely caused by alterations in the disease state present. The technique most likely to cause bowel penetration is the use of a sharp needle instead of the blunt cannula recommended, and forcibly thrusting the cannula through the linea alba without a prior incision. When the suggested incision is made in the linea alba, the cannula can be pushed gently through while rotating it.

Abdominocentesis in Cattle

The choice of sites for paracentesis is a problem, because the rumen covers such a large portion of the ventral abdominal wall, and avoiding penetration of it is difficult. Cattle have a low volume of peritoneal fluid, and failure to obtain a sample is not unusual. The most profitable sites are those that, on an anatomic basis, consist of recesses between the forestomachs, abomasum, diaphragm, and liver. These are usually caudal to the xiphoid sternum and 4 to 10 cm lateral to the midline. Another recommended site is left of the midline, 3 to 4 cm medial, and 5 to 7 cm cranial to the foramen for the left subcutaneous abdominal vein. A teat cannula similar to the one described for use in the horse is recommended but, with care and caution, a 16-gauge 5-cm hypodermic needle may also be used. The needle or cannula is pushed carefully and slowly through the abdominal wall, which will twitch when the peritoneum is punctured. When this happens the fluid will usually run out into a vial without the aid of a vacuum. However, if it does not, a syringe may be used and the needle may be moved backward and forward in a search for fluid, with the piston of the syringe withdrawn. A further site is the right caudoventral abdominal wall medial to the fold of the flank, using a 3.8-cm 15-gauge needle.

In calves, a reliable technique includes the use of sedation with intravenous xylazine hydrochloride and diazepam. The animal is placed in left lateral recumbency with the right hindlimb pulled dorsally and caudally. One site slightly dorsal and caudal to the umbilicus is prepared together with another site in the center of the inguinal region. The site is prepared with local anesthetic, and a 14-gauge needle is introduced and directed slightly caudally and toward the midline while keeping it parallel to the inner abdominal wall once the peritoneal cavity is entered. A 3.5-gauge urinary catheter (1.2 mm × 56 cm sterile feeding tube) is inserted through the needle, and a 3-mL sterile syringe is attached to the catheter. Gentle suction is applied. The fluid is placed in a 2-mL tube containing tripotassium ethylenediaminetetraacetic acid (EDTA). A 14-gauge over-the-needle catheter can also be used, followed by insertion of a 3.5 French feeding tube. If fluid cannot be obtained from the first site, the inguinal site is used using the same basic technique and with the catheter directed slightly cranially toward the midline.

Failure to obtain a sample does not preclude the possibility that peritonitis may be present: the exudate may be very thick and contain large masses of fibrin, or the peritonitis may be localized. Also, animals that are dehydrated may have less peritoneal fluid than normal. Most animals from which samples cannot be obtained, however, are in fact normal. In animals in which peritonitis is strongly suspected for clinical reasons, up to four attempts at paracentesis should be made before aborting the procedure. The fluid should be collected into an anticoagulant, preferably EDTA, to avoid clotting.

Abnormal peritoneal fluid in cattle is a highly sensitive indicator of peritoneal disease, but not a good indicator of the *nature* of the disease. The most pronounced abnormalities occur in acute diseases of the peritoneum; chronic peritonitis may be accompanied by peritoneal fluid that is almost normal.

Examination of the fluid should take into account the following characteristics:

- Large amounts (10–20 mL) of serosanguineous fluid suggest infarction or necrosis of the gut wall.
- Heavily bloodstained fluid, whole blood, or fluid with streaks of blood through it are more likely to result from puncture of a blood vessel or from bleeding into the cavity, as in dicoumarol poisoning or with a neoplasm of the vascular system.
- The same sort of bloodstained fluid as previously discussed may accompany a ruptured uterus or bladder or severe congestive heart failure.
- Large quantities of yellowish-colored turbid fluid suggest acute diffuse peritonitis. The degree of turbidity depends on the number of cells and the amount of fibrin present.
- Particulate food material in the sample indicates perforation or rupture of the gut, except that penetration of the gut with the instrument during collection may be misleading. Such samples are usually heavily fecal in appearance and contain no mesothelial cells.
- Laboratory examination is necessary to derive full benefit from the sample. This will include assessment of the number and type of **leukocytes** present (the number is increased in peritonitis), neutrophils predominating in acute peritonitis, and monocytes in chronic forms; the number of **erythrocytes** present; whether **bacteria** are present inside or outside the neutrophils; and **total protein** content.

The significant values for these items are included in Table 7-2.

Reference values for peritoneal fluid constituents of normal adult cattle may be inappropriate for interpretation of peritoneal fluid analysis in calves of up to 8 weeks of age. The peritoneal fluid nucleated cell count and mononuclear cell counts are higher in calves, and the eosinophil counts are lower than in adult cows.

INTESTINAL AND LIVER BIOPSY

An intestinal biopsy may be obtained from an exploratory laparotomy but is costly and time-consuming. Rectal biopsy is easily done and of low cost. It is a valuable diagnostic aid for evaluating certain intestinal diseases of the horse. Biopsy specimens are taken using minimal restraint and unaided by proctoscopic visualization in the standing horse. A rectal biopsy forceps is used to obtain the biopsy from the floor of the rectum approximately 30 cm proximal to the anal sphincter. The technique for liver biopsy is presented in Chapter 9.

Principles of Treatment in Alimentary Tract Disease

Removal of the primary cause of the disease is essential, but a major part of the treatment of diseases of the alimentary tract is supportive and symptomatic. This is aimed at relieving pain and distension, replacement of fluids and electrolytes, correcting abnormal motility, and relieving tenesmus and reconstitution of the digestive flora if necessary. Specific treatment for individual diseases is

presented with each disease throughout this book. General principles are outlined here.

RELIEF OF ABDOMINAL PAIN

The relief of abdominal pain is of prime importance from a humane aspect, to prevent the animal from self-injury associated with falling and throwing itself against a wall or other solid objects, and to allay the concerns of the owner. No single analgesic is completely satisfactory for every situation. Nonnarcotic and narcotic analgesics that are in general use and the analgesics used in the important subject of equine colic are presented later.

RELIEF OF DISTENSION

The relief of distension of the gastrointestinal viscera is a critical principle to minimize shock and to prevent rupture of the viscus. **Relief of distension of the stomach of the horse with colic is accomplished by nasogastric intubation**. Distension caused by bloat in cattle can be relieved by stomach tube or trocarization of the rumen. Relief of distension of the large colon by percutaneous or per rectal trocarization is used in horses. Either technique can be useful in relieving distension and signs of abdominal pain, but potential complications include peritonitis, infection, and abscessation at the site of trocarization.[34,35]

Relief of distension may be possible by medical means alone with the use of laxatives and purgatives when there is accumulation of ingesta without a physical obstruction. Surgical intervention is often necessary when the distension is associated with a physical obstruction. In functional distension (paralytic ileus), relief of the atony or spasm can be effected by the use of drugs such as metoclopramide. Distension caused by intestinal or gastric accidents requires surgical correction.

REPLACEMENT OF FLUIDS AND ELECTROLYTES

Replacement of fluid and electrolytes lost in gastrointestinal disease is one of the most important principles of treatment. In gastric or intestinal obstruction, or when diarrhea is severe, it is necessary to replace lost fluids and electrolytes by the parenteral administration of large quantities of isotonic glucose–saline or other physiologically normal electrolyte solutions. The amount of fluid lost may be very large and fluids must be given in quantities to replace losses and to support continuing losses and maintenance requirements. In acute, severe dehydration in horses, such as occurs in acute intestinal obstruction, the amount of fluid required before and during surgery ranges from 50 to 100 mL/kg BW per 24 hours. It is critical that administration of fluid is commenced at the earliest possible time because of the need to maintain homeostasis. Details of fluid therapy are given in Chapter 5.

In young animals the need is much greater still and amounts of 100 mL/kg BW, given slowly intravenously, are commonly necessary and not excessive. The treatment of shock is also presented in Chapters 2 and 9 and includes the administration of fluids, plasma or blood, and nonsteroidal antiinflammatory drugs (NSAIDs). The use of intravenous administration of hypertonic saline followed by the ingestion of large quantities of water by the animal is another aspect of fluid therapy in gastrointestinal disease (see Chapter 5).

CORRECTION OF ABNORMAL MOTILITY

INCREASED MOTILITY

When motility is increased, the administration of atropine or other spasmolytics such as dipyrone or proquamezine is usually followed by the disappearance of the abdominal pain and a diminution of fluid loss. Meperidine, butorphanol, and pentazocine inhibit regular cyclic myoelectric activity in the jejunum. There is a need for some scientific clinical investigation into the desirability of treating intestinal hypermotility, if it does exist in enteritis, for example, and the efficacy of anticholinergics. Loperamide has an antidiarrheal effect in experimentally induced diarrhea in calves, but the mechanism of action does not involve changes in intestinal motility.

DECREASED MOTILITY

When gastrointestinal motility is decreased, the usual practice is to administer parasympathomimetic drugs or purgatives, usually combined with an analgesic. Prokinetic drugs such as metoclopramide hydrochloride and cisapride monohydrate increase the movement of ingesta through the gastrointestinal tract. They are useful because they induce coordinated motility patterns.

Metoclopramide

Metoclopramide, acting in the upper gastrointestinal tract, increases acetylcholine release from neurons and increases cholinergic receptor sensitivity to acetylcholine. It is a dopamine antagonist and stimulates and coordinates esophageal, gastric, pyloric, and duodenal motor activity. It increases lower esophageal sphincter tone and stimulates gastric contractions, while relaxing the pylorus and duodenum. This results in accelerated gastric emptying and reduced esophageal reflux. The transit time of ingested material from the duodenum to the ileocecal valve is reduced because of increased jejunal peristalsis. It has little or no effect on colonic motility. The pharmacokinetics of metoclopramide in cattle has been studied.

Metoclopramide crosses the blood-brain barrier, where its dopamine antagonist activity at the chemoreceptor trigger zone can result in an antiemetic effect. It can also result in involuntary activity including tremors, restlessness, and aggressive behavior characterized by charging and jumping walls. This can be reversed by the use of an anticholinergic such as diphenhydramine hydrochloride intravenously at 0.5 to 2.0 mg/kg BW.

Indications for metoclopramide include reflux esophagitis and gastritis, chronic gastritis associated with delayed emptying, abomasal emptying defects in ruminants, gastric stasis following gastric dilatation and volvulus surgery, and **postoperative ileus**. It is contraindicated in animals with physical obstruction of the gastrointestinal tract.

In horses, the dose is 0.125 to 0.25 mg/kg BW diluted in multiple electrolyte solution and given intravenously over 60 minutes. It is used for stimulating equine gastric and small-intestinal activity at dose rates of 0.25 mg/kg BW per hour when there is intestinal hypomotility. Given as continuous intravenous infusion of 0.04 (mg/kg)/h it can decrease the incidence and severity of persistent postoperative ileus following resection and anastomosis of the small intestine in horses without serious side effects.

In cattle and sheep metoclopramide is used at 0.3 mg/kg BW subcutaneously every 6 to 8 hours. Metoclopramide did not alter cecocolic myoelectrical activity in cattle.

Cisapride

Cisapride promotes gastrointestinal motility by enhancing the release of acetylcholine from postganglionic nerve endings of the myenteric plexus. It is more potent and has broader prokinetic activity than metoclopramide by increasing the motility of the colon as well as the esophagus, stomach, and small intestine. It is does not have dopaminergic effects and does not have either the antiemetic or the extrapyramidal effects of metoclopramide. Cisapride is useful for the treatment of gastric stasis, gastroesophageal reflux, and postoperative ileus. In horses, it increases left dorsal colon motility and improves ileocecal junction coordination. The suggested dose is 0.1 mg/kg BW orally every 8 hours. Cisapride may have some value in the clinical management of cecal dilatation in cattle.

Xylazine and Naloxone

Although **xylazine** is used for alleviation of visceral pain in horses and cattle, it is not indicated in cecal dilatation in cattle because it reduces the myoelectric activity of the cecum and proximal loop of the ascending colon. **Naloxone**, a widely used opiate antagonist with a high affinity for μ-receptors, is also not indicated for medical treatment of cecal dilatation when hypomotility must be reversed.

Bethanechol and Neostigmine

Bethanechol is a methyl derivative of carbachol and classified as a direct-acting cholinomimetic drug. Its action is more specific on the gastrointestinal tract and urinary bladder. **Neostigmine**, a cholinesterase inhibitor, is an indirect-acting cholinergic drug with motor-stimulating activities but only on the gastrointestinal tract. Bethanechol at 0.07 mg/kg BW intramuscularly may be useful for medical treatment of cecal dilatation in cattle in which hypomotility of the cecum and proximal loop of the ascending colon must be reversed. Neostigmine at 0.02 mg/kg BW intramuscularly increased the number of propagated spike sequences, but they were uncoordinated.

RELIEF OF TENESMUS

Tenesmus can be difficult to treat effectively. Long-acting epidural anesthesia and sedation are in common use. Combinations of xylazine and lidocaine may be used. Irrigation of the rectum with water and the application of topical anesthetic in a jelly-like base are also used.

RECONSTITUTION OF RUMEN FLORA AND CORRECTION OF ACIDITY OR ALKALINITY

When prolonged anorexia or acute indigestion occurs in ruminants, the rumen flora may be seriously reduced. In convalescence, the reconstitution of the flora can be hastened by the oral administration of a suspension of ruminal contents from a normal cow, or of dried ruminal contents, which contain viable bacteria and yeasts and the substances necessary for growth of the organisms.

The pH of the rumen affects the growth of rumen organisms, and hyperacidity (such as occurs on overeating of grain), or hyperalkalinity (such as occurs on overeating of protein-rich feeds), should be corrected by the administration of alkalinizing or acidifying drugs as needed.

Diseases of the Buccal Cavity and Associated Organs

DISEASES OF THE MUZZLE

Severe dermatitis with scab formation, development of fissures, and sloughing and gangrene of the skin of the muzzle are common lesions in cattle affected with photosensitive dermatitis, bovine malignant catarrh, bovine virus diarrhea, and rinderpest.

In sheep severe lesions of the muzzle are less common, but occur in bluetongue and ecthyma.

In pigs, only the vesicular diseases—vesicular exanthema of swine (VES), swine vesicular disease, and FMD—cause such lesions on the snout and on other sites. The lesions are vesicular initially, and confusion has arisen in recent years because of isolated incidents in Australia and New Zealand in which such outbreaks occurred but no pathogenic agent was identified.

Congenital lesions of solely the muzzle are rare; the congenital defect of harelip can be contiguous with a cleft palate.

STOMATITIS

Stomatitis is inflammation of the oral mucosa and includes **glossitis** (inflammation of the tongue), **palatitis** (lampas; inflammation of the palate), and **gingivitis** (inflammation of the mucosa of the gums). Clinically it is characterized by partial or complete loss of appetite, smacking of the lips, and profuse salivation. It is commonly an accompaniment of systemic disease.

ETIOLOGY

Stomatitis can be caused by physical, chemical, or infectious agents, with the last being the largest group of causes. The agents are listed next.

Physical Agents

- Trauma while dosing orally with a balling gun or similar instruments.[1]
- Laceration of the tongue.
- Foreign body injury.
- Malocclusion of teeth.
- Sharp awns or spines on plants. The most common lesions are on the gums of cattle and sheep just below the corner incisors where tough grass is pulled around the corner of the incisor arcade. In spear grass country the alveoli are often stuffed full of grass seeds. Very young animals, e.g., 1- to 6-week-old lambs, are particularly susceptible to traumatic injury from abrasive feed. Among the most dramatic lesions are those in the mouths of horses. They are large (2–3 cm long and 5 mm wide) and linear in shape. They can be caused in horses or cattle by eating hairy caterpillars that infest pasture,[2] or by the awns in hay or chaff made from triticale (a hybrid of wheat and rye) and a yellow bristle grass (*Setaria lutescens*).[3] Foxtail awns can cause multiple painful nodules on the lips of horses that have eaten hay contaminated with the awns,[4] as can the seedheads of mouse barley (*Hordeum murinum*).[5]
- The strength and thickness of the awn in dwarf barley cultivars used to make silage fed to feedlot cattle in some regions is associated with mouth lesions. The incidence of tongue lesions in slaughter cattle in some areas can be about 19%, and the incidence is higher in cattle finished on silage from semidwarf rough awn (29.3%) compared with normal-stem rough awn (13.5%) and normal-stem smooth awn barley (11.8%).
- Eating frozen feed and drinking hot water are recorded, but seem highly improbable.
- Ulcers of the soft palate of horses can be caused by mechanical trauma associated with dorsal displacement of the soft palate.

Chemical Agents

- Irritant drugs, e.g., chloral hydrate, administered in excessive concentrations.
- Counterirritants applied to skin, left unprotected, and licked by the animal, including mercury and cantharides compounds.
- Irritant substances administered by mistake, including acids, alkalis, and phenolic compounds.
- Manifestation of systemic poisoning, e.g., chronic mercury poisoning. Poisoning with bracken, *Heracleum mantegazzianum,* furazolidone, and some fungi (*Stachybotrys, Fusarium* spp., and mushrooms) cause a combination of focal hemorrhages and necrotic ulcers

or erosions. They are a common cause of confusion with vesicular or erosive disease.
- Lesions associated with uremia syndrome in horses.

Infectious Agents

Cattle

- Oral necrobacillosis associated with *Fusobacterium necrophorum.*
- Actinobacillosis of the bovine tongue is not a stomatitis, but there can be one or two ulcers on the dorsum and sides of the tongue and on the lips. Characteristically, there is initially an acute diffuse myositis of the muscle of the tongue, followed by the development of multiple granulomas and subsequently fibrosis and shrinkage.
- Ulcerative, granulomatous lesions may occur on the gums in cases of actinomycosis.
- Stomatitis with vesicles occurs in FMD and in vesicular stomatitis (VS).
- Erosive, with some secondary ulcerative, stomatitis occurs in bovine viral diarrhea (mucosal disease), bovine malignant catarrh, rinderpest. and rarely in bluetongue. Cases of infectious bovine rhinotracheitis in young calves may have similar lesions.
- Proliferative lesions occur in papular stomatitis, proliferative stomatitis, and rare cases of rhinosporidiosis and papillomatosis where the oral mucosa is invaded.
- Oral mucosal necrosis in bovine sweating sickness.
- Nondescript lesions varying from erosions to ulcers occur late in the stages of many of the previously mentioned diseases when secondary bacteria have invaded the breaches in the mucosa. In some cases the involvement goes deeper still and a phlegmonous condition or a cellulitis may develop. Thus lesions that were initially vesicular are converted to what look like bacterial ulcers. Secondary infection with fungi, especially *Monilia* spp., may also occur.

Sheep

- Erosive lesions in bluetongue, rinderpest, and peste de petits ruminantes.
- Vesicular lesions rarely in foot-and-mouth disease (FMD).
- Granulomatous lesions caused by ecthyma are not unusual in the mouth, especially in young lambs. Similarly, oral lesions occur in bad cases of sheep pox, ulcerative dermatosis, coital exanthema, and mycotic dermatitis.

Horses

- Cheilitis and gingivitis (inflammatory nodules of the lips and gums caused by plant awns)
- Vesicular lesions in VS
- Lingual abscess associated with *Actinobacillus* spp.

Pigs

- The vesicular diseases: FMD, VS, VES, and swine vesicular disease.

Bullous Stomatitis

- Bullous stomatitis has been reported in the horse and can be associated with a paraneoplastic pemphigus syndrome.

Many other causes of stomatitis have been suggested, but the relationship of these conditions to the specific diseases listed previously is unknown. It is common to find stomatitides that cannot be defined as belonging to any of these etiologic groups. An example is necrotic glossitis reported in feeder steers in the United States in which the necrotic lesions are confined to the anterior part of the tongue.

PATHOGENESIS

The lesions of stomatitis are produced by the causative agents being applied directly to the mucosa, or gaining entrance to it by way of minor abrasions, or by localization in the mucosa from a viremia. In the first two instances, the stomatitis is designated as primary. In the third, it is usually described as secondary because of the common occurrence of similar lesions in other organs or on other parts of the body, and the presence of a systemic disease. The clinical signs of stomatitis are caused by the inflammation or erosion of the mucosa and the signs vary in severity with the degree of inflammation.

CLINICAL FINDINGS

There is partial or complete anorexia and slow, painful mastication. Chewing movements and smacking of the lips are accompanied by salivation, either frothy and in small amounts, or profuse and drooling if the animal does not swallow normally. The saliva may contain pus or shreds of epithelial tissue. A fetid odor is present on the breath only if bacterial invasion of the lesion has occurred. Enlargement of local lymph nodes may also occur if bacteria invade the lesions. Swelling of the face is observed only in cases where a cellulitis or phlegmon has extended to involve the soft tissues. An increased desire for water is apparent and the animal resents manipulation and examination of the mouth.

Toxemia may be present when the stomatitis is secondary to a systemic disease or where tissue necrosis occurs. This is a feature of oral necrobacillosis and many of the systemic viremias. In some of the specific diseases, lesions may be present on other parts of the body, especially at the coronets and mucocutaneous junctions.

Several different lesions of the oral cavity may be present and their characteristic appearances are as follows. The importance of vesicular diseases such as FMD means that the recognition and differentiation of these lesions assumes major importance.

Erosions are shallow, usually discrete, areas of necrosis, which are not readily seen in the early stages. They tend to occur most often on the lingual mucosa and at the commissures of the mouth. The necrotic tissue may remain in situ but is usually shed, leaving a very shallow discontinuity of the mucosa with a dark red base that is more readily seen. If recovery occurs, these lesions heal very quickly.

Vesicles are thin-walled swellings 1 to 2 cm in diameter filled with clear serous fluid. They are very painful and rupture readily to leave sharp-edged, shallow ulcers.

Ulcerative lesions penetrate more deeply to the lamina propria and are painful, such as in necrotic stomatitis in calves associated with *F. necrophorum.* In lambs the tongue may be swollen and contain many microabscesses infected with *Actinomyces (Corynebacterium) pyogenes.* There is an accompanying abscessation of the pharyngeal lymph nodes.

Proliferative lesions are characterized by an abnormality raised above the surface of the mucous membrane such as in oral papillomatosis. **Traumatic lesions** are usually solitary and characterized by a discontinuity in the mucous membrane often with evidence of healing and the presence of granulation tissue.

Catarrhal stomatitis is manifested by a diffuse inflammation of the buccal mucosa and is commonly the result of direct injury by chemical or physical agents. **Mycotic stomatitis** is characterized by a heavy, white velvety deposit with little obvious inflammation or damage to the mucosa.

Deformity of or loss of tissue at the tip of the tongue may result in a chronic syndrome of chewing and swallowing food in such a way that food is always oozing from between the lips. In sheep this may cause permanent staining of the hair around the mouth, creating an appearance similar to that of a tobacco chewer. Loss of the tip is usually the result of predator attack on a newborn or sick lamb.

Laceration of the tongue can result in complete or partial severance of the organ, with the severed portion protruding from the oral cavity. In cattle, glossectomy interferes with prehension and the animal is unable to eat. Excessive loss of saliva is common because of interference with swallowing.

Ulceration of the soft palate of horses may occur in 16% of horses with dorsal displacement of the soft palate and is characterized clinically by reduced exercise tolerance, respiratory noise during light exercise or racing, dysphagia, and coughing after exercising. The ulcers can be viewed by upper respiratory airway videoendoscopy. **Bullous stomatitis** in the horse is characterized by intact or ruptured vesicles on the peripheral

margin of the tongue, the sublingual region, and the mucosa of the oral cavity and lips.

CLINICAL PATHOLOGY

Material collected from lesions of stomatitis should be examined for the presence of pathogenic bacteria and fungi. Transmission experiments may be undertaken with filtrates of swabs or scrapings if the disease is thought to be caused by a viral agent.

NECROPSY FINDINGS

Oral lesions are easily observed, but complete necropsy examinations should be performed on all fatally affected animals to determine whether the oral lesions are primary or are local manifestations of a systemic disease.

DIFFERENTIAL DIAGNOSIS

- Particularly in cattle, and to a lesser extent in sheep, the diagnosis of stomatitis is most important because of the occurrence of oral lesions in a number of highly infectious viral diseases. The diseases are listed under etiology and their differentiation is described under their specific headings elsewhere in this book.
- Careful clinical and necropsy examinations are necessary to define the type and extent of the lesions if any attempt at field diagnosis is to be made.
- In cattle, lymphoma of the ramus of the mandible may spread extensively through the submucosal tissues of the mouth causing marked swelling of the gums, spreading of the teeth, inability to close the mouth, and profuse salivation. There is no discontinuity or inflammation of the buccal mucosa, but gross enlargement of the cranial lymph nodes is usual.
- The differentiation of causes of hypersalivation must depend on a careful examination of the mouth (the causative gingivitis is often surprisingly moderate in horses) and an awareness of the volume of increased saliva output caused by toxic hyperthermia, e.g., in fescue and ergot poisonings.
- Poisoning by the mycotoxin slaframine also causes hypersalivation.

TREATMENT

Affected animals should be isolated and fed and watered from separate utensils if an infectious agent is suspected. Specific treatments are described under the headings of the individual diseases. Nonspecific treatment includes frequent application of a mild antiseptic collutory such as a 2% solution of copper sulfate, a 2% suspension of borax, or a 1% suspension of a sulfonamide in glycerin. Indolent ulcers require more vigorous treatment and respond well to curettage or cauterization with a silver nitrate stick or tincture of iodine.

In stomatitis caused by trauma, the teeth might need attention. In all cases, soft, appetizing food should be offered and feeding by stomach tube or intravenous alimentation may be resorted to in severe, prolonged cases. If the disease is infectious, care should be exercised to ensure that it is not transmitted by the hands or dosing implements.

DISEASES OF THE TEETH

Surgical diseases of the teeth of animals are presented in textbooks of surgery. Some of the medical aspects of diseases of the teeth of farm animals are described here.

ETIOLOGY

The causes may be congenital or acquired.

Congenital Defects

- Polyodontia (excessive number of teeth) occurs in many species. It is detected in 2.3% of donkeys.[1]
- Malocclusion of sufficient degree to interfere with prehension and mastication
- Red-brown staining of inherited porphyrinuria of cattle
- Defective enamel formation on all teeth combined with excessive mobility of joints is an inherited defect of collagen metabolism in Holstein/Friesian cattle identified as bovine osteogenesis imperfecta. The teeth are pink and abnormal in appearance. This defect is also recorded in a foal with severe epitheliogenesis imperfecta.

Dental Fluorosis

The teeth are damaged before they erupt and show erosion of the enamel.

Enamel Erosion

The feeding of acidic by-product feed such as sweet potato cannery waste, which is acidic because of the presence of lactic acid, can cause erosion of the enamel of the incisors of cattle. Exposure of incisor teeth in vitro to a supernatant of cannery waste or lactic acid at pH 3.2 results in removal of calcium from the surface enamel of bovine teeth. Neutralizing the cannery waste to a pH of 5.5 does not cause detectable etching of the teeth. Feeding cattle with heavily compacted silage is also associated with loss of incisor enamel and severe incisor wear.

Premature Wear and Loss of Teeth in Sheep (Periodontal Disease)

Premature loss of incisor teeth or "broken mouth" causes concern because of the early age at which affected sheep have to be culled. Broken mouth is a chronic inflammatory disease of the tissue supports of the tooth. Between 60% and 70% of ewes sold at slaughter in England and Scotland have loose or missing incisor teeth. Broken mouth is geographically specific and it seems that once the disease is established on a particular farm, the animals are permanently susceptible. Many sheep are culled before the end of their useful reproductive life because of broken mouth. The problem is particularly severe in New Zealand and the hill country in Scotland. The cause is uncertain, but environmental factors that result in periodontal disease are probably important. Broken mouth is associated with abnormal bacterial flora in the mouth with affected sheep having a preponderance of *Mannheimia ruminalis* and *Moraxella caprae* compared with sheep with healthy mouths.[2] *Porphyromonas* (*Bacteroides) gingivalis,* an organism that is found in plaque from sheep's teeth, has been found with increased frequency in diseased compared with unaffected animals. The depths of the gingival crevice of sheep are heritable and it is possible that deeper crevices may already be harboring greater numbers of periodontally pathogenic bacteria so that when the animals are exposed to a broken-mouth environment they may be more prone to the changes. Although nutrition and mineral deficiencies influence dental development and tooth eruption of sheep, there is no significant difference in calcium or phosphorus status between control and affected populations of sheep. Low planes of nutrition have delayed eruption of the permanent dentition and retarded mandibular growth, but these changes are not seen in broken mouth in sheep. The occurrence of this periodontal disease is higher in some soil types than on others. The ingestion of irritating materials such as sand and spiny grass seeds has been suggested as causes, but they are considered to be secondary complications in a preexisting disease.

Another dental disease of sheep is also recorded on an extensive scale in New Zealand. There is excessive wear of deciduous incisors but no change in the rate of wear of the molar teeth. The incisor wear is episodic and is not caused by any change in the supportive tissues, and there is no change in the intrinsic resistance to wear of the incisor teeth. The disease is not related to an inadequate dietary intake of copper or vitamin D and is thought to be caused by the ingestion of soil particles. The two New Zealand diseases do not occur together and have no apparent effect on body condition score.

Dentigerous cysts have been described in ewes in the South Island of New Zealand with a prevalence of 0.91%.

PATHOGENESIS

There are some limitations to the use of number of incisors for determining age in

sheep. In mixed-age female sheep flocks, the median age when two, four, six, and eight incisors come into wear is 15, 23, 30, and 42 months of age, respectively. Errors will be made by assuming that all sheep gain a pair of permanent incisors at annual intervals between 1.5 and 4.5 years of age.

In periodontal disease or broken-mouth disease of sheep the primary lesion is an acute gingivitis around permanent incisors and premolars at the time of their eruption. This subsides leaving a chronic gingivitis and an accumulation of subgingival plaque. On some farms, for reasons not understood, this gingivitis penetrates down into the alveoli, causing a severe periodontitis and eventual shedding of the teeth. The severity of the gingivitis can vary between farms. The disease is episodic in nature, with discrete acute inflammatory incidents leading to periodontal injury that may resolve by healing. The balance between repair and the various short- and long-term acute episodes probably accounts for the large variation in incidence and age onset of tooth loss both within and between flocks. The inflammatory periodontal disease markedly affects the tooth's mobility. Collagen fibrils supporting the tooth become abnormal. The deepened periodontal pocket resulting from inflammation removes the major area of support for the tooth and abnormal loads are applied to fibers deeper within the tissue. Although the incisor teeth are usually most severely affected, the cheek teeth are also involved. In some unusual circumstances the gingivitis appears to arise from heavy deposits of dental calculus. In the Scottish disease there is local alveolar bone loss but no accompanying general skeletal deficiency.

CLINICAL FINDINGS

The most obvious evidence of broken-mouth disease is incisor tooth loss, which usually occurs when sheep are between 3.5 and 6.6 years; normal sheep without broken mouth will retain their teeth beyond 7 years of age. Several dental health indices can assist to assess the amount of gingivitis, tooth movement, gum recession, and pocketing. Gingivitis is characterized by redness and edema of the attached gingiva. Bleeding from the gingivae is also a feature. Clinical gingivitis is evident as soon as the permanent teeth erupt. Chronic gingivitis results in a downward retreat of the gum margin; loss of its normal, scalloped shape; and fibrosis of the gingiva. Within a year before tooth loss, tissue damage around the incisors leads to deepening of the gingival sulcus and the formation of pockets, which are readily detected by the use of graduated dental measuring probes. The normal sulcus is 0.5 to 1.0 mm deep labially and up to 4 mm deep lingually; pockets may be over 1.0 cm in depth before tooth loss. Crown lengthening, protrusion, hemorrhages, loosening, and lingual periodontitis are characteristic. If sheep affected with broken mouth periodontal disease are examined over a 12-month period, only a few animals undergo clinically significant destruction. The relationship between periodontal disease and body condition score in sheep is variable.

Secondary starvation occurs even with a plentiful feed supply. Inspection of the mouth may reveal the worn or damaged incisor teeth, but the molar teeth are not easily inspected in the living animal and tooth lesions can be missed. Because it is common to find that both incisors and molars are affected, damage to incisors should lead the clinician to suspect that molar disease is also present.

Cattle fed sweet potato cannery waste develop black, stained teeth with severe enamel erosion.

An abattoir survey of dental defects in cull cows, all over 30 months of age, found that 14.6% had one or more missing incisors, most of which were acquired losses. Rotation and overlapping of rostral teeth were common, as was attrition. Congenitally absent first lower premolars; other missing teeth; large and often multiple interdental spaces; and a few cases of macrodontia, cavitation, multiple defects, and fractures were observed in cheek tooth arcades. There were also some unusual patterns of premolar and molar attrition, often attributable to malocclusion, one result of which was the formation of a hook at the posterior extremity of the third maxillary molar.

CLINICAL PATHOLOGY

None definitive.

TREATMENT AND CONTROL

There is no reliable treatment and control for broken mouth in sheep. The use of dental prosthetics glued to the incisors when the ewe has three pairs of incisors in place is being investigated. The use of antimicrobials has been proposed to control the gingivitis, but there is no apparent effect on the periodontal disease. Cutting the incisor teeth of ewes to control premature tooth loss has been explored, but the practice has been banned in the UK.

DISEASES OF THE PAROTID SALIVARY GLANDS

Disease of the parotid gland includes parotitis, which can be septic or associated with sialolithiasis, congenital abnormalities including brachial cyst remnants, neoplasia, and trauma. Inflammation of the salivary glands (sialadenitis) can be secondary to sialolithiasis.

ETIOLOGY

Parotitis can be parenchymatous, when the glandular tissue is diffusely inflamed, or it may be a local suppurative process. There are no specific causes in farm animals, with cases occurring only sporadically and usually caused by localization of a blood-borne infection, invasion up the salivary ducts associated with stomatitis, irritation by grass awns in the duct, or salivary calculi. Avitaminosis A often appears to be a predisposing cause in cattle.

Septic sialadenitis of horses is an uncommon disease that causes pain, inappetence, dysphagia, and localized swelling of the parotid or submandibular salivary glands.[1] Some cases (one third) are associated with the presence of sialoliths.[1] Sialoliths can form around foreign bodies, such as grass seeds or grains.[2]

Local suppurative lesions are caused usually by penetrating wounds or extension from a retropharyngeal cellulitis or lymph node abscess. Neoplasia of the parotid glands of cattle, horses, and sheep occurs both as a primary tumor (adenocarcinoma and peripheral nerve sheath tumor), manifestation of a systemic tumor (lymphoma), or local extension of neoplasia in an adjacent structure, such as ocular squamous cell carcinoma.[3-7]

Trauma can injure the gland or draining duct.[8]

PATHOGENESIS

In most cases only one gland is involved. There is no loss of salivary function and the signs are restricted to those of inflammation of the gland.

CLINICAL FINDINGS

In the early stages, there is diffuse enlargement of the gland accompanied by warmth and pain on palpation. The pain can interfere with mastication and swallowing and induce abnormal carriage of the head and resentment when attempts are made to move the head. There can be marked local edema in severe cases. Diffuse parenchymatous parotitis usually subsides with systemic and local treatment within a few days, but suppurative lesions can discharge externally and form permanent salivary fistulae.

Examination should include careful oral examination and ultrasonographic examination of the gland and associated ducts.[1]

Treatment for septic sialolithiasis includes correction of the underlying defect (abnormal dentition or sialolith) and administration of antimicrobials.

CLINICAL PATHOLOGY

Bacteriologic examination of pus from discharging abscesses in horses reveals *Fusobacterium* sp. and a variety of other bacteria.[1]

NECROPSY FINDINGS

Death occurs rarely and necropsy findings are restricted to local involvement of the

gland or to primary lesions elsewhere in the case of secondary parotitis.

DIFFERENTIAL DIAGNOSIS

- Careful palpation is necessary to differentiate the condition from lymphadenitis, abscesses of the throat region, and metastases to the parotid lymph node in ocular carcinoma or mandibular lymphoma of cattle.
- Acute phlegmonous inflammation of the throat is relatively common in cattle and is accompanied by high fever, severe toxemia, and rapid death. It can be mistaken for an acute parotitis, but the swelling is more diffuse and causes pronounced obstruction to swallowing and respiration.

TREATMENT

Systemic treatment with sulfonamides or antibiotics is required in acute cases, especially if there is a systemic reaction. Abscesses might require draining. A salivary fistula is a common sequel.

Diseases of the Pharynx and Esophagus

PHARYNGITIS

Pharyngitis is inflammation of the pharynx and is characterized clinically by coughing, painful swallowing, and a variable appetite. Regurgitation through the nostrils and drooling of saliva may occur in severe cases.

ETIOLOGY

Pharyngitis in farm animals is usually traumatic. Infectious pharyngitis is often part of a syndrome with other more obvious signs.

Physical Causes

- Injury while giving oral treatment with balling or drenching gun or following endotracheal intubation. The administration of intraruminal anthelmintic coils to calves under a minimum BW have also been associated with pharyngeal and esophageal perforation
- Improper administration of a reticular magnet, resulting in a retropharyngeal abscess.
- Accidental administration or ingestion of irritant or hot or cold substances.
- Foreign bodies, including grass and cereal awns, wire, bones, and gelatin capsules lodged in the pharynx or suprapharyngeal diverticulum of pigs.

Infectious Causes

Cattle

- Oral necrobacillosis and actinobacillosis as a granuloma rather than the more usual lymphadenitis
- Infectious bovine rhinotracheitis
- Pharyngeal phlegmon or intermandibular cellulitis is a severe, often fatal, necrosis of the wall of the pharynx and peripharyngeal tissues without actually causing pharyngitis. *F. necrophorum* is a common isolate from the lesions.

Horses

- As part of strangles or anthrax
- Viral infections of the upper respiratory tract, including equine herpesvirus-1, Hoppengarten cough, parainfluenza virus, adenovirus, rhinovirus, viral arteritis, and influenza-1A/E1 and 1A/E2, cause pharyngitis.
- Chronic follicular pharyngitis with hyperplasia of lymphoid tissue in pharyngeal mucosa giving it a granular, nodular appearance with whitish tips on the lymphoid follicles.[1]

Pigs

- As part of anthrax in this species and in some outbreaks of Aujeszky's disease.

PATHOGENESIS

Inflammation of the pharynx is attended by painful swallowing and disinclination to eat. If the swelling of the mucosa and wall is severe, there may be virtual obstruction of the pharynx. This is especially so if the retropharyngeal lymph node is enlarged, as it is likely to be in equine viral infections such as rhinovirus.

In balling-gun–induced trauma of feedlot cattle treated for respiratory disease with boluses of sulfonamides, perforations of the pharynx and esophagus may occur with the development of periesophageal diverticulations with accumulations of ruminal ingesta and cellulitis. Improper administration of a magnet to a mature cow can result in a retropharyngeal abscess.

Pharyngeal lymphoid hyperplasia in horses can be graded into four grades (I–IV) of severity based on the size of the lymphoid follicles and their distribution over the pharyngeal wall.[2]

CLINICAL FINDINGS

The animal may refuse to eat or drink or it may swallow reluctantly and with evident pain. Opening of the jaws to examine the mouth is resented and manual compression of the throat from the exterior causes paroxysmal coughing. There may be a mucopurulent nasal discharge, sometimes containing blood, spontaneous cough and, in severe cases, regurgitation of fluid and food through the nostrils. Oral medication in such cases may be impossible. Affected animals often stand with the head extended, drool saliva, and make frequent tentative jaw movements. If the local swelling is severe, there may be obstruction of respiration and visible swelling of the throat. The retropharyngeal and parotid lymph nodes are commonly enlarged.

In "**pharyngeal phlegmon**" in cattle there is an acute onset with high fever (41–41.5°C [106–107°F]), rapid heart rate, profound depression, and severe swelling of the soft tissues within and posterior to the mandible to the point where dyspnea is pronounced. Death usually occurs 36 to 48 hours after the first signs of illness.

In **traumatic pharyngitis in cattle**, visual examination of the pharynx through the oral cavity reveals hyperemia, lymphoid hyperplasia, and erosions covered by diphtheritic membranes. Pharyngeal lacerations are visible, and palpation of these reveals the presence of accumulated ruminal ingesta in diverticula on either side of the glottis. External palpation of the most proximal aspect of the neck reveals firm swellings, which represent the diverticula containing rumen contents. A retropharyngeal abscess secondary to an improperly administered magnet can result in marked diffuse painful swelling of the cranial cervical region. Ultrasonographic examination of the swelling may reveal the magnet within the abscess.

Palpation of the pharynx may be performed in cattle with the use of a gag if a foreign body is suspected, and endoscopic examination through the nasal cavity is possible in the horse.

Most acute cases recover in several days but chronic cases may persist for many weeks, especially if there is ulceration, a persistent foreign body, or abscess formation.

Pharyngeal lymphoid hyperplasia is the most commonly recognized abnormality of the upper respiratory tract of the horse.[2-4] The disorder is characterized by chronic hyperplasia of lymphoid tissue in the pharynx of young horses evident as multiple, often coalescing, raised nodules in the pharynx. Up to 60% of Thoroughbred horses are affected and without apparent association with performance.[2] The disease is not associated with other abnormalities of the upper airway in sport horses.[3] If secondary bacterial infection is present a purulent exudate is seen on the pharyngeal mucosa and in the nostrils.

CLINICAL PATHOLOGY

Nasal discharge or swabs taken from accompanying oral lesions may assist in the identification of the causative agent. *Moraxella* spp. and *Streptococcus zooepidemicus* can be isolated in large numbers from horses with

lymphoid follicular hyperplasia grades III and IV.

NECROPSY FINDINGS

Deaths are rare in primary pharyngitis and necropsy examinations are usually undertaken only in those animals dying of specific diseases. In pharyngeal phlegmon there is edema, hemorrhage, and abscessation of the affected area, and on incision of the area a foul-smelling liquid and some gas usually escapes.

DIFFERENTIAL DIAGNOSIS

- Pharyngitis is manifested by an acute onset and local pain.
- In pharyngeal paralysis, the onset is usually slow.
- Acute obstruction by a foreign body can occur rapidly and cause severe distress and continuous, expulsive coughing, but there are no systemic signs.
- Endoscopic examination of the pharyngeal mucous membranes is often diagnostic.

TREATMENT

The primary disease must be treated, usually parenterally, by the use of antimicrobials. Pharyngeal phlegmon in cattle is frequently fatal and early, intensive antimicrobial treatment is indicated.

Pharyngeal lymphoid hyperplasia is not generally susceptible to antimicrobials or medical therapy and resolves as young horses age.

PHARYNGEAL OBSTRUCTION

Obstruction of the pharynx is accompanied by stertorous respiration, coughing, and difficult swallowing.

ETIOLOGY

Foreign bodies or tissue swellings are the usual causes.

Foreign Bodies

Foreign bodies include bones, corn cobs, and pieces of wire. Although horses are considered discriminating eaters in comparison to cattle, they will occasionally pick up pieces of metal while eating.

Tissue Swellings

Cattle

- Retropharyngeal lymphadenopathy or abscess caused by tuberculosis, actinobacillosis, or bovine viral leukosis
- Fibrous or mucoid polyps are usually pedunculated because of traction during swallowing and can cause intermittent obstruction of air and food intake.

Horses

- Retropharyngeal lymph node hyperplasia and lymphoid granulomas as part of pharyngeal lymphoid hyperplasia
- Retropharyngeal abscess and cellulitis
- Retropharyngeal lymphadenitis caused by strangles
- Pharyngeal cysts in the subepiglottic area of the pharynx, probably of thyroglossal duct origin, and fibroma; also similar cysts on the soft palate and pharyngeal dorsum, the latter probably being remnants of the craniopharyngeal ducts
- Dermoid cysts and goitrous thyroids

Pigs

- Diffuse lymphoid enlargement in the pharyngeal wall and soft palate
- Food and foreign-body impaction in the suprapharyngeal diverticulum

PATHOGENESIS

Reduction in caliber of the pharyngeal lumen interferes with swallowing and respiration.

CLINICAL FINDINGS

There is difficulty in swallowing and animals can be hungry enough to eat but, when they attempt to swallow, cannot do so and the food is coughed up through the mouth. Drinking is usually managed successfully. There is no dilatation of the esophagus and usually little or no regurgitation through the nostrils. An obvious sign is a snoring inspiration, often loud enough to be heard some yards away. The inspiration is prolonged and accompanied by marked abdominal effort. Auscultation over the pharynx reveals loud inspiratory stertor. Manual examination of the pharynx can reveal the nature of the lesion, but an examination with a fiberoptic endoscope is likely to be much more informative. When the disease runs a long course, emaciation usually follows. Rupture of abscessed lymph nodes can occur when a nasal tube is passed and can result in aspiration pneumonia.

In horses with metallic foreign bodies in the oral cavity or pharynx, the clinical findings include purulent nasal discharge, dysphagia, halitosis, changes in phonation, laceration of the tongue and stertorous breathing. In case studies, most horses were affected with clinical signs for more than 2 weeks and had been treated with antimicrobials with only temporary improvement.

CLINICAL PATHOLOGY

A tuberculin test might be advisable in bovine cases in areas where bovine tuberculosis is endemic. Nasal swabs can contain *S. equi* when there is streptococcal lymphadenitis in horses.

NECROPSY FINDINGS

Death occurs rarely and in fatal cases the physical lesion is apparent.

DIFFERENTIAL DIAGNOSIS

- Signs of the primary disease can aid in the diagnosis in tuberculosis, actinobacillosis, and strangles.
- Pharyngitis is accompanied by severe pain, systemic signs are common, and there is usually stertor.
- It is of particular importance to differentiate between obstruction and pharyngeal paralysis when rabies occurs in the area. Esophageal obstruction is also accompanied by the rejection of ingested food, but there is no respiratory distress. Laryngeal stenosis can cause a comparable stertor, but swallowing is not impeded. Nasal obstruction is manifested by noisy breathing, but the volume of breath from one or both nostrils is reduced and the respiratory noise is more wheezing than snoring.
- Radiography is useful for the identification of metallic foreign bodies.

TREATMENT

Removal of a foreign body can be accomplished through the mouth. Treatment of actinobacillary lymphadenitis with iodides is usually successful and some reduction in size often occurs in tuberculous enlargement of the glands, but complete recovery is unlikely to occur. Parenteral treatment of strangles abscesses with penicillin can affect a cure. Surgical treatment has been highly successful in cases caused by medial retropharyngeal abscess.

PHARYNGEAL PARALYSIS

Pharyngeal paralysis is manifested by inability to swallow and an absence of signs of pain and respiratory obstruction.

ETIOLOGY

Pharyngeal paralysis occurs sporadically, caused by peripheral nerve injury, and in some encephalitides with central lesions.

Peripheral Nerve Injury

- Guttural pouch infections in horses
- Trauma to the throat region

Secondary to Specific Diseases

- Rabies and other encephalitides
- Botulism
- African horse sickness
- As an idiopathic disease in neonatal foals[1]

PATHOGENESIS

Inability to swallow and regurgitation are the major manifestations of the disease. There may be an associated laryngeal paralysis, accompanied by "roaring." The condition known as "cud-dropping" in cattle might be a partial pharyngeal paralysis because there is difficulty in controlling the regurgitated bolus, which is often dropped from the mouth. In these circumstances, aspiration pneumonia is likely to develop.

CLINICAL FINDINGS

The animal is usually hungry but, on prehension of food or water, attempts at swallowing are followed by dropping of the food from the mouth, coughing, and the expulsion of food or regurgitation through the nostrils. Salivation occurs constantly and swallowing cannot be stimulated by external compression of the pharynx. The swallowing reflex is a complex one controlled by a number of nerves and the signs can be expected to vary greatly depending on which nerves are involved and to what degree. There is rapid loss of condition and dehydration. Clinical signs of the primary disease may be evident but, in cases of primary pharyngeal paralysis, there is no systemic reaction. Pneumonia may follow aspiration of food material into the lungs and produces loud gurgling sounds on auscultation.

In cud-dropping in cattle, the animals are normal except that regurgitated boluses are dropped from the mouth, usually in the form of flattened disks of fibrous food material. Affected animals may lose weight but the condition is usually transient, lasting for only a few days. On the other hand, complete pharyngeal paralysis is usually permanent and fatal.

Pharyngeal dysfunction in neonatal foals is characterized by the inability to nurse with discharge of milk from the nares. Affected foals are often premature or have signs of neonatal maladjustment syndrome. Diagnostic testing, including imaging studies, does not reveal abnormalities beyond a flaccid pharynx, persistent frequent dorsal displacement of the soft palate, laryngeal paralysis (unilateral or bilateral), and inability to swallow.[1]

CLINICAL PATHOLOGY

The use of clinicopathologic examinations is restricted to the identification of the primary specific diseases.

NECROPSY FINDINGS

If the primary lesion is physical, it can be detected on gross examination.

DIFFERENTIAL DIAGNOSIS

- In all species, often the first clinical impression is the presence of a foreign body in the mouth or pharynx, and this can only be determined by physical examination.
- Pharyngeal paralysis is a typical sign in rabies and botulism, but there are other clinical findings that suggest the presence of these diseases.
- Neonatal dysphagia in foals results from cleft palate or soft palate masses, esophageal disease including megaesophagus or esophageal stricture, or primary muscle or central neurological disease, including hyperkalemic periodic paralysis.[1]
- Absence of pain and respiratory obstruction are usually sufficient evidence to eliminate the possibility of pharyngitis or pharyngeal obstruction.
- Endoscopic examination of the guttural pouch is a useful diagnostic aid in the horse.

TREATMENT

Treatment is supportive in most cases in addition to management of any inciting disease, such as guttural pouch infection. Feeding by nasogastric tube allows for recovery of the ability to swallow in most (>90%) affected foals in 7 to 10 days.

ESOPHAGITIS

Inflammation of the esophagus is accompanied initially by clinical findings of spasm and obstruction, pain on swallowing and palpation, and regurgitation of bloodstained slimy material.

ETIOLOGY

Primary esophagitis caused by the ingestion of chemical or physical irritants is usually accompanied by stomatitis and pharyngitis. Laceration of the mucosa by a foreign body or complications of nasogastric intubation can occur. Nasogastric intubation is associated with a higher risk of pharyngeal and esophageal injury when performed in horses examined for colic. This can be related to the use of larger diameter nasogastric tubes to provide more effective gastric decompression, the longer duration of intubation in some horses, or the presence of gastric distension resulting in increased resistance to tube passage at the cardia.[1] In a series of six horses with esophageal trauma the lesions were detected 5 and 20 cm from the cranial esophageal opening.

Death of *Hypoderma lineatum* larvae in the submucosa of the esophagus of cattle can cause acute local inflammation and subsequent gangrene.

Inflammation of the esophagus occurs commonly in many specific diseases, particularly those that cause stomatitis, but the other clinical signs of these diseases dominate those of esophagitis.

PATHOGENESIS

Inflammation of the esophagus combined with local edema and swelling results in a functional obstruction and difficulty in swallowing.

CLINICAL FINDINGS

In the acute esophagitis, there is salivation and attempts to swallow, which cause severe pain, particularly in horses. In some cases, attempts at swallowing are followed by regurgitation and coughing, pain, retching activities, and vigorous contractions of the cervical and abdominal muscles. If the esophagitis is in the cervical region, palpation in the jugular furrow causes pain and edematous tissues around the esophagus can be palpable. In specific diseases such as mucosal disease and bovine malignant catarrh, there are no obvious clinical findings of esophagitis, because the lesions are mainly erosive.

Endoscopy of the esophagus will usually reveal the location and severity of the lesion.

CLINICAL PATHOLOGY

In severe esophagitis of traumatic origin a marked neutrophilia can occur, suggesting active inflammation.

NECROPSY FINDINGS

Pathologic findings are restricted to those pertaining to the various specific diseases in which esophagitis occur. In traumatic lesions or those caused by irritant substances, there is gross edema, inflammation and, in some cases, perforation.

DIFFERENTIAL DIAGNOSIS

- Esophagitis must be differentiated from pharyngitis, in which attempted swallowing is not as marked and coughing is more likely to occur. Palpation can also help to localize the lesion; however, pharyngitis and esophagitis usually occur together.

TREATMENT

Feed should be withheld for 2 to 3 days and fluid and electrolyte therapy can be necessary for several days. Parenteral antimicrobials are indicated, especially if laceration or perforation has occurred. Reintroduction to feed should be monitored carefully and all feed should be moistened to avoid the possible accumulation of dry feed in the esophagus, which might not be fully functional.

ESOPHAGEAL RUPTURE

Rupture of the esophagus is usually traumatic and can be life-threatening.

ETIOLOGY

Rupture of the esophagus occurs from localized ischemia and necrosis secondary to

long-standing impaction or obstruction by foreign bodies or feed material, external trauma, nasogastric intubation, and perforation of ulcers in horses and cattle and death of *Hypoderma lineatum* larvae in cattle. In a series of six horses with esophageal trauma the lesions were detected 5 and 20 cm from the cranial esophageal opening. Spontaneous rupture can occur in horses with idiopathic muscular hypertrophy of the esophagus.[1] The case–fatality rate is high, approaching 100% for horses treated conservatively (without surgery), and somewhat better for horses subject to surgical intervention early in the disease.[2,3]

The administration of sustained-release anthelmintic boluses to young calves not large enough for the size of the bolus used can cause esophageal injury and perforation. The boluses are 8.5 cm in length and 2.5 cm in diameter and the calves 100 to 150 kg. The minimum BW for these boluses is 100 kg, but in the study some calves were younger than the recommended age and were also fractious when handled, which can have contributed to the injury.

PATHOGENESIS

Traumatic injury to the esophagus results in edema, hemorrhage, laceration of the mucosa, and possible perforation of the esophagus, resulting in periesophageal cellulitis, which spreads proximally and distally along the esophagus in fascial planes from the site of perforation. Perforation of the thoracic esophagus can result in severe and fatal pleuritis. There is extensive edema and accumulation of swallowed or regurgitated ingesta along with gas. The extensive cellulitis and the presence of ingesta results in severe toxemia, and dysphagia can cause aspiration pneumonia.

CLINICAL FINDINGS

In the acute injury of the esophagus, there is salivation and attempts to swallow, which cause severe pain, particularly in horses. In some cases, attempts at swallowing are followed by regurgitation and coughing, pain, retching activities, and vigorous contractions of the cervical and abdominal muscles. Marked drooling of saliva, grinding of the teeth, coughing, and profuse nasal discharge are common in the horse with esophageal trauma with complications following nasogastric intubation. Regurgitation can occur and the regurgitus contains mucus and some fresh blood.

If the esophageal rupture is in the cervical region, palpation in the jugular furrow causes pain and edematous tissues around the esophagus can be palpable. When perforation has occurred, there is local pain and swelling and often crepitus and swelling can extend to involve the head. Local cervical cellulitis can cause rupture through the skin and development of an esophageal fistula, or infiltration along fascial planes with resulting compression obstruction of the esophagus, and toxemia. Perforation of the thoracic esophagus can lead to fatal pleuritis. Animals that recover from esophageal traumatic injury are commonly affected by chronic esophageal stenosis with distension above the stenosis. Fistulae are usually persistent, but spontaneous healing can occur.

Endoscopy of the esophagus will usually reveal the location and severity of the lesion. Lateral cervical radiographs can reveal foreign bodies and extensive soft tissue swelling with pockets of gas.

CLINICAL PATHOLOGY

There is often hematological evidence of inflammation, dehydration, metabolic alkalosis, and toxemia.[2]

NECROPSY FINDINGS

Gross necropsy findings are consistent with esophageal perforation and cellulitis.

DIFFERENTIAL DIAGNOSIS

- Tracheal laceration and subcutaneous emphysema
  - Skin wounds over the axilla with subsequent subcutaneous emphysema
  - Severe guttural pouch empyema
- Clostridial myositis secondary to puncture wounds of the neck or cervical intramuscular injections
- Pharyngeal phlegmon in cattle

TREATMENT

Treatment involves effective drainage of the site over the esophageal perforation, prevention of further contamination, control of infection and inflammation, and provision of water and food.

Surgical treatment involves fasciotomy to provide drainage and access to the perforated esophagus. The perforation in the esophagus is debrided through a ventral fasciotomy. The fasciotomy wound is dressed and managed as an open wound. A stomach tube, of similar size as that used to perform nasogastric intubation on the animal (14–20 mm), is inserted through a separate incision in the esophagus in the midcervical region. The tip is placed in the distal esophagus. The horse is provided food (a pellet-based slurry) and water through this tube, as well as being offered water to drink. The tube remains in place until the esophageal perforation has sealed (5–7 days) and then removed.[2,3]

Loss of saliva can cause important abnormalities in electrolyte and acid-base status, and horses should be supplemented with sodium and potassium chloride while there is significant loss of saliva from the fistula.

Broad-spectrum antimicrobials and tetanus prophylaxis should be administered. Pain and swelling can be controlled by administration of NSAIDs.

ESOPHAGEAL OBSTRUCTION

Esophageal obstruction can be acute or chronic and is characterized clinically by the inability to swallow, regurgitation of feed and water, continuous drooling of saliva, and bloat in ruminants. Acute cases are accompanied by signs of distress including retching and extension of the head. Horses with choke commonly regurgitate a mixture of saliva, feed, and water through the nostrils because of the anatomic characteristics of the equine soft palate.

ETIOLOGY

Obstruction can be **intraluminal** and caused by swallowed material or **extraluminal** caused by pressure on the esophagus by surrounding organs or tissues. Esophageal paralysis can also result in obstruction, for example, in horses with grass sickness.

Intraluminal Obstructions

Intraluminal obstructions are usually caused by ingestion of materials that are of inappropriate size and that then become lodged in the esophagus:

- Solid obstructions, especially in cattle, by turnips, onions, potatoes, peaches, apples, oranges, and similar objects.
- Fifteen-gram gelatin capsules in Shetland ponies.
- Feedstuffs are a common cause of obstruction in horses and occasionally in other species.[1] Most impactions are caused by routine feedstuffs.[2] Improperly soaked sugarbeet pulp, inadvertent access to dry sugarbeet pulp, and cubed and pelleted feed can cause the disease in horses when eaten quickly.
- Eating while sedated
- Foreign bodies in horses include pieces of wood, antimicrobial boluses, and fragments of nasogastric tubes.
- A trichobezoar can cause esophageal obstruction cattle.
- Poor dentition is often mooted as a cause[2] and, although sensible, there is no objective evidence of an association between dental abnormalities and esophageal obstruction.

Extraluminal Obstructions

- Enlarged lymph nodes in the mediastinum (tuberculosis, neoplasia, *Rhodococcus equi, Corynebacterium* spp., strangles, and secondary to pleuritis)
- Cervical or mediastinal abscess
- Persistent right aortic arch

- Thymoma
- Megaesophagus and caudal esophageal muscle hypertrophy in Friesian horses can cause esophageal obstruction.[3]
- Secondary to esophageal strictures, which can occur subsequent to esophageal trauma or performation.[6]

Esophageal Paralysis

Esophageal paralysis can be caused by **congenital or acquired abnormalities of the esophagus,** and there are many examples of such abnormalities that interfere with swallowing and cause varying degrees of obstruction, even though it may be possible to pass a stomach tube through the esophagus into the stomach or rumen.

Esophageal paralysis, diverticulum, or megaesophagus has been recorded in horses and in cattle. Congenital hypertrophy of esophageal musculature and esophagotracheal fistula has been found in calves. Congenital esophageal ectasia is recognized in foals, caused by degeneration of musculature and reduced ganglion cells in the myenteric plexus. Congenital esophageal dysfunction has also occurred in foals with no detectable histopathological lesion but with prolonged simultaneous contractions throughout the esophagus.

Megaesophagus

Megaesophagus is a dilatation and atony of the body of the esophagus usually associated with asynchronous function of the esophagus and the caudal esophageal sphincter. It occurs sporadically in cattle and in horses with preexisting esophageal disease. It is usually a congenital condition that causes regurgitation and aspiration pneumonia. A mild esophagitis has been observed in some cases and congenital stenosis of the esophagus in a foal has been associated with megaesophagus. Megaesophagus and caudal esophageal muscular hypertrophy occur in Friesian horses.[3]

Esophageal Strictures

These arise as a result of cicatricial or granulation tissue deposition, usually as result of previous laceration or trauma of the esophagus. They can occur in the adult horse with a history of previous obstruction. Esophageal strictures resulting in obstruction occur in foals from 1 to 6 months of age without any history of ingestion of a foreign body. An esophageal stricture has also been described in a goat.

Other Causes of Obstruction

- **Carcinoma of stomach** causing obstruction of cardia
- Squamous cell carcinoma of the esophagus of a horse
- Esophageal hiatus hernia in cattle
- Paraesophageal cyst in a horse
- Combined esophageal and tracheal duplication cyst in a young horse
- Esophageal duplication in a horse
- Tubular duplication of the cervical portion of the esophagus in a foal
- Cranial esophageal pulsion (pushing outward) diverticulum in a horse
- Esophageal phytobezoar in a horse
- Esophageal mucosal granuloma
- Traumatic rupture of the esophagus from an external injury (e.g., a kick or striking the neck during transportation in a float involved in a motor vehicle accident or similar causing sudden slowing or stopping) or during treatment using a nasogastric tube
- Esophageal paralysis can also be associated with lesions of encephalitis, especially in the brainstem

The **case–fatality rate** for simple choke treated in the field is approximately 2%, while that in presumably more severe cases treated in referral institutions is approximately 12%. Approximately 8% of horses (60 of 758) examined by one author in primary care practice were caused by esophageal obstruction.[2]

Arabian horses and ponies appear to be overrepresented and Thoroughbreds underrepresented among equids with choke.[2,4] There is no readily apparent sex predilection. Equids can be affected at any age.

PATHOGENESIS

An **esophageal obstruction** results in a physical inability to swallow and, in cattle, inability to eructate, with resulting bloat. In acute obstruction, there is initial spasm at the site of obstruction and forceful, painful peristalsis and swallowing movements. Complications of esophageal obstruction include laceration and rupture of the esophagus, esophagitis, stricture and stenosis, and the development of a diverticulum.

Acquired esophageal diverticula can occur in the horse. A traction diverticulum occurs following periesophageal scarring and is of little consequence. An esophageal pulsion diverticulum is a circumscribed sac of mucosa protruding through a defect in the muscular layer of the esophagus. Causes that have been proposed to explain pulsion diverticula include excessive intraluminal pressure from impacted feed, fluctuations in esophageal pressure, and external trauma. Complications associated with esophageal diverticula include peridiverticulitis, pulmonary adhesions, abscesses, and mediastinitis. Esophageal stricture and subsequent obstruction secondary to impaction of a diverticulum can also occur.

In **megaesophagus**, the esophagus is dysfunctional, dilated, and filled with saliva, feed, and water. This results in regurgitation and can lead to aspiration pneumonia. It can be congenital or secondary to other lesions and has been associated with gastric ulceration in foals.

Using esophageal manometry, the normal values for esophageal pressure profiles in healthy horses, cows, and sheep have been recorded. The body of the equine and bovine esophagus has two functionally different regions: the caudal portion and the remainder of the esophageal body (cranial portion).

CLINICAL FINDINGS

Acute Obstruction or Choke

Cattle

The obstruction is usually in the cervical esophagus just above the larynx or at the thoracic inlet. Obstructions can also occur at the base of the heart or the cardia. The animal suddenly stops eating and shows anxiety and restlessness. There are forceful attempts to swallow and regurgitate, salivation, coughing, and continuous chewing movements. If obstruction is complete, bloating occurs rapidly and adds to the animal's discomfort. Ruminal movements are continuous and forceful and there can be a systolic murmur audible on auscultation of the heart. However, rarely is the bloat severe enough to seriously affect the cardiovascular system of the animal, such as occurs in primary leguminous (frothy) bloat.

The acute signs, other than bloat, usually disappear within a few hours. This is caused by relaxation of the initial esophageal spasm and can or cannot be accompanied by onward passage of the obstruction. Many obstructions pass on spontaneously, but others can persist for several days and up to a week. In these cases, there is **inability to swallow**, **salivation,** and **continued bloat**. Passage of a nasogastric tube is impossible. Persistent obstruction causes pressure necrosis of the mucosa and can result in perforation or subsequent stenosis caused by fibrous tissue construction.

Horse

In the horse with esophageal obstruction caused by feed, the obstruction can occur at any level of the esophagus from the upper cervical region all the way to the thoracic portion. The ingestion of large quantities of grain or pelleted feed can cause obstruction over a long portion of the esophagus.

The clinical findings vary with the location, nature, extent, and duration of the obstruction. Typically, the major clinical finding is **dysphagia** with **nasal reflux of saliva, feed, and water**. Affected horses will usually not attempt further eating but will drink and attempt to swallow water. External palpation of the **cervical esophagus** can reveal a **firm cylindrical swelling** along the course of the neck on the left side when the esophagus is obstructed with feed.[2] In cases of foreign-body obstruction such as a piece of wood, there can be no palpable abnormality.

Horses with acute esophageal obstruction are commonly difficult to handle because they are panicky and make forceful attempts to swallow or retch.[2] They often vigorously extend and flex their necks and stamp their front feet. In some horses it can be difficult to

pass a nasogastric tube because they resist the procedure. During these episodes of hyperactivity they can sweat profusely, tachycardia can be present, and they can appear to be in abdominal pain. Such clinical findings on first examination can resemble colic, but attempted passage of a nasogastric tube as part of the examination of a horse with colic reveals the obstruction.

Passage of a nasogastric tube is necessary to make the diagnosis and to assess the level of the obstruction. The level of obstruction can be approximated by the amount of tube that has been passed. Care must be taken not to push the tube more than gently to avoid injury to the esophagus. Occasionally, a foreign body or bolus of feed will move distally into the stomach as the tube is gently advanced.

The nature of the obstruction can be assessed more adequately with a fiberoptic endoscope, but visualization of the entire esophagus of an adult horse requires an endoscope of 2.5 m length. The endoscope allows determination of the rostral but not the distal limit of the obstruction. Endoscopic examination of the esophagus after relief of the obstruction is useful in identifying any preexisting abnormalities or injuries caused by the obstruction. If radiographic equipment is available, standing lateral radiographs of the cervical and thoracic esophagus along with contrast media may be required to determine the extent and nature of an obstruction.

Persistent obstruction can occur in the horse and death can occur in either species from subsequent aspiration pneumonia or, when the obstruction persists, from dehydration. In **foals** with esophageal obstruction the clinical findings include **nasal reflux of saliva**, feed, and milk; reluctance to eat solid feed; and dyspnea if aspiration pneumonia has occurred. Unthriftiness occurs if the obstruction has been present for a few weeks. Affected foals can have had several episodes of choke within the previous few weeks from which they appeared to recover spontaneously. Passage of a nasogastric tube can be possible in some and not in others.

Chronic Obstruction

No acute signs of obstruction are evident and in cattle the earliest sign is chronic bloat, which is usually of moderate severity and can persist for several days without the appearance of other signs. Rumen contractions can be within the normal range. In horses and in cattle in which the obstruction is sufficiently severe to interfere with swallowing, a characteristic syndrome develops. Swallowing movements are usually normal until the bolus reaches the obstruction, when they are replaced by more forceful movements. Dilatation of the esophagus can cause a pronounced swelling at the base of the neck. The swallowed material either passes slowly through the stenotic area or accumulates and is then regurgitated. Projectile expulsion of ingested material occurs with esophageal diverticula, but water is retained and there is no impedance to the passage of the stomach tube. In the later stages, there can be no attempt made to eat solid food, but fluids can be taken and swallowed satisfactorily.

When there is **paralysis of the esophagus**, as in megaesophagus, regurgitation does not occur, but the esophagus fills and overflows, and saliva drools from the mouth and nostrils. Aspiration into the lungs can follow. Passage of a stomach tube or probang is obstructed by stenosis but can be unimpeded by paralysis.

Complications Following Esophageal Obstruction

The risk of complications increases proportionate to the duration of obstruction.[4] Complications following an esophageal obstruction are most common in the horse and include esophagitis, mucosal ulceration, esophageal perforation and esophageal stricture, and aspiration pneumonia.[4] Complications developed in 51% of 109 horses hospitalized, with choke and the most frequent complication was aspiration pneumonia (39 of 109 horses).[4] The complication rate is much lower among horses treated in the field and in which resolution of the choke occurs within 24 hours.[2]

Mild cases of esophagitis heal spontaneously. Circumferential full-thickness mucosal ulceration can result in a stricture, which will be clinically evident in 2 to 5 weeks and can require surgical correction or balloon dilatation.[5] Esophageal perforation can occur and is characterized by diffuse cellulitis of the periesophageal tissues, often with subcutaneous emphysema, and a fistula can develop.

CLINICAL PATHOLOGY

Laboratory tests are not used in diagnosis, although radiographic examination is helpful to outline the site of stenosis, diverticulum, or dilatation, even in animals as large as the horse. Radiologic examination after a barium swallow is a practicable procedure if the obstruction is in the cervical esophagus. Viewing of the internal lumen of the esophagus with a fiberoptic endoscope has completely revolutionized the diagnosis of esophageal malfunction. Biopsy samples of lesions and tumor masses can be taken using the endoscope. Electromyography has been used to localize the area of paralysis of the esophagus in a cow with functional megaesophagus.

TREATMENT

Conservative Approach

Many obstructions will resolve spontaneously and a careful conservative approach is recommended. Of 60 cases first treated in the field, 45 resolved within 12 hours, 51 within 24 hours, and 58 in 48 hours.[2] If there is a history of prolonged choke with considerable nasal reflux having occurred, the animal should be examined carefully for evidence of foreign material in the upper respiratory tract and the risk of aspiration pneumonia. It can require several hours of monitoring, reexamination, and repeated sedation before the obstruction is resolved. During this time, the animal should not have access to feed and water.

Sedation

In acute obstruction, if there is marked anxiety and distress, the animal should be sedated before proceeding with specific treatment. Administration of a sedative such as an α-2 receptor agonist, with or without an opiod, can also help to relax the esophageal spasm and allow passage of the impacted material. For sedation and esophageal relaxation in the horse, one of the following is recommended:

- Acepromazine 0.05 mg/kg BW intravenously
- Xylazine 0.5 to 1.0 mg/kg BW intravenously
- Detomidine 0.01 to 0.02 mg/kg BW intravenously
- Romifidine 0.04 to 0.12 mg/kg intravenously.

DIFFERENTIAL DIAGNOSIS

- The clinical findings of acute esophageal obstruction in cattle and horses are usually typical but can be similar to those of esophagitis, in which local pain is more apparent and there is often an accompanying stomatitis and pharyngitis.
- The excitement, sweating, and tachycardia observed in acute choke in the horse often suggests colic. Passage of a nasogastric tube reveals the obstruction. The use of a fiberoptic endoscope will usually locate the obstruction for visualization, and obstructions are easiest to see when the endoscope is being withdrawn rather than advanced.

Chronic obstruction

- Differentiation of the causes of chronic obstruction can be difficult. A history of previous esophagitis or acute obstruction suggests cicatricial stenosis. Contrast radiography of the esophagus is valuable in the investigation of horses with dysphagia, choke, and nasogastric reflux. The use of the sedative detomidine can affect the function of the esophagus and make interpretation of barium swallowing studies difficult.
- Persistent right aortic arch is rare and confined to young animals.
- Mediastinal lymph node enlargement is usually accompanied by other signs of tuberculosis or lymphomatosis.
- Chronic ruminal tympany in cattle can be caused by ruminal atony, in which case there is an absence of normal ruminal movements.

Continued

- Diaphragmatic hernia can also be a cause of chronic ruminal tympany in cattle and is sometimes accompanied by obstruction of the esophagus with incompletely regurgitated ingesta. This condition and vagus indigestion, another cause of chronic tympany, are usually accompanied by a systolic cardiac murmur, but passage of a stomach tube is unimpeded. Dysphagia can also result from purely neurogenic defects. Thus early paralytic rabies "choke" is often suspected, with dire results for the examining veterinarian.
- Equine encephalomyelitis and botulism are other diseases in which there is difficulty in swallowing.
- Cleft palate is a cause of recurrent nasal regurgitation in foals.

For esophageal relaxation, analgesia and antiinflammatory effect hyoscine: dipyrone 0.5:0.22 mg/kg BW intravenously can be used and for analgesia and antiinflammatory effect flunixin meglumine 1.1 mg/kg BW intravenously or phenylbutazone 2 to 4 mg/kg intravenously are suggested. For analgesia butorphanol 0.02 to 0.1 mg/kg intravenously can be administered.

Pass a Stomach Tube and Allow Object to Move Into Stomach

The passage of the nasogastric tube is always necessary to locate the obstruction. Gentle attempts can be made to push the obstruction caudad, but care must be taken to avoid damage to the esophageal mucosa. A fiberoptic endoscope can be used to determine the presence of an obstruction, its nature, and the extent of any injury to the esophageal mucosa.

If the previously discussed simple procedures are unsuccessful it is then necessary to proceed to more vigorous methods. In cattle, it is usual to attempt further measures immediately, partly because of the animal's distress and the risk of self-injury and partly because of bloat. However, rarely is the bloat associated with esophageal obstruction life-threatening. The important decision is whether to proceed and risk damaging the esophagus or wait and allow the esophageal spasm to relax and the obstruction to pass spontaneously. This problem is most important in the horse. Attempts to push the obstruction too vigorously can injure the mucosa, causing esophagitis and even esophageal perforation. Alternatively, leaving a large obstruction in place can restrict blood flow to the local area of mucosa and result in ischemic necrosis. Complications such as strictures and diverticula can occur but are uncommon. As a guide in the horse it is suggested that conservative measures (principally sedation, waiting, and lavaging the esophagus) be continued for several hours before attempting radical procedures such as general anesthesia and manipulation or esophagotomy.

Removal by Endoscope

If a specific foreign body, such as a piece of wood, is the cause of the obstruction, it can be removed by endoscopy. The foreign body must be visible endoscopically, and suitable forceps or a snare through the scope is required. In some cases, impacted feed anterior to the foreign object must be lavaged out before the object is retrieved.

Manual Removal Through Oral Cavity in Cattle

Solid obstructions in the upper esophagus of cattle can be reached by passing the hand into the pharynx with the aid of a speculum and having an assistant press the foreign body up toward the mouth. Because of slippery saliva, it is often difficult to grasp the obstruction sufficiently strongly to be able to extricate it from the esophagus. A long piece of strong wire bent into a loop can be passed over the object and an attempt made to pull it up into the pharynx. The use of Thygesens probang with a cutting loop is a simple and effective method of relieving choke in cattle that have attempted to swallow beets and other similar-sized vegetables and fruits. If both methods fail, it is advisable to leave the object in situ and use treatments aimed at relaxing the esophagus. In such cases in cattle it can be necessary to trocarize the rumen and leave the cannula in place until the obstruction is relieved. However, this should not be undertaken unless specifically required.

General Anesthesia in the Horse

In horses, attempts to manually remove solid obstructions from the cranial portion of the esophagus require a general anesthetic, a speculum in the mouth, and a manipulator with a small hand. The fauces are much narrower in the horse than in the cow and it is only with difficulty that the hand can be advanced through the pharynx to the beginning of the esophagus. Fragments of nasogastric tubes have been retrieved from the esophagus of horses using sedation with xylazine and butorphanol intravenously and the use of a fiberoptic endoscope.

Esophageal Lavage in the Horse

Accumulations of feedstuffs, which are most common in the horse, can be removed by careful lavage or flushing of the obstructed esophagus. Lavage can be performed in the **standing horse** or in **lateral recumbency under general anesthesia.** Small quantities of warm water, 0.5 to 1 L each time, are pumped through a nasogastric tube passed to the point of obstruction, and then the tube is disconnected from the pump and the liquid material is allowed to siphon out through the tube by gravity flow. Return of the fluid through the oral cavity and nostrils is minimized by ensuring that the tube is not plugged by returning material and by using only small quantities of fluid for each input of the lavage. Throughout the procedure, the tube is gently manipulated against the impaction. The use of a transparent tube assists in helping to see the amount and nature of the material coming through the tube. This is repeated many times until the fluid becomes clear. This procedure can require a few hours, but perseverance will be successful. After each lavage the tube can be advanced caudad a few centimeters and eventually all the way to the stomach. Care must be taken to avoid overflowing the esophagus and causing aspiration into the lungs. This is a constant hazard whenever irrigative removal is attempted and the animal's head must always be kept as low as possible to avoid aspiration. Following relief of obstruction the horse can be offered water to drink and a wet mash of feed for several days.

Lavage is similar in the recumbent horse under general anesthesia. A cuffed endotracheal tube is used to maintain an airway and to prevent aspiration of foreign material. Lavage under general anesthesia provides relaxation of the esophagus, which can enhance the procedure and allow a greater volume of water to be used.

Surgical Removal of Foreign Bodies

Surgical removal by esophagostomy can be necessary if other measures fail. Gastrotomy or rumenotomy can be necessary to relieve obstructions of the caudal portion of the esophagus adjacent to the cardia. Although stricture or fistula formation is often associated with esophageal surgery, complications do not occur in every case and healing by secondary intention is common.

Repeated Siphonage in Chronic Cases

In chronic cases, especially those caused by paralysis, repeated siphonage can be necessary to remove fluid accumulations. Successful results are reported in foals using resection and anastomosis of the esophagus and in a horse using esophagomyotomy, but the treatment of chronic obstruction is usually unsuccessful.

Cervical Esophagostomy Alimentation

Alimentation of horses with esophageal ruptures can be attempted by various means. Maintenance of nasogastric tubes through the nostrils is difficult but possible. Tube feeding through a **cervical esophagostomy** has some disadvantages, but it is a reasonably satisfactory procedure in any situation where continued extraoral alimentation is required in the horse. However, the death rate is higher than with nasogastric tube feeding. When the obstruction is caused by circumferential esophageal ulceration, the lumen is smallest at about 50 days and begins to dilate at that

point so that it is normal again at about 60 days.

Antimicrobial Administration

Animals with prolonged obstruction (>12–24 hours), fever, abnormal lung sounds, ultrasonographic or radiographic evidence of aspiration, or in which there is a suspicion of aspiration of regurgitus should be administered broad-spectrum antimicrobials for 5 to 7 days.

Diseases of the Nonruminant Stomach and Intestines

Diseases that are accompanied by physical lesions, such as displacement or strangulation, or disturbances of motility, such as ileus, are presented first for the horse and pig. Bacterial and viral infectious diseases specific to the pig are then discussed, followed by bacterial infectious diseases of large animals (including horses, pigs, and neonatal and adult ruminants) such as salmonellosis and viral diseases of large animals such as VS. Bacterial, viral, and parasitic infectious diseases of the stomach and intestine are then presented for the foal; piglet; and neonatal calf, lamb, and kid. Diseases of the stomach and intestine for the horse and pig, as well as neonatal and adult ruminants, caused by toxins or those that are caused by congenital or inherited disease, are discussed last. Diseases associated with functional disturbances of secretion are not recognized in animals. Deficiencies of biliary and pancreatic secretion are dealt with in Chapter 9. Those diseases of the stomach and intestines peculiar to adult ruminants are dealt with separately in Chapter 8.

GASTRITIS

Inflammation of the stomach is manifested clinically by vomiting and is commonly associated with enteritis in gastroenteritis.

ETIOLOGY

Gastritis may be acute or chronic, but both forms of the disease may be caused by the same etiologic agents acting with varying degrees of severity and for varying periods. The inflammation may be associated with physical, chemical, bacterial, viral, or metazoan agents.

Cattle and Sheep

Diseases of the rumen and abomasum are presented in Chapter 8. For comparative purposes the causes of abomasitis are listed here. For sheep there is no information other than about parasites. They are listed with cattle for convenience sake.

Physical Agents

Physical agents such as frosted feeds affect only the rumen. In calves, gross overeating and the ingestion of foreign materials may cause abomasitis. In adults, there is a very low incidence of foreign bodies in the abomasum, and half the cases are associated with traumatic reticulitis.

Chemical Agents

All of the irritant and caustic poisons (including arsenic, mercury, copper, phosphorus, and lead) cause abomasitis. Fungal toxins cause abomasal irritation, especially those of *Fusarium* spp. and *Stachybotrys alternans*. Acute lactic acidosis caused by engorgement on carbohydrate-rich food causes rumenitis with some runoff into the abomasum and the development of some abomasitis/enteritis.

Infectious Agents

Only the viruses of rinderpest, bovine virus diarrhea, and bovine malignant catarrh cause abomasal erosions. Bacterial causes are very rare and include sporadic cases of extension from oral necrobacillosis and hemorrhagic enterotoxemia caused by *Clostridium perfringens* Types A, B, C, rarely as an adjunct to colibacillosis and its enteric lesion in calves. Fungi, e.g., *Mucor* spp. and *Aspergillus* spp. complicate abomasal ulcers from other causes.

Metazoan Agents

Metazoan agents include nematodes such as *Trichostrongylus axei*, *Ostertagia* spp., *Haemonchus* spp., and larval paramphistomes migrating to the rumen.

Pigs

Most often lesions are associated with ulceration of the pars esophagea (PE), which is discussed under the separate topic of gastric ulceration.

Physical Agents

Foreign bodies, bedding, frosted feeds, moldy and fermented feeds are all possible causes. In older pigs, particularly outdoor sows, the presence of stones is a common feature and in some cases may be so bad as to be heard when sows move because considerable loss of weight is associated with the gastric fill. It may be one of the causes of the thin sow syndrome.

Chemical Agents

As listed under cattle, these are also possible causes of gastritis in pigs. It may also occur in the achlorhydria associated with diarrhea. Pigs are extremely inquisitive and will investigate all compounds, but hopefully in this day and age there should be more care over on-farm storage. Bitterweed and blister beetle will also cause gastritis in pigs.

Infectious Agents

Venous hyperemia and infarction of the gastric mucosa occur in erysipelas, salmonellosis, porcine dermatitis and nephropathy syndrome (PDNS), TGE, swine dysentery and acute colibacillosis in weaned pigs. Similar lesions occur in classical swine fever, African swine fever, and swine influenza. Fungal gastritis also occurs secondarily particularly to antibiotic therapy.

Metazoan Agents

The red stomach worm, *Hyostrongylus rubidus*, and the thick stomach worms *Ascarops strongylina* and *Physocephalus sexalatus* are of low pathogenicity but cannot be disregarded as causes of gastritis in pigs. *Simondsia* spp. are found in Europe, Asia, and Australia and cause nodular gastritis. *Gnathostoma* spp. occur in Asia and produce cysts in the submucosa. On most commercial units, especially if outdoors, routine medication is practiced, but backyard pigs are seldom treated because of unawareness. These agents are also found in many wild boar and feral pigs.

Horses

Physical and chemical agents as listed under cattle rarely may cause gastritis. Infectious causes of gastritis are rare in the horse, but emphysematous gastritis associated with *C. perfringens* has been recorded.

Metazoan agents causing gastritis in horses include massive infestation with botfly larvae (*Gasterophilus* spp.); *Habronema muscae* and *H. microstoma* infestation; *H. megastoma* causes granulomatous and ulcerative lesions and can lead to perforation and peritonitis.

PATHOGENESIS

Gastritis does not often occur in animals without involvement of other parts of the alimentary tract. Even in parasitic infestations in which the nematodes are relatively selective in their habitat, infestation with one nematode is usually accompanied by infestation with others, and gastroenteritis is produced. It is dealt with as a specific entity here because it may occur as such, and enteritis is common without gastric involvement. The net effects of gastroenteritis can be determined by a summation of the effects of gastritis and enteritis.

The reactions of the stomach to inflammation include increased motility and increased secretion. There is an increase in the secretion of mucus, which protects the mucosa to some extent but also delays digestion and may allow putrefactive breakdown of the ingesta. This abnormal digestion

may cause further inflammation and favors spread of the inflammation to the intestines. In acute gastritis, the major effect is on motility, and in chronic gastritis it is on secretion. In acute gastritis there is an increase in motility, causing abdominal pain and more rapid emptying of the stomach, either by vomiting or via the pylorus in animals unable to vomit. In chronic gastritis, the emptying of the stomach is prolonged because of the delay in digestion caused by excessive secretion of mucus. This may result in chronic gastric dilatation. The motility is not necessarily diminished and there may be subacute abdominal pain or a depraved appetite caused by increased stomach contractions equivalent to hunger pains.

CLINICAL FINDINGS

Acute Gastritis

When the inflammation is severe, pigs and, rarely, horses and ruminants vomit (or ruminants regurgitate excessive quantities of rumen contents). In monogastric animals, such as pigs, the vomitus contains a great deal of mucus, sometimes blood, and is small in amount, and vomiting is repeated with forceful retching movements. The appetite is always reduced, and often absent, but thirst is usually excessive and pigs affected with gastroenteritis may stand continually lapping water or even licking cool objects. The breath has an offensive odor and there may be abdominal pain. Diarrhea is not marked unless there is accompanying enteritis, but the feces are usually pasty and soft. Additional signs are usually evident when gastritis is part of a primary disease syndrome. Dehydration and alkalosis with tetany and rapid breathing may develop if vomiting is excessive.

Chronic Gastritis

Chronic gastritis is much less severe. The appetite is depressed or depraved and vomiting occurs only sporadically, usually after feeding. The vomitus contains much viscid mucus. Abdominal pain is minor and dehydration is unlikely to occur, but the animal becomes emaciated through lack of food intake and incomplete digestion.

Anorexia, tympanites, gastritis, pyloric stenosis, and gastric ulcers are the clinical manifestations of abomasal foreign body in cattle.

CLINICAL PATHOLOGY

Specimens taken for laboratory examination are usually for the purpose of identifying the causative agent in specific diseases. Estimations of gastric acidity are not usually undertaken, but samples of vomitus should be collected if a chemical poison is suspected.

NECROPSY FINDINGS

The signs of inflammation vary in severity from a diffuse catarrhal gastritis to severe hemorrhagic and ulcerative erosion of the mucosa. In the mucosal diseases there are discrete erosive lesions. In parasitic gastritis there is usually marked thickening and edema of the wall if the process has been in existence for some time. Chemical inflammation is usually most marked on the tips of the rugae and in the pyloric region. In severe cases the stomach contents may be hemorrhagic; in chronic cases the wall is thickened and the contents contain much mucus and have a rancid odor suggestive of a prolonged sojourn and putrefaction of the food.

It is important to differentiate between gastritis and the erythematous flush of normal gastric mucosa in animals that have died suddenly. Venous infarction in the stomach wall occurs in a number of bacterial and viral septicemias of pigs and causes extensive submucosal hemorrhages, which may easily be mistaken for hemorrhagic gastritis.

DIFFERENTIAL DIAGNOSIS

- Gastritis and gastric dilatation have many similarities, but in the latter the vomitus is more profuse and vomiting is of a more projectile nature, although this difference is not so marked in the horse, in which any form of vomiting is severe.
- Gastritis in the horse is not usually accompanied by vomiting but may occur in gastric dilatation.
- In esophageal obstruction, the vomitus is neutral in reaction and does not have the rancid odor of stomach contents.
- Intestinal obstruction may be accompanied by vomiting and, although the vomitus is alkaline and may contain bile or even fecal material, this may also be the case in gastritis when intestinal contents are regurgitated into the stomach.
- Vomiting of central origin is extremely rare in farm animals.
- Determination of the cause of gastritis may be difficult, but the presence of signs of the specific diseases and history of access to poisons or physical agents listed under etiology may provide the necessary clues.
- Analysis of vomitus or food materials may have diagnostic value if chemical poisoning is suspected.

TREATMENT

Treatment of the primary disease is the first principle and requires a specific diagnosis. Ancillary treatment includes the withholding of feed, the use of gastric sedatives, the administration of electrolyte solutions to replace fluids and electrolytes lost by vomiting, and stimulation of normal stomach motility in the convalescent period.

In horses and pigs, gastric lavage may be attempted to remove irritant chemicals. Gastric sedatives usually contain insoluble magnesium hydroxide or carbonate, kaolin, pectin, or charcoal. Frequent dosing at intervals of 2 to 3 hours is advisable. If purgatives are used to empty the alimentary tract, they should be bland preparations such as mineral oil to avoid further irritation to the mucosa.

If vomiting is severe, large quantities of electrolyte solution should be administered parenterally. Details of the available solutions are given under the heading of disturbances of body water. If the liquids can be given orally without vomiting occurring, this route of administration is satisfactory.

During convalescence, the animal should be offered only soft, palatable, highly nutritious foods. Bran mashes for cattle and horses and gruels for calves and pigs are most suitable and are relished by the animal.

ENTERITIS (INCLUDING MALABSORPTION, ENTEROPATHY, AND DIARRHEA)

The term enteritis is used to describe inflammation of the intestinal mucosa resulting in diarrhea and sometimes dysentery, abdominal pain occasionally, and varying degrees of dehydration and acid-base imbalance, depending on the cause of the lesion, its severity, and location. In many cases, gastritis also occurs together with enteritis.

There are several diseases of the intestines of farm animals in which diarrhea and dehydration are major clinical findings, but classical inflammation of the mucosa may not be present. The best example of this is the diarrhea associated with enterotoxigenic *E. coli* (ETEC) which elaborates an enterotoxin that causes a large net increase of secretion of fluids into the lumen of the gut, with very minor, if any, structural changes in the intestinal mucosa. This suggests that a word other than enteritis may be necessary to describe alterations in the intestinal secretory and absorptive mechanisms that result in diarrhea but in which pathologic lesions are not present. However, with these qualifications, for convenience, the term enteritis is used to describe those diseases in which diarrhea is a major clinical finding caused by malabsorption in the intestinal tract.

ETIOLOGY AND EPIDEMIOLOGY

There are many causes of enteritis or malabsorption in farm animals and the disease varies considerably in its severity depending on the causative agent. Enteropathogens include bacteria, viruses, fungi, protozoa, and helminths. Many chemicals and toxins can also cause enteritis (Tables 7-4 to 7-7). In addition to the primary etiologic agents of enteritis, there are many epidemiologic characteristics of the animal and the environment that are important in facilitating or suppressing the ability of the causative agent to cause enteritis. Thus newborn calves and piglets deficient in colostral immunoglobulins are much more susceptible to diarrhea, and have a higher case–fatality rate from diarrhea than animals with adequate

Table 7-4 Epidemiological and clinical features of diseases of cattle in which diarrhea is a significant clinical finding

Etiological agent or disease	Age and class of animal affected and important epidemiological factors	Major clinical findings and diagnostic criteria
Bacteria		
Enterotoxigenic *Escherichia coli*	Newborn calves <3–5 days of age, colostral immune status determines survival; outbreaks common	Acute profuse watery diarrhea, dehydration and acidosis Culture feces for enteropathogenic type
Salmonella spp.	All ages; outbreaks occur; stress induced	Acute diarrhea, dysentery, fever, and high mortality possible Culture feces
Clostridium perfringens types B and C	Young well-nourished calves <10 days of age	Severe hemorrhagic enterotoxemia, rapid death; fecal smear
Mycobacterium avium subsp. *paratuberculosis*	Mature cattle, sporadic, single animal	Chronic diarrhea with loss of weight, long course No response to therapy; special tests
Proteus spp. and *Pseudomonas* spp.	Calves treated for diarrhea with prolonged course of antibiotics	Chronic to subacute diarrhea, poor response to treatment, progressive loss of weight; culture feces
Fungi		
Candida spp.	Young calves following prolonged use of oral antibacterials	Chronic diarrhea, no response to treatment; fecal smears
Viruses		
Rotavirus and coronavirus	Newborn calves, 5–21 days old, explosive outbreaks	Acute profuse watery diarrhea; demonstrate virus in feces
Winter dysentery (Coronavirus)	Mature housed cows, explosive outbreaks	Acute epizootic of transient diarrhea and dysentery lasting 24 h; definitive diagnosis not possible currently
Bovine virus diarrhea (mucosal disease)	Young cattle 8 months to 2 years; usually sporadic but epidemics occur	Erosive gastroenteritis and stomatitis; usually fatal; virus isolation
Rinderpest	Highly contagious, occurs in plague form	Erosive stomatitis and gastroenteritis; high morbidity and mortality
Bovine malignant catarrh	Usually mature cattle, sporadic but small outbreaks occur	Erosive stomatitis and gastroenteritis, enlarged lymph nodes, ocular lesions, hematuria and terminal encephalitis Transmission with whole blood
Helminths		
Ostertagiasis	Young cattle on pasture	Acute or chronic diarrhea, dehydration, and hypoproteinemia Fecal examination; plasma pepsinogen
Protozoa		
Eimeria spp.	Calves over 3 weeks old and cattle up to 12 months of age; outbreaks common	Dysentery, tenesmus, nervous signs; Fecal examination diagnostic
Cryptosporidium spp.	Calves 5–35 days of age	Diarrhea; fecal smear and special stain
Chemical agents		
Arsenic, fluorine, copper, sodium chloride, mercury, molybdenum, nitrates, poisonous plants, mycotoxicoses	All ages, history of access to substance Outbreaks occur	All severities of diarrhea, dysentery, abdominal pain, in some cases nervous signs, dehydration, toxemia; fecal and tissue analyses
Physical agents		
Sand, soil, silage, and feed containing lactic acid (sour brewers' grains)	Usually mature cattle, history of access; outbreaks occur	Acute, subacute diarrhea, and toxemia; see sand in feces Rumen pH
Nutritional deficiency		
Copper deficiency, conditioned by excess molybdenum	Usually mature cattle on pasture with high levels of molybdenum	Subacute and chronic diarrhea, osteodystrophy, no systemic effects, hair color changes; liver and blood analyses
Dietary		
Overfeeding	Young calves overfed on milk	Mild diarrhea, feces voluminous and pale yellow; clinical diagnosis
Simple indigestion	Change of ration of mature cows (hay to silage) or grain to feedlot cattle	Subacute diarrhea; normal in 24 h; Clinical diagnosis usually sufficient
Inferior milk replacers	Heat-denatured skim milk used in manufacturing of milk replacers for calves	Subacute to chronic diarrhea, progressive emaciation, no response to conventional treatment except cow's whole milk Clotting tests on milk replacer
Miscellaneous or uncertain etiology		
Intestinal disaccharidase deficiency	May occur in young calves. Sporadic	Subacute diarrhea unresponsive to usual therapy except withdrawal of milk; lactose digestion tests
Congestive heart failure	Sporadic; mature cattle	Profuse watery diarrhea associated with visceral edema
Toxemia (peracute coliform mastitis)	Sporadic	Acute diarrhea caused by endotoxemia from peracute mastitis Culture milk

Table 7-5 Epidemiological and clinical features of horses with diarrhea

Etiological agent or disease	Age and class of animal affected and important epidemiological factors	Major clinical findings; *diagnostic criteria*
Bacteria		
Salmonella spp.	Young foals; mature horses, following stress	Acute profuse diarrhea, severe dehydration, foul-smelling feces; leukopenia and neutropenia, culture feces, hyponatremia
Rhodococcus equi	Foals 2–5 months of age, some with history of respiratory disease	Diarrhea associated with *R. equi* pneumonia; culture respiratory tract
Clostridium perfringens or	Mature horses administered antibiotics; young foals	Profuse, watery diarrhea, hypovolemia, hyponatremia.
C. difficile		Fecal culture and demonstration of toxin in feces
Aeromonas spp.	Adult horses, tends to be more common in summer; often isolated from horses with diarrhea	Febrile, acute diarrhea; culture feces
	Definitive etiological role not proved	
Viruses and rickettsia		
Neorickettsia risticii (formerly *Ehrlichia risticii*)	Endemic to certain regions in North and South America and Europe; ingestion of organism spread by insects (mayflies)	Profuse watery diarrhea, fever, laminitis; IFA, PCR
Parasites		
Cyathostomes and large strongyles	Individual horses; poor deworming history	Acute to chronic diarrhea. *Patent infections evident by fecal examination for parasite eggs*
	Seasonal occurrence of larval cyathostomiosis	
Physical		
Sand accumulation	Individual horses or farm problem; Ingestion of sand or gravel	Watery diarrhea, not malodorous, not profuse; *abdominal radiography or ultrasonography, examination of feces*
Overdosing of cathartics (DSS, $MgSO_4$, $NaSO_4$, castor oil)	Treated animals	Moderate to profuse diarrhea; *historical confirmation of administration of compounds*
Miscellaneous or unknown		
Colitis X	Single animal; adult horses; high death rate	Acute, pyrexic diarrhea, hypovolemia, leukopenia; *postmortem examination*
Granulomatous or eosinophilic colitis	Single animal; adults	Chronic diarrhea; *necropsy or colonic biopsy*
Right dorsal colitis/ phenylbutazone toxicity	Administration of NSAIDs in large doses or prolonged administration	Mild diarrhea; low-grade fever; Mild colic; hypoproteinemia, hyponatremia; *necropsy, surgery*
Antibiotic-induced diarrhea	History of antimicrobial administration; high case–fatality rate	Acute onset diarrhea with or without fever; leukopenia, hypovolemia; *history*

DSS, dioctyl sodium sulfosuccinate; IFA, indirect fluorescence antibody test; NSAIDs, nonsteroidal antiinflammatory drugs; PCR, polymerase chain reaction.

Table 7-6 Epidemiological and clinical features of diseases of the pig in which diarrhea is a significant clinical finding

Etiological agent or disease epidemiological factors	Age and class of animal affected and important	Major clinical findings and diagnostic criteria
Viruses		
Classical and African swine fever	Hemorrhagic diarrhea at any age	Many other signs (pyrexia); a variety of lab tests (isolation, ELISA, PCR etc.)
Transmissible gastroenteritis	Explosive outbreaks in newborn piglets; high morbidity and mortality	Acute diarrhea, vomition, dehydration, and death; no response to treatment (lab tests include virus isolation, ELISA, EM, FATs)
Rotavirus and coronavirus (epidemic diarrhea)	Outbreaks in newborn piglets and weaned piglets May occur in well-managed herds	Acute diarrhea and dehydration; may continue to suck the sow; death in 2–4 days; virus isolation and pathology of gut, EM, FATs (PED); PAGE for rotavirus
Bacteria		
Enterotoxigenic *Escherichia coli*	Common disease of newborn, 3-week-old and weaned piglets; outbreaks; colostral immune status important	Acute diarrhea, dehydration; responds to early treatment Fecal culture and serotype; virulence factor determination
Salmonella spp.	All ages; most common in feeder pigs	Acute septicemia or chronic diarrhea; responds to early treatment; culture and serotyping

Table 7-6 Epidemiological and clinical features of diseases of the pig in which diarrhea is a significant clinical finding—cont'd

Etiological agent or disease epidemiological factors	Age and class of animal affected and important	Major clinical findings and diagnostic criteria
Clostridium perfringens type C	Newborn piglets; high mortality	Acute and peracute hemorrhagic enterotoxemia; toxin demonstration and culture
C. perfringens type A	Slightly older pigs, first week of life, lower mortality	As previously mentioned
C. difficile	Diarrhea in preweaned pigs	Smears of colon wall, culture, FAT, PCR
Brachyspira hyodysenteriae (swine dysentery)	Usually feeder pigs; outbreaks common	Dysentery, acute to subacute, fever; responds to treatment Culture, FATs, PCR on mucosal smears
Lawsonia *intracellularis* (PIA, PHE)	Growing and mature pigs; outbreaks common	Acute dysentery and death; MZN on mucosal smears, PCR, silver-stained sections
Brachyspira pilosicoli	Usually weaned pigs	PCR
Protozoa		
Isospora spp.	Newborn piglets 5–14 days of age; high morbidity, low mortality	Acute diarrhea; poor response to therapy with amprolium Fecal examination for oocysts
Other species (*Eimeria*)	In older pigs	Histology of gut sections
Parasites		
Ascaris suum and	Young pigs	
A. lumbricoides	All ages, usually older pigs	Mild diarrhea for few days; worm egg count
Trichuris suis		Diarrhea, dysentery, and loss of weight; fecal examination and gross pathology
Nutritional deficiency		
Iron deficiency	Young piglets 6–8 weeks; not common in well-managed swine herds	Mild diarrhea and anemia

ELISA, enzyme-linked immunoassay; EM, electron micrograph; FAT, fluorescence antibody transfer; MZN, modified Ziehl–Neilson; PAGE, polyacrylamide gel electrophoresis; PCR, polymerase chain reaction; PED, porcine epidemic diarrhea; PHE, proliferative hemorrhagic enteropathy; PIA, porcine intestinal adenomatosis.

Table 7-7 Epidemiological and clinical features of the diseases of sheep and goats in which diarrhea is a significant clinical finding

Etiological agent or disease	Age and class of animal affected and important epidemiological factors	Major clinical findings and diagnostic criteria
Bacteria		
Enterotoxigenic *Escherichia coli* (colibacillosis)	Newborn lambs in crowded lambing sheds; cold chilling weather; outbreaks; inadequate colostrum. Mismothering problems; poor udder development	Acute diarrhea (yellow feces), septicemia, and rapid death Culture feces for enterotoxigenic *E. coli*
Clostridium perfringens type B (lamb dysentery)	Newborn lambs up to 10 days of age; overcrowded lambing sheds	Sudden death, diarrhea, dysentery, and toxemia; fecal smear
C. perfringens type D (enterotoxemia)	Adult lactating does	Peracute, acute, and chronic forms occur; enterocolitis; watery diarrhea with feces containing blood and mucus, weakness, abdominal colic
Salmonella spp.	Newborn lambs; adult sheep in pregnancy	Acute diarrhea and dysentery in lambs; acute toxemia, diarrhea in ewes followed by abortion; fecal culture and pathology
Mycobacterium paratuberculosis	Mature sheep and goats; several animals may be affected	Loss of weight, chronic diarrhea, long course, no response to therapy; serological tests
Viruses		
Rotavirus and coronavirus	Newborn lambs; many lambs affected	Acute profuse watery diarrhea; no toxemia; usually recover spontaneously if no secondary complications; virus isolation
Parasites		
Nematodirus spp.	Lambs 4–10 weeks of age on pasture Sudden onset; outbreaks; ideal environmental conditions for parasite are necessary	Anorexia, diarrhea, thirsty, 10%–20% of lambs may die if not treated; fecal examination
Ostertagia spp.	Lambs 10 weeks of age and older lambs and young	Many lambs develop diarrhea, weight loss; abomasitis
Ewes on grass; types I and II		
Trichostrongylus spp.	Older lambs 4–9 months of age	Dull, anorexic, loss of weight and chronic diarrhea; fecal examination

Continued

Table 7-7 Epidemiological and clinical features of the diseases of sheep and goats in which diarrhea is a significant clinical finding—cont'd

Etiological agent or disease	Age and class of animal affected and important epidemiological factors	Major clinical findings and diagnostic criteria
Protozoa		
Eimeria spp.	Overstocking on pasture and overcrowding indoors, poor sanitation, and hygiene; commonly occurs following weaning and introduction into feedlot	Acute and subacute diarrhea and dysentery; loss of weight Mortality may be high; fecal examination
Cryptosporidium	Lambs 7–10 days of age	Dullness, anorexia, afebrile, diarrhea, may die in 2–3 days, survivors may be unthrifty; examination of feces and intestinal mucosa; no specific treatment

levels. Enteric salmonellosis is commonly precipitated by the stressors of transportation or deprivation of feed and water. The stress of weaning in pigs is a risk factor for PWD. The prolonged use of antimicrobials orally in all species may alter the intestinal microflora and allow the development of a superinfection by organisms that would not normally cause disease.

The salient epidemiologic characteristics and clinical findings of the diseases in which diarrhea, caused by enteritis or malabsorption, is a principal clinical finding in each species are summarized by species in Tables 7-4 to 7-7. There are many other diseases in which diarrhea might be present but in which it is only of minor importance.

PATHOGENESIS

Normal Intestinal Absorption

Under normal conditions, a large quantity of fluid enters the small intestine from the saliva, stomach, pancreas, liver, and intestinal mucosa. This fluid and its electrolytes and other nutrients must be absorbed, mainly by the small intestines, although large quantities move into the large intestine for digestion and absorption, especially in the horse. The brush border membrane of the villous epithelial cells is of paramount importance for the absorption of water, electrolytes, and nutrients.

Details of the physiology and pathophysiology of epithelial secretion in the gastrointestinal tract are becoming clear, leading to new models of the mechanisms underlying diarrhea. The enteric nervous system is a critical component of the mechanism regulating fluid secretion in the normal intestine and a key element in the pathophysiology of diarrhea. Neural reflex pathways increase epithelial fluid secretion in response to several enteric pathogens of veterinary importance such as *Salmonella* spp., *Cryptosporidium parvum,* rotavirus, and *C. difficile.* The enteric nervous system also has an important role in epithelial secretion triggered by products of activated leukocytes during inflammation.

Mechanisms of Diarrhea

Any dysfunction of the intestines will result in failure of adequate absorption and diarrhea. Depending on the causative agent, intestinal malabsorption may be the result of at least four different mechanisms:

- Osmotic diarrhea
- Exudative diarrhea
- Secretory diarrhea
- Abnormal intestinal motility

Osmotic Diarrhea

There may be an osmotic effect when substances within the lumen of the intestine increase the osmotic pressure over a greater than normal length of intestine, resulting in an osmotic movement of an excessive amount of fluid into the lumen of the intestine. The fluid is not reabsorbed and accumulates in the lumen. Examples include **saline purgatives**, **overfeeding**, **indigestible feeds,** and **disaccharidase deficiencies**. A deficiency of a disaccharidase leads to incomplete digestion and the accumulation of large quantities of undigested material, which acts as a hypertonic solution.

Malabsorption is associated with several epitheliotropic viruses that affect the villous absorptive cells, causing a disaccharidase deficiency. Examples include the TGE virus in newborn piglets and rotavirus and coronavirus infections in newborn calves and other species. The usual pathogenetic sequence of events is selective destruction of villous absorptive cells, villous atrophy, loss of digestive and absorptive capacities (malabsorption), diarrhea, crypt hyperplasia, and recovery. Recovery depends on the severity of the lesion, the relative injury done to the villous cells and crypt epithelium, and the age of the animal. Newborn piglets affected with TGE commonly die of dehydration and starvation before there is sufficient time for regeneration of the villous cells from the crypt epithelium. In contrast, older pigs have a greater capacity for regeneration of the villous cells and the diarrhea may be only transient.

Exudative Diarrhea

Acute or chronic inflammation or necrosis of the intestinal mucosa results in a net increase in fluid production; inflammatory products, including loss of serum proteins; and a reduction in absorption of fluids and electrolytes. Examples include many of the diseases associated with bacteria, viruses, fungi, protozoa, chemical agents, and tumors that are summarized in Tables 7-4 to 7-7. The classic example is enteric salmonellosis, in which there is severe inflammation with the production of fibrinous, hemorrhagic enteritis. Other notable examples include swine dysentery, bovine virus diarrhea, and inorganic arsenic poisoning.

Secretory Diarrhea

A **secretory–absorptive imbalance** results in a large net increase in fluid secretion with little if any structural change in the mucosal cells. The enterotoxin elaborated by ETEC results in intestinal hypersecretion. The villi, along with their digestive and absorptive capabilities, remain intact. The crypts also remain intact; however, their secretion is increased beyond the absorptive capacity of the intestines, resulting in diarrhea. The increased secretion is caused by an increase in cyclic adenosine monophosphate, which in turn may be stimulated by prostaglandins. The integrity of the mucosal structure is maintained and the secreted fluid is isotonic, electrolyte-rich, alkaline, and free of exudates. This is useful diagnostically in enterotoxic colibacillosis.

An important therapeutic principle can be applied in secretory diarrhea disease. Whenever possible, because of the cost of parenteral fluid therapy, fluids and electrolytes should be given orally. The mucosa remains relatively intact and retains normal absorptive capacity. Fluid replacement solutions containing water, glucose, and amino acids can be given orally and are absorbed efficiently. Glucose and amino acids enhance the absorption of sodium and water, replacing or diminishing fluid and electrolyte losses.

There is also evidence that active electrolyte secretion occurs in enterocolitis caused by salmonellosis in several species of animal. In diseases such as swine dysentery, the permeability of the colon may remain normal or even decrease, but the absorption of water and electrolytes is decreased. This suggests that the primary cause of fluid and electrolyte loss in some diseases of the colon may be failure of the affected epithelium to absorb fluids and electrolytes.

Abnormal Intestinal Motility

Hyperexcitability, convulsions, and the stress of unexpected sudden confinement may result in diarrhea, which may be caused by increased peristalsis, resulting in "**intestinal hurry**" and reduced intestinal absorption caused by rapid passage of intestinal fluids in an otherwise normal intestine. This can occur in animals that are being assembled for transportation and during transportation.

Location of Lesion

The location of the lesion in the intestinal tract may also influence the severity of the enteritis or malabsorption. Lesions involving the small intestine are considered to be more acute and severe than those in the large intestine, because approximately 75% to 80% of the intestinal fluids are absorbed by the small intestine and much lesser quantities by the large intestine. Generally, when lesions of the large intestine predominate, the fluid and electrolyte losses are not as acute or as severe as when the lesions of the small intestine predominate. However, the horse is an exception. The total amount of fluid entering the large intestine from the small intestine, plus the amount entering from the mucosa of the large intestine, is equal to the animal's total extracellular fluid volume, and 95% of this is reabsorbed by the large intestine. This illustrates the major importance of the large intestine of the horse in absorbing a large quantity of fluid originating from saliva, the stomach, liver, pancreas, and small and large intestine. Any significant dysfunction of the absorptive mechanism of the large intestine of the horse results in large losses of fluids and electrolytes. This may explain the rapid dehydration and circulatory collapse that occurs in horses with colitis X. Moderate to severe ulcerative colitis of the right dorsal colon in horses treated with phenylbutazone results in marked dehydration, endotoxic shock, and death.

Dehydration, Electrolyte, and Acid-Base Imbalance

The net effect of an increase in the total amount of fluid in the intestinal lumen and a reduction in intestinal absorption is a loss of fluids and electrolytes at the expense of body fluids and electrolytes and the normal intestinal juices. The fluid that is lost consists primarily of water; the electrolytes sodium, chloride, potassium, and bicarbonate; and varying quantities of protein. Protein is lost (protein-losing enteropathy) in both acute and chronic inflammation, leading to hypoproteinemia in some cases. The loss of bicarbonate results in **metabolic acidosis**, which is of major importance in acute diarrhea. The loss of sodium, chloride, and potassium results in **serum electrolyte imbalances**. In the horse with enteric salmonellosis, there is severe dehydration and marked hyponatremia. In the calf with neonatal diarrhea there are varying **degrees of dehydration** and a moderate loss of all electrolytes. With acute severe diarrhea, there is severe acidosis and reduced circulating blood volume, resulting in reduced perfusion of the liver and kidney and of peripheral tissues. This results in uremia, anaerobic oxidation, and lactic acidosis, which accentuates the metabolic acidosis. Hyperventilation occurs in some animals in an attempt to compensate for the acidosis.

In acute diarrhea, large quantities of intestinal fluid are lost in the feces and large quantities are present in the intestinal lumen (**intraluminal dehydration**), which accounts for the remarkable clinical dehydration in some affected animals. The fluid moves out of the intravascular compartment first, then out of the extravascular compartment (interstitial spaces), followed last by fluid from the intracellular space. Thus in acute diarrhea of sudden onset the actual degree of dehydration present initially may be much more severe than is recognizable clinically; as the diarrhea continues, the degree of clinical dehydration becomes much more evident.

Chronic Enteritis

In chronic enteritis, as a sequel to acute enteritis or developing insidiously, the intestinal wall becomes thickened and mucus secretion is stimulated, the absorption of intestinal fluids is also decreased but not of the same magnitude as in acute enteritis. In chronic enteritis there is a negative nutrient balance because of decreased digestion of nutrients and decreased absorption, resulting in body wasting. The animal may continue to drink and maintain almost normal hydration. In some cases of chronic enteritis, depending on the cause, there is continuous loss of protein, leading to clinical hypoproteinemia. Intestinal helminthiasis of all species, Johne's disease of ruminants, and chronic diarrheas of the horse are examples. Lymphocytic plasmacytic enteritis causing chronic weight loss occurs in the horse.

Regional ileitis is a functional obstruction of the lower ileum associated with granulation tissue proliferation in the lamina propria and submucosa, with or without ulceration of the mucosa, and a massive muscular hypertrophy of the wall of affected areas of the intestine. It has been recognized with increased frequency in recent years in pigs, horses, and lambs. The lesion undoubtedly interferes with normal digestion and absorption, but diarrhea is not a common clinical finding.

Replacement of Villous Epithelial Cells

The villous absorptive epithelial cells of the small intestine are involved in almost every type of enteritis or malabsorptive syndrome. These cells that line the villi and face the lumen of the intestine contain important digestive enzymes such as the disaccharidases. They are also involved in absorption of fluids, electrolytes, monosaccharides such as glucose, and amino acids, and in the transport of fat micelles. Their replacement time is up to several days in the newborn calf and piglet, and only a few days when these animals are older (at 3 weeks). This may explain the relatively greater susceptibility of the newborn to the viral enteritides, such as TGE in piglets and rotavirus infection in all newborn farm animal species. Almost any noxious influence can increase the rate of extrusion of these cells, which are then replaced by cells that are immature and not fully functional. The villi become shortened (villous atrophy) and chronic malabsorption similar to the "sprue gut" of humans may be the result. The destruction of villous epithelial cells explains the long recovery period of several days in some animals with acute enteritis and the chronic diarrhea in others with chronic villous atrophy.

The literature on the mechanisms of intestinal mucosal repair has been reviewed.

Role of Neutrophils in Intestinal Mucosal Injury

Neutrophils are critical elements of the cascade of events that culminates in mucosal injury in many inflammatory diseases of the gastrointestinal tract, including ischemia and reperfusion injury. Neutrophils mediate their detrimental actions by several mechanisms, especially physical disruption of the epithelium. These findings have resulted in consideration of strategies to attenuate neutrophil-mediated mucosal injury by preventing neutrophil transendothelial migration into the intestinal mucosa and subsequent activation during inflammation. Newer pharmacologic drugs that inhibit -β-2-integrin activation, and therefore β-2-integrin function, may be useful clinically to inhibit neutrophil-mediated injury during inflammation.

Intestinal Motility in Enteritis

The motility of the intestinal tract in animals with enteritis has not been sufficiently examined and little information is available. It was thought for many years that intestinal hypermotility, and increased frequency and amplitude of peristalsis, was present in most enteritides as a response to the enteritis and that the hypermotility accounted for the reduced absorption. However, when the pathogenesis of the infectious enteritides is

considered, for example, the unique secretory effect of enterotoxin, it seems more likely that, if hypermotility is present, it is a response to the distension of the intestinal lumen with fluid rather than a response to irritation. With a fluid-filled intestinal lumen, very little intestinal peristalsis would be necessary to move large quantities of fluid down the intestinal tract. This may explain the fluid-rushing sounds that are audible on auscultation of the abdomen in animals with enteritis. It is possible that the intestines may be in a state of relative hypomotility rather than hypermotility, which makes the use of antimotility drugs for the treatment of enteritis questionable.

Concurrent Gastritis

Gastritis commonly accompanies enteritis but does not cause vomition except perhaps in the pig. Gastritis (or abomasitis) may also be the primary lesion, resulting in a profuse diarrhea without lesions of the intestines. Examples are ostertagiasis and abomasal ulceration in cattle. Presumably the excessive amount of fluid secreted into the affected abomasum cannot be reabsorbed by the intestines.

Effects of Enteritis on Pharmacodynamics of Drugs

Enteritis may alter the pharmacodynamics of orally administered drugs. In acute diarrheal states there is delayed or impaired absorption, resulting in subtherapeutic plasma concentration. In chronic malabsorption states, decreased, increased, or delayed absorption may occur, depending on the drug. Also, gastric antacids, anticholinergic drugs, and opiates, administered orally for the treatment of diarrhea, may impair absorption of other drugs by altering solubility or delaying gastric emptying time.

CLINICAL FINDINGS

The major clinical finding in enteritis or malabsorption is **diarrhea**. **Dehydration**, **abdominal pain**, **septicemia,** and **toxemia** with **fever** occur commonly and their degree of severity depends on the causative agent, the age, the species of the animal, and the stage of the disease.

In **acute enteritis**, the feces are soft or fluid in consistency and may have an unpleasant odor. They may contain blood (**dysentery**), fibrinous casts, and mucus or obvious foreign material such as sand. The color of the feces will vary considerably: they are usually pale yellow because of the dilution of the brown bile pigments, but almost any color other than the normal is possible and, with the exception of frank blood (**hematochezia**) or **melena** (**black tarry feces**), the color of the feces is usually not representative of a particular disease. When the feces are watery, they may escape notice on clinical examination. Some indication of the nature of the enteritis may be obtained from the distribution of the feces on the animal's perineum. Thus in calves, the smudge pattern may suggest coccidiosis when both the staining that accompanies it and the feces are smeared horizontally across the ischial tuberosities and the adjoining tail, or helminth infestation when there is little smearing on the pinbones, but the tail and insides of the hocks are liberally coated with feces. Straining may occur, especially in calves, and be followed by rectal prolapse, particularly when the lesions are present in the colon and rectum. Intussusception may occur when the enteritis involves the small intestine.

There are a number of diseases in which **dysentery** with or without toxemia occurs and death may occur rapidly. These include lamb dysentery, hemorrhagic enterotoxemia of calves, acute swine dysentery, and hemorrhagic bowel syndrome of pigs.

Acute intraluminal hemorrhage caused by ulceration of unknown etiology in the small intestine has been recorded in adult cows. Duodenal ulceration may also occur in cattle in association with left-side displacement of the abomasum.

Systemic Effects

The **systemic effects in enteritis** vary considerably. Septicemia, toxemia, and fever are common in the infectious enteritides. An increased body temperature may return to normal following the onset of diarrhea or if circulatory collapse and shock are imminent. **Dehydration** will vary from being just barely detectable at 4% to 6% of BW up to 10% to 12% of BW, when it is clinically very evident. The degree of dehydration can be best assessed by tenting the skin of the upper eyelid or neck and determining the time taken for the skin fold to return to normal. The degree of recession of the eyeball is also a useful aid. In the early stages of acute enteritis, the degree of clinical dehydration may be underestimated because of the time required for fluid to shift from the interstitial and intracellular spaces to the intravascular space to replace fluids already lost. Dehydration is usually evident by 10 to 12 hours following the onset of acute enteritis and clinically obvious by 18 to 24 hours. Peripheral circulatory collapse (**shock**) occurs commonly in acute and peracute cases. There may be tachycardia or bradycardia and arrhythmia depending on the degree of acidosis and electrolyte imbalance. In acute enteritis, there may be severe abdominal pain, which is most severe in the horse and is often sufficient in this species to cause rolling and kicking at the abdomen. Abdominal pain in enteritis is unusual in the other species although it does occur in heavy inorganic metal poisonings, such as arsenic and lead, and in acute salmonellosis in cattle. Some severe cases of enteric colibacillosis in calves are characterized by abdominal pain evidenced by intermittent bouts of stretching and kicking at the abdomen. The passage of intestinal gas also occurs commonly in horses with acute and chronic diarrhea.

Intestinal Sounds in Enteritis

Auscultation of the abdomen usually reveals sounds of **increased peristalsis** and **fluid-rushing sounds** in the early stages of acute enteritis. Later there may be **paralytic ileus** and an absence of peristaltic sounds with only fluid and gas tinkling sounds. The abdomen may be distended in the early stages because of distension of intestines and gaunt in the later stages when the fluid has been passed out in the feces. Pain may be evidenced on palpation of the abdomen in young animals.

Chronic Enteritis

In **chronic enteritis,** the feces are usually soft and homogeneous in consistency, contain considerable mucus, and usually do not have a grossly abnormal odor. Progressive weight loss and emaciation or "runting" are common and there are usually no systemic abnormalities. Animals with chronic enteritis will often drink and absorb sufficient water to maintain clinical hydration, but there may be laboratory evidence of dehydration and electrolyte loss. In parasitic enteritis and abomasitis there may be hypoproteinemia and subcutaneous edema. In terminal ileitis, there is usually chronic progressive weight loss and occasionally some mild diarrhea. The lesion is usually recognized only at necropsy. Intestinal adenomatosis of pigs, rectal strictures in pigs, granulomatous enteritis of horses, and lymphosarcoma of the intestine of horses are examples of enteric disease causing chronic anorexia and progressive weight loss, usually without clinical evidence of diarrhea. These are commonly referred to as malabsorption syndromes.

CLINICAL PATHOLOGY

The laboratory testing of animals to obtain an etiologic diagnosis of enteritis can be a complex and expensive procedure, which requires careful consideration of the history, the clinical findings, and the number of animals affected. In outbreaks of enteric syndromes, it may be important to submit samples from both affected and normal animals. The details of the sampling techniques and the tissues required for the diagnosis of diseases of the digestive tract caused by feeding mismanagement, infections, toxins, and other agents have been outlined and this is recommended as a reference.

Fecal Examination

Examination of the feces to determine the presence of causative **bacteria**, **helminths**, **protozoa**, **viruses,** and **chemical agents** is described under specific diseases throughout this book. It is important that fecal specimens are taken as the differentiation of the etiologic groups depends on laboratory

examinations. In outbreaks of diarrhea, fecal samples should also be taken from a representative number of normal animals in the same group as the affected animals. Comparison of the fecal examination results between affected and normal animals will improve the accuracy of interpretation.

Fecal samples can be examined for the presence of leukocytes and epithelial cells, which occur in exudative enteritis.

Intestinal Tissue Samples

In outbreaks of diarrhea, especially in neonates, it may be useful to do necropsies on selected early untreated cases of acute diarrhea. The lesions associated with the enteropathogens are well known, and a provisional etiologic diagnosis may be possible by gross and histopathological examination of the intestinal mucosa.

Hematology and Serum Biochemistry

With increasing sophistication in diagnostic laboratories and in large-animal practice, it is becoming common to do considerable laboratory evaluation to determine the actual changes that are present for purposes of a more rational approach to therapy. For each specific enteritis there are changes in the hemogram and serum biochemistry that aid in the diagnosis and differential diagnosis. In bacterial enteritis, such as acute enteric salmonellosis in the horse, there may be marked changes in the total and differential leukocyte count, which is a useful diagnostic aid. In most cases of acute enteritis there is hemoconcentration, metabolic acidosis, an increase in total serum solids concentration, a decrease in plasma bicarbonate, hyponatremia, hypochloremia, and hypokalemia. However, abnormalities in body fluid compartments caused by diarrhea depend on the pathogenetic mechanisms involved and the duration of the diarrhea. In horses with diarrhea of less than 6 days' duration, the most common abnormality may be a combined anion gap, metabolic acidosis, and metabolic alkalosis characterized by hyponatremia, hypochloremia, and hyperkalemia. The **acid-base imbalances** may vary considerably from case to case, and it is suggested that optimal fluid therapy should be based on laboratory evaluation of the animal's blood gas and electrolytes. **Hyperkalemia** may occur in severe acidosis. An increase in serum creatinine may be caused by inadequate renal perfusion associated with the dehydration and circulatory failure.

Digestion/Absorption Tests

Digestion and absorption tests are available for the investigation of chronic malabsorptive conditions, particularly in the horse. Intestinal biopsy may be necessary for a definitive diagnosis of chronic intestinal lesions that cannot be determined by the usual diagnostic tests. Examples include intestinal lymphosarcoma, granulomatous enteritis, and perhaps Johne's disease. Serum electrophoresis and the administration of radioactively labeled albumin may be necessary to determine the presence of a protein-losing enteropathy.

NECROPSY FINDINGS

The pathology of enteritis or malabsorption varies considerably depending on the cause. There may be an absence of grossly visible changes of the mucosa, but the intestinal lumen will be fluid-filled or relatively empty, depending on the stage of examination in enterotoxigenic colibacillosis. When there is gross evidence of inflammation of the mucosa there will be varying degrees of edema, hyperemia, hemorrhage, foul-smelling intestinal contents, fibrinous inflammation, ulceration, and necrosis of the mucosa. With acute necrosis there is evidence of frank blood, fibrinous casts, and epithelial shreds. The mesenteric lymph nodes show varying degrees of enlargement, edema and congestion, and secondary involvement of spleen and liver is not unusual. In chronic enteritis, the epithelium may appear relatively normal, but the wall is usually thickened and may be edematous. In some specific diseases there are lesions typical of the particular disease.

DIFFERENTIAL DIAGNOSIS

Approach

- The approach to the diagnosis of diarrhea requires consideration of the epidemiological history and the nature and severity of the clinical findings. With the exception of acute enteritides in newborn farm animals, most of the other common enteritides have reasonably distinct epidemiological and clinical features.
- In some cases, a necropsy on an untreated case of diarrhea in the early stages of the disease can be very useful.
- If possible, a hemogram should be obtained to assist in determining the presence or absence of infection.

Appearance of feces

- The gross appearance of the feces may provide some clues about the cause of the diarrhea. Generally, diarrhea caused by lesions of the small intestine are profuse and the feces are liquid and sometimes as clear as water. The diarrhea associated with lesions of the large intestine are characterized by small volumes of soft feces, often containing excess quantities of mucus.
- The presence of toxemia and fever-marked changes in the total and differential leukocyte count suggest bacterial enteritis, possibly with septicemia. This is of particular importance in horses and cattle with salmonellosis.
- The presence of frank blood and/or fibrinous casts in the feces usually indicates a severe inflammatory lesion of the intestines. In sand-induced diarrhea in horses the feces may contain sand.

Weight loss

- Chronic diarrhea with a history of chronic weight loss in a mature cow suggests Johne's disease.
- Chronic weight loss and chronic diarrhea, or even the absence of diarrhea, in the horse may indicate the presence of granulomatous enteritis, chronic eosinophilic gastroenteritis, alimentary lymphosarcoma, tuberculosis, and histoplasmosis.

Dietary diarrhea and toxicities

- In dietary diarrhea the feces are usually voluminous, soft, and odoriferous. The animal is usually bright and alert and there are minimal systemic effects. An examination of the diet will usually reveal if the composition of the diet or irregular feeding practices are responsible for the diarrhea. Analysis of samples of new feed may be necessary to determine the presence of toxic chemical agents.
- Arsenic poisoning is characterized by dysentery, toxemia, normal temperature, and nervous signs.
- Copper deficiency conditioned by an excess of molybdenum causes a moderately profuse diarrhea with soft feces and moderate weight loss. There is usually normal hydration and possibly depigmentation of hair.

Parasitism

- Intestinal helminthiasis such as ostertagiasis causes a profuse diarrhea and marked loss of weight; the temperature is normal and there is no toxemia.

Miscellaneous causes

- In cattle, the oral cavity must be examined for evidence of lesions characteristic of viral diseases.
- Many diseases of the stomach, including ulceration, parasitism, gastritis, and tumors, may result in diarrhea and must be considered in the differential diagnosis of chronic diarrhea.
- The soft scant feces associated with some cases of incomplete obstruction of the digestive tract of cattle affected with the complications of traumatic reticuloperitonitis must not be confused with diarrhea.

TREATMENT

The principles of treatment of enteritis include the following:

- Removal of the causative agent
- Alteration of the diet
- Fluids and electrolytes
- Intestinal protectants and adsorbents
- Antidiarrheal drugs

Removal of Causative Agent

Specific treatment is usually directed at intestinal helminthiasis with anthelmintics, antiprotozoan agents against diseases such as coccidiosis, and antimicrobial agents against the bacterial enteritides. There are no specific treatments available for the viral enteritides in farm animals.

Although a considerable number of investigations have been done on the enteritides on farm animals, the emphasis has been on the immunology, pathology, microbiology, and body fluid dynamics, each with different emphasis in different species. For example, there is considerable information on the microbiology and immunology of the common enteritides in calves and piglets in addition to the extensive knowledge of the body fluid dynamics in calves. In the horse there is some information on body fluid dynamics, but the microbiology of the diarrheas is not well understood. In none of the species is there sufficient information on the effects of antibiotics on the intestinal microflora.

Antimicrobials

The use of antimicrobials, either orally or parenterally, or by both routes simultaneously, for the treatment of bacterial enteritides is a controversial subject in both human and veterinary medicine. Those who support their use in acute bacterial enteritis claim that they are necessary to help reduce the overgrowth of pathogenic bacteria responsible for the enteritis and to prevent or treat bacteremia or septicemia that may occur secondary to an enteritis. Those who suggest that they are contraindicated or unnecessary in bacterial enteritis suggest that the drugs may eliminate a significant proportion of the intestinal flora in addition to the pathogenic flora. This may reduce the effect of competitive antagonism in the intestine, which in turn may permit the development of a superinfection (the appearance of bacteriologic and clinical evidence of a new infection during the chemotherapy of a primary one). Also, the use of antimicrobials in infectious enteric disease allows the development of **multiple drug resistance**, which is a major public health concern. The use of antimicrobials may also increase the length of time over which affected animals excrete the organisms which, for example, may occur in enteric salmonellosis.

Many different antimicrobial preparations for both oral and parenteral administration are available. The choice will depend on previous experience, the disease suspected, and the results of culture and drug sensitivity tests. Parenteral preparations are indicated in animals with acute diarrhea, toxemia, and fever. Many antimicrobials, when given parenterally, are excreted by the liver into the lumen of the intestine and oral preparations may not be necessary. In cases of subacute diarrhea with minimal systemic effects, the use of an oral preparation may be sufficient. However, oral preparations should not be used for more than 3 days to avoid a superinfection. The preparations and doses of the antimicrobials commonly used in bacterial enteritides are described under each disease.

Mass Medication of Feed and Water Supplies

Mass medication of the drinking water supply with antimicrobials for the treatment of outbreaks of specific infectious enteritides in animals is used commonly and with success. One of the best examples is the use of antimicrobials in the drinking water of pigs affected with swine dysentery. However, not all affected animals will drink a sufficient quantity of the medicated water and daily intake must be monitored carefully. Severely affected animals in an outbreak need individual treatment.

Alteration of the Diet

If the cause of the diarrhea is dietary in origin the feed should be removed until the animal has fully recovered; feed should then be replaced by another source or reintroduced gradually. The question of whether or not a normally digestible diet should be removed temporarily or the total daily intake reduced in animals with acute enteritis is a difficult one. The rationale is that in acute enteritis the digestibility of nutrients is reduced considerably and undigested feed provides a substrate for fermentation and putrefaction to occur, the products of which may accentuate the malabsorptive state. However, temporary withdrawal of feed presents practical problems, especially in the young. For example, the temporary removal from the sow of newborn piglets affected with acute enteritis presents practical problems and is of doubtful value, which is similar with beef calves nursing cows on pasture. With foals it is relatively easy to muzzle them for 24 hours. With weaned piglets affected with weanling diarrhea and feeder pigs with swine dysentery, it is common practice to reduce the normal daily intake by half for a few days until recovery is apparent. Mature horses affected with diarrhea should not have access to any feed for at least 24 hours. During the period of temporary starvation, the oral intake of fluids containing glucose and electrolytes is desirable and necessary to assist in maintaining hydration. In newborn calves with diarrhea, if oral fluid intake is maintained, the total loss of water from feces and through the kidney is not significantly greater than in normal calves, because in diarrheic calves the kidney will effectively compensate for fecal losses. When recovery is apparent, the animal's usual diet may be reintroduced gradually over a period of a few days.

Fluids and Electrolytes

The initial goals of fluid and electrolyte therapy for the effects of enteritis are the restoration of the body fluids to normal volume, effective osmolality, and composition and acid-base balance. The quality and quantity of fluids required to achieve these goals depend on the characteristics of the dehydration and acid-base electrolyte imbalance. Under ideal conditions when a laboratory is available, the determination of PCV, total serum proteins, plasma bicarbonate, blood pH, serum electrolytes, and a hemogram would provide the clinician with a laboratory evaluation initially and throughout the course of therapy to assess the effectiveness of the treatment. However, such laboratory service is expensive and usually not readily available. The clinician must therefore assess the degree of clinical dehydration and, based on the history and clinical findings, estimate the degree of acidosis and electrolyte deficits that are likely to be present. A practical approach to fluid therapy in the horse has been described. Fluids should be given orally whenever possible to save time and expense and to avoid the complications that can arise from long-term parenteral fluid therapy. Also, fluids should be given as early as possible to minimize the degree of dehydration. With good kidney function there is a wider safe latitude in the solution used.

The three major abnormalities of **dehydration**, **acidosis,** and **electrolyte deficit** are usually corrected simultaneously with fluid therapy. When severe acidosis is suspected, this should be corrected immediately with a hypertonic (5%) solution of bicarbonate given intravenously at the rate of 5 to 7 mL/kg BW at a speed of about 100 mL/min. This is followed by the administration of electrolyte solutions in quantities necessary to correct the dehydration. With severe dehydration, equivalent to 10% of BW, large amounts of fluids are necessary (Table 7-8).

The initial hydration therapy should be given over the first 4 to 6 hours by continuous intravenous infusion, followed by maintenance therapy for the next 20 to 24 hours, or for the duration of the diarrhea if severe, at a rate of 100 to 150 mL/kg BW per 24 hours. Horses with acute enteritis have severe hyponatremia and following fluid therapy may become severely hypokalemic, as evidenced by weakness and muscular tremors. The hypertonic solution of sodium bicarbonate will assist in correcting the hyponatremia, but potassium chloride may need to be added to the large quantity of

Table 7-8 Fluid deficits (L) in horses, foals and calves with 10% dehydration

Animal	Dehydration (%)	Fluid deficit (L)
500-kg horse	10	50
75-kg foal	10	7.5
45-kg calf	10	4.5

fluids given for dehydration; 1 g of potassium chloride added to each liter of fluid will provide an additional 14 mOsm/L (14 mmol/L) of potassium. In preruminant calves with diarrhea, the fluids and electrolytes required for maintenance may be given orally in divided doses every few hours. In the early stage of acute diarrhea and for animals that are not severely dehydrated, the oral route can also be used successfully to correct dehydration and prevent it from becoming worse. The formula of oral glucose–electrolyte solutions are given in the section Colibacillosis. Piglets and lambs affected with dehydration are most effectively treated using balanced electrolyte solutions given subcutaneously at the dose rates of 20 mL/kg BW every 4 hours and orally at 20 mL/kg BW every 2 hours. Details of the treatment of fluid and electrolyte disturbances are given in Chapter 5.

Intestinal Protectants and Adsorbents

Kaolin and pectin mixtures are used widely to coat the intestinal mucosa, inhibit secretions, and increase the bulk of the feces in animals with enteritis. In children with diarrhea, kaolin and pectin will result in formed rather than watery feces, but the water content of the feces is unchanged. It is not possible at this time to make a recommendation on their use in animals.

Antidiarrheal Drugs

Antimotility Drugs

Anticholinergic drugs and opiates are available to decrease intestinal motility. The anticholinergic drugs block the action of acetylcholine on smooth muscle and glands. This results in decreased gastric secretion and emptying and a reduction on both segmental and propulsive movements of the intestines. Dosages of anticholinergics necessary to produce effectiveness may also cause side effects such as xerostomia, photophobia, tachycardia, urinary retention, and neuromuscular paralysis. The opiates function by producing an increase in segmentation while reducing propulsive movements in the intestine. The net effect is an increase in resistance to passage of intestinal contents, and more complete absorption of both water and nutrients occurs with a subsequent decrease in the frequency of defecation. There are no published reports of clinical trials using antimotility drugs for the treatment of diarrhea in farm animals; therefore at the present time they cannot be recommended with any assurance of effectiveness.

Antisecretory Drugs

Antisecretory drugs are also available for the treatment of diarrhea caused by the hypersecretory activity of enterotoxin produced by bacteria such as ETEC. Loperamide hydrochloride given orally to calves with experimentally induced diarrhea can delay the onset of diarrhea by its inhibition of fluid secretion. Antisecretory drugs include chlorpromazine, opiates, atropine, and prostaglandin inhibitors. These have not yet been adequately evaluated and the provision of balanced fluids and electrolytes, containing sodium chloride, sodium bicarbonate, potassium chloride, and glucose, given both parenterally and orally, are considered to be adequate and effective for treating the effects of the hypersecretion.

Because prostaglandins have an important reparative role in the intestine, NSAIDs may retard recovery of ischemic-injured intestine and are contraindicated.

CONTROL

The control and prevention of enteritis in farm animals is a major topic and activity of large-animal practice. The control of each specific enteritis is presented under each specific disease in Part II of this book. The principles of control include the following:

- Reduce infection pressure by controlling population density
- Ensure adequate nonspecific resistance by adequate colostrum intake of neonatal farm animals and maintaining adequate nutritional status
- Vaccinate for those diseases for which there is an effective vaccine
- Minimize managerial and environmental stressors
- Monitor morbidity and mortality and ensure that a diagnosis is obtained so that control measures for newly introduced diseases into a herd can be instituted

INTESTINAL HYPERMOTILITY

A functional increase in intestinal motility seems to be the basis of a number of diseases of animals. Clinically there is some abdominal pain and, on auscultation, an increase in alimentary tract sounds and, in some cases, diarrhea. Affected animals do not usually die and necropsy lesions cannot be defined, but it is probable that the classification as it is used here includes many of the diseases often referred to as catarrhal enteritis or indigestion.

The major occurrence of intestinal hypermotility is spasmodic colic of the horse. Other circumstances in which hypermotility and diarrhea occur without evidence of enteritis include allergic and anaphylactic states and a change of feed to lush pasture.

DIETARY DIARRHEA

Dietary diarrhea occurs in all species and all ages but is most common in neonatal animals in which there is either absolute or relative inability to digest food or to which inappropriate food is provided. An absolute inability to digest food occurs in primary, or severe secondary, lactose intolerance in which the neonate does not have intestinal lactase activity. The result is failure to cleave lactose to its constituent monosaccharides and therefore fermentation of lactose in the small or large intestine. Bacterial fermentation of lactose causes osmotic diarrhea. Relative lactose deficiency presumably occurs in neonates that ingest large quantities of milk that then exceed the digestive capacity of the intestine. The frequency with which this occurs is unclear and withholding or restricting of feed to neonates should be approached with caution. The feeding of indigestible feedstuffs, such as inferior milk replacers, can cause diarrhea.

ETIOLOGY

Milk Replacers

The use of inferior-quality milk replacers in young calves under 3 weeks of age is one of the most common causes of dietary diarrhea. The quality of the milk replacer may be affected by the use of skim-milk powder that was heat denatured during processing, resulting in a decrease in the concentration of noncasein proteins. This results in ineffective clotting in the abomasum and reduced digestibility. The use of excessive quantities of nonmilk carbohydrates and proteins in milk replacers for calves is also associated with a high incidence of diarrhea, loss of weight, emaciation, and starvation. The use of large quantities of soybean protein and fish protein concentration in milk replacers for calves will result in chronic diarrhea and poor growth rates.

Most attempts to raise calves on diets based on large amounts of certain soybean products, such as heated soybean flour, have been unsuccessful because the animals developed diarrhea, lost appetite, and had lower weight or inferior growth rate. Preruminant calves develop gastrointestinal hypersensitive responses to certain soybean products because major proteases of the digestive tract do not denature soluble antigenic constituents of the soybean protein.

Diarrhea of nutritional origin has become one of the most important problems in which large numbers of calves are raised under intensive conditions. Because of the relatively high cost of good-quality skim-milk powder, large quantities of both nonmilk proteins and carbohydrates are used in formulating milk replacers. Although some calves in these large units can satisfactorily digest the nutrients in these milk replacers, many cannot, and this leads to a high incidence of diarrhea and secondary colibacillosis and enteric salmonellosis.

Milk replacers made from bovine milk and milk by-products used to feed orphan piglets, lambs, and foals may cause nutritional diarrhea for the same reasons given earlier. In milk-replacer–fed calves, increasing the total daily fluid intake as a percentage of BW causes a greater incidence of loose feces, dehydration, and dullness than lower levels of fluid intake and higher dry matter concentration. This suggests that a greater amount of fluid intake increases the passage rate of dry matter and decreases absorption. The concentration of solids in the liquid diet should range between 10% and 13% and should be offered at 8% of BW in calves fed milk replacer once daily and allowed free access to calf starter.

Overfeeding of Milk

The feeding of excessive amounts of cows' whole milk to hand-fed calves will result in large amounts of abnormal feces but usually not a profuse watery diarrhea with dehydration and loss of weight. This suggests that simple overfeeding of milk might not be a cause of acute neonatal diarrhea of calves. There is some limited evidence that dietary diarrhea can occur in nursing beef calves ingesting milk that does not clot properly. Only the milk from cows with diarrheic calves showed evidence of impaired clotting in an in vitro test.

The ingestion of excessive quantities of sows' milk by piglets at 3 weeks of age is thought to be a contributory cause of 3-week diarrhea of piglets. This could be caused by the sow reaching peak production at 3 weeks.

Beef calves suckling high-producing cows grazing on lush pasture are often affected with a mild diarrhea at about 3 weeks of age. The cause is thought to be simple overconsumption of milk. Similarly, vigorous lambs sucking high-producing ewes can develop diarrhea.

Foals commonly have diarrhea at about 9 days of age, which coincides with the foal heat of the mare. It has been thought for many years that the cause was a sudden change in the composition of the mare's milk, but this has not been supported by analyses of mares' milk at that time. Diarrhea is associated with age-related changes in the microbiota of the foals' gastrointestinal tract.[1]

There is considerable interest in the optimal conditions for feeding liquid diets to young calves. The temperature of the liquid when fed, feeding once or twice daily, and the amount of dry matter intake can affect the performance of calves. However, there is a range of safety in which the performance of the calves will not be significantly affected if management is good.

Change of Diet

Dietary diarrhea also occurs in all species following a sudden change in diet, but particularly in animals at weaning time. This is particularly important in the pig weaned at 3 weeks of age and not adjusted to the post-weaning ration. Diarrhea occurs commonly when animals are moved from a dry pasture to a lush pasture and when first introduced to liberal quantities of concentrates containing a large percentage of the common cereal grains.

PATHOGENESIS

Digestion of Milk

In calves, the ingestion of excessive quantities of cows' whole milk after several hours of no intake causes gross distension of the abomasum and possibly of the rumen. Under these conditions, the milk-clotting capacity of the abomasum may be limited, resulting in incomplete clotting. The flow of nutrients from the abomasum is more uniform in calves fed twice daily than once daily, which suggests that twice-daily feeding allows for more effective clotting and digestion.

Under normal conditions, the milk clot forms in the abomasum within minutes after feeding, and the whey moves to the duodenum 5 to 10 minutes later. The dilution of cows' whole milk will result in increased clotting time when treated with rennin (chymosin). Overfeeding could result in whole milk or excessive quantities of whey entering the duodenum, which cannot digest whole milk or satisfactorily digest and hydrolyze the substrates in whey. The presence of excessive quantities of such substrate, especially lactose, in the intestinal lumen would serve as a hydragogue and result in a large increase in intestinal fluid, failure of complete absorption, and abnormal feces. The speed of drinking is probably also important. Prolongation of drinking time results in dilution of the milk with saliva and the production of a more easily digested milk clot. Failure of the esophageal reflex in pail-fed calves may also be important. The milk enters the rumen, where it undergoes putrefaction.

Milk Replacers and Diarrhea

The pathogenesis of diarrhea in calves fed inferior-quality milk replacers is well known. In calves fed low-heat–treated skim-milk powder milk replacer, curd formation in the abomasum, compared with no curd formation, slows down the passage of total abomasal content (retained matter from the last feeding, residual matter from the penultimate feeding, saliva, and gastric secretions), dry matter, crude protein, and fat from the abomasum to the intestine. Heat-denatured skim-milk powder is incompletely clotted in the abomasum, leading to reduced digestibility.

Nonmilk carbohydrates and nonmilk proteins are not well digested by preruminant calves under 3 weeks of age because their amylase, maltase, and sucrase activities are insignificant, and their pepsin-HCl activity is not well developed until at least 3 weeks of age. Following the ingestion of these nutrients, there is reduced digestibility, malabsorption, and diarrhea. This results in a negative nutrient balance, loss of BW, and gradual starvation, all of which are reversible by the feeding of cows' whole milk. The digestion of fat is particularly affected, resulting in varying degrees of steatorrhea. Preruminant calves fed milk replacer containing corn oil will have diarrhea.

The mechanism for the diarrhea, which may occur in all species following a sudden change in diet, is not well understood. However, several days may be necessary for the necessary qualitative and quantitative changes to occur in the digestive enzyme capacity. Not much is known about the development of intestinal enzymes in the fetus and newborn, but this is likely to be of importance in individual animals. In calves, lactase activity is fully developed at birth and in the period between birth and weaning there are significant changes in enzyme activity, some of which are influenced by the presence or absence of dietary substances.

In dietary diarrhea, the presence of undigested substrate in the intestine can result in marked changes of the bacterial flora, which could result in excess fermentation of carbohydrates and putrefaction of protein, the products of which accentuate the malabsorption.

CLINICAL FINDINGS

Nursing Beef Calves

Dietary diarrhea of beef calves at 3 weeks of age on pasture is characterized by the passage of light yellow feces that is foul smelling and soft. The perineum and tail are usually smudged with feces. The calves are bright and alert and usually recover spontaneously without treatment in a few days.

Hand-Fed Dairy Calves

When overfed on cow's whole milk these animals are usually dull and anorexic and their feces are voluminous, foul smelling, and contain considerable mucus. The abdomen may be distended because of distension of the abomasum and intestines. Secondary enteric colibacillosis and salmonellosis may occur, resulting in severe dehydration. Most uncomplicated cases will respond to oral fluid therapy and withdrawal from or deprivation of milk.

Milk-Replacer Diarrhea

In calves fed inferior-quality milk replacers, there will be a chronic diarrhea with gradual weight loss. The calves are bright and alert, they usually drink normally, appear distended after drinking, and spend considerable time in recumbency. Not uncommonly, many treatments will have been tried unsuccessfully. The diarrhea and weight loss continues and in 2 to 4 weeks emaciation is evident and death from starvation may occur. Affected calves will often have a depraved appetite and eat bedding and other

indigestible materials, which further accentuates the condition. When large numbers of calves are involved, the incidence of enteric colibacillosis and salmonellosis may become high and the case mortality very high. This is a common situation in veal-calf–rearing units.

Alopecia occurs occasionally in calves fed a milk replacer, but the cause is unknown.

CLINICAL PATHOLOGY

Laboratory evaluation of the animals with dietary diarrhea is usually not necessary other than for elimination of other possible causes of the diarrhea. When milk replacers are being used the determination of the rennet-clotting time of the milk replacer compared with whole milk is a useful aid in assessing the quality of the skim-milk powder for calves.

NECROPSY FINDINGS

Emaciation, an absence of body fat, dehydration, and serous atrophy are present in calves that have died from diarrhea and starvation while being fed inferior-quality milk replacers.

DIFFERENTIAL DIAGNOSIS

- Dietary diarrhea occurs following a change in diet, the consumption of too much feed at once, or poor quality feed. There are usually no systemic signs and recovery occurs spontaneously when the dietary abnormality is corrected or the animal adapts to a new diet.
- Dietary diarrhea must be differentiated from all other common causes of diarrhea in a particular age group within each species.
- Examination of the recent dietary history and examination of the diet and its components will usually provide the evidence for a dietary diarrhea.

TREATMENT

Alter Diet of Hand-Fed Calves

In hand-fed calves affected with dietary diarrhea, milk feeding should be stopped and oral electrolyte solutions given for 24 hours. Milk is then gradually reintroduced. If milk replacers are being used their nutrient composition and quality should be examined for evidence of indigestible nutrients. The feeding practices should be examined and the necessary adjustments made.

The care and management of hand-fed calves to minimize the incidence of dietary diarrhea is an art. Much has been said about the use of slow-flowing nipple bottles and pails to reduce dietary diarrhea, but they are not a replacement for good management. Calves that are raised for herd replacements should be fed on whole milk if possible for up to 3 weeks. When large numbers of calves are reared for veal or for feedlots the milk replacer used should be formulated using the highest quality milk and milk by-products economically possible. The more inferior the milk replacer the more impeccable the management must become.

Monitor Beef Calves With Dietary Diarrhea

Beef calves affected with dietary diarrhea while sucking the cow and running on pasture do not usually require treatment unless complications develop. They must be observed daily for evidence of dullness, anorexia, inactivity, and profuse watery diarrhea, at which point they need some medical care.

ABDOMINAL FAT NECROSIS (LIPOMATOSIS)

Abdominal fat necrosis is a variant of generalized steatitis and is dealt with in more detail in Chapter 17. The **hard masses of necrotic fat** that occur relatively commonly in the peritoneal cavity of adult cattle, especially the Channel Island breeds and possibly Aberdeen Angus, are commonly mistaken for a developing fetus and can cause intestinal obstruction. The latter usually develops slowly, resulting in the appearance of attacks of moderate abdominal pain and the passage of small amounts of feces. Many cases are detected during routine rectal examination of normal animals. The lipomatous masses are located in the small and large omentum and mesentery in cattle and more diffusely to other parts of the body in sheep and goats. The composition of the fatty deposits is identical with the fat of normal cows and there is no suggestion that the disease is neoplastic. Sporadic cases are most common but there are reports of a herd prevalence as high as 67%. The cause is unknown, but there appears to be a relationship between such high prevalence and the grazing of tall fescue grass, and an inherited predisposition is suggested. The rate of occurrence increases with age with the peak occurrence at 7 years of age. It has been suggested that excessive fatiness of abdominal adipose tissue may predispose cattle to fat necrosis. An unusual form of the disease with many lesions in subcutaneous sites has been recorded in Holstein Friesian cattle and is regarded as being inherited. There is no treatment and affected animals should be salvaged. A generalized steatitis has been reported in pony foals.

Pedunculated lipomas provide a special problem, especially in older horses. Their pedicles can be 20 to 30 cm long, and during periods of active gut motility these pedicles can become tied around a loop of intestine anywhere from the pylorus to the rectum. At the pylorus they cause acute intestinal obstruction with gastric dilatation. At the rectum they cause subacute colic and a characteristic inability to enter the rectum with the hand. This is accompanied by a folded coning down of the mucosa, not unlike that in a torsion of the uterus. Early diagnosis and surgical intervention can produce a resolution, but delay in the acute disease is associated with a poor prognosis because the blood supply is compromised. Less acute disease causing small-colon impaction or recurrent colic occurs.[1,2]

Diseases of the Peritoneum

PERITONITIS

Inflammation of the peritoneum is accompanied by abdominal pain, fever, toxemia, and a reduction in the amount of feces. Signs vary in degree with the severity and extent of the peritonitis.

ETIOLOGY

Peritonitis can occur as a primary disease affecting the peritoneum or secondarily as part of a disease affecting primarily other organs with secondary involvement of the peritoneum.[1] Primary diseases of the peritoneum include malignancies of the peritoneum, *Actinobaccillus equuli* infection in horses, *Haemophilus suis* in pigs, or *Pasteurella multocida* infection in calves.[2,3] Primary causes of peritonitis are much less frequent than causes of secondary peritonitis. Secondary peritonitis occurs most commonly from loss of integrity of the visceral peritoneum, often from injury to the alimentary tract within the abdomen, allowing gastrointestinal contents to enter the peritoneal cavity. Less common is perforation of the abdominal wall from the exterior from traumatic injury, perforation of the reproductive tract, or the introduction of pathogens or irritating substances as a result of injections into the peritoneal cavity or exploratory laparotomy. Some of the more common individual causes are as follows.

Cattle

- Traumatic reticuloperitonitis, which also occurs in camelids[4,5]
- Secondary to ruminal trocarization
- Perforation or leakage of abomasal ulcer
- Concurrent abomasal displacement and perforating ulcer
- Necrosis and rupture of abomasal wall after abomasal volvulus
- Rumenitis of cattle subsequent to acute carbohydrate indigestion

- Complication of cesarean section
- Rupture of vagina in young heifers during coitus
- Deposition of semen into the peritoneal cavity, for example, during traumatic artificial insemination
- Injection of sterile solutions, e.g., calcium preparations for milk fever or vitamin/mineral supplements (selenium)[6]
- Transection of small intestine when it becomes pinched between the uterus and the pelvic cavity at parturition
- Intraperitoneal injection of nonsterile solutions
- Spontaneous uterine rupture during parturition, or during manual correction of dystocia
- Sadistic rupture of vagina or rectum[7]
- Spontaneous rupture of rectum at calving
- As part of specific diseases such as tuberculosis, pasteurellosis,[3] or algal peritonitis[8]

Horses

Peritonitis in horses is often secondary to gastrointestinal disease (colic) and can be a major complication after abdominal surgery. These diseases are discussed under the appropriate topic in the sections of this text dealing with equine colic. If cases attributable to gastrointestinal disease are excluded, most cases are idiopathic.[9] Primary causes are infrequent and include infection associated with *A. equuli.*[2,10] Peritonitis can be secondary to infectious, chemical, or parasitic peritoneal injuries:

- Rupture of dorsal sac of cecum or colon at foaling
- Cecal rupture in foals subjected to anesthesia and gastric endoscopy
- Cecal rupture of adult horses[11]
- As a sequela to cecal trocarization[12]
- Secondary to torsion and infarction of a liver lobe[13]
- Rectal rupture or tear during rectal examination, predisposed to by inflammation of mucosa and overenthusiasm by the operator; this subject is presented separately in the section **Rectal Tears**
- Extension from a retroperitoneal infection or intraabdominal abscess,[14] e.g., *S. equi,* as a result of metastatic strangles, *R. equi* in foals under 1 year of age,
- Gastric erosion or rupture related to ulceration associated with larvae of *Gasterophilus* or *Habronema* spp. or gastric ulceration (a rare sequel of gastric ulceration in adult horses)[15]
- Colonic perforation associated with aberrant migration of *Gasterophilus intestinalis*
- Leakage from a cecal perforation apparently associated with a heavy infestation of *Anoplocephala perfoliata* tapeworms
- Spontaneous gastric rupture
- *A. equuli* infection, in some cases secondary to immunodeficiency[10,16,17]
- Secondary to penetrating gastrointestinal foreign bodies[18]
- Rupture of the bladder or urinary tract[9]
- Periorchitis[19]
- Pancreatitis[20]

Pigs

- Ileal perforation in regional ileitis
- Glasser's disease associated with *H. suis.*

Sheep

- Spread from intestinal wall abscess following infestation with *Esophagostomum* sp. larvae
- Serositis-arthritis associated with *Mycoplasma* sp.
  - Intraperitoneal injection of selenium[6]

Goats

- Serositis-arthritis associated with *Mycoplasma* sp.

All Species

- Traumatic perforation from the exterior of the abdominal wall by horn gore or stake wound
- Faulty asepsis at laparotomy, peritoneal injection, or trocarization for tympany of rumen or cecum
- Leakage through wall of infarcted gut segment
- Spread from subperitoneal sites in spleen, liver, and umbilical vessels

PATHOGENESIS

At least six factors account for the clinical findings and the various consequences of peritonitis: toxemia or septicemia, shock and hemorrhage, abdominal pain, paralytic ileus, accumulation of fluid exudate, and the development of adhesions.

Toxemia and Septicemia

Toxins produced by bacteria and by the breakdown of tissue are absorbed readily through the peritoneum. The resulting toxemia is the most important factor in the production of clinical illness, and its severity is usually governed by the size of the area of peritoneum involved. In **acute diffuse peritonitis**, the toxemia is profound, but in local inflammation, it is negligible. The type of infection present is obviously important because of variations between bacteria in their virulence and toxin production.

With rupture of the alimentary tract wall and the spillage of a large quantity of gut contents into the peritoneal cavity, some acute peritonitis does develop, but death is usually too sudden, within 2 to 3 hours in horses, for more than an early lesion to develop. These animals die of endotoxic shock caused by absorption of toxins from the gut contents. In acute diffuse peritonitis caused solely by bacterial contamination from the gut, the reaction depends on the bacteria that gain entry, the capacity of the omentum to deal with the peritonitis, and the amount of body movement that the animal has to perform. Cows that suffer penetration of the reticular wall at calving have lowered immunologic competence, a greater than normal negative pressure in the peritoneal cavity; are invaded by *F. necrophorum, Corynebacterium* spp., and *E. coli*; and are required to walk to the milking parlor, to the feed supply, and so on. They are likely to develop a massive diffuse purulent peritonitis and a profound toxemia and die within 24 hours. In contrast, horses that develop acute peritonitis from streptococci or *A. equuli* show little toxemia and manifest only abdominal pain caused by the inflammatory reaction of the peritoneum.

Shock and Hemorrhage

The shock caused by sudden deposition of gut contents, or infected uterine contents, into the peritoneal cavity, plus the hemorrhage resulting from the rupture, may be significant contributors to the common fatal outcome when an infected viscus ruptures. Following rupture of the uterus in cows, the shock and hemorrhage may be minor and peritonitis may not develop if the uterine contents are not contaminated. Failure of the uterus to heal or be repaired may be followed by peritonitis several days later.

Abdominal Pain

Abdominal pain is a variable sign in peritonitis. In acute, diffuse peritonitis, the toxemia may be sufficiently severe to depress the response of the animal to pain stimuli, but in less severe cases the animal usually adopts an arched-back posture and shows evidence of pain on palpation of the abdominal wall. Inflammation of the serous surfaces of the peritoneum causes pain, which may be severe enough to result in rigidity of the abdominal wall and the assumption of an abnormal humped-up posture.

Paralytic Ileus

Paralytic ileus occurs as a result of reflex inhibition of alimentary tract tone and movement in acute peritonitis. It is also an important sequel to intestinal obstruction and to traumatic abdominal surgery, in which much handling of viscera is unavoidable. Rarely, it arises because of ganglionitis and a loss of neural control of peristalsis, similar to the idiopathic intestinal pseudoobstruction of humans. The net effect is **functional obstruction of the intestine**, which, if persistent, will increase the likelihood of death. The end result is a complete

absence of defecation, often with no feces present in the rectum.

Accumulation of Fluid Exudate

Accumulation of large quantities of inflammatory exudate in the peritoneal cavity may cause visible abdominal distension and, if severe enough, interfere with respiration by obstruction of diaphragmatic movement. It is a comparatively rare occurrence but needs to be considered in the differential diagnosis of abdominal distension.

Adhesions

Trauma to the peritoneum results in a serosanguineous exudate, which contains two closely bound proteins, fibrinogen and plasminogen. **Fibrinogen** is converted by thrombin to fibrin, forming an early fibrinous adhesion. **Plasminogen** may be converted by plasminogen activators to plasmin, a specific fibrinolytic enzyme favoring lysis of the early adhesion. Peritoneal mesothelial cells are a source of plasminogen activators and each species of domestic animal has its own baseline peritoneal plasminogen activity. Cattle have a high capacity to respond to trauma with fibrin deposition. Intraabdominal fibrin deposition and adhesion formation is the most important factor in localizing peritonitis after peritoneal trauma from penetrating foreign bodies or abomasal ulcers. However, these adhesions can cause mechanical or functional intestinal obstruction.

In **chronic peritonitis**, the formation of adhesions is more important than either of the two preceding pathogenetic mechanisms. Adhesions are an essential part of the healing process and are important to localize the inflammation to a particular segment of the peritoneum. If this healing process is developing satisfactorily and the signs of peritonitis are diminishing, it is common to find that vigorous exercise causes breakdown of the adhesions, spread of the peritonitis, and return of the clinical signs. Thus a cow treated conservatively for traumatic reticuloperitonitis by immobilization might show an excellent recovery by the third day but, if allowed to go out to pasture at this time, could suffer an acute relapse. The secondary adverse effects of adhesions may cause partial or complete **obstruction of the intestine** or stomach, or fixation to the body wall, interfering with normal gut motility. Adhesions are important in the pathogenesis of vagus indigestion in cattle.

CLINICAL FINDINGS

Peritonitis is common in cattle, less common in horses and rarely, if ever, identified clinically in sheep, pigs, or goats. There are general signs applicable to all species and most forms of the disease in a general way. In addition, there are special findings peculiar to individual species and to various forms of the disease.

Acute and Subacute Peritonitis

Inappetence and Anorexia

Inappetence occurs in less severe and chronic cases, and complete anorexia in acute diffuse peritonitis.

Toxemia and Fever

Toxemia, usually with a fever, is often present, but the severity varies depending on the area of peritoneum involved, the identity of the pathogens, and the amount of tissue injury. For example, in cattle with acute local peritonitis the temperature will be elevated (39.5°C [103°F]) for the first 24 to 36 hours, but then return to normal even though the animal may still be partly or completely anorexic. A high fever (up to 41.5°C [106°F]) suggests an acute diffuse peritonitis, but in the terminal stages the temperature usually falls to subnormal. It is most noteworthy that a normal temperature does not preclude the presence of peritonitis. In horses with peritonitis, the temperature will usually exceed 38.5°C, but the fever may be intermittent. There is usually a moderate increase in heart and respiratory rates, and the latter is contributed to by the relative fixation of the abdominal wall because of pain. In some cases there is spontaneous grunting at the end of each expiratory movement.

Feces

The amount and composition of feces is usually abnormal. The transit time of ingesta through the alimentary tract is increased and the dry matter content of the feces increases. The amount of feces is reduced, although in the early stages there may be a transient period of increased frequency of passage of small volumes of soft feces, which may give the false impression of increased fecal output. In some horses with peritonitis, periods of diarrhea can occur but the feces are usually reduced in amount. Feces may be completely absent for periods of up to 3 days, even in animals that recover, and the rectum may be so dry and tacky, because of the presence of small amounts of tenacious mucus, that it is difficult to do a rectal examination. This might suggest a complete intestinal obstruction.

In pastured cattle with peritonitis the feces are characteristically scant, dark, and like small fecal balls accompanied by thick, jelly-like mucus. The feces may alternatively have a thick, sludge-like consistency, be tenacious and difficult to remove from a rubber glove, and have a foul smell.

Alimentary Tract Stasis

As well as absence of feces, there are other indicators of intestinal stasis. In cows with acute peritonitis ruminal contractions are reduced or absent; in chronic peritonitis the contractions may be present but are weaker than normal. In the horse, intestinal stasis is evidenced by an absence or reduction of typical intestinal peristaltic sounds on auscultation, although the tinkling sounds of paralytic ileus may be audible. It is very important to differentiate the two.

Abdominal Pain Evidenced by Posture and Movement

In cattle with acute peritonitis there is a disinclination to move, disinclination to lie down, lying down with great care, and grunting with pain. The posture includes a characteristically arched back and a shuffling and cautious gait with the back held rigid and arched. Grunting at each step and when feces or urine are passed is common, and when urine is eventually passed it is usually in a very large volume. Sudden movements are avoided and there is an absence of kicking or bellowing or licking the coat.

In horses these overt signs of peritonitis that characterize the condition in cattle are uncommon, which makes the diagnosis difficult. In the horse peritonitis is often manifested as an episode of abdominal pain including flank watching, kicking at the belly, and going down and rolling, which suggests colic caused by intestinal obstruction.

In a series of 51 cases of peritonitis associated with ***A. equuli*** in horses, most had tachycardia, increased respiratory rates, fever, and reduced intestinal borborygmi. Affected horses were depressed, lethargic, and inappetent. Mild to moderate abdominal pain was manifested as reluctance to move, pawing on the ground, lying down, or splinting of the abdominal musculature. The onset of clinical signs was acute (<24 hours) in 30 horses, 1 to 4 days in eight horses, or longer and associated with weight loss in three horses. In 10 horses, there was no record of the duration of clinical signs. The disease is usually primary although recurrent or chronic cases can be attributable to immunodeficiency, such as common variable immunodeficiency of aged horses.[17]

Abdominal Pain as Evidenced by Deep Palpation

In cattle, deep firm palpation of the abdominal wall elicits an easily recognized pain response. It may be possible to elicit pain over the entire abdominal wall if the peritonitis is widespread. If it is localized the response may be detectable over only a very small area. Increased tenseness of the abdominal wall is not usually detectable in the cow, although it is responsible for the characteristic arched-back posture and apparent gauntness of the abdomen, because the wall is already tightly stretched anyway.

Several methods are used to elicit a grunt in cattle with abdominal pain. In average-sized cows with acute local peritonitis (most commonly traumatic reticuloperitonitis), while listening over the trachea with a stethoscope, a controlled upward push with the closed fist of the ventral body wall caudal to the xiphoid sternum is most successful. In large bulls, especially if the peritonitis is

subsiding, it may be difficult to elicit a grunt with this method. In these cases, the best technique is to use a heavy pole held horizontally under the area immediately caudal to the xiphoid sternum to provide a sharp lift given by assistants holding the pole on either side. **Pinching of the withers** while auscultating over the trachea is also used and with some clinical experience is highly reliable.

In horses with acute or subacute peritonitis, it is usually easy to elicit a pain response manifested by the animal lifting its leg and turning its head with anger when its lower flank is firmly lifted, but not punched. The abdominal wall also feels tense if it is lifted firmly with the heel of the hand. In all cases of peritonitis in all species a pain response is always much more evident in the early stages of the disease, and severe chronic peritonitis can be present without pain being detected on palpation.

Rectal Examination

The general absence of feces is characteristic. In cattle, it may be possible to palpate slightly distended, saggy, thick-walled loops of intestine in some cases. Also, it may be possible to feel fibrinous adhesions separating as the intestines are manipulated. Adhesions are not often palpable, and their absence should not be interpreted as precluding the presence of peritonitis. Only adhesions in the caudal part of the abdomen may be palpable. Tough, fibrous adhesions may be present in long-standing cases. In horses, there are no specific rectal findings, other than a reduced fecal output, to indicate the presence of peritonitis. Distension of segments of both the small and large intestines may provide indirect evidence of paralytic ileus. However, there is a lack of clarity as to what can be felt in chronic cases because of the presence of fibrin deposits and thickening of the peritoneum. There may also be more than usual pain when an inflamed area is palpated or a mesenteric band or adhesion is manipulated.

In rupture of the rectum associated with a difficult dystocia, the rupture is usually easily palpable rectally in the ventral aspect of the rectum deep in the abdomen. Distended loops of intestine may become entrapped in the rectal tear.

Peracute Diffuse Peritonitis

In those cases in which profound toxemia occurs, especially in cows immediately after calving or when rupture of the alimentary tract occurs, the syndrome is quite different. There is severe weakness, depression, and circulatory failure. The animal is recumbent and often unable to rise, depressed almost to the point of coma, has a subnormal temperature of 37 to 37.5°C (99–100°F), a high heart rate (110–120 beats/min), and a weak pulse. No abdominal pain is evidenced spontaneously or on palpation of the abdominal wall. In mares that rupture the dorsal sac of the cecum during foaling, the owner observes that the mare has been straining and getting results when suddenly she stops making violent muscular contractions, and progress toward expelling the foal ceases. Moderate abdominal pain followed by shock is a characteristic development. Death follows 4 to 15 hours after the rupture.

The outcome in cases of acute, diffuse peritonitis varies with the severity. Peracute cases accompanied by severe toxemia usually die within 24 to 48 hours. The more common, less severe cases may be fatal in 4 to 7 days, but adequate treatment may result in recovery in about the same length of time.

In a series of 31 cases of generalized peritonitis in cattle most cases occurred peripartum. The most consistent clinical findings were depression, anorexia, decreased fecal output, and varying degrees of dehydration. The duration of illness ranged from 1 to 90 days with a median of 4 days. In 19 animals, the duration of clinical disease was less than 1 week, and in 12 cases the duration of illness was more than 1 week. All animals died or were euthanized.

Chronic Peritonitis

Cattle

The development of adhesions, which interfere with normal alimentary tract movements, and the gradual spread of infection as adhesions break down combine to produce a chronic syndrome of indigestion and toxemia punctuated by short, recurrent attacks of more severe illness. The adhesions may be detectable on rectal examination, but they are usually situated in the anterior abdomen and are impalpable. If partial intestinal obstruction occurs, the bouts of pain are usually accompanied by a marked increase in alimentary tract sounds and palpable distension of intestinal loops with gas and fluid. The course in chronic peritonitis may be several weeks and the prognosis is not favorable because of the presence of physical lesions caused by scar tissue and adhesions. In some cases there is marked abdominal distension with many liters of turbid-infected fluid present. This may be restricted in its location to the omental bursa. Detection of fluid in the peritoneal cavity of a cow is not easy because of the fluid nature of the ruminal contents. Results obtained by testing for a fluid wave should be interpreted cautiously. Collection of fluid by paracentesis abdominis is the critical test.

Horses

Horses with chronic peritonitis usually have a history of ill-thrift for a period of several weeks. Weight loss is severe and there are usually intermittent episodes of abdominal pain suggesting intestinal colic. Gut sounds are greatly diminished or absent, and subcutaneous edema of the ventral abdominal wall occurs in some cases. There may also be a contiguous pleurisy. Identification of the cause of the colic depends on the examination of a sample of peritoneal fluid.

Diagnostic Medical Imaging

In cattle with traumatic reticuloperitonitis, inflammatory fibrinous changes, and abscesses can be imaged (see also Chapter 8).

In cattle, standing reticular radiography is a useful aid for the diagnosis and management of traumatic reticuloperitonitis. It can accurately detect the presence of a foreign body and in most instances if the foreign body is perforating the reticular wall.

CLINICAL PATHOLOGY

Hematology

The total and differential leukocyte count is a useful aid in the diagnosis of peritonitis and in assessing its severity. In acute diffuse peritonitis with toxemia there is usually a leukopenia, neutropenia, and a marked increase in immature neutrophils (a degenerative left shift). There is "toxic" granulation of neutrophils. In less severe forms of acute peritonitis of a few days' duration there may be a leukocytosis caused by a neutrophilia with the appearance of immature neutrophils. In acute local peritonitis, commonly seen in acute traumatic reticuloperitonitis in cattle, there is commonly a normal total leukocyte count, or a slight increase, with regenerative left shift. In chronic peritonitis, depending on the extent of the lesion (diffuse or local), the total and differential leukocyte count may be normal, or there may be a leukocytosis with a marked neutrophilia and occasionally an increase in the total numbers of lymphocytes and monocytes. The plasma fibrinogen levels in cattle generally tend to increase as the severity of acute peritonitis increases and may be a useful adjunct to the cell counts for assessing severity.

In horses with peritonitis associated with *A. equuli,* there is hemoconcentration, hypoproteinemia, and a neutrophilia count with a left shift.

Abdominocentesis and Peritoneal Fluid

Examination of peritoneal fluid obtained by paracentesis is a valuable aid in the diagnosis of peritonitis and in assessing its severity. It can also provide an indication of the kind of antibacterial treatment required. The values in healthy horses and horses with various intestinal or peritoneal diseases are provided in Table 7-3. The maximum peritoneal fluid nucleated cell count in healthy foals is much lower than reported maximum values for adult horses and similarly for calves. Particular attention should be paid to the following:

- The ease of collection of the sample as a guide to the amount of fluid present
- Whether it is bloodstained, indicating damage to a wall of the viscus

- The presence of feed or fecal material, indicating intestinal ischemic necrosis or rupture
- Whether it clots and has a high protein content, indicating inflammation rather than simple transudation
- The number and kinds of leukocytes present, as an indication of the presence of inflammation, and also its duration
- Microbiological examination

When these results are available they should be interpreted in conjunction with the history, clinical signs, and other results, including hematology, serum chemistry, and possibly radiology. In particular, it must be noted that failure to obtain a sample does not preclude a possible diagnosis of peritonitis.

Interpretation of peritoneal fluid is also influenced by simple manipulation of the abdominal viscera, and the response is greater than that following opening and closing of the abdomen without manipulation of the viscera. Surgical manipulation results in a significant and rapid postoperative peritoneal inflammatory reaction.

In peritonitis in horses associated with *A. equuli,* the peritoneal fluid was turbid and had an abnormal color in 98% of cases. The protein content was elevated above normal in 50 samples (range 25–84 g/L, mean 44 g/L, normal <20 g/L). Total nucleated cell count was elevated in all samples (range 46–810 × 10 cells/L, mean 230 × 10 cells/L, normal <10 × 10 cells/L). A nucleated cell count above 100 × 10 cells/L, was present in 88% of animals. Pleomorphic gram-negative rods were seen on cytology in 53% of samples, and a positive culture of *A. equuli* was obtained in 72% of samples.

Experimentally, resection and anastomosis of the small colon in healthy horses causes a different inflammatory response than does manipulation. Absolute values in the peritoneal fluid for cell count, total protein, and differential count are inadequate to differentiate between a normal surgical reaction and a postoperative infection. Cytologic examination of peritoneal fluid is necessary to demonstrate degenerative cell changes and the presence of bacteria and ingesta. The peripheral leukon and fibrinogen concentration should always be compared with the peritoneal fluid for evidence of postsurgical infection. The nucleated cell and red blood counts of peritoneal fluid are commonly elevated for several days in horses following open castration. These elevated counts may be mistaken for peritonitis.

Septic Peritonitis in the Horse

Diagnosis of septic peritonitis is routinely made on the basis of physical examination and hematologic findings and peritoneal fluid analysis. After abdominal surgery, differentiation between septic peritonitis and other postoperative complications can be difficult using physical and hematological findings alone. As a result of the exploratory process itself, diagnosis of septic peritonitis is often complicated in horses after surgery because the total nucleated cell count and protein concentration in the peritoneal fluid are often high. Consequently, identification of bacteria on cytologic evaluation or isolation of bacteria from peritoneal fluid is a more definitive indicator of septic peritonitis, but sometimes there are false-negative results. Although bacterial cultures are considered the standard criterion for the diagnosis of sepsis, positive results may not always be obtained and results may be delayed by a minimum of 24 hours for aerobic organisms and up to 10 to 14 days for anaerobic organisms. Thus ancillary tests such as pH, glucose concentrations, and lactate dehydrogenase (LDH) activity in equine pleural and synovial fluid have been used to detect sepsis with the potential advantages of speed, ease of measurement, and lower cost relative to bacterial cultures.

Horses with septic peritonitis have significantly lower peritoneal fluid pH and glucose concentrations than horses with nonseptic peritonitis and healthy horses. Compared with other tests, serum-to-peritoneal fluid glucose concentration differences of more than 50 mg/dL had the highest diagnostic use for detection of septic peritonitis. A peritoneal fluid pH below 7.3, a glucose concentration below 30 mg/dL, and a fibrinogen concentration above 200 mg/dL were also highly indicative of septic peritonitis.

Peritonitis in Cattle

Tests for total protein, albumin, glucose, cholesterol, fibrinogen, L-lactate, D-dimer, LDH, alkaline phosphatase, creatine phosphokinase, white blood cells, and red blood cells are sometimes used to detect peritonitis in cattle. Peritoneal fluid D-dimer is most accurate in diagnosing peritonitis in cows (sensitivity and specificity >95.0% for concentrations <0.60 mg/L), LDH and LDH ratio in serum and peritoneal fluid, and the serum-ascites albumin concentration gradient have sensitivities between 49.0% and 67.1% and specificities between 88.4% and 95.5%.[21] A low-peritoneal fluid glucose concentration is highly indicative of septic peritonitis, as it is in horses.[21]

NECROPSY FINDINGS

In acute diffuse peritonitis, the entire peritoneum is involved, but the most severe lesions are usually in the ventral abdomen. Gross hemorrhage into the subserosa, exudation, and fibrin deposits in the peritoneal cavity and fresh adhesions that are easily broken down are present. In less acute cases, the exudate is purulent and may be less fluid, often forming a thick, cheesy covering over most of the viscera. In cattle, *F. necrophorum* and *Actinomyces (Corynebacterium) pyogenes* are often present in large numbers and produce a typical, nauseating odor. Acute local peritonitis and chronic peritonitis are not usually fatal, and the lesions are discovered only if the animal dies of intercurrent disease such as traumatic pericarditis or intestinal obstruction.

DIAGNOSIS

The diagnosis of peritonitis can be difficult because the predominant clinical findings are often common in other diseases. The clinical features that are the most reliable as indicators of peritonitis include the following:

- Abnormal feces, in amount and composition
- Alimentary tract stasis based on auscultation and evaluation of the passage of feces
- Abdominal pain evinced as a groan with each respiration or on light or deep percussion of the abdomen
- Abnormality of intestines on rectal palpation
- Fibrinous or fibrous adhesions on rectal palpation
- Abnormal peritoneal fluid with an increased leukocyte count collected by paracentesis
- A normal or low blood leukocyte count with a degenerative left shift
- The peritonitis may be chemical, and although microbiological examination usually yields positive results, these are not essential to a diagnosis of peritonitis

PROGNOSIS

Case–Fatality Rate in Horses

Peritonitis in the horse is a potentially life-threatening disease that must be treated promptly and aggressively.[1,22] Therapy must be aimed at reducing systemic shock and hypovolemia, correction of the primary cause, antibiotic therapy, and abdominal drainage and lavage. The case–fatality rates for peritonitis of any cause in horses range from 30% to 67%, although this includes cases with peritonitis secondary to colic, which have a worse prognosis than idiopathic cases or those caused by *A. equuli.* The case–fatality rate in horses with peritonitis not related to colic or rupture of the gastrointestinal tract is approximately 14%.[9] In a series of 67 cases of peritonitis in horses, of those that developed peritonitis after abdominal surgery, the case fatality was 56%. Peritonitis not associated with intestinal rupture or abdominal surgery had a lower case–fatality rate of 43%. Horses that died had higher heart rates, red blood cell count, serum creatinine concentration, PCV, and anion gap; lower venous blood pH; and a greater number of bacterial species cultured from the peritoneal fluid compared with survivors. Those that died were more likely to have clinical evidence of abdominal pain, shock, and bacteria in the peritoneal fluid.

DIFFERENTIAL DIAGNOSIS

The diseases that could be considered in the differential diagnosis of peritonitis are as follows.

Cattle

- **Acute local peritonitis:** Traumatic reticuloperitonitis, acute intestinal obstruction, splenic or hepatic abscess, simple indigestion, abomasal displacement (right and left), postpartum metritis, ketosis
- **Acute diffuse peritonitis:** Parturient paresis, coliform mastitis (peracute form), acute carbohydrate indigestion, perforation of or rupture at abomasal ulcer, acute intestinal obstruction, uterine rupture, postpartum metritis
- **Chronic peritonitis:** Vagus indigestion, lipomatosis or extensive fat necrosis of the mesentery and omentum, persistent minor leakage from an intestinal lesion, large accumulations of fluid as in ascites, rupture of the bladder, chronic pneumonia and chronic toxemias from a great variety of causes
- **Ascites:** Associated most often with primary or secondary cardiac disease, cor pulmonale with chronic pneumonia, endocarditis, thrombosis of the caudal vena cava, and diffuse abdominal epithelioid mesothelioma

Horses

- **Acute and subacute peritonitis:** Acute intestinal obstruction and thromboembolic colic
- **Chronic peritonitis:** Internal abdominal abscess (retroperitoneal or mesenteric abscess) may be classified as chronic peritonitis but is dealt with separately under the heading Retroperitoneal Abscess; horses with both intraabdominal neoplasms and abscesses will have clinical findings including anorexia, weight loss, fever, colic, and depression; both groups may also have peritoneal fluid that can be classified as an exudate

Pigs, sheep, and goats

Peritonitis is not usually diagnosed antemortem in these species.

TREATMENT

The specific cause must be treated in each case, and the treatments used are described under the specific diseases listed earlier. An exploratory laparotomy may be indicated to determine the cause of the peritonitis and to effect repair. The literature on the treatment of peritonitis in horses has been reviewed.

Antimicrobials

Broad-spectrum antimicrobials given intravenously or intramuscularly are indicated for the infection and toxemia. However, there are no published reports of clinical trials to evaluate the effectiveness of various antimicrobials for the treatment of peritonitis in cattle or horses. Thus the recommendations are empirical. Generally, **peritonitis in cattle** is commonly treated with any of the broad-spectrum antimicrobials, with the choice dependent on ease of administration and drug withdrawal times necessary in lactating dairy cattle. Treatment for traumatic reticuloperitonitis has commonly been restricted to the use of antimicrobials; supportive therapy has not been indicated with the exception of diffuse peritonitis.

Peritonitis in horses associated with abdominal surgery or rupture of the gastrointestinal tract is likely be accompanied by a mixed flora of bacteria, and broad-spectrum antimicrobials are necessary. They must be given at doses high enough to achieve high blood and tissue levels and maintained daily until recovery has occurred. In a series of cases of peritonitis in horses, the most commonly used antimicrobials were gentamicin at 2.2 to 3.3 mg/kg BW intravenously every 8 to 12 hours or 6.6 mg/kg BW intravenously every 24 hours, and penicillin at 22000 IU/kg BW intravenously or intramuscularly every 6 to 12 hours. Metronidazole given orally at 15 to 25 mg/kg BW has also been used in horses with peritonitis.

Horses with peritonitis associated with *A. equuli* respond quickly to treatment with penicillin at 22,000 units/kg BW intramuscularly twice daily for 5 days to 2 weeks. Most isolates of the organism are sensitive to penicillin, but some are resistant and gentamicin sulfate at 6.6 mg/kg BW intravenously once daily for 5 days to 2 weeks in combination with the penicillin has also been used successfully. In a series of 51 cases in horses, the recovery rate following treatment with penicillin and gentamicin and supportive therapy was 100%. Most horses responded favorably within 48 hours following commencement of treatment.

Administration of antimicrobials into the peritoneal cavity has been attempted on the basis that higher levels of the drug may be achieved at the site of the inflammation. However, there is no scientific evidence that it is superior to daily parenteral administration, and there is some danger of causing adhesions and subsequent intestinal obstruction.

Fluid and Electrolytes

Intensive intravenous fluid and electrolyte therapy are a vital part of treatment of peritonitis when accompanied by severe toxemia and shock, especially during the first 24 to 72 hours following abdominal surgery in the horse. It is continued until recovery is apparent and the animal is drinking water voluntarily; water can then be supplemented with electrolytes (see Chapter 5).

Nonsteroidal Antiinflammatory Drugs

Flunixin meglumine is recommended at 0.25 to 1.1 mg/kg BW intravenously every 8 to 12 hours when the peritonitis is accompanied by shock. However, no information is available on efficacy.

Lavage

Peritoneal lavage with large volumes of fluid containing antimicrobials is rational and has been attempted when large quantities of exudate are present. However, it is not easy to maintain the patency of drains, especially in cattle. Also, the peritoneum is highly susceptible to inflammation, and chemical peritonitis is common following the introduction of certain materials into the peritoneal cavity. Peritoneal lavage of ponies with saline and antimicrobials induces a mild, transient inflammatory response with minimal change visible at necropsy. Solutions containing povidone iodine-induced chemical peritonitis, which was severe when 10% povidone iodine solution was used. A 3% solution also causes peritonitis, and the use of these solutions is not recommended. Extreme caution is required when foreign materials are introduced into the cavity to avoid exacerbating the existing inflammation. The peritoneum is also a very vascular organ and toxic material is rapidly absorbed from it.

An **active intraabdominal drain** has been used successfully to treat abdominal contamination in horses. Closed-suction abdominal drains were placed, mostly under general anesthesia. Abdominal lavage was done every 4 to 12 hours, and about 83% of the peritoneal lavage solution was retrieved.

Prevention of Adhesions

Attempts can be made to prevent the development of adhesions but the efficacy has not been demonstrated.

Abdominal Diseases of the Horse Including Colic and Diarrhea

GENERAL PRINCIPLES

Abdominal pain in horses, evident as a constellation of clinical and behavioral signs

Table 7-9 Origin and examples of visceral pain in the horse

Origin	Example: acute	Example: chronic
Thorax		
Lung	Pleuropneumonia	Pleural abscessation
Pleura	Choke	Neoplasia
Esophagus	Trauma	Pericarditis
Heart	Pericarditis	
Abdomen		
Stomach	Most causes of acute colic	Inflammatory bowel diseases
Small intestine	Pancreatitis	Enterolithiasis
Large intestine	Nephrolithiasis	Chronic diarrhea
Cecum	Uterine artery hematoma, rupture	Nephrolithiasis
Large colon	Metritis	Neoplasia
Small colon	Cholelithiasis	Cholelithiasis
Spleen	Uterine torsion	
Liver		
Pancreas		
Kidneys		
Ureters		
Ovaries		
Uterus		
Pelvis		
Bladder	Cystitis	Cystitis
Testicles	Urolithiasis	Urolithiasis
Rectum	Rectal tear	Neoplasia
Anus	Foaling trauma	
Vagina	Necrotic vaginitis	

Reproduced with permission.[2]

described next, is commonly referred to as colic. Colic is most often caused by gastrointestinal disease, although it can manifest as a result of disease in any intraabdominal organ (Table 7-9). The discussion in this section deals with colic caused by gastrointestinal disease, which is a frequent and important cause of death and is considered the most important disease of horses encountered by practicing veterinarians. It is estimated to cost the horse industry in the United States approximately $115,000,000 annually.[1]

ETIOLOGY

Several classification systems of equine colic have been described including a disease-based system (Table 7-10) classifying the cause of colic as

- **Obstructive, nonstrangulating:** Aboral movement of ingesta and secretions is prevented or hindered by luminal or extraluminal obstructions without a physiologically important reduction in blood flow to the gastrointestinal tract during the early stages of the disease (e.g., impaction of the large colon). Distension of the stomach or intestines can reduce blood flow in later stages of the disease.
- **Obstructive and strangulating:** Obstruction of aboral movement of ingesta and secretions with impairment of blood flow caused by mechanical compression of the vessels (arterial, venous, or both). Both the obstruction and impairment of blood flow occur at the same time (e.g., small-intestinal volvulus).
- **Nonstrangulating infarctive:** Reduction in nutritive blood supply (infarction) that is not attributable to mechanical compression of the vessels (e.g., thromboembolic colic).
- **Inflammatory** (peritonitis, enteritis): Inflammation of the stomach, intestines, or parietal and visceral peritoneum (e.g., colitis, peritonitis).

Colic cases can also be classified on the basis of the duration of the disease: **acute** (<24–36 hours), **chronic** (>24–36 hours), and **recurrent** (multiple episodes separated by periods of >2 days of normality). Another classification system is anatomically based and is listed in Table 7-11.

Regardless of the classification system used, some estimates are that fewer than >25% of colic cases seen in the field do not have a definitive diagnosis.[3] Horses with acute transient colic relieved by analgesics are often referred to as having "spasmodic colic," and this is the most common diagnosis at the primary presentation of horses with colic (24%–35%).[3] Large-colon impaction (20%) and undiagnosed (13%–25%) are the other largest diagnostic categories.[1,3]

SYNOPSIS

Etiology See Tables 7-9 to 7-11 and 7-13.

Epidemiology Incidence of 2 to 30 cases per 100 horse-years, mortality of 0.5 to 0.7 cases per 100 horse-years, and case–fatality rate of 7% to 13%. Any age predisposition is weak, although certain diseases (e.g., meconium impaction, strangulation by pedunculated lipoma) have specific age distributions. Consumption of a diet high in concentrate increases the risk of colic, as does a poor parasite control program.

Clinical signs Signs of abdominal pain include agitation, flank watching, flank biting, pawing, frequent lying down, kicking at the abdomen, frequent attempts to urinate or defecate, and rolling. Tachycardia is common. Normal gut sounds are absent and replaced by tympanitic sounds. Abdominal distension may develop. Reflux through a nasogastric tube may occur. Rectal examination may reveal abnormalities.

Clinical pathology Few changes have diagnostic significance but many are used to monitor the severity of the disease. Hemoconcentration, azotemia, and metabolic acidosis are frequent findings. Peritoneal fluid may have increased protein **and leukocyte concentration.**

Lesions Consistent with the particular disease.

Diagnostic confirmation Physical examination, exploratory laparotomy, necropsy.

Treatment Analgesia (Table 7-15), correction of fluid, acid-base and electrolyte abnormalities (Chapter 5), gastric decompression via nasogastric intubation, administration of fecal softeners or lubricants (Table 7-16), surgical correction of the lesion.

Control Parasite control. Ensure adequate roughage in the diet.

EPIDEMIOLOGY

Most studies of the epidemiology of colic do not provide details of specific diseases; instead they consider colic as one disease. This inclusion of many diseases into one category, wile maximizing the statistical power of the studies, is unfortunate because it can obscure important details regarding the occurrence and risk factors of individual diseases. Furthermore, much of the information related to incidence, treatments, and outcome of horses with colic is derived from studies of horses examined at referral centers. Horses examined at these centers are in all

Table 7-10 Etiological classification of equine colic

Type of colic	Etiology	Lesion	Typical clinical signs	Diagnosis
Simple obstruction (not infarctive)	Luminal obstruction	Impaction of stomach, ileum or large intestine with dry ingesta Concretion-type body, e.g., fecalith, meconium, phytobezoar, enterolith, foreign body, sand colic, congenital atresia	Mild to moderate pain, heart rate mildly increased initially, moderate dehydration Mild to moderate pain, moderate dehydration	Usually subacute course Diagnosis on rectal exam or imaging; exploratory celiotomy Subacute to acute course Diagnosis on rectal exam or imaging; exploratory celiotomy
	Mural blockage	Hematoma, neoplasm, idiopathic muscular hypertrophy	Pain, moderate dehydration	Rectal exam, reflux through nasogastric tube; exploratory celiotomy
	Extramural blockage	Large colon displacement	Mild to moderate pain, mild dehydration, abdominal distension	Rectal exam; exploratory celiotomy
	Functional	Spasm (spasmodic colic) Paralytic ileus Gastric reflux (acute gastric dilatation, gastric ulcer, anterior enteritis)	Moderate to severe pain, moderate to severe signs of hypovolemia	Rectal exam, gut sounds, nasogastric intubation, ultrasonographic examination
Inflammation (irritation of peritoneal pain receptors)	Infectious (e.g., *Salmonella* spp., *Actinobacillus equuli*), chemical irritation (urine, ingesta)	Peritonitis Enteritis	Mild pain, fever, toxemia, tachycardia, hypovolemia	Leukocytosis, abdominal paracentesis, diarrhea
Simple infarction (no obstruction)	Infarction; ischemia	Thromboembolic colic (verminous arteritis), arterial occlusion (pedunculated lipoma around mesentery), detachment of mesentery (traumatic or congenital)	Mild to severe pain, toxemia Possibly blood loss	Abdominal paracentesis, total white cell count; exploratory celiotomy
Obstruction plus infarction	Intestinal accidents	Intussusception Torsion Strangulation (epiploic foramen, diaphragmatic, inguinal hernias, mesenteric tear or congenital defect, pedunculated lipoma)	Intractable pain followed by profound depression, toxemia, severe tachycardia, hypovolemia	Rectal exam; abdominal paracentesis, packed cell volume, total white cell count, nasogastric intubation, ultrasonographic examination

Table 7-11 Disorders of the equine gastrointestinal tract causing colic, by anatomical site

SITE	DISORDER
Stomach	Gastric dilatation Primary Secondary to outflow obstruction, pyloric stenosis, ileus, or anterior enteritis
	Gastric impaction
	Gastroduodenal ulceration
Small intestine	Volvulus
	Intussusception Ileocecal Jejunojejunal
	Infarction or ischemia Thromboembolic disease Disruption of blood supply by mesenteric tear
	Strangulation, including entrapment through the epiploic foramen, mesenteric rents (including cecocolic fold, splenic ligament, uterine ligaments, spermatic cord), Meckel's diverticulum and hernias (diaphragmatic, inguinal/scrotal, umbilical)
	Strangulation by pedunculated lipoma
	Luminal obstruction Foreign bodies Ascarids
	Luminal compression Lipomas Intramural masses such as *Pythium* spp. and neoplasms (adenocarcinoma, lymphoma, eosinophilic enteritis)
	Adhesions
	Enteritis

Table 7-11 Disorders of the equine gastrointestinal tract causing colic, by anatomical site—cont'd

SITE	DISORDER
Cecum	Impaction
	Rupture and perforation
	Intussusception Cecocolic Cecocecal
	Cecal torsion
	Infarction (thromboembolic disease, necrotizing enterocolitis)
	Typhlitis
	Tympany
Ascending (large) colon	Impaction
	Intestinal tympany
	Volvulus
	Displacement, including left dorsal (renosplenic or nephrosplenic), right dorsal, cranial displacement of pelvic flexure
	Infarction (verminous mesenteric arteritis, necrotizing enterocolitis)
	Luminal obstruction Sand accumulation Enterolith
	Right dorsal ulcerative colitis
	Colitis
	Necrotizing enterocolitis
Descending (small) colon	Impaction
	Luminal obstruction Fecalith Enterolith
	Luminal compression Pedunculated lipoma Intramural hematoma Perirectal abscess Perirectal tumor (melanoma)
	Avulsion of mesocolon and rectal prolapse in mares at parturition
	Strangulation

likelihood not representative of horses with colic that are not referred for examination by specialists. Details of the epidemiology of specific etiologic entities are included under those headings. Only general principles are included here.

Occurrence

Equine colic occurs worldwide, although there are regional differences in the types of colic (for example, enterolithiasis), and is a common and important disease of horses. For cases of equine colic recognized in the field, as distinct from those referred for specialized treatment, the **incidence** rate ranges between 3.5 and 10.6 cases per 100 horse years, although individual farms can have rates as high as 30 or more cases per 100 horse years. Owners of horses in the UK report annual prevalence of colic, as a proportion of all health concerns, of 2.1% to 5.6%.[4] These estimates are self-reported by owners and are not based on systematic reporting or collection of data. Estimates using a population of insured horses in Japan identified an annual incidence rate for colic of 18.6% (of ~45,000 horses).[5] **Mortality** from colic is estimated to be between 0.5 and 0.7 deaths per 100 horse years in the United States and 0.7% in Japan, representing 28% of overall horse deaths (2.5 deaths per 100 horse years) in both populations.[1,5] The **case–fatality rate** is 6% to 13% of field cases, although a lower rate of 3.6% is reported for insured horses in Japan.[5] Approximately 1% to 2% of colic events in the United States and the British Isles result in surgery. It should be borne in mind that these estimates of incidence and mortality are highly influenced by the population of horses studied and can be biased or unduly influenced by inclusion of farms or groups of horses with an extremely high, or low, incidence of colic.

Risk Factors

Risk factors for colic can be categorized as (1) intrinsic horse characteristics, (2) those associated with feeding practices, (3) management, (4) medical history, (5) parasite control, and (6) season.[6]

Horse Characteristics

Age

There are conflicting results of studies that examine the association of colic and age. The conflicting results might be the result of varying study populations, study design, presence of varying confounding factors, and interpretation of data. Confounding factors are those that alter with the age of the horse, such as use, feeding, and management of horses, and mask an effect of age or give the impression of an effect of age when in fact such an effect is not present. Horses 2 to 10 years of age are 2.8 times more likely to develop colic that horses less than 2 years. One large-scale study reported that foals less than 6 months of age had an incidence of 0.2 cases of colic per 100 horses per year, whereas horses more than 6 months of age had an incidence of approximately 4 to 6 colic-affected horses per 100 horse years, with the incidence varying to a limited extent among older age groups. The mortality rate varies widely among insured horses in Japan, with a much higher incidence of death from colic

in older horses: 9% in horses >21 years of age compared with 1.5% in foals and yearlings.[5] Other studies have not found a similar effect of age. However, each age group has a particular set of diseases unique or common to it. Newborn foals can have congenital colon or anal atresia or meconium impaction (see the section Colic in Foals), diseases that do not affect older horses, whereas strangulating or obstructive lesions caused by pedunculated lipomas are found only in older horses.

Sex

There is no overall effect of gender on risk of colic, but certain diseases are restricted by gender. For instance, inguinal hernias occur only in males, whereas entrapment of intestine in the mesometrium is restricted to mares. Mares that have had a foal are at increased risk of developing volvulus of the large colon (adjusted OR of 12.9, 95% confidence interval [CI] 3.2–52).[7]

Breed

There is a generally consistent, although not universal, finding that Arabian horses are at increased risk of colic, but the reason for this apparently greater risk has not been determined. Thoroughbreds are reported to be at increased risk of colic, independent of their use.

Diet and Feeding Practices

Horses on pasture are at a lower risk of developing colic than are **stabled horses** fed concentrate feeds. The risk of colic increases with the amount of concentrate fed,[8] such that a horse fed 5 kg of concentrated feed per day has six times as great a risk of developing colic as a horse not fed concentrate.[1] However, another report did not detect an effect of diet composition on risk of colic. Changes to the horse's diet through changes in quantity and quality of feed, feeding frequency, or time of feeding increase the risk of colic by two to five times.

Management

Watering

Horses without constant **access to water** are at increased risk of developing colic,[8] whereas horses with access to ponds or dams have a reduced risk of colic compared with horses provided with water from buckets or troughs. This might represent a confounding effect of pasturing, in that horses with access to dams are probably on pasture and benefit from the lower risk of colic associated with that management practice. Alternatively, horses provided with water from buckets could be at greater risk of having periods when water is not available.

Housing

Increased duration of stabling per day is associated with an increased risk of colic. Horses cared for by their owner and horses in stables with large numbers of horses are less likely to develop colic. Horses with more than three carers are at greater risk of developing large-colon volvulus.[7]

Exercise

Overall, there appears to be an increased risk of colic among horses undertaking physical activity or that have a recent change in the amount of physical activity. However, the finding of this association should be considered in the context of other differences that exist between active and inactive horses, such as in feeding practices, housing (stabling versus pasture), and transportation. Increased stabling is associated with an increased risk of large-colon volvulus (5.5, 95% CI 1.03–29).[7]

Colic during the hours after endurance racing occurs in approximately 1.6% (47 of 2832) of horses with small-intestinal volvulus common (13 of 15 horses) among those horses requiring surgery.[9] Most horses with colic associated with endurance racing do not require surgical exploration of the abdomen or correction of abnormalities.[10] The etiology is unclear but could be associated with an exercise-induced reduction in intestinal blood flow.

Colic associated with swimming is an important cause of colic in Thoroughbred horses in training with a 3-year incidence rate of 0.08%.[11] Over a 3-year period, 38% (136) of 361 colic cases were associated with swimming, of which 131 resolved spontaneously or with medical care.[11]

Season and Weather

There appears to be a seasonal distribution or pattern to some types of colic both in the field and in those examined at a referral hospital, with epiploic foramen entrapment, large-colon impaction and/or torsion, and medical colic having an apparent seasonal distribution.[5,12] There were increases in incidence of colic in early spring and autumn in the UK and increases in cases of acute abdomen during the summer in horses in Japan.[5,12] The seasonal pattern might represent changes in management and use of horses rather than a direct effect of weather. Despite the widespread belief that colic is associated with changes in weather, particularly thunderstorms, there is no conclusive evidence of such an association.

Medical History

Horses with a history of colic are more likely to have another episode, and horses that have had colic surgery are approximately five times more likely to have another episode of colic than are horses that have not had colic. There is no association between dental care and incidence of colic, although horses that "quid" (drop partially masticated food when eating) are at increased (7.8, 95% CI 1.8–33) risk of large-colon volvulus,[7] or recent vaccination and colic. Horses with a history of **crib biting or wind sucking** are at markedly increased risk of developing colic (~2-fold risk) and more specifically epiploic entrapment of the small intestine (adjusted OR 72, 95% CI 14–359).[6,13] A history of colic in the past 12 months (5.1, 95% CI 1.4–18.9), increased stabling in the past 4 weeks (3.7, 95% CI 1.4–9.7), and increased height (1.07, 95% CI 1.01–1.12 per cm) are also being significantly associated with increased risk of colic caused by epiploic entrapment.[6] Similarly, horses that have had colic in the previous 12 months are at increased risk of a large-colon volvulus (adjusted OR of 8.7, 95% CI 1.8–43).[7]

Hospitalized horses are at increased risk of developing colic (see the section Cecal Impaction) and among horses hospitalized for treatment of ocular disease 21% developed signs of colic with 14% of those horses having a cecal impaction.[14] Duration of hospitalization (>8 days) was a strong risk factor for colic.[14]

Parasite Control

Inadequate parasite control programs have been estimated to put horses at two to nine times greater risk of developing colic, although other studies have not demonstrated a relationship between anthelmintic administration and colic. The presence of tapeworms (assessed by examination of feces) is associated with a three times greater risk of ileal impaction and 16 times increased risk of colic[15] likely because *A. perfoliata* infestation causes lesions at the ileocecal junction of horses.[16] The detection of exposure to *A. perfoliata* by detecting specific antibodies in the blood is either not associated, or weakly associated, with the risk of colic.[15,17]

Infestation by roundworms (*Parascaris equorum*) is associated with severe colic in young horses as a result of impaction or obstruction of the small intestine.[18] Approximately 75% of the affected horses had been administered anthelmintics in the previous 24 hours, suggesting that death or paralysis of a large burden of ascarids resulted in obstruction of the lumen of the small intestine by the dead or dying parasites.

There is an increased incidence of colic in horses on farms on which rotation of anthelmintics is practiced. This apparently paradoxical finding may be because farms with a higher incidence of colic are more likely to alter rotation of anthelmintics as a result of having more horses with colic. The apparently conflicting results of some of the epidemiologic studies should not deter veterinarians from recommending effective parasite control programs for horses, given the clear association at an individual level of the presence of tapeworms, cyathostomes, and/or large strongyles and ileocecal disease, diarrhea and ill-thrift, and verminous arteritis, respectively.

Importance

Losses caused by colic in horses are due almost entirely to death of the patient. However, the cost of treatment and the emotional trauma to the owners of their horse being afflicted with a potentially fatal disease are important considerations. A 1989 survey of veterinarians in the United States rated colic the most serious medical disease in horses, ahead of viral respiratory disease, and recent studies estimated the cost of colic to the horse industry in the United States at $115,000,000 annually.

PATHOGENESIS

The pathogenesis of equine colic is variable depending on the cause and severity of the inciting disease. A horse with a strangulating lesion involving 50% of its small intestine has a much more rapidly evolving disease, with severe abnormalities, than does a horse affected with mild spasmodic colic or impaction of the pelvic flexure of the large colon. Although equine colic often involves changes in many body systems, notably the gastrointestinal, cardiovascular, metabolic, and endocrine systems, there are several features and mechanisms that are common to most causes of colic that depend only on the severity of the disease for the magnitude of their change. The features common to severe colic, and often present to a lesser degree in milder colic, are pain, gastrointestinal dysfunction, intestinal ischemia, endotoxemia or toxemia, compromised cardiovascular function (shock), and metabolic abnormalities.

Pain

Pain is the **hallmark of gastrointestinal disease** in horses and is attributable to distension of the gastrointestinal tract and stimulation of stretch receptors in the bowel wall and mesentery; stretching of mesentery by displaced or entrapped bowel; and inflammation and irritation of the bowel, peritoneum, or mesentery. Methods for objectively assessing and scoring pain in horses have been developed but as yet have not been rigorously tested and validated in large numbers of horses in varying situations.[19-21] Scoring systems that provide a composite score, and for which there is good interrater and intrarater agreement, have usefulness in developing prognostic criteria, for monitoring response to treatment, and for determining the need and efficacy of analgesia/hypalgesia.

The **intensity of the pain** is often, but not always, related to the severity of the inciting disease. Horses with mild impaction of the large colon of short duration (<24 hours) often have very mild pain, whereas a horse with a strangulating lesion of the small intestine will have very severe pain. Horses that recovered from gastrointestinal tract surgery (colic surgery) had lower pain scores after surgery than did horses that did not survive.[19]

Gastrointestinal pain has an inhibitory effect on normal gastrointestinal function, causing a feedback loop in which the pain inhibits normal gut motility and function, allowing accumulation of ingesta and fluid, resulting in distension and further pain. Horses can respond very violently to abdominal pain and may injure themselves when rolling or thrashing.

Gastrointestinal Dysfunction

Colic is almost invariably associated with impaired gastrointestinal function, usually alterations to **motility** or **absorptive** function. Gastrointestinal motility may be increased, as is presumed to be the case in spasmodic colic, altered in its character or coordination, as in some cases of impaction colic, or absent, such as in ileus secondary to inflammation or ischemia of the bowel or to the presence of endotoxemia. Increased or uncoordinated gastrointestinal motility probably causes pain through excessive contraction of individual segments of bowel or distension of bowel because of the loss of normal propulsive activity. **Ileus** is associated with fluid distension of the small intestine and stomach and fluid and gas distension of the large colon, both of which cause severe pain and can lead to gastric or colonic rupture. The absorptive function of the intestine may be decreased by inflammation or ischemia, which results in distension of the small intestine or large colon, pain, and potentially rupture of the stomach or colon.

Impairment of the **barrier function** of the gastrointestinal mucosa by inflammation or ischemia can result in leakage of endotoxin and other toxic compounds into peritoneal fluid with subsequent endotoxemia, toxemia, and systemic inflammatory response syndrome (see the section Endotoxemia).

Ischemia of the Intestinal Wall

Ultimately, most forms of lethal colic involve some degree of ischemia of the intestine, with subsequent loss of barrier function, evident in its most extreme form as rupture of the viscus, endotoxemia, bacteremia, cardiovascular collapse, and death. Ischemia may be the result of impaired blood flow to or from the intestine because of torsion or volvulus of the intestine, entrapment of the intestine and associated mesentery in rents or hernias, strangulation such as by a pedunculated lipoma, or thromboembolic disease. Ischemia may also result from severe gastrointestinal distension, such as occurs in the terminal stage of severe colon impaction. Mild ischemia probably impairs normal intestinal motility and function. The role of reperfusion injury in pathogenesis of ischemic disease is uncertain at this time.

Endotoxemia

Death in fatal cases of colic in which the affected viscus ruptures secondary to distension, or when ischemia and/or infarction damages a segment of bowel wall, is caused by the absorption of endotoxins and other compounds from the gut lumen into the systemic circulation (see the section Endotoxemia). Endotoxin absorption causes increased concentrations of tumor necrosis factor and interleukin (IL)-6 in peritoneal fluid and blood concentrations.

Rupture of the stomach or intestine is also a characteristic termination of distension of the intestine in the horse. The resulting deposition of large quantities of highly toxic ingesta or fecal contents into the peritoneal cavity causes profound shock and death within a few hours.

Shock

The usual cause of death in severe colic is cardiovascular collapse secondary to endotoxemia/toxemia and hypovolemia. In less severe colic, hypovolemia and cardiovascular dysfunction may contribute to the development of the disease, and rapid correction of hypovolemia is central to the effective treatment of colic.

Hypovolemia is caused by the loss of fluid and electrolytes into the lumen of the gastrointestinal tract or loss of protein from the vascular space with subsequent reduction in the circulating blood volume. Hypovolemia impairs venous return to the heart and therefore cardiac output, arterial blood pressure, and oxygen delivery to tissues. Not surprisingly, measures of circulatory status are good predictors of the outcome of colic (see the section Prognosis).

Cardiorespiratory function is impaired if there is severe distension of gut, such as in large-colon torsion, because of restricted respiration by pressure on the diaphragm and reduced venous return to the heart because of pressure on the caudal vena cava. Cardiac function is impaired in some horses with colic, as indicated by the high incidence of arrhythmias, elevated serum concentrations of troponin, and abnormal contractile function detected by echocardiographic examination.[22-25] The reduction in myocardial function is most evident as an increase in the ratio of preejection time to ejection time for the left ventricle.[24]

Coagulation and Fibrinolysis

Severe colic, especially that involving ischemia or necrosis of intestine, is associated with abnormalities in coagulation and fibrinolysis characterized by hypercoagulation or hypocoagulation of blood and abnormal fibrinolysis.[26-28] The particular abnormalities present at a point in time depend on the severity of disease and its duration. Initial increases in coagulability or fibrinolysis can progress to hypocoagulable and hypofibrinolytic states as the severity of the disease increases.[28]

Disseminated intravascular coagulation is common among horses with ischemia or necrosis of the gut and is a good prognostic indicator of survival.[26,27] Changes in coagulation and fibrinolysis include decreases in

antithrombin activity and fibrinogen concentration and increases in prothrombin time, activated partial thromboplastin time, and concentration of thrombin–antithrombin complexes in plasma.[27,29] Dynamic measures of clotting function or fibrinolysis also reveal that hypocoagulation, indicated by abnormalities in one or more measures by thromboelastography, is indicative of a poor prognosis.[27] However, changes in these variables do not always correlate well with more dynamic measures of clotting function, such as thromboelastography.[27,29]

Overview of the Pathogenesis of Common Colics

Simple Obstructive

Simple obstructive colics are those in which there is obstruction to the aboral passage of ingesta but no ischemia or strangulation of bowel. In the terminal stages there is often ischemia caused by distension of the intestine.

Small-intestinal obstructive lesions include ileal hypertrophy, ileocecal intussusception, and foreign-body obstruction of the lumen. The course of the disease is often 24 to 72 hours, and sometimes longer depending on the extent of the obstruction, and partial obstructions have much less severe signs and disease of longer duration. The principal abnormality is reduced aboral flow of ingesta, with subsequent distension of intestine cranial to the obstruction, causing pain and, if the distension is severe, gastric rupture.

Large-intestinal obstructive lesions include impaction and simple (nonstrangulating) displacements of the large colon. The course of disease is prolonged, often more than 72 hours. Signs of abdominal pain are caused by distension of the bowel. There is progressive distension with fluid and gas and ultimately ischemia of the bowel and rupture.

Obstructive and Strangulating

Diseases that cause both obstruction and strangulation as an initial event, such as torsion of the small intestine or volvulus of the large colon, result in severe and unrelenting pain that is difficult to relieve with analgesics. Obstruction causes distension and strangulation causes ischemia, loss of barrier function, and endotoxemia. These diseases have a short course, usually less than 24 hours and sometimes as short as 6 hours, and profound clinical signs. Endotoxemia/toxemia, systemic inflammation, and cardiovascular collapse are characteristic of these diseases.

Infarctive

Infarctive diseases, such as thromboembolic colic, are characterized by ischemia of the intestinal wall with subsequent alterations in motility and absorptive and barrier functions. Ileus causes distension of the intestines and stomach and altered barrier function causes endotoxemia. The course of the disease is usually less than 48 hours and is terminated by cardiovascular collapse and death.

Inflammatory

Inflammation of the intestine or peritoneum alters gastrointestinal motility and absorptive function leading to accumulation of fluid and ingesta, distension, and abdominal pain.

CLINICAL FINDINGS

The bulk of the following description is generally applicable to severe acute colic. Clinical findings characteristic of each etiologic type of colic are dealt with under their individual headings. The purposes of the clinical examination are **diagnostic**—to determine whether the pain is caused gastrointestinal tract disease and, if so, to determine the nature of the lesion—and **prognostic**—to provide some estimate of the likely outcome of the disease. Veterinary clinicians are able to accurately predict the site of lesions (small intestine versus large intestine), type of lesion (simple obstructive versus strangulating or infarctive), and outcome. The ability to predict these events increases with training and experience.

Accurate diagnosis of the cause of the colic has some prognostic usefulness, but assessment of the horse's physiologic state by measurement of heart and respiratory rates, mucous membrane color and refill time, arterial blood pressure, hematocrit and serum total protein concentration, as well as other measures, allows more accurate prognostication. Furthermore, the cause of colic is determined in only approximately 20% of field cases.

Table 7-12 Criteria for evaluation of pain in horses[30]

Behavior	Score
Depression	1
Flank watching Weight shifting	2
Restlessness Kicking abdomen Pawing Stretching Sternal recumbency	3
Attempting to lie down Lateral recumbency	4
Rolling Collapse	5

Visual Examination

Behavior

Pain is manifested by **pawing, stamping, or kicking** at the belly or by restlessness evident as pacing in small circles and repeatedly getting up and lying down, often with exaggerated care. Methodology for identifying and rating pain has been validated for horses and has high intraobserver ($\kappa = 0.9$) and interobserver (intraclass correlation coefficient 0.8) values indicating the repeatability of the assessments either by the same observer or by different observers. The pain scale also has good sensitivity and specificity for outcome (lived versus died, 70% and 71%) and treatment (medical, surgical, euthanasia, 70% and 57%)[30] (Table 7-12).

Other signs are looking or nipping at the flank, **rolling**, and lying on the back. Often the penis is protruded without urinating or with frequent urination of small volumes. Continuous playing with water without actually drinking (sham drinking) is common.

Pain may be continuous or, more commonly, intermittent with bouts of pain lasting as long as 10 minutes interspersed with similar periods of relaxation. Generally, the intensity of the pain is of about the same severity for the duration of the illness; sudden exacerbations may indicate a change in the disease status or the development of another abnormality, such as a horse with impaction of the large colon developing a displacement of the colon or horses with diarrhea developing necrotizing enteritis. Horses in the terminal phase of the disease may have a marked diminution of pain associated with relief of pressure after rupture of distended bowel and depression caused by toxemia and shock. Pain responses in colic can be so severe, and uncontrolled movements so violent, that the horse might do

itself serious injury. Other causes of pain, such as pleuritis or rhabdomyositis, can be confused with colic, although a horse that goes down and rolls almost certainly has alimentary tract colic.

Posture

The posture is often abnormal, with the horse standing stretched out with the forefeet more cranial and the hindfeet more caudal than normal or the so-called "sawhorse" stance. Some horses lie down on their backs with their legs in the air, suggesting a need to relieve tension on the mesentery.

Abdomen Size

Distension of the abdomen is an uncommon but important diagnostic sign. **Symmetric, severe distension** is usually caused by distension of the colon, sometimes including the cecum, secondary to colon torsion, or impaction of the large or small colon and subsequent fluid and gas accumulation. If only the cecum is distended the abdomen can show an **asymmetric enlargement** in the right sublumbar fossa. Maximum distension of stomach or small intestines does not cause appreciable distension of the abdomen.

Vomiting

Projectile vomiting or regurgitation of intestinal contents through the nose is very unusual in horses and is a serious sign suggesting severe gastric distension and impending rupture.

Defecation and Feces

Defecation patterns can be misleading. It is often mistakenly assumed that there is no complete obstruction because feces are still being passed, but in the very early stages of acute intestinal obstruction there can be normal feces in the rectum, and the animal might defecate several times before the more usual sign of an empty rectum with a sticky mucosa is observed.

Physical Examination

Heart and Respiratory Rates

The **heart rate** is a useful indicator of the severity of the disease and its progression but has little diagnostic usefulness. Horses with heart rates less than 40 beats/min usually have mild disease, whereas horses with heart rates above 120 beats/min are usually in the terminal stages of severe disease. Horses with obstructive, nonstrangulating disease often have heart rates between 40 and 60 beats/min, whereas horses with strangulating disease or necrotic bowel will usually have heart rates over 80 beats/min. However, heart rate is not an infallible indicator of disease severity, as horses with torsion of the colon can have heart rates of 40 to 50 beats/min.

The **respiratory rate** is variable and can be as high as 80 beats/min during periods of severe pain.

Mucous Membranes and Extremities

Mucous membranes of normal horses and of horses without significantly impaired cardiovascular function are pink, moist, and regain their normal color within 2 seconds after firm digital pressure is removed. Dehydrated horses have dry mucous membranes, although the capillary refill time and color are normal. Horses with impaired cardiovascular function have pale, dry mucous membranes with delayed capillary refill (>2 seconds). Endotoxemic horses will often have bright red mucous membranes with normal or delayed capillary refill. As the disease becomes more severe the mucous membranes develop a bluish tint and capillary refill is longer than 3 seconds. **Terminal** stages of disease are associated with cold, purple, dry mucous membranes with a capillary refill time of more than 3 seconds; necrosis of the mucosa of the gingival margins of the gums, the so-called "toxic line," is often seen.

Cool extremities can be indicative of compromised cardiovascular function but should be interpreted with caution and only in the context of the rest of the clinical examination. **Sweating** is common in horses with severe abdominal pain and, when present in a horse with cool extremities and signs of cardiovascular collapse, is indicative of a poor prognosis.

Auscultation and Percussion

Auscultation of the abdomen can provide useful diagnostic and prognostic information and should be performed thoroughly and without haste. All four quadrants (dorsal and ventral, left and right sides) of the abdomen should be examined for at least 1 minute at each site. Attention should be paid to the intensity, frequency, and characteristics of the spontaneous gut sounds (borborygmi). Repeated observations are often necessary to detect intermittent or rapid changes in the character of the borborygmi.

Continuous, loud borborygmi distributed in all or most quadrants are indicative of intestinal hypermotility and consistent with spasmodic colic, impending diarrhea, or the very early stages of a small-intestinal obstructive/strangulating lesion. The **absence of sounds**, or the presence of occasional high-pitched, brief sounds, sometimes with a splashing character, is consistent with ileus. These sounds should not be mistaken for the rolling, prolonged sounds of normal peristalsis.

Combined percussion and auscultation is a valuable procedure for defining the presence of extensive gas caps; a flick or abrupt tap with a finger while auscultating with a stethoscope will elicit a **pinging** sound similar to that made by flicking an inflated balloon. The detection of such sounds indicates the presence of tightly gas-distended bowel near the body wall. Such bowel is almost always large colon or cecum and is consistent with gas distension secondary to ileus, small or large-colon impaction, gas colic, or colon displacement, including torsion.

Rectal Examination

A careful rectal examination is probably the most important part of the clinical examination in colic and should not be neglected. The examiner must know the anatomy of the posterior abdomen to make reasonably accurate decisions about the location of various organs. Recognition that an important abnormality exists is a critical factor in the decision to refer the horse for specialized evaluation and care.

Normal Anatomy

The horse should be restrained so that the examination can be performed with minimal risk to both the examiner and patient. Fractious or horses in pain should be tranquilized. A twitch should be applied to all but the most cooperative horses to minimize straining and the chance of kicking. Rectal examination in small or unruly horses should be approached with caution.

Only approximately 40% of the abdomen can be examined in a mature horse, because the cranial and ventral structures are outside the reach of the examiner. In the normal 425-kg (1000-lb) horse there should not be any distended intestine and the small intestine should not be palpable. The **cecum** is readily palpable in the right caudal abdomen, with its ventral band running from the dorsal right quadrant ventrally and slightly to the left. The base of the cecum may be palpable as a soft, compressible structure containing fluid and gas. The caudal border of the **spleen** is readily palpable as it lies on the left side of the abdomen against the body wall. There should be no bowel between the spleen and the body wall, although occasionally the small colon can be detected dorsal to the spleen. Dorsal and medial to the spleen, the **left kidney** should be readily palpable, as should the **nephrosplenic ligament** and **space**. There should be no bowel in the nephrosplenic space, although some horses have portions of small colon in the region of the nephrosplenic space. Portions of **large colon**, especially the pelvic flexure, can be palpated in the caudal ventral abdomen if they contain ingesta. The inguinal rings may be palpated in males. The ovaries and uterus can be palpated in mares. The bladder can be palpated if it contains urine.

Abnormal Findings

Abnormalities associated with specific diseases are discussed under those headings (Table 7-13). One should be able to recognize gas and fluid distension of the cecum and colon, fluid distension of the small intestine, impaction of the large and small colon, and displacement of the large colon.

Small-intestinal distension is evident as loops of tubular structures of up to 10 to

Table 7-13 Rectal findings and associated causes of equine colic

Rectal abnormality	Disease	Clinical characteristics	Treatment
Distended small intestine	Proximal jejunitis/duodenitis, anterior enteritis	Small intestine mildly to moderately distended; voluminous gastric reflux; marked pain relief on gastric decompression Normal peritoneal fluid in most cases	Supportive; repetitive decompression of stomach
	Strangulating intestinal lesion; small intestinal volvulus or entrapment	Severe, tight distension of small intestine; gastric reflux Severe pain not relieved by gastric decompression; abnormal peritoneal fluid	Surgery
	Ileal impaction	Mild and progressive pain; gastric reflux only late in disease Impaction occasionally palpable per rectum	Medical initially, then surgery if no resolution
	Ileal hypertrophy	Mild to moderate chronic pain occurring after feeding Hypertrophy may be palpable	Surgical resection
	Ileocecal intussusception	Moderate to severe pain; gastric reflux later in disease Usually young horse	Surgical correction
Large colon distension	Colon torsion	Tenia dorsal in some cases; cecum displaced medially Severe pain; abdominal distension; no gastric reflux Short disease course	Surgical correction
	Left dorsal colon displacement (renosplenic entrapment)	Mild to moderate pain; bands on rectal examination leading to renosplenic space; ultrasonographic confirmation	Replacement by rolling horse Surgery
	Right dorsal displacement of colon	Moderate to severe pain; bands leading ventral to right dorsal quadrant; colon lateral to base of cecum	Surgical correction
	Impaction of large colon	Impaction palpable per rectum	Fecal softeners and lubricants, oral and intravenous fluids Surgery in refractory cases
	Enterolith	Obstruction usually of right dorsal or transverse colon Not palpable rectally; refractory pain; radiography	Surgical removal
	Gas colic	Gas distension of large colon; pain readily relieved with analgesics; short course with rapid recovery; major differential is colon torsion	Analgesics, mineral oil
	Sand colic	Mild to moderate pain; Sand auscultable in ventral abdomen; sand in feces; occasional watery feces	Analgesics, psyllium orally
Cecal distension	Cecal impaction	Mild to moderate pain, course of several days with sudden deterioration when cecum ruptures	Analgesics, lubricants, fecal softeners; surgical correction
	Cecal torsion	Acute, severe pain; rare	Surgical removal or correction
Displaced spleen	Renosplenic entrapment of large colon	See previously	
	Large colon displacement	Mild to moderate pain; ultrasonographic diagnosis	Analgesics; surgery
Intraabdominal masses	Mesenteric abscess	Fever, mild chronic or intermittent abdominal pain Increased leukocyte numbers in blood and peritoneal fluid	Long-term antibiotics
	Neoplasia	Neoplastic cells in peritoneal fluid; exploratory laparotomy	None

15 cm in diameter that may extend as far caudally as the pelvic canal. The structure is often compressible, akin to squeezing a fluid-filled tubular balloon, and slightly moveable. The presence of distended small intestine is an important sign suggestive of a small-intestinal obstructive lesion or anterior enteritis.

Colonic distension, impaction and displacement can be evident on rectal palpation. Gas and fluid distension of the **large colon** is evident as large (>20 cm) taut structures often extending into the pelvic canal. Tenial bands are often not palpable because of the distension. The distended bowel may extend into the pelvic canal, preventing examination of the caudal abdomen. **Impaction** is evident as columns of firm ingesta in the large or small colon. The most common site is the pelvic flexure in the caudoventral abdomen and the inlet to the pelvic canal. The impacted material remains indented when pressed with the finger tips.

Distension of the small colon is detectable as loops of tubular structures in the caudal abdomen. The loops of intestine have a prominent antimesenteric band, a feature not present on small intestine.

Displacement of the large colon is evident rectally as tight bands extending from the ventral abdomen cranially, dorsally, and to the left or cranially, dorsally, and to the right in left and right displacements of the colon, respectively. Displacement of the colon, if it obstructs aboral flow of ingesta and gas, may cause distension.

Nasogastric Intubation

Passage of a nasogastric tube is an essential part of the examination of a horse with colic because of the diagnostic information it provides and because relief of gastric distension can be life-saving.

The nasogastric tube **must** be passed into the stomach. This is usually evident by the release of a small amount of sweet-smelling gas as the stomach is entered. The tube should then be advanced further into the stomach

and, if reflux of material does not occur spontaneously, a siphon should be established by filling the tube with approximately 500 mL of water and rapidly dropping the end of the tube below the level of the horse's stomach. This procedure should be repeated at least three or four times if reflux is not obtained. If **reflux** is obtained, its volume and character should be noted. The volume should be measured, and anything more than 2 L of net reflux is likely important. If reflux is obtained, the nasogastric tube should be left in place or replaced frequently (1-hour intervals) until the colic resolves. If there is no reflux but the horse remains colicky, then repeated attempts should be made to obtain reflux. **Oral medications** should not be given to horses with nasogastric reflux.

Ancillary Diagnostic Techniques

Ultrasonography

Ultrasonographic examination of the abdomen of adult horses is useful in identifying a number of abnormalities, including small-intestinal distension, ileocecal intussusception, gastric distension, gastric squamous cell carcinoma, diaphragmatic hernia, peritoneal effusion, and other conditions.[31-35] Ultrasonographic examination is useful for detecting small-intestinal distension (such as occurs with anterior enteritis or small-intestinal accidents), reduced motility (anterior enteritis, enteritis, and obstruction), thickening of intestinal wall (>4 mm, enteritis, right dorsal colitis), volume and characteristics of peritoneal fluid (peritonitis and hemoperitoneum[36]), abnormalities in intestinal contents (such as presence of sand or excessively fluid ingesta), the presence of sacculations of the ventral colon (absence indicates distension), abnormalities in intestinal architecture (intussusceptions), and the presence of abnormal structures (neoplasia[37] and abscess[38]). Detection of colonic mesenteric vessels in an abnormal location (lateral or ventral to the colon) is strongly associated with a diagnosis of colon displacement or volvulus.[32,39] Ultrasonographic detection of small-intestinal distension is more sensitive than is rectal examination. (Fig. 7-1, A–D[33]).

Abdominal ultrasonography can be used for the accurate definitive diagnosis of some small-intestinal and large-intestinal diseases. Distended and nonmotile small-intestinal loops are associated with strangulated obstruction. Failure to visualize the left kidney is associated with renosplenic entrapment, and thickened large colon is associated with strangulating volvulus.[40]

Ultrasonographic examination reveals colon with a mural thickness of 9 mm or greater in horses with colon torsion. The test has a sensitivity of approximately 67% (i.e., correctly predicts the presence of colon torsion in two-thirds of horses that have the disease) and specificity of 100% (correctly rules out the diagnosis in 100% of horses that do not have the disease). Similarly, ultrasonography has a sensitivity of 80% and a specificity of 98% for detection of dilated small intestine.[33]

The abdomen should be examined in a systematic fashion with a 2.0 to 3.5-mHz transducer, and a procedure allowing rapid examination of the abdomen of horses has been proposed (Table 7-14).[33] The value of this protocol is that it ensures a systematic and thorough examination of the abdomen and thorax for signs of the cause of colic. The normal ultrasonographic anatomy of equids is described.[34]

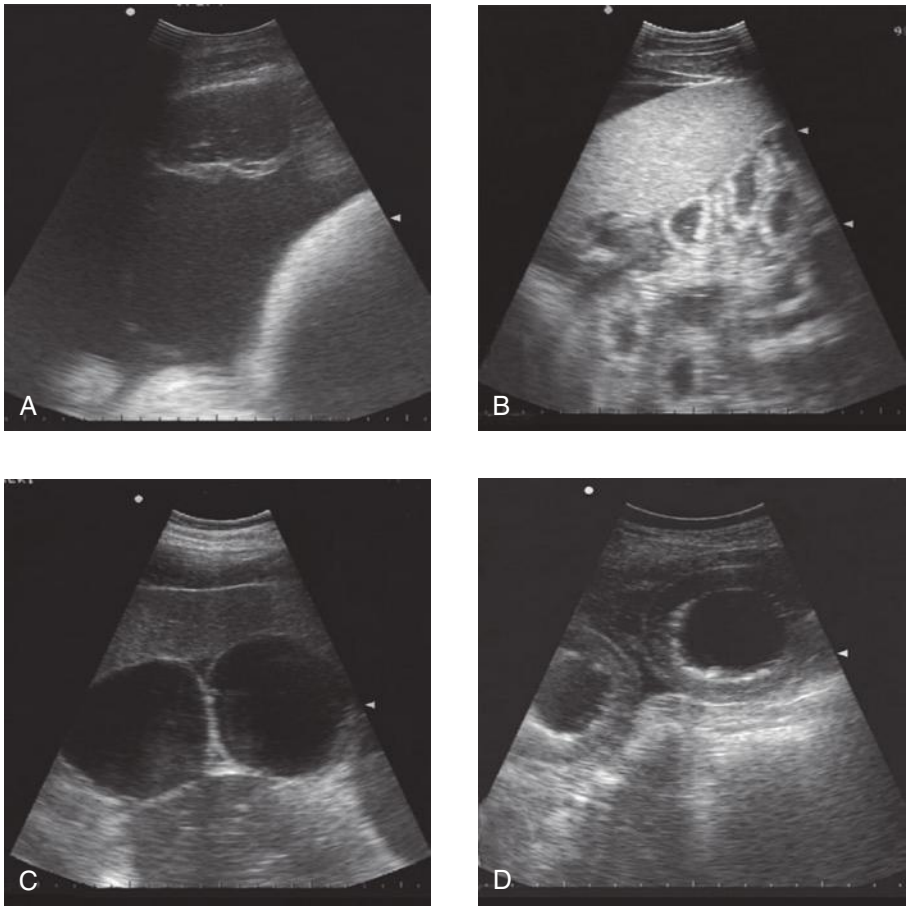

Fig. 7-1 **A,** Ultrasonographic image obtained at site 1: an abnormal amount of anechoic fluid is visible. **B,** Ultrasonographic image showing nonturgid fluid-filled small-intestinal loops. **C,** Ultrasonographic image showing turgid small-intestinal loops without wall thickening in a horse with small-intestinal obstruction. **D,** Ultrasonographic image showing turgid small-intestinal loops with marked wall thickening in a horse with strangulated small-intestinal obstruction.

Radiology

The large size of the adult horse precludes detailed radiographic examination of intra-abdominal structures. Enteroliths can be detected by computed radiography with a sensitivity of 85% and a specificity of 93%. Sensitivity is lower for small-colon enteroliths than for large-colon enteroliths (50% and 94.5%, respectively) and is significantly affected by gas distension.[41] Computed (digital) radiography provides some improvement in sensitivity over analog radiography, but both are useful techniques in diagnosis of enterolithiasis. Sand accumulation can be detected by radiographic examination of the abdomen.[42,43] Diaphragmatic hernias can be detected by radiographic (or ultrasonographic) examination of the thorax.

Arterial Blood Pressure

Arterial blood pressure is a very good indicator of the degree of shock in colic, and the availability of a simple technique makes it a practical aid in assessing prognosis in a clinical case. If normal systolic pressure is about 100 mm Hg (13.3 kPa), a pressure below 80 mm Hg (10.6 kPa) indicates a critical situation (it can be as low as 50 mm Hg [6.6 kPa]). In horses with very severe pain but not shock, the systolic pressure is likely to be very high, up to 250 mm Hg (33.3 kPa).

Course of the Disease

The course of the disease depends on its cause and the severity of the associated lesions. Spasmodic and gas colic usually resolves within hours of onset. Horses with

Table 7-14 Method for brief examination of the abdomen of a horse with colic

Side	Site	Scanning procedure
Left	Ventral abdomen	Place the probe just caudal to the sternum and move caudally to assess the most gravity-dependent area of the abdomen.
	Gastric window	Visualize the stomach at the level of the 10th left ICS in the middle third (dorsoventrally) of the abdomen and then move the probe in the 2–3 ICSs cranial and caudal to the 10th one.
	Splenorenal window	Place the probe between dorsal and middle third of the abdomen at the level of the 17th ICS.
	Left middle third of the abdomen	Freely move the probe around in the middle third of the abdomen.
Right	Duodenal window	Place the probe in the 14–15th right ICS in the dorsal part of the middle third (dorsoventrally) of the abdomen.
	Right middle third of the abdomen	Freely move the probe around in the middle third of the abdomen.
	Cranial ventral thorax	Place the probe on the cranial ventral thorax just caudal to the triceps muscle.

Reproduced with permission from XX[23]
ICS, intercostal space.

strangulating lesions have severe clinical signs and usually die within 24 hours of the onset of signs. Horses with nonstrangulating obstructive lesions have longer courses, often 48 hours to 1 week, and die when distension causes bowel to become devitalized and rupture.

When intestinal rupture does occur, there is a sudden onset of shock and toxemia, the acute pain that preceded it disappears, and the horse becomes quiet and immobile. The terminal stages after rupture of the intestine or stomach, or from profound endotoxemia, are very distressing. The horse might be recumbent but most continue to stand until the last few minutes, when they can literally drop dead. The respiration is sobbing and there is gross muscle tremor and profuse sweating, and there is often a delirious, staggering wandering. Euthanasia should be performed before this stage is reached.

CLINICAL PATHOLOGY

Examination of various clinical pathology variables is useful in assessing the severity of the changes occurring as a consequence of the disease rather than in providing a definitive diagnosis. Therefore some of these variables have prognostic significance (see "Prognosis") and should be monitored repeatedly in severe cases.

Hematology and Serum Biochemistry

Measurement of **hematocrit** and **plasma total protein** concentration is useful in assessing hydration status (see Chapter 5). Hematocrit increases as a consequence of splenic contraction or dehydration, making the use of this variable as a sole indicator of hydration status unreliable. However, increases in both hematocrit and total protein concentration indicate dehydration, and these variables can be used as crude estimates of response to fluid therapy. Plasma total protein concentrations may decline if there is significant loss of protein into the gut lumen or peritoneal space.

Measurement of the **blood leukocyte** count has little diagnostic significance, with the exception that the combination of leukopenia and a left shift are consistent with the endotoxemia that accompanies devitalized bowel, enteritis, or peritonitis. Serum concentrations of amyloid A, an acute phase protein, are higher in horses with colic than in healthy horses.[44]

Horses with severe colic often have abnormalities in coagulation, with nonsurviving horses and horses with strangulating lesions having the most severe changes, characterized by low antithrombin activity and prolonged prothrombin and activated partial thromboplastin times.[26,27,29] Disseminated intravascular coagulation is common among horses with ischemia or necrosis of the gut and is a good prognostic indicator of survival.[26,27] Changes in coagulation and fibrinolysis include decreases in antithrombin activity and fibrinogen concentration and increases in prothrombin time, activated partial thromboplastin time, and concentrations of D-dimer and thrombin–antithrombin complexes in plasma.[26,27,29,45] Dynamic measures of clotting function or fibrinolysis also reveal that hypocoagulation, indicated by abnormalities in one or more measures by thromboelastography, is indicative of a poor prognosis.[27] However, changes in these variables do not always correlate well with more dynamic measures of clotting function, such as thromboelastography.[27,29]

There is evidence of abnormal cardiac function or cardiac injury in up to one-half of horses with severe colic.[25,46] Plasma concentrations of cardiac troponin I (cTnI) exceed the reference range for healthy horses in horses with strangulating or nonstrangulating obstructive lesions of the small or large intestine or inflammatory (noninfarctive) lesions of the intestines or peritoneum.[25,46] The cTnI concentration exceeded the upper reference range (>0.03 ng/mL) in 36% (9/25) horses with strangulating lesions and 47% (9/19) with nonstrangulating inflammatory (9/19 [47%]) disease.[25] The proportion of horses with high cTnI concentration was significantly greater among nonsurvivors (12/24 [50%]) than among survivors (10/45 [22%]).[25] Concentrations are higher in horses that do not survive and are negatively correlated with hematocrit and blood lactate concentration and negatively with left ventricular ejection time (a measure of cardiac function in which a shorter ejection time indicates compromised function).[25]

Measures of **serum electrolyte concentration** are important in providing an assessment of the horse's electrolyte status and in tailoring fluid therapy (see Chapter 5). The nature of the abnormalities depends to some extent on the cause of the disease, but is more markedly affected by the severity of the disease. Mild hyponatremia is not uncommon but is clinically unimportant in the vast majority of cases.[47] **Hyperkalemia** is common in horses with severe acidosis and large sections of devitalized intestine.

Hypokalemia is common in horses with more long-standing colic, for instance impaction of the large colon, that have not eaten for several days. **Hypocalcemia** and **hypomagnesemia** are common in horses with colic, especially horses with severe colic.[47,48] Measurement of total concentrations (ionized plus nonionized) can be misleading in that reductions in concentration of the physiologically important ionized component can be present in horses with normal concentrations of the total ion. Hospitalized horses with colic or diarrhea are more likely to have hypomagnesemia than are horses with other diagnoses.

Serum enzyme activities are rarely useful in aiding diagnosis or treatment of horses with colic, with the exception that **serum γ-glutamyl transferase (GGT)** activity is elevated in approximately 50% of horses with right dorsal displacement of the colon, whereas such elevations are rare in horses with left dorsal displacement. The elevated GGT, and less commonly serum bilirubin concentration, in horses with right dorsal displacement is attributable to compression of the common bile duct in the hepatoduodenal ligament by the displaced colon. Serum and peritoneal **alkaline phosphatase** activities are higher in horses with ischemic or inflammatory bowel disease than in horses with other forms of colic, although the differences are not sufficiently large as to be useful diagnostically. Serum creatine kinase activity above the normal range (385 U/L) is

associated with a fourfold increase in the likelihood that a horse with colic has small-intestinal ischemia.

Serum **urea nitrogen** and **creatinine** concentrations are useful indicators of hydration status and renal function. Prerenal azotemia is common in horses with colic, and can progress to acute renal failure in severe cases of colic of sufficient duration. High plasma concentrations of intestinal fatty acid binding protein (>100 pg/mL) are associated with increased need for surgery in horses with colic.

Hyperglycemia is common in horses with colic examined in referral institutions with 45% of cases having blood glucose concentrations about the reference range.[49] Blood glucose concentrations are indicative of the severity of disease with more severely ill horses having higher concentrations of glucose in blood.[49,50]

Horses that die of colic have higher circulating concentrations of epinephrine, cortisol, and lactate than do horses that survive, indicating a greater degree of sympathetic and adrenal cortical activation.[51]

Acid-Base Status

Most horses with severe colic have **metabolic acidosis**, although respiratory acidosis and metabolic alkalosis also occur. Horses with less severe disease, such as simple obstructive disease or spasmodic colic, might not have abnormalities in acid-base status.

Metabolic acidosis, when severe, is usually but not always attributable to L-lactic acidosis. Lactate is present as the L-isomer, which is produced by mammalian metabolism, and the D-isomer, which is produced only by bacterial metabolism. L-Lactate accumulates as a result of increased production or decreased clearance of L-lactate by the animal. D-Lactate accumulates because of the production of this isomer in the blood or peritoneal fluid as a result of the presence of bacterial infection of these anatomic spaces or because of leakage of D-lactate produced by bacteria in the gastrointestinal tract into the circulation through compromised mucosa or as a result of a ruptured viscus.[52] Increases in blood and peritoneal fluid D-lactate concentrations are signs of a poor prognosis.[52]

L-Lactate concentrations can be estimated by calculating the anion gap:

$$Anion\ gap = (sodium + potassium) - (bicarbonate + chloride).$$

(If bicarbonate concentrations are not available, total serum carbon dioxide can be substituted.) However, the increasing availability of laboratory-based or stall side (point-of-care) L-lactate analyzers means that direct measurement of plasma or blood L-lactate concentrations is feasible in a variety of clinical situations.[53-56] Samples should be analyzed within minutes of collection unless collected into evacuated tubes containing sodium fluoride/potassium oxalate in which case lactate concentration in plasma is stable in refrigerated samples for up to 6 hours (and perhaps longer).[55] Measurement of plasma lactate concentration is useful in assessing disease severity and likelihood of survival with one study documenting a 29% increase in odds of death (OR 1.20, 95% CI 1.2–1.4) for every 1 mmol/L increase in plasma lactate concentration.[54] Others report similar evidence in horses with surgical lesions of the small or large intestine.[46] Similarly, increases in plasma lactate concentration over time are indicative of a worsening prognosis.[46,54]

Anion gap of less than 20 mEq/L (mmol/L) is associated with 81% survival, 20 to 24.9 mEq/L (mmol/L) with 47% survival, and 25 mEq/L (mmol/L) or more with 0% survival.[1]

Abdominocentesis

Analysis of peritoneal fluid is an important component of the complete examination of a horse with colic. Details of the technique and interpretation of the results were discussed previously but, briefly, if there is an increase in the total protein concentration, a change in the color to red or blood-tinged, and an increase in the leukocyte count in peritoneal fluid, it is likely that there is some insult to intraabdominal structures. The color of peritoneal fluid is also indicative of its L-lactate concentration, with yellow fluid an indicator of a low lactate concentration and red fluid having the highest concentrations.[50] **Total protein concentration** increases when there is an insult to the gastrointestinal tract that compromises the serosal surface of the bowel, for instance strangulating lesions of the small intestine or in the terminal stages of an impaction colic in which the bowel wall is devitalized.

Increased concentrations of **D-lactate or L-lactate** are associated with more severe disease and decreased chances of survival.[50,52] Peritoneal lactate concentrations increase with increasing disease such that 55% to 60% of horses with peritoneal lactate concentrations <2.0 mmol/L die, whereas 100% of horses with peritoneal lactate concentrations >10 mmol/L die.[50]

Concentrations of D-dimers in peritoneal fluid are increased in horses with increased fibrinolytic activity as a result of inflammation of the peritoneum or impaired intestinal blood flow.[45,57] D-dimer concentrations in peritoneal fluid are highest in horses with endotoxin in the peritoneal fluid.[45] Prognosis for survival declines with increasing D-dimer concentration.

The presence of intracellular bacteria, plant material, and degenerate neutrophils is indicative of gastrointestinal rupture provided that one is *certain* that the sample came from the peritoneal space and not from the bowel lumen (by inadvertent enterocentesis).

PROTOCOL FOR EVALUATING A COLIC PATIENT

When evaluating a horse with colic the aims are to

- Determine the nature and cause of the lesion
- Establish a prognosis
- Determine the most appropriate therapy, including consideration of euthanasia
- Determine the need for referral for specialized care, including surgery

The suggested protocol for evaluating a horse with colic is discussed in the following sections. The time intervals between repeated examinations depend on a number of factors, including severity of the disease and the accessibility of the horse. For a horse with a possible intestinal obstruction this should be every hour, for a horse with probable colonic impaction examinations every 4 hours are adequate, and for a chronic colic with ileal hypertrophy an examination every day is usual. The following observations should be made.

Behavior

The following should be assessed: severity of pain, frequency and duration of attacks, whether food is taken, amount and character of feces, and frequency of urination.

Clinical and Clinicopathologic Observations

- **Elevated pulse rate** with a fall in **pulse amplitude** are among the most reliable indicators of the state of dehydration or shock. They can be temporarily misleading in a horse that is excited because it is in strange surroundings, or separated from its dam, foal, or close companion. They may also be marginally influenced by a bout of pain. A rate of more than 60 beats/min and a steady climb in heart rate of about 20 beats/min at each hour in a series of monitoring examinations signal a deterioration in prognosis. A high rate that continues to worsen during a period of analgesia as a result of medication also indicates a bad outcome. A small-amplitude, "thready" pulse characterizes severe shock.
- **Mucous membrane color** and **capillary refill time** are assessed. Deep congestion (dark red) or cyanosis (purple) and capillary refill times much longer than 2 seconds are indicators of peripheral circulatory failure.
- **Temperature** is infrequently taken unless there is some positive indication, such as suspicion of peritonitis, to do so.
- **Respiratory rate**, also of minor importance except as an indicator of severity of pain, or in terminal stages of endotoxic shock or dehydration, when it becomes gasping.
- **Intestinal sounds**. The disappearance of intestinal sounds indicates ileus.

Hypermotility is usually a sign of less serious disease, except in the very early stages of a small-intestinal accident. The development of a ping on auscultation–percussion indicates accumulation of gas under some pressure.

- **Rectal findings**. The development of palpable abnormalities is an ominous finding. A decision to intervene surgically is often made at this point. The inherent inadequacy of the rectal examination is that only the caudal half of the abdominal cavity can be reached. Therefore large bowel and terminal ileal problems are more easily detected. With anterior abdomen small-intestinal lesions, distended loops do not usually come into reach until 6 hours after colic commences. They may reach back as far as the pelvis by 18 hours.
- Amount and nature of **feces** is important. Failure to defecate within 12 hours of treatment is a bad sign. The empty rectum with a dry, tacky feel, or with a smear of mucus and degenerated blood some hours after the last defecation, presages a completely blocked intestine. The passage of oil but no feces suggests a partial blockage of large bowel that will permit the passage of oil but not fecal balls.
- **Reflux** through a nasogastric tube. Acute gastric dilatation or small-intestinal regurgitation of fluid sufficient to cause reflux of fluid via the stomach tube is a grim development. Large-bowel distension is also associated with fluid accumulations in the stomach. A negative test in a case suggestive of small-intestinal obstruction should be followed by repeated tests; reflux from a lesion well down in the small intestine may take some hours to reach the stomach. In ileocecal valve impaction gastric reflux may not develop until 24 hours after the commencement of the colic.
- **Abdominal paracentesis**. Repeated examinations are without serious risk and can herald the development of infarction and necrosis of gut wall, leakage and the development of peritonitis, or rupture and death caused by endotoxic shock.
- Visible **distension** of the abdomen.
- **PCV** and **plasma protein**. A rise in PCV of 5% (i.e., from 55%–60%) in an hour is a serious sign. A rise in PCV with a stable or declining serum protein concentration is often indicative of loss of capillary integrity and leakage of vascular proteins into extravascular spaces, such as the intestinal lumen. This is a sign of a poor prognosis.
- **Skin tenting** on its own can be a very misleading indicator of the state of a horse's dehydration, but significant changes from one examination to another are likely to confirm deductions made on the basis of heart rate and mucosal color.
- **Arterial blood pressure** is one of the most reliable prognostic indicators in cases of colic.
- Response to **analgesics**. Diminution in the relief of pain after administration of detomidine, xylazine, butorphanol, or flunixin meglumine can be interpreted as a serious decline in the status of the affected intestine.

When to Refer the Patient

The decision to refer a horse for specialist care and evaluation is often difficult. Most referrals occur because of the need for specialized medical or surgical treatment and therefore involve considerable expense and inconvenience to the owner. However, early referral is critical because of the improved chances of survival associated with early medical and surgical therapy of horses with severe colic.[58]

The criteria for referral include:

- Severe persistent pain without identifiable cause for more than 24 hours. Referral should be sooner if there is evidence of compromised cardiovascular function, or any of the signs described next.
- Recurrent attacks of colic over a period as long as several months.
- Failure of an efficient analgesic to provide analgesia or relief for at least 20 minutes.
- A rectally palpable lesion including distended small intestine, large colon, or small colon, or impaction of the large colon that does not resolve in 24 hours.
- Reflux of more than 4 L of fluid through a nasogastric tube.
- Abdominal distension.
- Blood-tinged, high-protein peritoneal fluid with a high white cell count.
- A rapid worsening of the pain and vital signs during a period of 2 to 4 hours

Not all of these criteria need to be fulfilled to warrant a decision to refer, and in most cases the presence of one of these findings is sufficient to justify a recommendation to the owner to refer the horse for further evaluation and specialized care.

Important in the decision to refer, or to perform a laparotomy, is the client's understanding of the **costs** involved and the **likely outcomes**. Because decisions to refer are often complicated by the emotional pressures on the owner and the need to make a decision quickly, it is important to take the time to fully inform the owner of the likely costs and outcomes before a final commitment is made to refer. **If there is doubt—refer it!**

Surgery

The **decision to perform surgery** is best made by trained specialists and is usually based on a variety of clinical and clinicopathologic findings with most weight given to the presence of severe unrelenting or intermittent pain, severe abdominal distension, large quantities of reflux through a nasogastric tube, intestinal distension palpable per rectum, serosanguinous peritoneal fluid, evidence of cardiovascular compromise including a high (>60 beats/min) and increasing heart rate, poor capillary refill, discolored mucous membranes, and the absence of borborygmi. The presence of abnormal abdominal fluid (turbid or serosanguinous) and peritoneal fluid with an elevated total protein concentration has good sensitivity (92%) and moderate specificity (74%) for the need for surgery. Formal modeling of the need for surgery in horses with colic at referral institutions provides a numerical estimate of the need for surgery, but is seldom used in most referral practices.

Prognosis

Given the enormous emotional and financial costs of having a severely ill horse with colic, there is an obvious need for accurate prognostication. The prognosis is heavily dependent on the underlying disease, and efforts to determine the diagnosis are useful in improving the accuracy of the estimate of prognosis. For instance, strangulating infarctive lesions carry a poorer prognosis than does an uncomplicated impaction of the large colon, and a much worse prognosis than spasmodic colic. The case–fatality rates for the various causes of colic are provided in the sections addressing those diseases.

Aside from the importance to prognostication of determining an accurate diagnosis, much effort has been devoted to determining the prognostic value of various clinical and clinicopathologic factors.[59] Overall best predictors of survival are those clinical and clinicopathologic factors that assess cardiovascular and metabolic status. The important factors include arterial blood pressure or its clinical correlates, pulse pressure and/or capillary refill time, pulse rate, mucous membrane color, indicators of hydration status (hematocrit and serum urea nitrogen concentration), blood lactate concentration, and anion gap.

Arterial systolic blood pressure is one of the best predictors of survival, with horses with systolic pressures of 90 mm Hg (12 kPa) having a 50% chance of survival, whereas fewer than 20% of horses with a pressure below 80 mm Hg (10.6 kPa) survive.

Capillary refill time, the clinical manifestation of arterial blood pressure, is also a good predictor of the probability of survival. Capillary refill times of 3 seconds or more are associated with a survival rate of 30%. Similarly, increasing **heart rate** is associated with diminishing chances of survival—a horse with a heart rate of 80 beats/min has a 50% chance of survival, whereas one with a heart rate of 50 beats/min has a 90% chance of survival. Increasing blood lactate

concentration and anion gap (see the section Clinical Pathology) are associated with increased chance of death. Measures of hydration status are also good indicators of prognosis. A **hematocrit** of 50% (0.50 L/L) is associated with a 50% chance of survival, whereas the chance of surviving drops to 15% when the hematocrit is 60% (0.60 L/L). Horses with high circulating epinephrine, cortisol, or lactate concentrations are at greater risk of death.

Although individual variables can be good prognostic indicators, their predictive utility improves when they are combined, although this introduces the need for either remembering models or keeping the model close at hand, something often not easily accomplished in the field. Furthermore, these models have been developed from cases at specific referral institutions and are likely not be applicable to field cases or even cases at other referral sites. However, the general principles probably apply in all circumstances even if the precise weighting appropriate for each variable does not.

NECROPSY FINDINGS

The nature of the necropsy findings depends on the underlying disease.

DIFFERENTIAL DIAGNOSIS

Differential diagnostic features of common causes of equine colic are provided in Table 7-15. The following diseases may be mistaken for colic:

- Laminitis
- Pleuritis
- Enterocolitis
- Rhabdomyolysis
- Obstructive urolithiasis
- Uroperitoneum
- Foaling and dystocia
- Uterine torsion
- Peritonitis
- Cholelithiasis
- Ovulation and ovarian pain
- Esophageal obstruction
- Duodenitis-proximal jejunitis
- Gastric ulceration
- Anthrax
- Testicular torsion
- Lactation tetany
- Tetanus
- Rabies
- Botulism
- Grass sickness
- Purpura hemorrhagica
- Clostridial myonecrosis (gas gangrene)
- Psychogenic colic

TREATMENT

Medical Treatment

The specific treatment of each case of colic varies and depends on the nature of the lesion and the severity of the disease. However, several principles are common to the treatment of most colic:

- Provision of analgesia
- Correction of fluid, electrolyte, acid-base and hemostatic abnormalities
- Gastrointestinal lubrication or administration of fecal softeners
- Treatment of underlying disease

Analgesia[2]

Analgesia is important in that it relieves the horse's discomfort; minimizes the physiologic consequences of pain, including the pain-induced reduction in gastrointestinal motility; permits a thorough clinical examination; and reduces the likelihood of the horse injuring itself while rolling or thrashing. Analgesics can be broadly divided into NSAIDs, sedating analgesics, opiates, and spasmolytics. The doses of these drugs are provided in Table 7-15.

The analgesic and its dose rate should be chosen such that the horse's pain is relieved, but signs of progressive cardiovascular compromise indicative of the need for more

Table 7-15 Analgesics and spasmolytics for use in equine colic

Drug class	Drug	Dose	Comments
NSAIDs	Flunixin meglumine	0.25–1.0 mg/kg, IV or IM every 8–24 h	Potent analgesic for up to 12 h May mask signs of surgical disease
	Ketoprofen	2.2 mg/kg, IV every 12 h	Potent analgesic for up to 12 h
	Phenylbutazone	2.2–4.4 mg/kg, IV or PO every 12 h	Weak analgesic for gastrointestinal pain Minimal effect on motility
	Dipyrone	10 mg/kg, IV or IM every 4–6 h	Weak analgesic; often combined with hyoscine in commercial preparations (Buscopan compositum)
Opiates	Butorphanol	0.025–0.1 mg/kg, IV or IM as required	Potent analgesia for 30–90 min; safe. Often combined with an α-2 agonist May cause ataxia
	Meperidine (pethidine)	0.2–2.0 mg/kg, slowly IV or IM as required	Moderate analgesia for 0.5–4 h; can cause excitement and/or ataxia
	Pentazocine	0.5–1.0 mg/kg, IV or IM as required	Moderate analgesia; may cause ataxia
	Morphine sulfate	0.05–0.1 mg/kg slowly IV or IM as required	Potent analgesia; can cause excitement
α-2 Agonists	Xylazine	0.1–1.0 mg/kg, IV or IM, as needed	Potent analgesia and sedation for up to 30 min; decreases intestinal motility Often combined with butorphanol
	Detomidine	10–40 µg/kg, IV or IM as needed	Potent analgesia and sedation for up to 120 min
	Romifidine	0.04 to 0.12 mg/kg, IV or IM	Potent analgesia and sedation
	Medetomidine	0.01–0.02 mg/kg, IV or IM	Potent analgesia for up to 120 min Sedation
Spasmolytics	Atropine	0.01–0.04 mg/kg IV or IM	Do not use because of induction of ileus
	Hyoscine butylbromide	0.1–0.4 mg/kg, IV or IM every 6–12 h	Reduces gastrointestinal motility; mild analgesic; often combined with dipyrone
Other	Acetylpromazine	0.02–0.04 mg/kg, IV or IM every 6–24 h	No analgesia but marked sedation; potent hypotensive agent; do not use
	Lidocaine	1.5 mg/kg IV loading dose followed by 0.05 (mg/kg)/min IV infusion	substance P inhibitor; analgesic, antiinflammatory, promotility agent

IM, intramuscularly; IV, intravenously; NSAIDs, nonsteroidal antiinflammatory drugs; PO, orally.

aggressive therapy or surgery are not masked. **Acupuncture** does not provide effective analgesia in horses with colic and should not be used in these animals.

Nonsteroidal Antiinflammatory Drugs

Flunixin meglumine is a potent, long-acting analgesic with the ability to mask signs of surgical disease, with the consequence that surgery might be delayed and the chance of recovery diminished. Flunixin meglumine should only be used to control pain when the diagnosis is clear or when surgical intervention is not an option. It should not be used routinely in horses being monitored for progression of disease unless such monitoring is frequent and thorough, which might not be the situation in field colics. A horse that remains painful 30 minutes after the administration of flunixin meglumine is likely to have severe gastrointestinal disease and should be further evaluated.

Comments similar to flunixin meglumine apply to **ketoprofen** but not to **phenylbutazone**, which has relatively weak analgesic effects in colic patients (as opposed to its potent analgesic effects in musculoskeletal disease). **Dipyrone** is a weak analgesic that is useful in treatment of mild cases of colic.

Flunixin meglumine and etodolac retard recovery of equine jejunum and barrier function and flunixin inhibits electrical activity in the ventral colon. However, these effects detected in vitro have not been demonstrated to have practical relevance to treatment of horses with colic with NSAIDs. Horses in pain should not, based on current information, be deprived of these drugs.

α-2 Agonists

The **α-2 agonists** (xylazine, detomidine, and romifidine) provide potent analgesia, especially when combined with the opiate **butorphanol**. Duration is relatively short (up to 90 minutes for detomidine), which means that signs of progressive disease are readily detectable. The effect of β-2 agonists in reducing gastrointestinal motility is not clinically important in most colic cases and should not discourage use of these very useful drugs.

Opiates

Opiates, including butorphanol, meperidine (pethidine), morphine, and pentazocine, are potent analgesics useful in the management of abdominal pain in the horse. These drugs are often combined with an α-2 agonist. Morphine and meperidine can cause excitement or urticaria in some horses. All are drugs with the potential for human abuse and the consequent limitation on their availability limits their use in horses.

Other Agents

Acetylpromazine has almost no analgesic properties, although it is a potent sedative, and should not be used in the routine treatment of colic. It is a potent hypotensive agent and should not be administered to any horse that is dehydrated or has compromised cardiovascular function.

Hyoscine butylbromide, a parasympatholytic drug, is widely used in certain parts of the world as the drug of choice in the initial treatment of field cases of colic. It is often combined with dipyrone and is effective in the field treatment of mild, uncomplicated colic.

Atropine causes gastrointestinal stasis in horses and should not be used in the routine treatment of colic.

Lidocaine is a potent analgesic when administered systemically, but must be given by constant intravenous infusion. Overdosing results in central nervous system (CNS) excitement.

Prophylaxis and Treatment of Endotoxemia

Treatment of endotoxemia is provided elsewhere (see Chapter 4). Administration of plasma from horses **hyperimmunized** with *Salmonella typhimurium* or *E. coli* reduces the severity of clinical signs and shortens the duration of disease in horses with endotoxemia secondary to enterocolitis or colic. **Polymyxin** (5000 IU/kg intravenously every 8–12 hours) attenuates the effect of endotoxin in experimental disease and is used for the prevention and treatment of endotoxemia in hospitalized horses. Its efficacy in clinical settings has not been determined. **Aspirin** (10 mg/kg orally every 48 hours) is administered to diminish platelet aggregation around intravenous catheters. **Flunixin meglumine** (1 mg/kg intravenously every 8–12 hours) or **phenylbutazone** (2.2 mg/kg intravenously every 12 hours) is given for analgesia and to prevent endotoxin-induced increases in plasma prostaglandins. **Pentoxifylline** (8 mg/kg orally every 8 hours) is administered for its putative effective in attenuating the effects of endotoxemia. The efficacy of these treatments in a clinical setting and their effect on measures of outcome of disease, such as duration of illness, case–fatality rate, or incidence of complications, has not been determined, with the exception of hyperimmune plasma or serum.

Antibiotics are often administered to horses with severe colic and evidence of toxemia because of presumed bacteremia. The antibiotics of choice should have a broad spectrum including gram-negative, gram-positive, and anaerobic bacteria. A suitable regimen includes an aminoglycoside and a penicillin, possibly combined with metronidazole. NSAIDs are administered to prevent the increased production of prostaglandins induced by endotoxin and the associated clinical abnormalities including fever, malaise, and tachycardia. However, the effect of NSAIDs in improving survival or shortening the duration of treatment has not been demonstrated.

Fluid and Electrolyte Therapy

Horses with evidence of dehydration, compromised cardiovascular function, or electrolyte imbalances should be administered fluids intravenously, preferably a balanced, isotonic, polyionic fluid such as lactated Ringer's solution. Horses with severe colic and signs of cardiovascular collapse require urgent resuscitation by intravenous administration of large quantities of fluids or administration of hypertonic saline followed by administration of isotonic fluids. Horses with hypoproteinemia could benefit from administration of plasma or colloidal fluids such as hetastarch (see Chapter 4 for details on fluid therapy and the section on Shock for a discussion of the treatment of this syndrome.)

Intestinal Lubricants and Fecal Softeners

The intestinal lubricant of choice is **mineral oil** (Table 7-16). It should be given only through a nasogastric tube because its aspiration is associated with severe and usually fatal pneumonia. Mineral oil is useful in cases of mild impaction colic and is often administered when the cause of the colic is not known, provided that there is no reflux of gastric contents through the nasogastric tube.

Dioctyl sodium sulfosuccinate is a fecal softener with the potential to be toxic at therapeutic doses, and its use is now not generally recommended. **Magnesium sulfate** is an effective fecal softener useful in the treatment of impaction colic. However, it can cause hypermagnesemia and toxicosis characterized by depression and signs of CNS dysfunction. **Sodium sulfate** is a safe and effective fecal softener, although it can induce mild hypernatremia and hypokalemia.

Other Treatments

Promotility agents (see Table 7-16) may be used in cases of ileus or large-colon impaction. Postoperative ileus is a common complication of surgical colic and should be treated by maintenance of hydration and electrolyte status and the administration of promotility agents.[60] **Cisapride** is apparently effective in reducing the incidence of postoperative ileus and may be useful in the treatment of ileus from other causes. The clinical efficacy of other putative promotility agents has not been demonstrated.

Heparin and low molecular weight heparins have been recommended for the treatment and prevention of coagulopathies associated with severe colic. The use of heparin or low molecular weight heparin is associated with increased risk of hemorrhage and heparin use causes a decrease in hematocrit. The efficacy of this treatment

Table 7-16 Promotility agents, lubricants, and fecal softeners for use in horses with colic

Drug group	Drug	Dose	Comments
Lubricants	Mineral oil	10–15 mL/kg, via nasogastric tube, every 12–24 h	Safe; lubricant only, does not soften feces; usually passed in 12–36 h*
Fecal softeners	Dioctyl sodium sulfosuccinate	12–25 mg/kg, via nasogastric tube, every 24 h	No more than two doses; toxic at higher doses*
	Magnesium sulfate	0.5–1.0 g/kg, via nasogastric tube, in water	Osmotic cathartic; toxic (CNS signs caused by hypermagnesemia) with repeated dosing*
	Sodium sulfate	1.0 g/kg, via nasogastric tube, in water, every 12 h	Osmotic cathartic; mild hypernatremia; safe*
	Psyllium	1 g/kg, orally, every 24 h	Bulk laxative; used for treatment of sand accumulation; efficacy uncertain but widely used*
Promotility agents	Lidocaine	1.5 mg/kg slow IV, then 0.05 mg/kg/min infusion	Analgesic, antiinflammatory, promotility; used to treat ileus; toxicity evident as CNS signs
	Metoclopramide	0.25 mg/kg IV slowly over 30 min every 12 h	Toxic; minimally effective
	Erythromycin	1 (mg/kg)/h IV	Questionable efficacy; may induce colitis
	Cisapride	0.1 mg/kg, IV every 8 h	Effective in prevention and treatment of postoperative ileus; may prolong cardiac Q-T interval (importance unknown)
	Neostigmine	0.02 mg/kg, IM or SC, every 8–12 h	Increases large-colon motility, decreases small-intestine motility; may cause colon rupture around hard impaction

CNS, central nervous system; IM, intramuscularly; IV, intravenously; SC, subcutaneously.
**None of these agents should be given if there is reflux through the nasogastric tube.*

in improving survival has not been demonstrated.

Trocarization

Occasionally in severe cases of flatulent (gas) colic or in cases of colon torsion in which the abdominal distension is impairing respiration, it may be necessary to relieve the gas distension of the colon or cecum by trocarization. Trocarization is usually performed through the **right paralumbar fossa** immediately caudal to the last rib. The exact place for trocarization can be located by simultaneously flicking the body wall with a finger and listening with a stethoscope. The area of loudest ping will indicate the point of insertion of the trocar. A suitable trocar is a 12.5- to 15-cm 14- to 16-gauge needle. The needle is inserted through the skin and advanced into the abdomen until there is an audible expulsion of gas through the trocar. The trocar should be kept in position as long as gas is escaping. It may need to be replaced as the bowel is decompressed and moves away from the trocar. The procedure is reasonably safe but will cause inflammatory changes in the peritoneal fluid. The major danger is laceration of the colon or cecum and leakage of ingesta. It is advisable to administer systemic antibiotics to horses that have been trocarized.

A device for facilitating transrectal decompression of intestinal tympany is described with encouraging results.[61] However, this technique cannot be recommended until there are further studies of its efficacy and safety.

Management of Field Colic

Initial treatment of field cases of colic that do not have signs indicative of the need for referral or surgery usually includes administration of an analgesic and an intestinal lubricant. Analgesics suitable for the initial treatment of colic in the field are an α-2 agonist, such as xylazine, hyoscine butylbromide, dipyrone, butorphanol, or phenylbutazone. If there is no reflux through the nasogastric tube, then mineral oil should be administered. Fluids should be administered intravenously if there are signs of dehydration, cardiovascular compromise, or electrolyte imbalance. The response to this therapy should be monitored as described under the section "**Protocol for Evaluating a Colic Patient**" in this chapter. Further doses of analgesic can be given as required, and the horse should be monitored for any evidence of deterioration. If referral is contemplated, the referral institution should be contacted for advice on analgesia during transportation. Horses should be transported with a nasogastric tube in place.

Surgery

The only definitive treatment for many causes of equine colic is surgical correction or removal of the lesion. The availability of surgical facilities staffed by appropriately trained personnel has increased over the past two decades and there is often the opportunity to refer horses for examination by personnel with specialist training. Gastrointestinal surgery should not be attempted by those untrained or inexperienced in the necessary techniques or without the facilities to provide postoperative care.

The decision to perform an exploratory laparotomy on a horse with colic is based on a number of factors, including the provisional diagnosis, findings on physical and laboratory examination, and degree of pain. Horses with severe pain refractory to treatment with analgesics should have an exploratory laparotomy even if no other significant abnormalities can be detected. Algorithms for the decision to perform surgery have been developed, but are not perfect and do not replace the opinion of an appropriately trained and experienced examiner. Examination of peritoneal fluid contributes to the decision to perform surgery. The survival rate for horses undergoing surgical correction of lesions depends on the nature and location of the underlying disease and its duration. However, survival rates range from 50% to 75%, with approximately two-thirds of horses returning to their intended use.[62] The survival rate of horses with small-intestinal lesions is less than that of horses with large-intestinal disease, and the survival rate for horses with strangulating disease is much less than that of horses with nonstrangulating disease.[59] Thoroughbred racehorses that return to racing after colic surgery do so successfully.[63]

Prevention

Minimization of colic episodes depends on management factors, including ensuring adequate parasite control, feeding large quantities of forage and minimizing the

amount of concentrate fed, and providing dental care. However, most cases of colic not attributable to parasites or dietary factors cannot be prevented.

COLIC IN THE PREGNANT AND POSTPARTURIENT MARE

Diagnosis and management of colic in pregnant and immediately postparturient mares is challenging because of the variety of conditions that can cause the disease, the difficulty in examination of intraabdominal organs in late-term mares, and concern about the viability of the fetus. There are also substantial technical challenges in surgical correction of abnormalities of either the gastrointestinal tract or reproductive tract in the presence of a gravid uterus. Colic in late-term mares can be caused by any of the causes of colic in adult horses (see the section Equine Colic), but some disorders are more common in late-term mares and, in addition to abnormalities of the reproductive tract, can cause signs of colic.[1] Causes of colic in the late-term mare include:

- Idiopathic, chronic, or recurrent, low-grade colic
- Large colon torsion
- Large colon impaction
- Incarceration of small intestine through a mesenteric rent
- Rupture of the cecum or colon
- Uterine torsion
- Uterine rupture
- Middle uterine or uteroovarian artery rupture
- Abdominal wall hernia
- Diaphragmatic hernia
- Dystocia
- Hydrops
- Imminent foaling

A common presentation of colic in late-term mares is chronic or recurrent, low-grade abdominal pain that is not associated with any signs of compromised cardiovascular or gastrointestinal function. It is assumed that the large gravid uterus interferes with normal motility or positioning of bowel, with subsequent pain. Severe colic in late-term mares is rarely associated with the uterus, with the exception of uterine torsion.

Colic in immediately postparturient mares (<24 hours after foaling) include:

- Cramping associated with uterine contractions and involution, often coincident with nursing or administration of oxytocin
- Rupture of the cecum or colon
- Primary idiopathic ileus and gastric rupture[2]
- Incarceration of the small intestine through a mesenteric rent
- Rupture of the mesocolon with segmental ischemia of the small colon
- Rectal prolapse
- Uterine tear, with or without prolapse of intestine
- Uterine prolapse
- Inversion of uterine horn
- Bladder prolapse through urethra
- Hemorrhage from uterine or uteroovarian artery
- Retained fetal membranes
- Uroperitoneum, usually secondary to rupture of the bladder

Colic in postparturient mares that is anything more than transient and associated with passage of placenta or nursing of the foal should be considered important and the mare should be examined closely and, if the colic does not resolve, repeatedly.

Idiopathic primary ileus and gastric rupture refers to a specific syndrome in postparturient mares that present with moderate to severe colic secondary to gastric and small-intestinal distension and ileus. There can be rupture of the stomach and death. The disease is most common in mares with 1 week of foaling, but can occur up to 2 months after parturition. The colic is acute and moderate to severe. Nasogastric intubation returns excess gas and fluid, and rectal or ultrasonographic examination reveals distended loops of atonic small intestine. Treatment is by relief of gastric distension by nasogastric intubation and supportive therapy (fluids and pain relief). Approximately 50% of mares require surgical exploration of the abdomen to confirm the diagnosis and allow decompression of the small intestine and stomach. Survival rate is approximately 90% with appropriate treatment.[2]

Survival rates for colic associated with anatomic abnormalities in late-term or postparturient mares are 50% and 30%, respectively.

Clinical examination of late-term or postparturient mares with colic uses the same principles as applied to examination of nonpregnant adult horses with colic. Monitoring of vital signs, passage of a nasogastric tube, rectal examination, and collection of peritoneal fluid should all be performed as indicated. However, the presence of a gravid uterus in late-term mares impairs rectal examination of the abdomen and often makes collection of peritoneal fluid impossible. Manual and visual (through a speculum) examination of the vagina and cervix should be performed.

Rectal examination should be performed and careful attention should be paid to examination of the uterus, including

position and viability of the fetus and broad ligaments. Uterine torsion can be detected by examination of the broad ligaments, which in mares with uterine torsion will be taut and spiral in the direction of the torsion. Hemorrhage into the broad ligament, which can extend into the uterus and perivaginal regions, is detectable as swelling in these structures. Additionally, affected mares will have signs of hemorrhagic shock, including tachycardia, sweating, and pallor of mucous membranes. Palpation of gastrointestinal structures per rectum is limited in the late-term mare, although the cecum and small colon should be palpable. The spleen and left kidney can be palpated in almost all normal late-term mares.

The reduced uterine size in postparturient mares permits more thorough per rectum examination of the caudal abdomen. Again, careful attention should be given to palpation of the uterus and associated structures for evidence of hemorrhage, prolapse, or rupture. **Rectal prolapse** and eversion of the small colon in a postparturient mare is an ominous finding because it is usually associated with rupture of the mesocolon and ischemic necrosis of the small colon, a condition that is almost always fatal. Prolapse of small amounts of anal or perirectal tissue is not a serious concern.

The **abdominal silhouette** should be examined for evidence of abdominal distension, such as can occur with colon torsion or uterine hydrops, and abnormalities in contour caused by rupture of the prepubic tendon and herniation of abdominal contents.

Vaginal and cervical examination can reveal discharge associated with impending abortion or parturition. Vaginal examination for uterine torsion is of limited value because the torsion almost always occurs cranial to the cervix so that, unlike the cow, the torsion is not apparent as deformation of the cervix. Manual examination of the vagina, cervix, and uterus of postparturient mares with colic is important to detect uterine, cervical and vaginal trauma, uterine inversion, and retained fetal membranes.

Ultrasonographic examination of the abdomen in the late-term mare, both per rectum and percutaneously, allows examination of structures not palpable per rectum. The presence and any abnormalities in structure, location, and motility of bowel should be noted. For example, small-intestinal distension caused by entrapment through a mesenteric rent may not be palpable per rectum but can be imaged. Peritoneal fluid should be examined for quantity and echogenicity. Intraabdominal hemorrhage caused by uterine artery rupture is evident as large quantities of echogenic fluid that has a characteristic swirling pattern similar to turbulent blood flow imaged ultrasonographically in the cardiac ventricles of some horses. The position, number, and viability of the fetus or fetuses should be ascertained. The nature of allantoic fluid should be noted.

Collection of **peritoneal fluid** from late-term mares can be difficult because of contact between the gravid uterus and the ventral abdominal wall. Ultrasonographic examination can be useful in locating pockets of fluid for collection. Collection of peritoneal fluid is more readily accomplished in the postpartum mare. Peritoneal fluid from late-term and postpartum mares, even those with assisted vaginal delivery, should have protein and cell concentrations within the reference range of normal horses. Abnormalities in peritoneal fluid in late-term or postparturient mares should be considered to be indicative of intraabdominal disease.

The **differential diagnosis** of colic is similar to that of nonpregnant horses except as indicated previously.

Treatment of colic depends on its cause. Horses with low-grade to moderate, recurrent colic respond to administration of low doses of NSAIDs, mineral oil, or fecal softeners. Clenbuterol is sometimes administered for its tocolytic effect,[3] but the efficacy of this practice is unclear. Progestins are sometimes administered in an attempt to prevent abortion of mares after resolution of colic, but there is evidence of their lack of efficacy in this respect.[4]

The **risk of abortion** in mares with colic is partially dependent on the severity of the colic and it cause, necessity for surgical intervention, the duration of colic, and the stage of gestation.[3-6] Abortion rates in pregnant mares treated for colic at referral institutions vary from ~20% to 50% depending on the particular disease.[3-6] Severely ill mares with signs of toxemia have abortion rates of almost 70%, whereas mares with less severe disease have abortion rates of 8% to 18%, which is not markedly different from the rate in mares without colic.[3] Mares treated surgically have a greater relative risk of abortion (3.5, 95% CI 1.7–7.3) than mares treated medically. For mares treated surgically, hypotension during surgery and prolonged anesthesia are significant risk factors for abortion.[4] The need for surgical intervention, hypotension during surgery, and prolonged anesthesia are likely indicative of more severe disease, which could account for the higher abortion rate in these mares.[4]

COLIC IN FOALS

SYNOPSIS

Etiology See Table 7-17.

Epidemiology Sporadic. Some causes are congenital, others heritable. Inguinal and scrotal hernias occur only in males.

Clinical signs Abdominal pain evidenced by kicking at the abdomen, flank watching, repeated tail movements as if chasing flies, repeated aborted attempts to suck, frequent lying down and standing within a short period, and rolling and lying in dorsal recumbency. Abdominal distension in some diseases and straining to defecate with meconium impaction. Radiography and ultrasonography are useful in identifying affected bowel.

Clinical pathology Nonspecific.

Lesions Are of the causative disease

Diagnostic confirmation Physical examination, radiography, ultrasonography, laparotomy, and necropsy

Treatment Pain control, fluid therapy, supportive care including consideration of the foal's nutritional requirements, and treatment of causative disease

ETIOLOGY

Diseases that cause colic in horses less than 1 year of age include both congenital and acquired conditions and are listed in Table 7-17. Fifty percent of neonatal Thoroughbred foals subjected to exploratory laparotomy had nonstrangulating lesions and 30% had enteritis. Among foals 2 weeks to 6 months of age, 30% of foals subjected to exploratory laparotomy had gastric ulcer disease, 27% strangulating lesions, 21% nonstrangulating lesions, and 17% enteritis.[1] The most common causes of colic in foals less than 30 days of age examined at a referral institution were enterocolitis (27%), meconium-associated colic (20%), transient colic of undetermined cause (19%), and necrotizing enterocolitis (16%).[2] Eight percent of foals examined had small-intestinal infarctive/obstructive lesions and 7% had other lesions, with 1.5% having overo lethal white syndrome.[2]

Diaphragmatic hernia is an uncommon cause of colic in newborn foals and can be congenital or acquired.[3-5] Intestinal accidents including displacements of the large colon and extraluminal obstruction of the small colon by ovarian pedicle are uncommon.[6,7] Herniation of the large colon through umbilical hernia is reported.[16] Pancreatitis in foals can cause signs of colic.[8] Intestinal hyperammonemia can cause colic, diarrhea, and signs of neurologic disease in foals.[9]

Table 7-17 Diseases causing colic in foals

Congenital anomalies	Anal atresia
	Colonic atresia
	Rectal atresia
	Ileocolonic agangliosis
	Myenteric hypoganglionosis
	Inguinal hernia
	Diaphragmatic hernia
	Umbilical hernia
	Scrotal hernia
Gastrointestinal obstruction with or without infarction	Meconium impaction
	Ileus, secondary to extraintestinal disease including neonatal hypoxia
	Small-intestinal volvulus
	Large-intestinal volvulus
	Intussusception Jejunojejunal Ileocecal
	Small colon obstruction Fecalith Impaction Meconium Entrapment in hernia, mesenteric rents
	Large colon obstruction Impaction Intussusception Torsion
	Necrotizing enterocolitis
	Adhesions
	Colonic stricture
	Ileal impaction: foreign body
	Ascarid impaction: small intestine
	Phytobezoar
Other	Gastric ulcer
	Duodenal ulcer
	Abdominal abscess
	Umbilical abscess
	Peritonitis
	Tyzzer's disease (*Clostridium piliforme*)[1]
	Uroperitoneum
	Enteritis
	Ovarian torsion[2]

EPIDEMIOLOGY

Risk factors vary with the cause of colic, although congenital conditions such as **ileocolonic aganglionosis** in white progeny of overo spotted horses are clearly heritable, whereas others, such as "short colon" are not.[10] Most conditions occur sporadically, although **meconium impaction** is more common in colt foals and occurs only in the newborn foal, **intussusceptions** are most common in foals of 3 to 5 weeks of age and particularly those with diarrhea or extraintestinal illness, and impaction of the small colon by **fecaliths** is common in miniature horse foals.[1] Impaction by roundworms (*P. equorum*) is a common cause of small-intestinal obstruction in foals.[11] **Inguinal and scrotal hernias** occur only in male foals.

Case–fatality rate varies with the underlying disease, but 75% of foals treated at a referral institution survived to discharge from hospital, with similar survival rates for medically and surgically treated foals.[2] Foals with clinical or clinicopathologic signs of more severe disease (greater pain, absent borborygmi, abdominal distension, and evidence of hypoperfusion) had a lower survival rate.[2] The long-term survival rate and suitability for use is excellent for most foals that have recovered from colic (93%).[2] The **mortality rate** attributable to colic in foals in Japan was 1.5% (74/4843).[12]

PATHOPHYSIOLOGY

The pathophysiology of colic in foals does not differ qualitatively from that of adult horses (see the section Equine Colic). The importance of pain, gastrointestinal distension, motility, and absorptive disturbances and loss of barrier function are all similar in foals and adults. Additionally, in young foals gastrointestinal disease may prevent nursing and ingestion of colostrum, causing failure of transfer of passive immunity (FTPI) to the foal. Failure to nurse also results in hypoglycemia and dehydration, which may exacerbate the abnormalities induced directly by the disease causing colic.

CLINICAL FINDINGS

Pain is the cardinal feature of gastrointestinal disease of foals. Foals with mild **abdominal pain** are apprehensive and walk continuously with frequent but brief (<1 min) periods of sternal or lateral recumbency. Affected foals make frequent attempts to nurse but do not continue to suckle and may butt the mare's udder even though there is a letdown of milk. The foal vigorously moves its tail as if chasing flies, looks at the abdomen, and may nip at its flanks. There are often frequent attempts to urinate or defecate but without passage of significant quantities of urine or feces. Severely affected foals will roll, often violently, and may spend considerable periods of time in dorsal recumbency, often propped up against walls or fences.

Severely affected foals are **tachycardic** (>100 beats/min) and **tachypneic** (<40 beats/min; recall that young foals have higher heart and respiratory rates and rectal temperature than do older foals and adults). **Mucous membrane color** and **capillary refill time** are similar to that of adult horses, and changes can be interpreted in the same manner as for adults.

The **external abdomen** should be examined closely for the presence of inguinal, scrotal, or umbilical hernias. Abdominal distension in foals can be the result of large-colon or small-intestinal distension (or uroperitoneum), although the abdominal distension is greater with large-colon distension. Abdominal circumference should be monitored frequently by direct measurement to detect changes in the degree of abdominal distension.

Auscultation of the abdomen may reveal increased or decreased borborygmi and, if there is gas distension of the large colon or cecum, pinging sounds on simultaneous flicking and auscultation of the abdomen.

Rectal examination in foals is limited to exploration of the rectum with one or two fingers. The presence or absence of feces should be noted. Lack of fecal staining of the rectum suggests a complete obstruction such as intestinal agenesis.

Nasogastric intubation should be performed. The presence of more than 300 mL of reflux in a foal is significant and suggestive of gastric dilatation secondary to an outflow obstruction or regurgitation of small-intestinal fluid into the stomach because of a small-intestinal obstruction.

Meconium is usually passed within the first 10 to 12 hours (usually 3 hours) after birth. **Retention of meconium** is evident as signs of colic and the presence of firm meconium in the rectum. Palpation of the caudal abdomen may reveal firm material in the small colon. Enemas (see the section Treatment) usually provide rapid relief and confirmation of the diagnosis.

Ancillary Diagnostic Tests

Diagnostic Imaging

Radiography is useful in the evaluation of foals with colic, although it seldom provides a definitive diagnosis, with the possible exception of meconium impaction and contrast studies of foals with lesions of the small or large colon, or gastric outflow obstructions. **Retrograde contrast radiography** of the lower gastrointestinal tract of foals less than 30 days old is a sensitive technique for detection of anatomic anomalies such as **atresia coli** and obstruction of the **small colon**. The technique is performed by the intrarectal infusion of up to 20 mL/kg of barium sulfate (30% w/v) in sedated, laterally recumbent foals. **Meconium impaction** can be evident as a mass of radiopaque material in the caudal abdomen with accumulation of fluid and gas oral to the obstruction. Upper gastrointestinal contrast radiography is useful to detect abnormalities of the stomach and small intestine, in particular gastric outflow obstructions.

Ultrasonographic examination of the foal abdomen can demonstrate intussusceptions, the presence of excessive peritoneal fluid (such as urine or blood), edematous intestine, hernias, and colonic impaction. The presence of atonic, distended small intestine suggests the presence of ileus, possibly secondary to a small-intestinal strangulating lesion. However, early ultrasonographic differentiation of ileus secondary to enteritis from that accompanying a strangulating lesion is difficult. Detection of gas within the wall of the small or large intestine (pneumatosis intestinalis) is indicative of a poor prognosis and the presence of necrotizing enterocolitis.[13] There is a high prevalence of asymptomatic intussusceptions (~50%) detected in healthy neonatal foals by ultrasonographic examination.[14] Detection of an intussusception in this way should be considered in light of the foal's other clinical signs and in a healthy foal should not necessarily provoke more extensive examination.

Endoscopy

Endoscopic examination of the stomach is indicated in any foal with recurrent or continuous mild to moderate colic, bruxism, or ptyalism suggestive of gastric or duodenal ulceration. Gastroscopy reveals the presence of any ulcers and their extent and severity.

CLINICAL PATHOLOGY

There are few changes detected by routine hematological or serum biochemical examination of foals with colic that provide a definitive diagnosis. However, changes in the hemogram and serum biochemical profile are useful in evaluating the physiologic state of the foal and the severity of the disease. Principles used in the evaluation of these variables in adult horses apply to foals. It should be appreciated that the normal range of values for many clinical pathology variables in foals is age dependent and markedly different from that of adult horses.

Profound leukopenia is more likely to be indicative of enteritis and colic secondary to ileus than of small-intestinal strangulating obstructions. Similarly, hyponatremia is uncommon with strangulating obstructions but is a common finding in foals with enteritis.

Newborn foals with colic should have the adequacy of transfer of passive immunity examined by measurement of serum IgG concentration, or an equivalent test.

Examination of abdominal fluid is useful in the assessment of colic in foals, as it is in adults. The normal values for abdominal fluid in foals differs from that of adult horses and white cell counts greater than 1500 cells/μL (1.5×10 cells/L) should be considered abnormal.

NECROPSY FINDINGS

The findings on necropsy examination depend on the nature of the disease.

TREATMENT

The principles of treatment of foals with colic are the same as those for adult horses: relief of pain, correction of fluid and electrolyte abnormalities, and treatment of the underlying disease. In addition, foals with **FTPI** should receive plasma.

Foals with gastrointestinal disease that cannot eat may require **parenteral nutrition** to ensure adequate caloric intake.

DIFFERENTIAL DIAGNOSIS

Diagnostic features of common causes of colic in foals are listed in Table 7-18. The principal differential diagnoses for gastrointestinal disease of foals with abdominal pain are

- Enteritis caused by rotavirus infection, salmonellosis intestinal clostridiosis (*Clostridium perfringens* or *C. difficile* or other causes).
- Uroperitoneum
- Peritonitis
- Gastroduodenal ulcer disease

Meconium impaction can be treated by administration of an enema of soap and warm water, commercial enema preparations, or acetylcysteine. Soap and water enemas can be administered at a rate of 5 mL/kg through a soft Foley catheter inserted into the rectum. **Acetylcysteine** (8 g in 200 mL of water with 20 g sodium bicarbonate) has the advantage of actually dissolving part of the meconium, enhancing passage of the meconium. Affected foals may require analgesics to control pain, intravenous fluids to correct or prevent dehydration, oral laxatives such as mineral oil (300 mL via nasogastric tube), and plasma to correct FTPI. Surgical correction of the impaction is rarely required.

Surgical Treatment

The proportion of foals surviving varies with the disease and age of the foal.[15] Younger foals (<6 months of age) appear to have a worse prognosis after surgical correction of intestinal lesions than do older foals. Fewer foals having surgery for colic live to race than do their normal cohorts, although affected foals that do race have similar racing careers.[1] Others have reported no adverse effect of surgical treatment for colic on surviving foals.[2] Foals with nonstrangulating lesions and enteritis are more likely to survive than foals with gastric ulcer disease or strangulating lesions. Suckling foals are at greatest risk of development of postoperative adhesions and need for repeated celiotomy.[1]

PREVENTION

Although not proven, the suspected association between diarrhea and small-intestinal surgical lesions in foals suggests that measures to reduce the incidence of enteritis in foals could reduce the incidence of colic. Adequate deworming programs that reduce or eliminate infestation with parasites should be implemented. Care should be taken when deworming foals with heavy infestations of *P. equorum,* as rapid killing or paralysis of the ascarids can lead to impaction and obstruction of the small intestine.[11]

Table 7-18 Differential diagnosis of common foal colics

Disease	History	Clinical findings	Clinical pathology	Treatment
Intestinal atresia or hypoganglionosis	White progeny of overo horses; Otherwise sporadic Newborn foals <4 days old	Failure to pass feces Abdominal distension pain	None specific	None
Small-intestinal volvulus	Any age but more common at 3–6 months; abrupt-onset abdominal pain; diarrhea	Severe pain; nasogastric reflux; abdominal distension Ultrasonography: distended, atonic intestine Radiography: gas and fluid distension of small bowel	Increased protein and leukocytes in abdominal fluid	Surgical; low survival rate
Small-intestinal intussusception	Any age, but usually 3–6 weeks; diarrhea	Severe pain, abrupt onset Nasogastric reflux Ultrasonography: intussusception Radiography: gas and fluid distension of small bowel	Increased protein and leukocytes in abdominal fluid	Surgery; 40% survival rate
Ascarid impaction	More than 3 months of age Recent history (<3 days) of anthelmintic administration	Severe pain; nasogastric reflux Ultrasonography: distended, atonic bowel, ascarids	Nonspecific	Medical therapy; lubricants and analgesics; surgery
Meconium impaction	Newborn; no passage of meconium; more common in males	Mild pain initially, becoming more severe; Abdominal distension Ultrasonography: distended large colon, may see impaction Radiography: contrast may outline impaction	Nonspecific	Warm soapy enemas Acetylcysteine; mineral oil orally; surgery for refractory cases
Large-colon torsion	Sporadic	Severe pain and abdominal distension Ultrasonography: gas-distended colon Radiography: gas-distended colon	Nonspecific	Surgery; 20% recovery rate
Large-colon impaction	Sporadic; poor diet, eating sand-polluted feed	Mild to moderate pain initially Progressive abdominal distension Ultrasonography: distended colon with impacted material	Nonspecific	Medical treatment of lubricants, fecal softeners and analgesics; surgery
Small-colon impaction	Common in Miniature horses	Moderate to marked pain Lack of feces; abdominal distension Ultrasonography: gas-distended colon Radiography: impaction of small colon	Nonspecific	Medical as previously; surgery
Gastroduodenal ulcer	Common in foals with other disease or stress	Usually clinically inapparent Colic, inappetence, teeth grinding, excessive salivation, diarrhea; gastroscopy diagnostic	None diagnostic	Antacids and antiulcer compounds (Table 7-20) Rarely surgery to correct gastric outflow obstruction

GASTRIC DILATION IN THE HORSE

SYNOPSIS

Etiology Gastric outflow obstruction. Idiopathic. Ingestion of excess fluid or feedstuffs

Epidemiology Sporadic. No age, breed, or sex predilection

Clinical signs Colic. Reflux from nasogastric tube. Gastric rupture, acute severe peritonitis, and death

Clinical pathology Nondiagnostic. Inflammatory cells and ingesta in peritoneal fluid of horses with gastric rupture

Diagnostic confirmation Nasogastric reflux without other identifiable cause

Lesions Gastric dilatation. Gastric rupture with hemorrhage at margins of rupture

Treatment Gastric decompression. Treat underlying disease.

Control Prevent overeating. Control inciting diseases.

ETIOLOGY

Chronic gastric dilatation can be caused by the following:

- Outflow obstruction, such as cicatricial constriction of the pylorus secondary to gastroduodenal ulceration or pressure by a tumor
- Gastric atony in older horses or wind-sucking (aerophagic) horses

Acute gastric dilatation is associated with:

- Reflux of intestinal contents secondary to acute intestinal obstruction, e.g., anterior enteritis, small-intestinal strangulation, or ileus
- Ingestion of excess fluid or feedstuffs such as whey or grain
- Acute idiopathic dilatation after racing

EPIDEMIOLOGY

The incidence of gastric rupture, the most severe sequela to gastric dilatation, in horses with colic is approximately 5%, although in horses subjected to exploratory laparotomy the rate may be as high as 11%.[1] There is no detectable effect of age, breed, or season on the risk of gastric rupture. Risk factors for gastric dilatation include consumption of excess grain, although horses routinely fed grain are at lower risk, and ingestion of palatable fluids such as whey has been implicated. **Acute idiopathic dilatation** of the stomach occurs sporadically and is a common cause of gastric rupture, representing between 16% and 60% of cases of gastric rupture. **Chronic dilatation** secondary to pyloric obstruction caused by a tumor is a sporadic occurrence in older horses, whereas cicatricial obstruction secondary to gastroduodenal ulceration is more common in younger horses and those at risk of developing gastroduodenal ulcers.

Acute dilatation occurs secondarily to acute obstruction of the small intestine.

PATHOGENESIS

Acute obstruction of outflow from the stomach or aboral passage of ingesta and secretions through the small intestine results in gastric dilatation. This causes severe pain and signs of shock, including elevated heart rate, sweating, and delayed mucosal capillary refill time. Gastric rupture can occur within hours and death shortly thereafter. Chronic dilatation results from partial obstruction and delayed gastric emptying. The disease is more prolonged and clinical signs can be related to the primary disease.

The obstruction can be as aboral as the ileocecal valve. Gastric distension with fluid also occurs late in the course of impaction of the large or small colon. Horses with large-intestinal volvulus have accumulation of fluid in the proximal small intestine and stomach because of tension on the duodenocolic fold causing extramural compression of the duodenum.

Gastric distension causes severe pain and there is often dehydration and hypochloremia as a result of sequestration of gastric secretions. Experimental distension of the stomach of healthy horses with water increases the intraabdominal pressure from −2.7 cmH_2O (i.e., subatmospheric) to + 3.1 cmH_2O after instillation of 20 L of water. Whether similar increases occur during gastric distension associated with gastrointestinal disease and its contribution to intraabdominal hypertension awaits clinical studies.[2]

Engorgement of a readily fermentable carbohydrate, such as wheat, glucose, or calf feeds, results in a syndrome characterized by shock, ileus, and laminitis. Gastric dilatation can occur secondary to grain engorgement, but the clinical signs of gastric dilatation are often masked by more severe signs secondary to endotoxemia.

CLINICAL FINDINGS

The clinical findings in gastric distension depend in large part on the underlying disease. However, horses with primary gastric distension have abdominal pain, often of 12 to 36 hours' duration, that progressively worsens. The heart and respiratory rates increase progressively as the distension worsens, and the horse may sweat and exhibit signs of increasingly severe abdominal pain. Paradoxically, some horses with gastric distension, especially the type that develops over several days or in horses recovering from intestinal surgery and being treated with analgesics, may not exhibit any but the most subtle signs until rupture of the stomach occurs.

Vomition in horses is very rare, is always associated with gastric distension, and is usually a terminal event.

In **grain engorgement dilatation** abdominal pain is usually severe. Dehydration and shock develop rapidly, often within 6 to 8 hours of ingestion of the grain, and can be severe. Death from gastric rupture can occur within 18 hours.

Passage of a nasogastric tube usually results in the evacuation of large quantities of foul-smelling fluid, except in cases of grain engorgement, in which the fluid is absorbed by the grain. However, significant and life-threatening gastric dilatation can be present even though there is no reflux through a nasogastric tube. If gastric dilatation is suspected then repeated, persistent efforts should be made to obtain reflux. The nasogastric tube should be left in situ until the disease has resolved.

Acute postrace dilatation occurring immediately after racing is accompanied by more serious and acute signs. There is abdominal distension, coughing, and dyspnea. Tympany is also detectable on percussion of the anterior abdomen and large amounts of foul-smelling gas, and usually fluid, are passed via the stomach tube. This immediately relieves the animal's distress.

In **chronic dilatation** there is anorexia; mild pain, which is either continuous or recurrent; scanty feces; and gradual loss of BW persisting for a period of months. Vomiting and bouts of pain may occur after feeding, but they are not usually severe. Dehydration may be present but is usually only of moderate degree.

The distended stomach cannot be palpated on **rectal examination**, but the presence of distended loops of small intestine should alert the clinician to the probability of gastric distension. Rupture of the stomach, or other viscus, is characterized during rectal examination by a negative pressure in the abdomen and the presence of particulate matter on the serosal surface of intestine.

Ultrasonographic examination will reveal a distended stomach containing large quantities of fluid or ingesta and can reveal evidence of the predisposing lesion, such as the presence of distended small intestine. **Radiographic examination**, with or without a barium meal, can be of diagnostic value in young animals with chronic outflow obstruction. **Gastroscopy** performed after the stomach has been emptied can reveal lesions consistent with obstructed outflow, such as gastric squamous cell carcinoma or pyloric abnormalities secondary to gastric ulcer disease in foals.

CLINICAL PATHOLOGY

Horses with severe gastric dilatation often, but not always, have slightly **low serum chloride concentrations**. Metabolic alkalosis, metabolic acidosis, or mixed disturbances can be present. Other abnormalities depend on the underlying disease.

Abdominal fluid of horses with gastric dilatation is normal, whereas that of horses with gastric rupture is characterized by an elevated total protein concentration (>2.5 g/dL, 25 g/L) and leukocyte count (>10,000 cells/μL, 10 × 10 cells/L) which is predominantly composed of degenerate neutrophils. Microscopic examination of the fluid reveals intracellular and extracellular bacteria and plant material.

NECROPSY FINDINGS

After grain engorgement in horses, the stomach is distended with a doughy, malodorous mass of ingesta. In acute gastric dilatation caused by other causes, the stomach is grossly distended with fluid and the wall shows patchy hemorrhages. Rupture, when it occurs, is usually along the greater curvature and results in gross contamination of the abdominal cavity with ingesta.

DIFFERENTIAL DIAGNOSIS

See Table 7-19.

TREATMENT

Relief of the gastric distension should be considered an **emergency** because gastric rupture invariably causes death. Passage of a nasogastric tube, important in diagnosing the accumulation of fluid within the stomach, also provides a means for relieving the distension. Repetition and persistence may be needed to relieve the gastric distension.

Table 7-19 Differential diagnosis of common equine colics

	Epidemiology and history	Clinical findings	Clinical pathology	Response to treatment
Acute gastric dilatation	Feeding on grain or whey; Outflow obstruction Lipoma at pylorus Reflux with proximal enteritis	Acute severe pain, gut sounds negative, rectal negative; voluminous reflux through nasogastric tube and relief of pain; regurgitation	Depends on underlying disease; no diagnostic changes	Good to relief of gastric distension; prognosis guarded and depends on underlying disease
Acute obstruction and infarction of small intestine	Sporadic	Acute, severe intractable pain, no gut sounds, rectal exam reveals distended loops of small intestine, tight bands of mesentery at 12 h; no feces after 12 h; nasogastric reflux	Hypovolemia; toxemia late in disease Packed cell volume (PCV) more than 50% after 12 h Blood-tinged peritoneal fluid	Pain intractable; surgical correction
Acute obstruction of large intestine	As previously	As previously except abdomen visibly distended; rectal exam impeded by large loops of distended large colon	As previously	As previously
Ileocecal valve impaction	Feed includes finely chopped oat straw, or sorghum, Sudan grass, coastal Bermuda grass; infestation with *Anoplocephala perfoliata*	Subacute pain for 24 h as small intestine descends; then as for small intestinal obstruction; impaction palpable rectally	PCV normal first 24 h No characteristic changes	Medical therapy initially, then surgery for refractory cases
Spasmodic/tympanic colic	Sporadic; increased incidence with poor worm control	Acute moderate pain but heart rate up to 80 Loud and gassy gut sounds; rectal exam and feces normal, recovers spontaneously, lasts only 1–2 h	Normal	Xylazine, detomidine, butorphanol, hyoscine all effective; mineral oil orally
Impaction of large intestine	Old horse, debilitated, poor teeth, indigestible feed; inadequate access to water; excessive consumption of low-energy grass	Moderate pain, depressed or absent gut sounds, rectally long columns of dry hard fecal material, distinct from individual balls	Normal	Responds well to standard analgesics, mineral oil, fecal softeners, and fluid therapy
Verminous mesenteric arteritis (thromboembolic colic)	Poor worm control; rare	Subacute pain continues for 3–4 days; no gut sounds; rectally slightly distended loops; paralytic ileus	Slight leukocytosis and shift to left Paracentesis yields bloody fluid	Irreversible even if surgery performed Prevention includes adequate parasite control
Enteroliths, colonic foreign bodies, phytobezoars	Endemic in some areas	Subacute or recurrent colic of moderate severity only; masses palpable in small colon	No changes	Surgery only
Subacute obstruction of small intestine (adhesions, neoplasm, idiopathic muscular hypertrophy of ileum, etc.*	History of recurrent moderate or persistent mild colic	Moderate pain; distended loops of small intestine on rectal exam; point of obstruction may be palpable; gut sounds normal to loud	No changes	Excellent to surgery
Sand colic	Access to polluted feed; grazing on sandy country when feed sparse; salt deficiency or boredom leading to soil eating or licking	May be severe pain with acute impaction or chronic mild pain, often with intermittent bouts of diarrhea; may palpate impacted loops containing sand; auscultate sand in ventral abdomen; radiography; ultrasonography	Normal; mixture of feces and water allowed to stand shows heavy sand sediment	Analgesia and psyllium orally; prevent ingestion of sand
Flatulent colic	Mostly on succulent green feed Some secondary to physical obstruction of large intestine	Severe acute pain; visibly distended abdomen Loud gut sounds present early; rectal exam difficult because of size of loops	Not recorded	Trocarization through right flank or exploratory laparotomy if time and analgesia not successful

Table 7-19 Differential diagnosis of common equine colics—cont'd

	Epidemiology and history	Clinical findings	Clinical pathology	Response to treatment
Dorsal displacement left colon (nephrosplenic ligament entrapment)	Sporadic	Intractable moderate pain continues for days Pelvic flexure of colon missing, spleen displaced medially	No changes No changes	Rolling of anesthetized patient to replace colon very successful; jogging with or without administration of phenylephrine
Small intestine or colon strangulation by lipoma	Only horses older than 10 years Sudden onset	Sudden onset moderate pain without toxemia May be palpable per rectum	No changes	Surgery

The clinical picture varies with time: descriptions relate to clinical signs at 12–24 h of illness.
**Chronic intussusception, terminal ileal hypertrophy, constructive adhesions, Meckel's diverticulum, and fibroma at the root of the mesentery.*

Passage of the nasogastric tube through the cardia can be difficult in horses with gastric distension. Blowing into the tube to dilate the esophagus or instillation of lidocaine (20 mL of 2% solution) can facilitate passage of the tube. If there is no spontaneous reflux of material, a siphon should be formed by filling the tube with 500 mL of water and rapidly lowering the end of the tube below the level of the horse's stomach. The nasogastric tube should be left in place until there are no longer clinically significant quantities of reflux (1–2 L every 3 hours for an adult 425-kg horse).

Gastric dilatation caused by overeating of grain, bread, or similar material may be impossible to resolve through a nasogastric tube because of the consistency of the material. Gastric lavage using water or isotonic saline administered through a large-bore nasogastric tube may aid in removal of inspissated ingesta. Surgical decompression may be attempted in refractory cases, but is technically demanding because of the position of the stomach in the adult horse.

The underlying disease should be treated to restore normal gastric emptying or stop reflux from the small intestine. Supportive therapy, including restoration of hydration and normal electrolyte and acid-base status, should be provided (see Chapter 5). Horses at risk of inhalation pneumonia should be treated with broad-spectrum antibiotics for at least 3 days.

GASTRIC IMPACTION IN HORSES

Primary gastric impaction is a usual primary cause of colic in adult horses, comprising approximately 1.4% of 857 colic cases in one report and 20 of 653 (3.0%) horses with colic and 20/6097 admissions (0.3%) in another.[1,2] The case–fatality rate is 10% to 50%.[1,2] There does not appear to be a breed or gender predisposition, and the disease occurs in mature horses.[2]

The etiology of gastric impaction is unclear in most cases, with poor dentition, rapid food intake, inadequate intake of water, and abnormal gastric motility being mooted as causes of the disease.[1] Gastric impaction occurs secondary to hepatic fibrosis and insufficiency associated with poisoning with *Senecio jacobaea*.[3] Ingestion of persimmon (*Diospyros virginiana*) causes gastric impaction, ulceration, and rupture in horses because of the formation of phytobezoars.[4] Ingestion of thorn apple (*Datura stramonium* and other species of *Datura*) cause colic and acute gastric rupture in horses.[5] For cases of undetermined cause, there is usually a history of a diet of mature grass, alfalfa hay, corn, sorghum fodder, or ensilage. Other causes include insufficient access to water, poor teeth causing poor digestion, or the atony of old age. Some affected horses have histologic abnormalities of the stomach or intestine, but the clinical importance of these lesions in development of the disease is unclear.[1,2]

Horses can present with acute, chronic, or recurrent colic. Horses with acute disease usually have clinical signs of <3 days' duration, and half have had previous episodes of colic.[2] The most common clinical sign is inappetence with or without colic.[1,2] Heart rate and respiratory rate are usually not markedly elevated and rectal examination does not reveal diagnostic abnormalities. If the stomach has ruptured, there will be signs of septic peritonitis with toxemia and cardiovascular compromise including sweating, tachycardia, delayed mucous membrane capillary refill time, and discolored mucous membranes. Signs of long-term (chronic) disease include weight loss; intermittent colic; anorexia; dullness; and passage of small amounts of hard, dry feces.

Gastroscopy confirms the diagnosis by visualization of large amounts of ingesta in the stomach or phytobezoars, although visualization of the stomach is impaired by the presence of large quantities of ingesta causing the impaction. At exploratory laparotomy the stomach is enlarged with dry, fibrous feed material but is not grossly or acutely distended, and the intestines are relatively empty.

Clinicopathologic examination commonly reveals leucopenia and hyperfibrinogenemia,[1,2] although these findings are not consistent and present in every case.

Treatment includes restoration of normal hydration, which can aid in passage of the impaction. Judicious administration of lubricants (mineral oil) or osmotic cathartics (magnesium sulfate and sodium sulfate) or water might aid in softening the impaction. Phytobezoars associated with ingestion of persimmon can be treated medically by the administration of fluids (intravenous or, if tolerated, oral), intragastric administration of cola or diet cola beverages, and feeding of pelleted food.[4] Analgesia should be provided as needed preferably by use of drugs that do not inhibit gastrointestinal motility. Exploratory laparotomy with gastrotomy and removal of the impacted material might be required in a small proportion of cases.[1,2,6] Rupture of the stomach can occur and is invariably fatal.[1]

GASTRIC (GASTRODUODENAL) ULCER IN FOALS

SYNOPSIS

Etiology Unknown in most cases

Epidemiology Foals from 1 day of age; 50% of normal foals have gastric mucosal ulceration. Clinical disease in 0.5% of foals. More severe ulceration in stressed foals or foals with other diseases

Clinical signs None in most foals. Teeth grinding, excessive salivation, colic, diarrhea, inappetence, and weight loss. Ulcers in glandular mucosa are considered most clinically important. Sudden death with perforation. Ulcers present on gastroduodenoscopy

Clinical pathology Nondiagnostic

Lesions Gastric mucosal ulceration, duodenal ulceration and stenosis, and esophagitis. Peracute septic peritonitis

Diagnostic confirmation Gastroscopic demonstration of ulcers in foals with appropriate clinical signs

Treatment Treatment should be reserved for foals with clinically important disease. Ranitidine 6.6 mg/kg, orally every 8 to 12 h, *or* cimetidine 6.6 to 20 mg/kg orally or intravenously every 6 h, *or* omeprazole 1 to 4 mg/kg orally or intravenously every 24 h

Control Minimize occurrence of inciting or exacerbating diseases. Do not administer antiulcer medications as prophylaxis.

Gastroduodenal ulcer disease in young equids has a variety of manifestations. Disease in neonates is characterized by ulceration of the glandular mucosa and occurs in foals that have other disease or are exposed to physiologically important stressors. Disease in suckling foals occurs in either or both of the squamous and glandular mucosa of the stomach and/or the duodenal mucosa. The disease in this age group can progress to scarring of the gastric outflow tract with subsequent gastritis, dysphagia, and esophageal ulceration leading to inappetence, ptyalism, and death. Disease in weanlings usually affects the gastric squamous mucosa. There is no evidence that the widespread occurrence of lesions of the gastric squamous mucosa is clinically important in weanlings.[1]

ETIOLOGY

There is no established etiology, although there is an association with stress (see later). There is no evidence of an infectious etiology, for instance, *Helicobacter* sp., in the development of ulcers in neonates or suckling or weanling foals. Nonsteroidal medications administered above recommended doses can induce gastroduodenal ulceration. There is no evidence that at recommended therapeutic doses they are a common cause of gastric ulcers.[2]

EPIDEMIOLOGY

Occurrence

Gastric ulcers are reported in foals in North America, Europe, and Australia and probably occur worldwide. The **prevalence** of erosion and ulcers of the gastric glandular and nonglandular mucosa, detected by gastroscopic examination, averages 50% in foals less than 2 months of age that do not have signs of gastric ulcer disease.[3] Lesions of the squamous mucosa are present in 45% of foals, whereas lesions in the glandular mucosa occur in fewer than 10% of foals less than 4 months of age. Fifty percent of asymptomatic weanling foals (5–7.5 months of age) have gastric mucosal lesions evident on gastroscopy.[1]

Ulceration of the gastric and/or duodenal mucosa is evident in 22% (155 of 691) of foals at necropsy examination.[4] The study was performed at a referral institution, and the foals were examined as a result of their death or euthanasia at that institution. The relevance of these results to asymptomatic foals or foals that recovered from their illness is unknown. Foals examined were all less than 6 months of age and lesions were most common in the nonglandular gastric mucosa (70 of 155 foals). Twenty-five of 155 foals had lesions only in the glandular mucosa, 25 had lesions in both glandular and nonglandular mucosa, and 20 had lesions in both squamous and duodenal mucosa. There was no association of age with lesion distribution or prevalence.[4] Gastric ulcers were significantly associated with the presence of other gastrointestinal disease, but not with the presence of any other disease category.

Disease attributable to gastric or duodenal ulcers occurs in approximately 0.5% of foals, although the prevalence is greater in foals with comorbid diseases such as pneumonia and septicemia.

Estimates of case–fatality rate are not available for any of the forms of gastroduodenal ulcer disease in foals.

Risk Factors

Age and Sex

Age is an important risk factor for ulceration of the squamous epithelium, with 88% of foals less than 9 days of age affected compared with 30% of foals more than 70 days of age. These estimates should be considered with caution, because findings considered as lesions in earlier studies (desquamation [sheeting] of the squamous mucosa) are not now considered to be abnormal or indicative of disease.[4] Gastric lesions occur in fewer than 10% of foals over 90 days of age. There does not appear to be an effect of age on the prevalence of ulceration of the gastric glandular mucosa, which is considered a much more clinically significant lesion. There is no effect of **gender** on the prevalence of ulcers.

Stress and Disease

Stress and disease are important risk factors for development of ulcers of the glandular mucosa. Lesions of the gastric glandular mucosa occur in 27% of foals with another disease but in 3% of otherwise healthy foals.

PATHOGENESIS

The pathogenesis of gastric ulceration in foals has not been definitively determined and much is extrapolated from the disease in humans and other animals. It is assumed that ulcers occur because of an imbalance between the erosive capability of the **low gastric pH** and the **protective mechanisms** of the gastric mucosa. Low gastric pH was considered essential for the development of a gastric ulcer, but there is less certainty about this now that it is recognized that critically ill foals, and especially those that are premature or recumbent, often have high (less acid to alkaline) and highly variable gastric pH.[5] Additionally, administration of omeprazole to weanlings is effective in reducing the prevalence of lesions of the gastric squamous mucosa but might worsen lesions of the glandular mucosa.[1]

The conventional wisdom is that preservation of adequate mucosal blood flow and the presence of an intact, bicarbonate-rich layer of mucus over the epithelium are essential to maintaining the resistance of the epithelium to digestion by gastric acid and pepsin. Mucosal blood flow and bicarbonate secretion into the protective mucous layer are dependent in part on normal prostaglandin E concentrations in the mucosa. Factors that inhibit prostaglandin E production, such as NSAIDs and ischemia, could contribute to the development of ulcers. Trauma to the gastric epithelium can disrupt the protective layer and allow an ulcer to develop, as can the presence of compounds in duodenal fluid, such as bile salts that intermittently reflux into the stomach of normal foals.

Normal foals develop the capacity for secretion of gastric acid and the ability to achieve gastric pH less than 4 within 1 to 2 days of birth. Ingestion of milk increases gastric pH, and it is a generally held belief that frequent ingestion of milk provides a protective effect against the adverse effects of low pH on gastric mucosa. However, the development of gastric lesions in foals is not solely a result of prolonged exposure to low pH, although this might be a necessary factor, because ill neonatal foals that are at high risk of gastric erosion or ulceration have gastric pH that is often greater than 5 to 6.[3] The elevated pH, which can be alkaline in severely ill foals at greatest risk of death, is not consistent with development of gastric lesions.

Most ulcers do not produce clinical signs. **Severe ulceration** is associated with delayed gastric emptying, gastric distension, gastroesophageal reflux, and subsequent reflux esophagitis and pain. Ulcers can perforate the stomach wall and cause a peracute, septic peritonitis or erode into a large blood vessel with subsequent hemorrhage and occasional exsanguination. Ulcers and the attendant inflammation and pain might cause gastroparesis and delay gastric emptying, and chronic lesions can result in both functional and physical obstructions to gastric emptying with subsequent gastric dilatation and reflux esophagitis.

CLINICAL FINDINGS

There are six syndromes associated with gastroduodenal ulcers in foals[3]:

1. Ulceration or epithelial desquamation of the squamous mucosa of the greater curvature and area adjacent to the margo plicatus. These lesions are very common in foals less than 60 days of age and usually do not cause clinical signs. The lesions heal without treatment and are now considered variations of normal.[4]
2. Ulceration of the squamous epithelium of the lesser curvature and fundus. This is more common in older foals (>60 days) and is sometimes associated with clinical signs including diarrhea, inappetence, and colic.
3. Ulceration of the glandular mucosa, sometimes extending into the pylorus. This lesion occurs in foals of any age and is most common in foals with a comorbid disease. Clinical signs caused by the ulcer can be severe and include teeth grinding, excessive salivation, inappetence, colic, and diarrhea. There is often reflux esophagitis.
4. Gastric outflow obstruction caused by pyloric or duodenal stricture secondary to pyloric or duodenal ulceration. This occurs in 2- to 5-month-old foals and is evident as colic, inappetence, weight loss, gastric dilatation, gastroesophageal reflux, excessive salivation, and teeth grinding.
5. Peracute peritonitis secondary to gastric perforation. This usually occurs in foals that do not have a history of signs of gastric ulceration. Clinical signs include unexpected death, shock, dehydration, sweating, and an increased respiratory rate.
6. Hemorrhagic shock secondary to blood loss into the gastrointestinal tract from a bleeding gastric ulcer. This is an unusual presentation.
7. The typical signs of gastric ulcers in foals include depression, teeth grinding, excessive salivation, and abdominal pain that can range in intensity from very mild to acute and severe, similar to that of a foal with an acute intestinal accident. Diarrhea, with or without mild to moderate abdominal pain, is often associated with gastric ulcer disease in foals. Treatment with antiulcer drugs is sometimes associated with resolution of diarrhea and signs of gastric ulcer disease. There might be pain evinced by deep palpation of the cranial abdomen, but this is not a reliable diagnostic sign.

Definitive diagnosis is provided by **gastroscopic examination**. The endoscope should be 2 m in length, although a 1-m endoscope might allow partial examination of the stomach of young or small foals. Diameter of the endoscope should be less than 1 cm. Foals can usually be examined without sedation, although sedation might facilitate examination in larger or fractious foals. Ideally, older foals should have food withheld for 12 hours before the examination but this might not be necessary or advisable in sick foals. Young foals (those relying on milk intake for their caloric needs) should have food withheld for 1 to 2 hours. Adequate examination of the nonglandular stomach can usually be achieved without fasting, especially in younger foals, but thorough examination of the glandular mucosa and pylorus requires fasting.

Nasogastric intubation might cause pain and cause affected foals to gag. Foals with gastric outflow obstruction, caused either by pyloric or duodenal stricture or by gastroparesis, will have reflux of material through a nasogastric tube.

Contrast **radiographic** examination is useful in defining gastric outflow obstruction and can demonstrate filling defects in the gastric wall that are consistent with ulcers. The principal use of radiography is to establish delays in gastric emptying. Normal foals have complete emptying of barium sulfate (10–20 mL/kg BW administered through a nasoesophageal or nasogastric tube) from the stomach within 2 hours of administration. Gastric ulcers are occasionally apparent as filling defects, but contrast radiography is not sufficiently sensitive to justify its routine use for diagnosis of gastric ulceration.

CLINICAL PATHOLOGY

There are no diagnostic changes in the hemogram or serum biochemical profile. Serum pepsinogen values are of no use in diagnosing gastric ulcers in foals. Testing for fecal occult blood is not sensitive to or specific for gastric ulceration in foals. Foals with perforation of the stomach have changes consistent with septic peritonitis. Measurement of an isoform of α1-antitrypsin in serum is reported to be sensitive and specific for detection of gastric ulcers in foals, but these results have not been validated and the test is not widely available.[6]

NECROPSY FINDINGS

Gastric ulcers and erosions are common findings in foals dying of unrelated disease and their presence should not be overinterpreted.[4] The gross characteristics of the gastric lesions were described earlier. Foals dying of gastric ulcer disease do so from peracute diffuse peritonitis, exsanguination, or starvation secondary to the gastric outflow obstruction.

DIAGNOSTIC CONFIRMATION

The combination of compatible clinical signs, endoscopic demonstration of gastric ulcers, a favorable response to antacid therapy, and the elimination of other diseases permits a diagnosis of gastric ulcer disease.

DIFFERENTIAL DIAGNOSIS

The combination of teeth grinding, excessive salivation, depression, inappetence, and colic in foals is virtually diagnostic of gastric ulcer disease. Other causes of colic in foals are listed in Table 7-17.

TREATMENT

Treatment of clinically important gastric ulcer disease must be differentiated from prophylaxis of animals considered to be at high risk of disease or those in which lesions have been detected incidentally. The principles of treatment of clinically important gastroduodenal ulcer disease in foals include the following:

- Promotion of healing by reducing gastric acidity and enhancing mucosal protection
- Enhancement of gastric emptying
- Provision of nutritional and metabolic support
- Treatment of comorbid disease

Reduction of gastric acidity is achieved by the administration of one of several drugs that reduce secretion of gastric acid and increase gastric pH (Table 7-20). These drugs are either histamine type 2 (H_2) receptor antagonists or inhibitors of the proton pump in the gastric parietal cells. Administration of ranitidine (6.6 mg/kg orally every 8 hour) effectively increases gastric pH in normal neonatal foals but does not affect gastric pH in hospitalized neonates.[3] Omeprazole (4 mg/kg orally every 24 hours), a proton pump inhibitor, increases gastric pH within 2 hours of administration and for 24 hours in clinically normal neonatal foals and in clinically ill neonatal foals.[7] Omeprazole enhances healing of spontaneous ulcers in foals older than 28 days and is usually considered to not have important or frequent adverse effects. However, recent evidence suggests that administration of omeprazole to clinically normal weanlings is associated with increased severity of lesions in the glandular mucosa.[1]

Sucralfate is used to provide protection of denuded gastric epithelium, although its

Table 7-20 Drugs used in the treatment of *clinically important* gastroduodenal ulcer disease of foals and adult horses and recommendations for treatment (not prophylaxis)

Drug class	Drug	Dose, route, and frequency	Comments
H_2-antagonists	Cimetidine	6.6–20 mg/kg PO every 6 h	Potent acid suppression; short elimination half-life necessitates frequent administration Preferably use at the higher dose rate
	Cimetidine	6.6 mg/kg IV every 6 h	Rapid and potent acid suppression; use when oral administration is not feasible or rapid effect is required
	Ranitidine	0.9–2.0 mg/kg IV or 6.6–8.8 mg/kg PO every 8–12 h	Potent acid suppression and rapid resolution of clinical signs
Proton pump inhibitor	Omeprazole	4 mg/kg PO as paste every 24 h	Potent, rapid onset and long-lasting acid suppression
Pantoprazole		1.5 mg/kg IV every 12–24 h	Potent acid suppression in foals
Protectants	Sucralfate	40 mg/kg PO every 6 h	Can be given at the same time as inhibitors of acid secretion
Prostaglandin analogs	Misoprostol	5 µg/kg PO every 12 h	Causes diarrhea and mild colic Effective as a prophylactic for NSAID-induced ulcers in humans but minimal efficacy in enhancing healing of existing ulcers
Antacids	Aluminum hydroxide	1–2 g PO every 4–6 h	Ineffective; do not use
	Magnesium hydroxide	1–2 g PO every 4–6 h	Ineffective; do not use
	Calcium carbonate	1–2 g PO every 4–6 h	Ineffective; do not use
Promotility agents	Bethanechol	0.025 mg/kg SC every 6 h	Enhances gastric motility with minimally increased gastric acid secretion; used to treat gastroparesis; contraindicated if physical outflow obstruction exists

H_2, histamine type 2 receptor; IV, intravenously; NSAID, nonsteroidal antiinflammatory drug; PO, orally; SC, subcutaneously.

efficacy in preventing lesions or enhancing healing of existing lesions in foals with spontaneous disease is doubted.

A common **treatment protocol** involves administration of an H_2 antagonist or omeprazole. Treatment should begin as soon as the presence of a clinically relevant ulcer is suspected and should continue for at least 1 week after the resolution of clinical signs or until there is endoscopic confirmation of healing. Foals are often treated for 2 to 6 weeks.

Foals with gastroparesis secondary to severe gastroduodenal ulceration or gastritis can benefit from the administration of bethanechol (see Table 7-20) to increase gastric motility and enhance gastric emptying. Surgical bypass of pyloric or duodenal strictures can be necessary in foals with physical obstructions to gastric emptying, and when performed by experienced surgeons have a reasonable (>50%) prognosis for recovery and survival to discharge from hospital.[8]

Nonsteroidal antiinflammatory drugs such as phenylbutazone or flunixin meglumine are ulcerogenic at high doses and should be used sparingly and at recommended doses in sick foals. There is no evidence that these compounds predispose or cause gastric ulcers when used at the recommended dose rate.[2] It would be prudent to minimize their use in foals with gastric or duodenal ulcers.

Nutritional and metabolic support should be provided as necessary to foals that are unable to eat or drink or that have abnormalities of fluid and electrolyte status.

CONTROL

Control of diseases that predispose foals to gastroduodenal ulcer might reduce the incidence or severity of ulcer disease. Prophylactic treatment of sick or stressed foals with H_2 antagonists, sucralfate, or omeprazole is widely practiced but has been questioned because the efficacy of pharmacologic prophylaxis in prevention of disease or death caused by gastric ulceration has not been demonstrated.[9] Indeed, suppression of gastric acidity (increasing gastric pH) in either sick or normal foals might be unwise because of the protective effect of low gastric pH on gastric colonization of bacteria. Foals in an intensive care unit administered acid suppressive medication were 2.0 (95% CI 1.4–2.9) times as likely to develop diarrhea as those not administered these drugs.[9] Furthermore, the presence of detected ulcers was not different between foals administered antiulcer medication (15%) and those not administered these medications (21%).[9]

Administration of omeprazole to clinically normal weanlings is not recommended at this time.[1] Body condition score and BW of weanlings was not improved by administration of omeprazole, despite a reduction in prevalence of lesions in the squamous mucosa, and was associated with an increase in severity of lesions in the glandular mucosa.[1]

GASTRIC ULCER IN ADULT HORSES

Ulceration of the esophageal, gastric squamous, gastric glandular, or duodenal mucosa, either alone or in various combinations, occurs in adult horses. This constellation of lesions has been labeled the equine gastric ulcer syndrome (EGUS).[1] However, this label does not provide sufficient granularity to descriptions of the syndrome, which is composed of a variety of diseases each with its own etiology and pathogenesis, to permit focused discussion of the risk factors, etiology, prognosis, and treatment of each disease.[1,2] For instance, ulceration and gastritis of the gastric squamous mucosa associated with intense training programs has a different presentation and etiology from ulceration of the gastric glandular mucosa caused by injudicious use of NSAIDs. The etiopathogenesis of lesions of the gastric squamous mucosa might well differ from that of lesions of the glandular mucosa; therefore the presence and severity of lesions in each site should be specified.[2,3] Furthermore, it is likely that optimal treatment of lesions of the squamous mucosa differs from that of lesions of the glandular mucosa.

There is not sufficient information to warrant a separate description of each disease (with the exception of NSAID toxicosis). For this reason, the syndrome is described rather than having separate discussions of each disease or circumstances in which the disease occurs. However, there are differences among the various diseases and the discussion should be interpreted in that light.

ETIOLOGY

The etiology of the most common occurrence of gastric ulcers in the horse is unknown but several risk factors have been identified, which are described in the section Epidemiology.

SYNOPSIS

Etiology Unknown in most cases. Nonsteroidal antiinflammatory drug intoxication. Not associated with *Helicobacter* sp. infection

Epidemiology Common in horses in intense training programs and used in competitive endeavors such as Thoroughbred, Standardbred, and Quarter horses in racing or training and horses used for endurance racing. Common in horses with colic, but clinical importance in most cases is unclear. Associated with periods of feed deprivation or intermittent feeding, such as can occur with stabling or housing on dirt lots

Clinical signs None in most horses. Poor appetite, failure to bloom, and mild colic in some horses. Ulcers or erosions present on gastroduodenoscopy

Clinical pathology Nondiagnostic. Sucrose absorption test has potential utility.

Necropsy lesions Gastritis and/or gastric ulceration, which is rarely a cause of death

Diagnostic confirmation Gastroscopic demonstration of ulcers

Treatment Omeprazole 1 to 4 mg/kg orally once daily. Ranitidine and cimetidine are used but are less efficacious and convenient.

Control Minimize risk factors, including confinement and intermittent feeding. Prolonged administration of omeprazole to at-risk horses

Individual cases of gastric ulcers are associated with parasitic gastritis, such as in horses infested with *Gasterophilus* spp. and *H. megastoma* larvae. Tumors of the stomach, such as gastric squamous cell carcinoma or lymphosarcoma, cause ulceration of the gastric mucosa. Gastric phytobezoars and persimmon seeds (*D. virginiana*) have been associated with gastric impaction, ulceration, and perforation of the glandular portion of the stomach of a horse.[4] Administration of NSAIDs at recommended dosages is not associated with increased risk of gastric ulcers.[5]

There is only weak evidence that infection by *Helicobacter* spp. or similar organisms are associated with gastric ulcer disease in horses.[5,7] A convenience sample of 20 racehorses euthanized because of fractures of the limb during racing revealed that 18 (90%) had lesions of either or both of ulceration of the gastric mucosa or gastritis.[7] Spiral-shaped bacteria were detected in lesions in two of the seven horses with ulcers, four of seven animals with gastritis, and five of six horses with both lesions. *Helicobacter* DNA was detected by PCR in a similar proportion of lesions and in one of the two horses that did not have lesions. Importantly, this study demonstrated the presence of the bacterium but not its causal role in the disease; it might be that similar proportions of horses that do not have gastric lesions are infected. A study of 63 horses slaughtered for human consumption revealed gastric mucosal lesions in 36 but no evidence of infection by *Helicobacter* spp. demonstrated by urease or fluorescence in situ hybridization testing.[5] There is at present no convincing evidence for a role of *Helicobacter* spp. infection in the etiopathogenesis of gastric ulcer disease in horses. However, further studies that clearly define the disease being studied are needed.

EPIDEMIOLOGY

Occurrence

The occurrence of gastric ulceration is detected by either postmortem examination or gastroscopic examination. The frequency with which gastric ulcers are detected depends on the method of examination, the group of horses examined, and the reasons for examining them. It is not uncommon for studies of large numbers of horses (>100) to report prevalence of gastric ulcers equal to or greater than 80%, although this is not universal.[8,9] Studies reporting on incidence of gastric ulceration in horses with clinical abnormalities or at necropsy revealed a high frequency of gastric lesions in horses with colic (49%).[10] More recent studies have examined large numbers of horses without clinical signs of gastric ulcer disease but from populations at risk and have demonstrated a high prevalence in horses undertaking strenuous exercise on a regular basis.[9,11-13]

Gastric ulcer disease in horses is a recently recognized disease, with most reports originating after 1990 and coinciding with the widespread availability of endoscopes of sufficient length to permit examination of the stomach of adult horses. However, a longitudinal study of horses submitted for postmortem examination in Sweden demonstrated that horses have been affected with gastric ulcers since 1924.[14]

The condition is common in racehorses and other breeds of horse used for athletic events, and this population represents the most important occurrence of the disease. That said, less active horses and horses on pasture can be affected and with relatively high prevalence.[3,11,15,16] Broodmares on pasture can have a high prevalence of gastric ulcers (71%, 44 of 62 horses examined) with 42 of the 44 affected horses having ulcers only in the squamous mucosa.[16] There was no difference in prevalence of ulcers between pregnant and nonpregnant mares or between pregnant and recently foaled mares.[16] The presence of ulcers was not correlated with the weight of foals or placenta, raising the issue of the clinical importance of the presence of the ulcers. Over 60% of a nonrandom selection of horses kept on pasture in Denmark had gastric ulcer lesions ≥2.[3]

Thoroughbred and Standardbred horses in training or racing have a high prevalence of gastric lesions.[8,9,11,12] Gastroscopic studies of convenience samples of clinically normal Thoroughbred racehorses in training reveal a prevalence of lesions of the gastric mucosa of 82% to 93%. Gastric lesions are detected in 52% to 87% of Standardbred horses in training and actively racing.[9] Postmortem examination of Thoroughbred racehorses in Hong Kong, where many horses that retire from racing are examined postmortem, reveals a prevalence of gastric lesions of 66%, with the prevalence increasing to 80% when only horses that had raced recently were considered. Among racehorses selected for gastroscopic examination because of clinical abnormalities, including inappetence, failure to race to expectation, poor hair coat, or poor body condition, lesions of the gastric mucosa were detected in 86% to 90%.[14]

Lesions of the gastric mucosa occur in approximately 80% of **endurance horses** between racing seasons and in over 90% during racing.[13] Gastric lesions were present in 58% of **show horses** that had competed in the 30 days before gastroscopic examination.[14]

Lesions of the Squamous Versus Glandular Mucosa

The frequency of ulcers of the squamous mucosa is usually, but not invariably,[17] greater than that of ulcers of the glandular mucosa with many horses having lesions at both sites. For example, of 201 horses of various breeds and uses examined in Denmark, 43% had lesions of both glandular and nonglandular gastric mucosa, 15% had lesions of only the glandular mucosa, and 26% had lesions of only the nonglandular mucosa.[3] The majority (86%) of severe lesions (greater than or equal to grade 2, using a simplified grading system) were in the squamous mucosa. Most lesions are located adjacent to the margo plicatus. Lesions of the glandular mucosa are *considered* to be of greater clinical importance than are lesions of the squamous mucosa, although severe lesions (EGUS > 2) of the squamous mucosa are *considered* clinically important. However, clear evidence of the importance of ulcers at either site, or of the relative

importance of ulcers of varying severity, is lacking.

Risk Factors

Risk factors for gastric lesions in horses include being in training for an athletic event, exercise and the amount of time exercising, and colic. Suspected risk factors include the disposition of the horse (nervous horses are at greater risk),[17] diet, feeding practices, housing (pasture versus stall), stress (although the definition of stress is often not clear), and administration of NSAIDs such as phenylbutazone. Although each of these risk factors can be considered separately, it is likely that many are related and act in concert to increase the risk of development of lesions of the gastric mucosa. For instance, being in training often coincides with confined housing, intermittent feeding, daily bouts of strenuous exercise, and administration of NSAIDs. The combination of these factors, even without NSAID administration, reliably induces ulcers in Thoroughbred racehorses. Young horses (2 years old) that had arrived at the track within the month before first gastroscopic examination had a marked increase in severity of lesions at the time of a second gastroscopic examination 1 month later.

Animal Risk Factors

Among adult horses, age and gender are the only weak risk factors, if at all, for presence of gastric lesions.[17] Gastric lesions tend to be more severe in older horses. Among Standardbred racehorses, trotters are twice as likely as pacers to have gastric lesions. Horses with gastric lesions are more likely to have a nervous disposition, exacerbated stress hormone response to novel stimuli, and to paw more frequently.[17] Nonsteroidal antiinflammatory drugs are ulcerogenic at high doses and often administered to horses in training. The impact of NSAIDs on gastric permeability varies among drugs,[19] although the risk of any NSAIDs causing gastric ulcers at doses effective for treatment of musculoskeletal pain appears to be minimal.[5] Furthermore, among Thoroughbred racehorses there is no clear association between administration of these drugs and the risk of having gastric lesions.[14,17]

Colic is associated with presence of gastric lesions, although a cause and effect relationship is often not clear in individual cases. In a series of 111 horses with clinical evidence of abdominal discomfort of varying duration and severity, 91 had endoscopic evidence of gastric ulceration. Other abnormalities of the gastrointestinal tract or abdominal viscera were not found in 57 of the 91 horses with gastric ulcers. Thus gastric ulceration was the primary cause of colic, based on lack of concurrent abnormalities, clinical response to treatment with H_2 antagonists, and confirmation of improvement or resolution of gastric ulceration by endoscopy. However, 34 of the 91 horses with gastric ulceration had concurrent abnormalities of the gastrointestinal tract, demonstrating that gastric lesions can develop in horses with colic. Thus colic can cause gastric lesions and gastric ulcers can cause colic.

Management and Environmental Risk Factors

Racehorses in **training** have a higher prevalence of ulcers than do racehorses that are spelling (not in active training), and horses that are racing regularly have a higher prevalence than resting horses or horses in training but not racing. Standardbred racehorses in training are 2.2 times more likely to have gastric lesions, and those racing regularly are 9.3 times more likely to have gastric lesions, than are horses not training or racing. Increasing time in training is associated with greater severity of gastric lesions in Thoroughbred racehorses.[20] Although, as discussed previously, many factors can contribute to the likelihood of a horse having gastric lesions, such as exercise. This is probably because of the increase in intragastric pressure and decrease in pH in the proximal (nonglandular) stomach that occurs during exercise.

Feed withholding causes gastric ulcers in horses, probably because of the lack of buffering of acid produced during periods when the stomach is empty. It is likely that the intermittent access to feed that occurs in many stables results in periods of time during each day when horses do not have feed within the stomach. The loss of buffering is caused by lack of feed material in the stomach and by decreased production of saliva, which normally buffers gastric acid. Intragastric pH declines during periods of feed withholding in horses, which provides an explanation for the mechanism of increased acid exposure as a consequence of management practices.[21] Horses grazing on pasture eat frequently and have food in the stomach almost all the time.

Diet is suggested to be a risk factor for development of gastric ulcers, but definitive studies are lacking. Horses in training for racing are usually fed diets high in concentrated rations, and this is suspected to predispose these horses to gastric ulcers. Feeding of alfalfa hay and grain was associated with fewer gastric lesions in six research horses than was feeding brome grass hay.

Confinement to stalls is associated with an increased prevalence of gastric lesions, although lesions do occur frequently in some groups of horses kept on pasture. Although horses with gastric lesions during confinement have healing of these lesions when they are pastured, this change is not explained by a higher pH in horses on pasture.[15] Horses on pasture do not have a higher pH of the proximal or ventral stomach than when the same horses are fed ad libitum in stalls,[15] suggesting that it is not the environment that is affecting intragastric pH. Again, there is considerable confounding among the various risk factors, because housing on pasture is associated with constant access to feed; thus there are no periods of feed withholding, changes in diet from that rich in concentrates to that predominated by grasses, and, often, cessation of forced exercise.

PATHOGENESIS

The equine stomach is comparatively small relative to the size of the gastrointestinal tract. The stomach mucosa is divided into two parts. The proventricular part is glistening white in color, is composed of thick **stratified squamous epithelium,** and contains no glands. It covers approximately one-third of the mucosal area and ends abruptly at the margo plicatus, a slightly raised irregular serrated border with the glandular mucosa. Most gastric lesions in horses occur in squamous mucosa.

The **glandular mucosa** has a velvet-like structure and is usually covered by a thick layer of viscous mucus. The mucosa contains three main gland types: mucous-secreting cardiac glands; fundic glands, which contain mucous-secreting cells, hydrochloric-acid–producing parietal cells and pepsinogen-secreting chief cells; and pyloric glands, which consist largely of mucous-secreting cells. The stratified squamous epithelial mucosa has minimal resistance to gastric acid. The glandular epithelium has elaborate mechanisms, including the mucus–bicarbonate barrier, prostaglandins, mucosal blood flow, and cellular restitution, to protect itself from peptic injury. Hydrochloric acid and pepsinogens, which are converted to the proteolytic enzyme pepsin in an acidic environment, are secreted in the glandular mucosa by parietal cells and chief cells, respectively. The horse is a continuous, variable hydrochloric acid secretor, and the pH of equine gastric contents in the pylorus and antrum is often less than 2.0. Gastric pH is lowest, and acidity highest, when horses have been deprived of feed or have voluntarily stopped eating, often for as little as 2 hours. Thus there are periods during the day when gastric acidity is high (notably during the nighttime hours from midnight to 9 am).[15,21] Periods of prolonged high gastric acidity (pH <2.0) can be induced in horses by intermittent deprivation of feed, which often results in severe ulceration in the gastric squamous epithelial mucosa. Concurrent administration of the H_2 antagonist ranitidine during feed deprivation substantially reduces the area of lesion in the gastric squamous epithelial mucosa.

The pathogenesis of gastric ulcer is uncertain. It is proposed that the stratified squamous epithelium reacts to excessive acidic exposure by thickening and becoming para/hyperkeratotic.[22] Sloughing of superficial layers then predisposes to secondary infection when opportunistic bacteria and

inflammatory cells migrate to the area. The lesion deepens and progresses from an erosion to ulceration, exposing unprotected tissue to acid contents.[22] Subsequent healing might occur depending on factors influencing acidity and healing capabilities of the individual animal.[22] Exposure of squamous mucosa to acid is probably involved in the development of ulcers in most horses and there is in vitro evidence that volatile fatty acids, in combination with hydrochloric acid, are important in the development of ulcers in the nonglandular mucosa.[23]

A particular circumstance appears to favor the development of gastritis and ulceration in horses that undertake intense exercise. During exercise intragastric pressure increases from approximately 14 mm Hg at rest to as high as 50 mm Hg, stomach volume decreases, and the acidity of fluid within the proximal part of the stomach declines from pH 5 to 7 to pH 2 to 4. The combination of reduced blood flow and exposure to low pH increases the likelihood of mucosal damage, loss of protective mechanisms, and development of gastric mucosal lesions.[14]

Other factors, including physical injury to gastric mucosa, reflux of bile acids from the duodenum, and the presence of volatile fatty acids in the stomach all can contribute to the development of gastric lesions, but the definitive roles, if any, of each of these factors have not been determined.

CLINICAL FINDINGS

The vast majority of horses with lesions of the gastric mucosa, including ulceration, do not have clinical signs. Among racehorses, signs of poor performance,[24] feed refusal, fussy eating (not consuming all of the meal at a constant rate), and poor body condition have been associated with the presence of gastric ulcers. Of these signs only poor hair coat and poor body condition have been demonstrated to be associated with gastric ulcers, although the association of lower body condition scores with the presence of gastric lesions is not consistent across studies.[9,17] The high prevalence of some of the clinical signs, for instance, failure to perform to expectation, and gastric ulcers means that there is a high likelihood that horses with a given clinical sign will have an ulcer by chance. However, clinical experience indicates that horses with more extensive or severe lesions will have more severe clinical signs, including colic and failure to perform.

Colic is associated with the presence of lesions of the gastric mucosa, including ulceration. Ulceration can result from lesions elsewhere in the gastrointestinal tract, probably because of feed withholding or feed refusal by horses with colic. Alternatively, gastric ulceration can cause colic. The four criteria to determine whether gastric ulceration is the primary cause of colic in horses include the following:

1. Endoscopic confirmation of gastric ulceration
2. Absence of another alimentary tract abnormality
3. Clinical response to treatment that effectively suppresses or neutralizes gastric acidity
4. Confirmation of improvement or complete healing of gastric lesions

Most gastric ulcers in horses are not associated with hemorrhage and so signs of anemia or melena are unusual in horses. Horses with severe gastric ulceration and reflux esophagitis often have bruxism and retching. Rupture of gastric ulcers, perforation and subsequent peritonitis, and exsanguination from a bleeding ulcer are rare in adult horses.

Involvement of the spleen in the horse with a perforating gastric ulcer, a rare event, results in fever, anorexia, toxemia, pain on deep palpation over the left flank, and leukocytosis with a left shift.

Gastroscopic examination is the only means of demonstrating gastric lesions and assessing their extent and severity. Gastroscopic examination of the adult horse requires an endoscope of at least 2.5 m in length, although 3 m is preferable. The presence of feed material within the stomach prevents complete examination of the gastric mucosa, and in particular of the pylorus and antrum. The horse should be prepared by having feed withheld for at least 12 hours and water withheld for 4 hours before examination. If the horse is stabled on edible material, such as straw or shavings, it should be muzzled to prevent it eating this material. The horse may need to be sedated before examination (xylazine hydrochloride 0.1–0.3 mg/kg intravenously) and a twitch applied. The gastric mucosa is examined in a systematic fashion. As the end of the endoscope passes through the cardia the greater curvature and margo plicatus are examined. The endoscope is then advanced and rotated so that the lesser curvature and cardia are examined. The stomach should be inflated with air during the procedure. Excess fluid in the pylorus and antrum can be aspirated to allow better visualization of these regions. Careful attention should be paid to the margo plicatus because this is the most common site for lesions. The gastric glandular mucosa should be examined carefully for lesions because they are easily missed in this region. Material adherent to the mucosa should be washed away by flushing water through the endoscope. The endoscope can be passed into the duodenum to permit complete examination of the antrum. Endoscopic examination usually underestimates the number of gastric ulcers, compared with necropsy examination, and does not accurately predict the severity or depth of ulcers.

Small-intestinal segmental volvulus occurs infrequently (0.3%–3.2% of examinations) in horses after gastroscopic examination.[25] Signs of colic develop 10 min to 3 hours after gastroscopy and are caused by nonstrangulating segmental volvulus of gas-distended small intestine. The cause is speculated to be gas distension of the small intestine, although this is not confirmed. Movement of air from the stomach into the small intestine after instillation of air into the stomach is a common occurance.[26] It is prudent to evacuate as much air as possible at completion of the gastroscopy.

A number of grading systems for description of gastric lesions in horses have been developed and proposed. Few have been validated and tested for diagnostic utility. The Gastric Ulcer Number/Severity score has been validated and compared with an unvalidated system proposed by a group of experts.[27] Notably, neither grading system makes explicit the anatomic location of the lesions. As this information is likely to be of diagnostic or prognostic importance, it should be recorded.[3] Specifically, esophageal lesions, gastric squamous lesions, gastric glandular mucosal lesions, and duodenal lesions should each be scored for location and severity regardless of the scoring system used.

The simplified scoring system, when used by three experienced observers, has greater agreement among observers (intraclass correlation coefficient [ICC]of 0.97) than does the number/severity system (ICC = 0.94 for number of lesions and 0.93 for severity).[27] The κ values for agreement among observers were significantly lower when using the number/severity system.[27] The simplified system was reported by the observers to be quick and easy to use.[27] The simplified system appears to offer a useful method of classifying the severity of gastric lesions in horses, with the caveat that the site of the lesions should be recorded.[2]

Gastric ulcer number/severity score

Score	Number of lesions	Gastric ulcer severity
0	No lesions	No lesions
1	1–2 localized lesions	Appears superficial
2	3–5 localized lesions	Deeper structures involved (deeper than 1)
3	6–10 lesions	Multiple lesions and variable severity
4	>10 lesions	Same as 2 and in addition the presence of hyperemia or darkened lesion crater
5	>10 lesions	Same as 4 but hemorrhage or blood clot adherent to ulcer

Continued

Score	Description
0	Intact mucosal epithelium
1	Intact mucosal epithelium with reddening or hyperkeratosis
2	Small single or small multifocal lesions
3	Large single or large multifocal lesions or extensive superficial lesions
4	Extensive often coalescing lesions with areas of apparent deep ulceration

Most lesions in racehorses are in the gastric squamous mucosa with less than 20% of lesions in the glandular mucosa. The situation is different in hospitalized adult horses, in which lesions in the squamous and glandular mucosa occur with about the same frequency (58%). Most lesions in the glandular mucosa of hospitalized horses occur in the antrum or pylorus, as opposed to the glandular mucosa of the body of the stomach.

Idiopathic gastroesophageal reflux disease occurs sporadically and rarely in adult horses. Affected horses have bruxism and ptyalism that can be severe. Endoscopic examination reveals ulceration and erosion of the esophagus that is more severe in the distal esophagus. Often there is no evidence of impaired gastric outflow, as is common in foals with this disease.

CLINICAL PATHOLOGY

Horses with gastric ulcers are reported to have higher concentrations of creatinine and activity of alkaline phosphatase in serum than do unaffected horses, but these differences are not sufficient to be clinically useful.[14] Horses with gastric ulcer disease are typically not anemic.

Permeability of the gastric mucosa can be assessed by measurement of concentrations of sucrose in blood (serum) or urine. Sucrose, a disaccharide, is degraded by sucrase in the small intestine to its component monosaccharides glucose and fructose, which are then absorbed. Sucrose is not absorbed intact in healthy animals. Abnormal gastric permeability allows passage of sucrose from the stomach into the blood with subsequent excretion in the urine. In horses with gastric lesions, sucrose concentrations in blood (serum) after nasogastric administration of 250 g of sucrose (table sugar) as a 10% solution in tap water increase after 30 minutes, with peak values at 45 minutes. The magnitude of the increase correlates with the severity of the lesions.[28] This test is quite sensitive for detection of abnormalities in permeability of gastric mucosa as evidenced by abnormal concentrations of sucrose in serum in the absence of lesions detectable by endoscopic examination in horses after administration of high doses of phenylbutazone (4.4 mg/kg PO q12h day 1, 2.2 mg/kg PO q12h for 4 days, 2.2 mg/kg PO q24h for 9 days).[19] A test using concentrations of sucrose greater than 0.7 mg/dL in urine after intragastric administration of a 10% sucrose solution (1 g/kg orally after feeding) has a sensitivity and specificity of 83% and 90%, respectively, for detection of gastric ulceration.[14]

NECROPSY FINDINGS

Ulcers may be singular or multiple and are most commonly located in the squamous epithelial mucosa adjacent to the margo plicatus along the lesser curvature of the stomach. They can be linear or irregular in shape; with the exception of those in the glandular mucosa, they are rarely circular in appearance. Ulcers in the squamous mucosa often have slightly raised brown-stained keratinized borders and contain small amounts of necrotic material at their base; frank blood is uncommon. Ulcers in the glandular zone are usually circular or oval depressions surrounded by an intense zone of inflammation. Classification of lesions within the squamous region included hyperkeratosis, punctate scars, diffuse erosions/ulcerations, and margo injuria, and within the glandular region included hyperemia, focal erosions, ulcerations, and glandular metaplasia.[22]

When perforation has occurred, there is an area of local peritonitis, the stomach wall is adherent to the tip of the spleen, and an extensive suppurative splenitis may be present. In some cases, especially when the stomach is full at the time of perforation, a long tear develops in the wall and large quantities of ingesta spill into the peritoneal cavity. Tumor masses can be present and accompanied by several glandular ulcers.

DIFFERENTIAL DIAGNOSIS

Gastric ulceration of adult horses must be differentiated from the common causes of recurrent colic.

TREATMENT

The goals of treatment of horses with gastric ulcer disease are healing of the ulcer, suppression of pain, and prevention of ulcer recurrence. The principle underlying treatment of gastric ulcers in horses is suppression of gastric acidity (increase intragastric pH). This can be achieved by inhibiting acid production or increasing buffering of acid. Mucosal protectants are administered with the aim of preventing exposure of damaged mucosa to acid. Management changes may reduce the risk of horses developing disease.

Acid Suppression

The agents available to suppress acid production are compounds including omeprazole and lansoprazole, which block the proton pump on the luminal surface of gastric parietal cells, and H_2 receptor antagonists including cimetidine, ranitidine, and famotidine.

Omeprazole

Omeprazole is currently the favored treatment for gastric ulcer disease in horses. The pharmacokinetics, pharmacodynamics, safety, and efficacy of the drug have been extensively investigated in horses under a variety of conditions and management systems. Omeprazole (4 mg/kg BW orally every 24 hours) is effective in promoting healing of ulcers of the squamous mucosa in horses that continue to train or race, a situation in which ulcers will not heal spontaneously. Omeprazole is safe and no adverse effects from its administration have been reported. Omeprazole at a dosage of 4.0 mg/kg once daily is more effective at healing ulcers of both the squamous and glandular portions of the stomach than is a dosage of 0.8 mg/kg.[29] However, omeprazole is less efficacious at healing ulcers of the glandular mucosa than the squamous mucosa.[29] A frequently used treatment regimen is omeprazole 4 mg/kg once daily for 14 days followed by maintenance therapy of 1 to 2 mg/kg once daily for as long as the horse is at risk of developing gastric ulcers. Administration of omeprazole (4 mg/kg once daily either before or after exercise) resulted in healing of 80% of squamous ulcers versus 21% of glandular ulcers ($P = 0.0002$), and improvement in 96% of squamous ulcers versus 53% of glandular ulcers ($P = 0.001$).[30] Omeprazole paste administered at 1 mg/kg orally once daily is effective in both preventing development of ulcers in horses entering race training and preventing recurrence of ulcers in horses in which ulcers have healed during treatment with a higher dose of omeprazole.[31,32] Omeprazole (0.5 mg/kg once daily) is as efficacious as 1 mg/kg once daily in treating Thoroughbred racehorses with ulcers in training. However, there was no untreated control group, or group administered a higher dose of omeprazole, and results might have reflected healing that could be expected without medication.[33] Administration of omeprazole (1 mg/kg) as an enteric-coated formulation is as effective as administration of omeprazole (4 mg/kg) as a paste in a nonplacebo controlled crossover trial. Administration of the enteric-coated formulation resulted in lower plasma omeprazole concentrations than those achieved with the higher dose of the paste formulation.[34]

Rectal administration of omeprazole does not reliably decrease gastric pH.[35] Intravenous administration of omeprazole (0.5 mg/kg) significantly increases intragastric pH within 1 hour and appears to enhance healing of nonglandular ulcers.[36]

The addition of trimethoprim-sulfonamide to treatment with omeprazole does

not enhance healing of ulcers of the glandular mucosa.[37]

The composition of the excipients and form of omeprazole is important in determining efficacy. Forms of omeprazole other than that in the commercial preparation are associated with reduced or nil efficacy. Omeprazole is more effective than cimetidine (20 mg/kg orally every 8 hours) for treatment of gastric ulcers in racehorses.

Esomeprazole (0.5 mg/kg intravenously every 24 hours) is effective in raising intragastric pH in adult horses.[38] Its efficacy in treatment or prevention of gastric lesions has not been determined.

Cimetidine

Cimetidine is the prototypical H_2 receptor antagonist. It acts by blocking action of histamine on the basilar membrane of the gastric parietal cells. It is used for treatment of gastric ulcer disease in horses, for which is must be administered frequently and in high doses (20–25 mg/kg orally every 6–8 hours). The drug has variable absorption after oral administration to horses. It is usually cheaper than omeprazole, but is less effective. Cimetidine can be administered intravenously (7 mg/kg every 6 hours) if rapid action is needed or the animal cannot take medication orally (e.g., a horse with colic).

Ranitidine and Famotidine

Ranitidine (6.6 mg/kg orally every 8 hours) effectively suppresses gastric acidity and prevents development of ulcers in horses deprived of feed. Ranitidine does not affect rates of gastric emptying.[39] Commercial preparations for its use in horses are marketed in some countries.

Famotidine is an H_2 receptor antagonist marketed for use in humans. It is effective in suppressing gastric acidity in horses (3 mg/kg orally every 12 hours or 0.3 mg/kg intravenously every 12 hours) but is expensive.

Gastric Antacids

Gastric antacids given orally neutralize stomach acid to form water and a neutral salt. They are not absorbed and decrease pepsin activity, binding to bile salts in the stomach, and stimulate local prostaglandin. One oral dose of 30 g of aluminum hydroxide and 15 g of magnesium hydroxide can result in a significant increase in gastric pH for up to 4 hours. The short duration of action, minimal and transient effect on gastric pH, and need for administration of large volumes orally render these products less than optimal. Moreover, there is evidence that antacids are not effective in treatment of gastric ulcers in racehorses.

Protectants and Other Treatments

Sucralfate is an antiulcer drug with a cytoprotective effect on the gastric mucosa. Sucralfate dissociates in gastric acid to sucrose octasulfate and aluminum hydroxide. The aluminum hydroxide acts as an antacid and the sucrose octasulfate polymerizes to a viscous, sticky substance that creates a protective effect by binding to ulcerated mucosa. This prevents back diffusion of hydrogen ions, inactivates pepsin, and absorbs bile acid. Sucralfate is administered to horses (22 mg/kg orally every 8 hours) but is not effective in promoting healing in induced disease or associated with a lower risk of gastric ulcers in racehorses administered the compound.

Pectin–lecithin complexes are not effective in treatment of gastric ulcer disease in horses. A combination of pectin, lecithin, and bicarbonate in unspecified amounts fed as a supplement demonstrated limited efficacy in reducing gastric ulcer scores induced by feed deprivation.[40]

Administration of concentrates or extracts of sea buckthorn berries (*Hippophae rhamnoides*) does not reduce the incidence of nonglandular gastric lesions in horses with experimentally induced (intermittent feed deprivation) gastric ulcerative disease.[41]

Misoprostol, a prostaglandin E analog, is administered for treatment of gastric and other enteric lesions,[42] and especially those attributable to NSAID toxicosis. However, its efficacy in treating or preventing gastric ulceration in horses has not been determined. It does appear to be safe to administer to pregnant mares.[43]

Management Changes

Horses with gastric ulcers experience spontaneous healing when removed from training and kept on pasture. These management changes are not appropriate in most instances, and emphasis should be placed on feeding diets that have a low ulcerogenic potential (such as alfalfa hay) and using feeding practices that minimize or eliminate periods when the horse does not have access to feed. Hay should be constantly available to horses, if at all possible.

Overview of Treatment

The usual approach to treatment is to promote healing of the ulcer by administration of effective agents (omeprazole or possibly ranitidine) at high dose until the ulcer has healed, as demonstrated by gastroscopy. The horse is then administered omeprazole at a lower dose (1–2 mg/kg orally every 24 hours) for the duration of time that it is at risk of developing gastric ulcers. Changes in management, including feeding practices and diet, should be instituted at the start of treatment. While not statistically associated with risk of gastric ulceration, use of phenylbutazone or other NSAIDs should be minimized in horses at high risk of disease.

CONTROL

Prevention of gastric ulcer disease in athletic horses centers on minimizing the effect of factors that promote ulcer development. This might involve the chronic administration of omeprazole (1 mg/kg orally once daily),[32] but should include attention to dietary and feeding practices (discussed previously) that minimize the time that horses have no feed in their stomach. Ideally, horses at risk would be kept on pasture, but this is not feasible under many management or husbandry systems and it does not reliably prevent the development of ulcers.[16] All horses in athletic training and confined to stalls should be considered at high risk of development of gastric ulcers and should be managed accordingly. Detailed recommendations about feeding practices are available.[44]

INTESTINAL OBSTRUCTION IN HORSES

Intestinal obstruction is an important cause of colic in horses, and can involve the small intestine, cecum, large (ascending) colon, or small (descending) colon. Because the clinical characteristics of obstruction of the various bowel segments are quite different, intestinal obstruction is discussed based on the site affected (small intestine, cecum, and large or small colon).

SMALL-INTESTINAL OBSTRUCTION IN HORSES

SYNOPSIS

Etiology Volvulus; intussusception; incarceration and strangulation in epiploic foramen, Meckel's diverticulum, mesenteric rents, or umbilical, inguinal, or diaphragmatic hernia, or by pedunculated lipoma; obstruction caused by foreign bodies or ascarids, intramural tumors including hematomas, eosinophilic infiltrates, neoplasms, and abscesses; ileal hypertrophy; ileal impaction

Epidemiology Mostly sporadic diseases, although the age affected can vary with the disease

Clinical signs Strangulating lesions cause acute, severe disease with intense pain, tachycardia, dehydration and hemoconcentration, and usually distended loops of small intestine palpable rectally or detectable by ultrasonographic examination; death occurs in untreated horses within 48 h; obstructive, nonstrangulating lesions cause less severe pain and clinical abnormalities and have a longer course until death

Clinical pathology Nondiagnostic; hemoconcentration and azotemia are indicative of dehydration; increases in blood (plasma) and/or peritoneal fluid lactate concentrations are useful for prognostication; leukopenia and left shift are consistent with endotoxemia and peritonitis; peritoneal fluid can be serosanguinous with infarcted intestine

Lesions Consistent with the disease

Diagnostic confirmation Surgical exploration or necropsy

Treatment Surgical correction of lesion; analgesia; correction of fluid, electrolyte, and acid-base abnormalities

ETIOLOGY

A working classification is outlined next.[1]

Obstruction With Infarction

- Volvulus or torsion of the mesentery
- Incarceration in or strangulation by
  - Mesenteric rents
  - Epiploic foramen
  - Meckel's diverticulum
  - Pedunculated lipoma
  - Neoplastic lesions (teratoma)[2]
  - Adhesions
  - Inguinal hernia
  - Umbilical hernia
  - Diaphragmatic hernia
  - Rents in mesentery or intraabdominal ligaments (e.g., gastrosplenic) or spleen
  - Spermatic cord in geldings
  - Developmental defects in mesentery

Obstruction Without Infarction

- Intussusception:
  - Jejunojejunal, ileoileal, and other small intestinal intussusceptions
  - Acute and chronic ileocecal
- Foreign body:
  - Wood chip or fencing material impaction of duodenum or jejunum
  - Phytobezoars[3]
  - Linear foreign bodies such as string or baling twine
  - Impaction of the duodenum or jejunum by molasses-containing feedblocks
- Impaction by *P. equorum*[4,5]
- Impaction of the terminal ileum
- Muscular hypertrophy of the terminal ileum
- Intramural masses such as neoplasms (intestinal adenocarcinoma, focal lymphosarcoma, and leiomyoma), hematomas, abscesses and fungal infections (intestinal pythiosis), focal eosinophilic enteritis,[6] and Lawsonia *intracellularis* (LI) proliferative enteropathy
- Compression of intestine by intraabdominal masses including abscesses and neoplastic tumors

Functional Obstruction

- Anterior enteritis
- Postoperative ileus
- Myenteric ganglioneuritis
- Intestinal ischemia of any cause (thromboembolic colic, mesenteric accidents, and postexertional ileus)

The classification used above should be used only as a guide, because the actual clinical presentations vary. For instance, intussusceptions usually result in infarction of the intussuscepted segment but, because this segment is effectively isolated from the body, the clinical signs are often not characteristic of a horse with an infarctive lesion. Similarly, horses with small intestine entrapped in the epiploic foramen often have less severe clinical signs than anticipated for the severity of the lesion.

EPIDEMIOLOGY

The epidemiology of colic is covered in a previous section. There are no recognized risk factors for small-intestinal volvulus and for many small-intestinal accidents. Epidemiologic information is available for some small-intestinal obstructive diseases and is presented later. Obstructive diseases of the small intestine compromise approximately 20% of colic cases referred for further evaluation and treatment. For small-intestinal diseases requiring surgical correction, the case–fatality rate is 100% if surgery is not performed. Short-term survival of horses undergoing surgical correction of small-intestinal obstruction is 34% to 74%. The fatality rate is greatest in the perioperative period. Survival rates vary depending on the nature and severity of the lesion, with long-term survival rates lower for horses that require resection of the intestine, especially for resections of more than 2 m or more than one surgery. Prognosis might be improved by accurate identification of compromised, but viable, intestine and its preservation rather than resection.[7]

Intestinal Herniation Through the Epiploic Foramen

This occurs in approximately 5% of horses with small-intestinal disease requiring surgery. Geldings are four times more likely than mares to be affected. Thoroughbreds were overrepresented in two studies, suggesting a breed predisposition, and there was no effect of age on incidence. There appears to be an increased in incidence of the disease between October and March in Britain. Horses in the UK with a history of crib biting or wind sucking (adjusted OR 72, 95% CI 14–359), with a history of colic in the past 12 months (5.1, 95% CI 1.4–18.9), increased stabling in the past 4 weeks (3.7, 95% CI 1.4–9.7), and increased height (1.07, 95% CI 1.01–1.12 per centimeter) are at markedly increased risk of developing epiploic entrapment of the small intestine.[8] Similar risk factors are identified in horses from the United States, Ireland, and UK.[9] Horses with colic that crib (a behavioral abnormality in which horses grasp a fixed object such as a fence rail or post with the incisors, flex the neck, and draw air into the esophagus) are more likely to have herniation of the small intestine through the epiploic foramen than are horses that do not crib.[1,8,9] The reason for this association is not known but might be related to factors that predispose horses to both cribbing and intestinal herniation through the epiploic foramen, such as diet, exercise, or housing. Alternatively, cribbing might cause changes in intraabdominal pressure that favor herniation. There is no age predisposition to development of this disorder.

The **case–fatality rate** for horses subjected to surgery is between 30% and 50%, although older reports of the disease had a much higher case–fatality rate.[10]

Pedunculated Lipomas

The prevalence of colic caused by pedunculated lipoma is 1% to 2.6% of horses with colic and 1% to 17% of all horses that have a celiotomy because of small-intestinal disease. The prevalence varies depending on the population of horses studied. The proportion of horses with colic caused by pedunculated lipomas increases with age, and the median age of affected horses is 19 years. Pedunculated lipomas cause small-intestinal obstruction in older horses (>8 years) with geldings (2×) and ponies (4×) being at increased risk. Pedunculated lipomas occasionally (5 of 75 cases) cause strangulating obstructive lesions of the small colon. The case–fatality rate for horses subjected to surgery is over 60%.

Inguinal Hernias

Inguinal hernias occur only in males. **Congenital inguinal hernias** are usually self-limiting, do not require medical or surgical therapy, and resolve by the time foals are 3 to 6 months of age. Congenital inguinal hernias rarely cause a strangulating lesion of the small intestine (see the section Colic in Foals). **Acquired inguinal hernias** occur almost exclusively in stallions, and the disease is rare in geldings. There is no apparent breed or age predilection. The case–fatality rate for horses subjected to surgery is 25%.

Intussusception

Small-intestinal intussusception is more common in young horses and foals but also occurs in adult horses. Approximately 50% of intussusceptions in adult horses are associated with a luminal or mural mass, whereas this is not the case in younger horses and foals. The case–fatality rate of horses subjected to surgery is 25% to 60%.

Both acute and chronic **ileocecal intussusceptions** occur more commonly in young (6–30 months) horses, although they are rare in foals. There is no breed or gender predilection. The disease is acute in approximately 70% of cases and chronic in the remainder. Ileocecal intussusceptions constitute approximately 75% of all intussusceptions involving the small intestine and 60% of all intussusceptions. The **case–fatality rate** for horses with acute ileocecal intussusception when surgery is available is approximately 70%, whereas that for chronic intussusception is less than 10%. There is strong evidence of an association between tapeworm (*A. perfoliata*) infestation and ileocecal disease causing colic in horses.[11,12]

Foreign Body

Foreign-body obstructions occur most frequently in foals and yearlings, possibly because of their tendency to explore and eat unusual items. Impaction by *P. equorum* occurs in foals between 3 and 18 months of age and is often associated with the administration of anthelmintics to previously untreated foals.[4,5] Small-intestinal obstructions by feedblocks containing molasses is associated with ingestion of large quantities of the material.

Impaction

Ileal impaction is more common in mares and only in animals over 1 year of age. The disease represented 7% of surgical colic cases in one series. The case–fatality rate is as low as 8% in animals treated at a referral institution,[13] although older reports are of much lower survival rates.[1] The disease is attributed to the feeding of finely ground, high-fiber feed such as Coastal Bermuda hay, but this is not the only cause. Horses with colic that have been fed coastal Bermuda hay are approximately three times more likely to have ileal impaction than are horses with colic that have not been fed this feedstuff. Similarly, lack of administration of a compound effective against tapeworms is associated with a three times greater risk of ileal impaction among horses with colic, and tapeworm infestation is associated with an increased incidence of spasmodic colic and ileocecal impaction in Thoroughbred racehorses.

Mesenteric Rents

Incarceration of small intestine through mesenteric rents is a cause of colic in approximately 2% of colic patients undergoing exploratory celiotomy. The long-term survival rate is approximately 40%. There are no identified age, breed, or gender predilections.

PATHOGENESIS

The effects of intestinal obstruction and the particular influence of the related endotoxemia in horses were detailed earlier. The type of lesion is important, depending on whether the blood supply to a large section of intestine is occluded or whether effective circulation is maintained. Obstructions that do not cause widespread intestinal ischemia, such as those caused by focal external pressure or with some form of disease caused by pedunculated lipomas or caused by internal foreign bodies such as phytobezoars, are less acutely lethal and do not cause as severe signs as volvulus and forms of intussusception that result in ischemia of large sections of intestine. In the latter case, endotoxins from the gut lumen pass through the devitalized tissues of the gut wall into the circulation, resulting in signs of toxemia and cardiovascular collapse. There does not appear to be an important role for translocation of intestinal bacteria into the bloodstream in horses with small-intestinal lesions.[14]

CLINICAL FINDINGS

Acute Disease: Infarctive Lesions

In acute, complete obstructions of the small intestine, with intestinal ischemia caused by volvulus, intussusception, or strangulation, there is usually an almost immediate onset of severe abdominal pain. The pain can be minimally or only transiently responsive to administration of analgesics. During this early stage intestinal sounds are still present and feces still passed. The pulse rate increases to 60 to 80 beats/min, the respiratory rate can be as high as 80 beats/min, and sweating begins in many horses. It might be 8 to 12 hours before distended loops of intestine are palpable on rectal examination, and it is about the same time that clinical and laboratory evidence of hypovolemia is first apparent. Depending on the site of the obstruction there can be reflux of fluid on passage of a nasogastric tube. More proximal lesions result in distension of the stomach earlier in the course of the disease. Small-intestinal distension is readily detected by percutaneous or rectal ultrasonographic examination. The sensitivity and specificity of ultrasonographic examination for detecting small-intestinal distension (98% and 84%, respectively) is greater than that of rectal examination (50% and 98%, respectively).[1,15]

In the period 12 to 24 hours after obstruction commences, the pulse rate rises to 80 to 100 beats/min, loops of distended intestine can be palpated per rectum, gut sounds and defecation cease, and the rectum is empty and sticky to the touch. Abdominal paracentesis yields bloodstained fluid. From 24 hours onward, signs of hypovolemia and toxic shock become marked, but the pain may not worsen. The horse will often appear depressed and poorly responsive to external stimuli. Sweating may persist. The heart rate increases to 100 to 120 beats/min, intestinal loops are easily palpable, and reflux filling of the stomach occurs, with a great deal of fluid evacuated via the stomach tube; the horse may vomit. Death from endotoxemia or rupture of the intestine usually occurs within 48 hours. The terminal stage is one of severe endotoxic shock, with or without intestinal rupture and peracute diffuse peritonitis.

Subacute Cases: Noninfarctive Lesions

If there is no vascular involvement in the small-intestinal obstruction, such as occurs with ileal impaction, the pain is less severe than for horses with infarctive lesions, it is usually responsive to analgesics, and the heart rate is only mildly elevated (50–60 beats/min). The pain can be low-level continuous or intermittent with moderate attacks of pain alternating with periods of uneasiness without signs of overt pain. Pain is usually responsive to the administration of analgesics. The duration of colic in these cases can be several days to several weeks. Palpable intestinal distension and clinical and laboratory evidence of hypovolemia can be evident; for example, ileal impaction is detectable by rectal examination in approximately 25% of affected horses.[13] Surgical intervention becomes an option because of the failure of the horse to improve.

Intussusception of the Small Intestine

This can cause a syndrome of acute, subacute, or chronic colic, depending on the degree of involvement of the blood supply. Horses with **acute ileocecal intussusception** have an abrupt onset of moderate to severe abdominal pain, tachycardia, reflux through a nasogastric tube, complete absence of borborygmi, and tightly distended small intestine evident on rectal palpation. The course of the disease is usually less than 24 hours. Horses with **chronic ileocecal intussusception** have a history of chronic, intermittent colic occurring after feeding, weight loss, and reduced fecal volume. The abdominal pain is mild and intermittent and the horses are not dehydrated or tachycardic. Rectal examination may reveal the presence of mildly distended small intestine, especially after a meal, and in approximately 25% of cases the intussusception can be palpated per rectum. Mild abdominal pain can be present for weeks without an abdominal crisis occurring. Ultrasonographic examination may reveal the intussusception in the right flank.

Volvulus of the Small Intestine

This presents a typical syndrome of acute intestinal obstruction and infarction. The onset of signs is abrupt and there is severe pain, tachycardia, sweating, and a rapid deterioration in the horse's clinical condition.

Strangulated Inguinal Hernia

This entity is often missed in the early stages because the distension of the scrotum is easily overlooked unless a specific examination of that area is performed. Severe pain in an intact male, even when distended loops of small intestine are not palpable, should prompt a thorough examination of the scrotum and, per rectum, the internal inguinal rings.

Strangulated Diaphragmatic Hernia

When acquired after birth, this lesion has no distinguishing characteristics and will be identified only on thoracic radiography or exploratory laparotomy.[16] There is often a history of trauma, such as dystocia or, in adults, a fall or being hit by a car. The clinical course is characteristic of any acute, strangulating intestinal lesion. Small intestine or large colon can herniate into the thoracic cavity and be evident on radiographic or ultrasonographic examination of the thorax.

Epiploic Foramen Entrapment

Entrapment of small intestine in the epiploic foramen is associated with an array of clinical signs, some of which are subtle. Strangulation of small intestine through the epiploic foramen typically causes signs of acute abdominal pain with reflux of material through a nasogastric tube. However, approximately 40% of affected horses do not have signs of abdominal pain when examined at a referral center and 52% do not have nasogastric reflux. Horses with less severe clinical signs presumably have shorter lengths of incarcerated small intestine or incomplete obstructions to passage of luminal material or blood flow. Herniation of the parietal (antimesenteric) margin of the small intestine is sometimes associated with incomplete obstruction of the small intestine and signs of mild disease. Because of the anterior location of the lesion, distended small intestine cannot usually be palpated per rectum and is not identifiable without ultrasonographic examination or surgical intervention. A fatal complication of epiploic foraminal herniation is rupture of the portal vein, leading to sudden death from internal hemorrhage. Tension by the incarcerated section of gut on the portal vein causes tearing of the wall and subsequent hemorrhage. Hemoperitoneum in a horse with colic should prompt consideration of entrapment of small intestine in the epiploic foramen as a cause of the disease. The outcome of this combination of diseases is almost always fatal.

Functional Obstruction

Functional obstructions caused by anterior enteritis, intestinal ischemia, or postoperative ileus can be difficult to discriminate from obstructive lesions of the small intestine that require surgical correction. Postoperative ileus is characterized by continued pain and reflux through a nasogastric tube after surgical correction of an intestinal lesion. The ileus is probably a result of the diffuse peritonitis and inflammation of the intestine that results from surgical exploration of the abdomen. If sufficient doubt exists over the cause of a horse's signs of intestinal obstruction, then laparotomy or repeat laparotomy should be performed.

Foreign Body

Foreign-body impaction of the duodenum by agglomerations of chewed wood or cracked corn kernels cause signs of acute obstruction but without the endotoxemia caused by infarction.

Ileocecal Valve Impaction

Impaction of the ileocecal valve is manifest as an initial period of 8 to 12 hours of subacute abdominal pain with mild increases in heart rate. Intestinal sounds are increased in frequency and intensity. Rectal examination may reveal the enlarged, impacted ileum in the upper right flank at the base of the cecum in approximately 10% of cases. It is easily confused with an impaction of the small colon. Reflux on nasogastric intubation occurs in approximately 50% of cases. After 24 to 36 hours the pain increases in severity. There is severe depression, patchy sweating, and coldness of the extremities, and the animal stands with its head hung down, sits on its haunches, and rolls and struggles violently. The abdominal pain becomes severe and continuous, the pulse rate rises to between 80 and 120 beats/min, and the pulse is weak. The abdominal sounds are absent and there is reflux of sanguineous fluid through a nasogastric tube. On rectal examination the small intestine is tightly distended with gas and fluid. Death usually occurs within 36 to 48 hours after the onset of illness without surgical or effective medical intervention.

Idiopathic Muscular Hypertrophy (Terminal Ileal Hypertrophy)

This causes a long-term chronic or mild intermittent colic, with reduced appetite and weight loss, which persists over a period of weeks, sometimes months, in horses more than 5 years and up to 18 years old. Colic pain is associated with feeding. On rectal examination the greatly thickened ileum can be palpated at the base of the cecum, and there may also be distended loops of thick-walled ileum.

Difficulty can be experienced in differentiating ileal hypertrophy from chronic intussusception, especially of the terminal ileum into the cecum. Fluid ingesta can pass the much constricted lumen of an intussusception so that mural hypertrophy occurs orally. A similar clinical picture results from stenosis of the small intestine by adhesions, usually resulting from verminous migration. In all three diseases there is increased motility of the small intestine and there is no interference with the blood supply.

Caudal Abdominal Obstructions

Obstructive lesions of the small intestine in the caudal abdomen, and therefore more likely to be palpable, include strangulation through tears in the mesentery, through a defect in the gastrosplenic ligament, entrapment behind the ventral ligament of the bladder, or through a tear in the broad ligament of the uterus.

Radiography is not useful in diagnosing the cause of small-intestinal obstruction in adult horses, but **ultrasonographic** examination of the abdomen is rewarding and has greater sensitivity for detection of distended loops of small intestine than does rectal examination. If available, ultrasonographic examination is indicated in the initial or second examination of all horses with colic. Ultrasonographic examination can detect, in addition to distended small intestine, reductions in or absence of motility associated with ileus, thickening of the intestinal wall, intussusceptions, increased volume of peritoneal fluid, and abnormalities in the echogenicity of peritoneal fluid.

CLINICAL PATHOLOGY

Although laboratory examinations of animals with intestinal obstruction may not be used in the diagnosis of the obstruction, they are useful in assessing its severity and providing an indication of survival. Generally, the

laboratory findings in acute intestinal obstruction include the following:

- Hemoconcentration (the PCV usually exceeds 50%)
- Increase in serum creatinine concentration (depending on severity of the decrease in circulating blood volume)
- Decreases in plasma bicarbonate and pH, with increases in lactate concentration and anion gap
- Leukopenia and neutropenia caused by devitalization of infarcted intestine and the development of endotoxemia and, in some cases, peritonitis
- An increase in the total number of leukocytes, erythrocytes, and the protein concentration in the **peritoneal fluid** obtained by paracentesis. In acute intestinal obstruction with infarction, the peritoneal fluid will be bloodstained. As necrosis and gangrene develop there is an increase in the total number of leukocytes with an increase in the number of immature neutrophils. As devitalization proceeds, but before perforation of the gut wall, intracellular and extracellular bacteria may be seen in the fluid. Peritoneal fluid from horses with intestinal infarctive lesions has a higher alkaline phosphatase activity than fluid from horses with nonstrangulating obstructions. Peritoneal fluid lactate concentrations can be measured and are associated with probability of survival. Lactate concentrations in peritoneal fluid of horses with colic of 1, 6, 12, and 16 mM were associated with death rates of 11, 29, 63, and 82% in horses without strangulating lesions and 25, 52, 82, and 92% in horses with strangulating lesions.[17]
- Serum alcohol dehydrogenase activity increases in horses with colic, with concentrations increasing from (median range) of 10.5 (8.7–11 u/L) in healthy horses, 16.5 (13.8–18 u/L) in horses with colon impaction, 40 (20–74.9 u/L) in horses with small-intestinal strangulation, and 63.2 (40–78 u/L) in horses with colon torsion.[18]

NECROPSY FINDINGS

The physical lesions are characteristic of the disease.

DIFFERENTIAL DIAGNOSIS

Other diseases that may mimic pain caused by gastrointestinal disease are listed under differential diagnosis in the Equine Colic section. Gastrointestinal causes of colic that must be differentiated from small intestinal obstructive disease include:

- Enteritis and acute diarrhea
- Equine neorickettsiosis (Potomac horse fever)
- Anterior enteritis
- Gastric ulcer in foals and adults
- Disorders of the large or small colon
- Intestinal tympany (gas colic)
- Thromboembolic colic

See also Table 7-10.

TREATMENT

The principles of treatment of horses with small-intestinal obstructive lesions are similar to those of any colic (see the section Equine Colic).

Every attempt should be made to relieve the horse's pain using appropriate doses of effective analgesics (see Table 7-15). Care should be taken when using flunixin meglumine that signs of a lesion requiring surgical correction are not masked until the severity of the disease makes successful treatment unlikely.

Almost all obstructive lesions of the small intestine require surgical correction. Surgical techniques including the need to resect small intestine vary with the physical lesion and viability of the intestine.[19,20] In addition to surgery, attention should be paid to maintaining the horse's fluid and acid-base and electrolyte status (see the section Equine Colic). Treatment of postoperative ileus should be aggressive and include correction of acid-base, fluid, and electrolyte abnormalities; continued gastric decompression through a nasogastric tube; and administration of promotility drugs such as cisapride, lidocaine, erythromycin, and metoclopramide (see Table 7-16).

Ileal impactions can be treated medically by the administration of intravenous fluids, gastric decompression, and administration of mineral oil. Horses treated medically should be closely monitored as prompt surgical intervention may be necessary if the horse's condition deteriorates.

DUODENITIS-PROXIMAL JEJUNITIS (ANTERIOR ENTERITIS, PROXIMAL ENTERITIS)

Duodenitis-proximal jejunitis is a syndrome of small-intestinal ileus characterized clinically by acute onset of abdominal pain and production of copious amounts of nasogastric reflux. It is idiopathic and associated with lesions in the duodenum and/or proximal jejunum.

SYNOPSIS

Etiology Unknown—suspect strains of *Clostridium difficile*

Epidemiology Sporadic disease. Case–fatality rate highly variable (6%–75%)

Clinical signs Colic, voluminous reflux on nasogastric intubation, mild fever, resolution of pain on gastric decompression

Clinical pathology Nondiagnostic

Lesions Duodenitis, proximal jejunitis, gastric and small intestinal distension

Diagnostic confirmation None antemortem, resolution of disease

Treatment Gastric decompression, correction of fluid and electrolyte abnormalities

ETIOLOGY

The etiology of duodenitis-proximal jejunitis is unknown with both infectious (*Salmonella* spp. and *C. difficile*) and toxigenic (aflatoxicosis, fusariotoxicosis) as putative causes. *Salmonella* spp. are isolated from some horses with duodenitis-proximal jejunitis, but this is not a consistent finding. *C. difficile* might be involved as evidenced by detection of toxigenic strains of *C. difficile* from nasogastric reflux fluid of all 10 horses with duodenitis-proximal enteritis sampled but from only one of 16 horses with other diseases causing nasogastric reflux.[1] This observation is based on a small number of cases and demonstrates an association rather than causation and should be interpreted in that light. Experimental intoxication with culture media of *F. moniliforme* produces histologic, but not clinical, signs consistent with the disease.

EPIDEMIOLOGY

The disease is reported from the United States and Europe,[2] and there are anecdotal reports of it occurring in Australia and other countries. There is no apparent effect of age, with the exception that the disease is not reported in horses less than 1 year of age and is uncommon in horses less than 2 years of age. There is no demonstrated breed or gender predilection for the disease.[3]

Feeding of large amounts of concentrated feeds to horses is a risk factor for the disease, as is grazing.[3] Duodenitis-proximal jejunitis occurs more commonly in the warmer months.

There are anecdotal reports of farms with a high incidence of the disease, especially among , suggesting an unidentified cause or risk factor. There are no reports of the incidence, or morbidity/mortality rates of duodenitis-proximal jejunitis. The **case–fatality rate** varies from 6% to 75% but in referral institutions is likely about 10%.[4]

PATHOGENESIS

The primary lesion is inflammation and edema of the duodenum and jejunum with sloughing of villous epithelium and villous atrophy. These lesions are probably associated with ileus and failure of small-intestinal absorptive function. Fluid accumulation in the atonic small intestine causes distension and pain and reflux of alkaline small-intestinal contents into the stomach. Sequestration of fluid, electrolytes, and bicarbonate in the stomach and small intestine causes a reduction in blood volume, shock, and metabolic acidosis. Gastric and small-intestinal distension and hypovolemia cause tachycardia. Disruption of the small-intestinal mucosal barrier allows absorption of toxins, including endotoxins, which further compromise cardiovascular and metabolic function. Death in untreated cases results from acute, diffuse peritonitis secondary to gastric rupture, or shock and metabolic disturbances secondary to hypovolemia and endotoxemia. Laminitis and persistent nasogastric reflux are causes of death (including euthanasia) in hospitalized horses.[5]

CLINICAL FINDINGS

The onset of clinical signs is usually abrupt and characterized by mild to severe colic. Affected horses are **depressed**, **dehydrated,** and have prolonged capillary refill time and heart rates between 50 and 80 beats/min. The respiratory rate is variable. The horse might sweat profusely and there are muscle fasciculations in severely affected cases. Approximately two-thirds of cases are pyrexic.[5] **Borborygmi are absent,** although there can be tinkling sounds of gas bubbling in fluid-filled atonic intestine. **Rectal examination** usually reveals the presence of multiple loops of moderately to severely distended small intestine. **Reflux of fluid** through a nasogastric tube is a consistent finding, and usually results in marked relief of pain and resolution of tachycardia. The fluid is often sanguineous, malodorous, alkaline, and of large (10–12 L) volume.

Gastric decompression and intravenous administration of fluids results in marked improvement of clinical signs, although affected horses can continue to have nasogastric reflux for 24 hours to 10 days. Most cases resolve within 5 days. If untreated, horses develop severe gastric distension with subsequent rupture and death from peracute, diffuse peritonitis, or die as a result of hypovolemia and toxemia. A common sequela is the development of laminitis (approximately 8%). Approximately 10% of horses with duodenitis-proximal jejunitis have cardiac arrhythmias, including ventricular depolarizations and atrioventricular conduction disturbances. Arrhythmia resolves with resolution of the duodenitis-proximal jejunitis or correction of hypokalemia and acid-base disturbances.

CLINICAL PATHOLOGY

There is hemoconcentration with hematocrits as high as 0.70 L/L (70%) and total serum protein as high as 96 g/L (9.6 g/dL) in severely affected horses. The leukogram is variable and not diagnostic, and leukocytosis and left shift are common. Serum potassium concentration can be mildly low and blood bicarbonate concentration and pH are low in most cases. Horses with duodenitis-proximal jejunitis have serum bilirubin concentrations and serum GGT, aspartate aminotransferase, and alkaline phosphatase activities higher than horses with small-intestinal infarctive lesions. However, the differences are not sufficiently large for these variables to be useful in the differentiation of horses with duodenitis-proximal jejunitis from horses with small-intestinal infarctive lesions.

Peritoneal fluid has a normal nucleated cell count in 65% of cases; in the remaining cases it is increased. Peritoneal fluid protein concentration is often normal in cases sampled early in the disease but can be increased in more severe or prolonged disease and is a useful prognostic indicator.

NECROPSY FINDINGS

Gross lesions are restricted to the stomach, duodenum, and jejunum in most cases. The affected stomach and small intestine are distended, and the serosal surface has numerous petechial and ecchymotic hemorrhages. The mucosa is deep red and contains petechial hemorrhages and occasional foci of necrosis and ulceration. Histologic changes include neutrophilic inflammation, edema, hyperemia, epithelial sloughing, and villous atrophy. There is necrosis of mucosa, fibrin-rich edema and heavy neutrophil infiltration of the submucosa, and extensive hemorrhage in the tunica muscularis and serosa. A proportion of horses with duodenitis-proximal jejunitis have biochemical and histologic evidence of liver disease, including hepatocellular vacuolization and neutrophilic inflammation. Some horses with duodenitis-proximal jejunitis have myocarditis.

DIFFERENTIAL DIAGNOSIS

The most important differential diagnosis is a small intestinal obstructive lesion.

DIAGNOSTIC CONFIRMATION

Horses with small-intestinal obstructive lesions require urgent surgical correction, whereas most horses with duodenitis-proximal jejunitis respond well to medical therapy. The differentiation of duodenitis-proximal jejunitis and a small-intestinal obstructive lesion on clinical grounds is difficult, and there is no one variable that allows the distinction to be made reliably. Horses with duodenitis-proximal jejunitis have a lower heart rate, higher rectal temperature (fever), lower volume of gastric reflux, and less turgid small intestine on rectal examination than do horses with obstructive lesions, although others report that horses with duodenitis-proximal jejunitis have a higher volume of reflux at first examination and during the first 24 hours of disease. However, these differences are not sufficiently great to be conclusive. Horses with duodenitis-proximal jejunitis more often have normal peritoneal fluid than do horses with small-intestinal obstructive lesions. The response to gastric decompression and intravenous administration of fluids is useful in discriminating between diseases because horses with duodenitis-proximal jejunitis have marked resolution of abdominal pain and tachycardia within minutes of gastric decompression, whereas horses with small-intestinal obstruction have minimal or no resolution of these signs. Generally, horses with a heart rate below 60 beats/min after gastric decompression, mildly to moderately distended loops of small intestine, resolution of abdominal pain after gastric decompression, and normal peritoneal fluid probably have duodenitis-proximal jejunitis. However, horses should be examined frequently for changes in clinical condition. Worsening pain and cardiovascular status in the face of adequate fluid therapy warrant reconsideration of a diagnosis of duodenitis-proximal jejunitis.

TREATMENT

The principles of treatment of duodenitis-proximal jejunitis are gastric decompression; correction of fluid, acid-base, and electrolyte abnormalities and provision of maintenance fluid and electrolytes; relief of pain; and prophylaxis of laminitis. The decision on whether to elect surgical treatment for affected horses is dependent on the availability of surgical expertise and experience of clinicians in managing such cases medically or with surgical intervention. Horses for which surgical intervention is more likely are those with more severe signs of pain and absence of fever (each of which increases the likelihood of a small-intestinal obstructive lesion that requires surgical intervention for correction).[5] The duration of hospitalization is not different for horses treated medically (10 ± 4 days) or surgically (10 ± 6 days), although the survival rate for surgically treated horses is lower (75% versus 91%).[5] This could be a result of treatment modality,

Table 7-21 Agents used to treat ileus in horses with duodenitis and proximal jejunitis

Medication	Dosing	Comments	Recommendation
Lidocaine	1.3 mg/kg slow IV, then 0.05 mg/kg infusion	Analgesic, antiinflammatory, promotility; used to treat ileus; toxicity evident as central nervous system signs	R2
Metoclopramide	0.25 mg/kg IV slowly over 30 min every 12 h	Toxic; minimally effective	R3
Erythromycin	1 (mg/kg)/h IV	Questionable efficacy; might induce colitis	R3
Cisapride	0.1 mg/kg, IV every 8 h	Effective in prevention and treatment of postoperative ileus; can prolong cardiac Q-T interval (importance unknown); availability very limited	R3

IV, intravenously.

but it could also be related to the selection of horses for surgical treatment. Surgically treated horses are more likely to develop diarrhea (12% versus 28%).[5]

Gastric decompression is an urgent need in affected horses and can be accomplished by nasogastric intubation. The nasogastric tube should be left in place, or replaced frequently, for as long as there is reflux of clinically significant quantities of fluid (more than 2–4 L/4 h in a 425-kg horse). Discontinuation of gastric siphonage should be approached cautiously and the horse monitored for any increase in heart rate, development of abdominal pain, or ultrasonographic evidence of gastric or small-intestinal distension that could indicate recurrence of gastric distension. After the nasogastric tube is removed, the horse should be reintroduced cautiously to oral fluids and food. Small amounts (1–2 L) of water should be offered frequently (every 1–2 hours) during the first 12 to 24 hours. Horses should not be given immediate access to ad libitum water because some horses in the early convalescent period from duodenitis-proximal jejunitis will consume a large quantity of water and develop gastric dilatation and colic. Feed should be reintroduced gradually over 24 to 48 hours.

Complications of prolonged or repeated gastric siphonage through a nasogastric tube are pharyngitis, esophagitis, esophageal stricture, and esophageal perforation with subsequent cellulitis.

Fluid, electrolyte, and acid-base abnormalities should be corrected by the intravenous administration of isotonic, polyionic fluids such as lactated Ringer's solution. Affected horses lose considerable chloride and potassium in reflux fluid necessitating supplementation of fluids with potassium (up to 20 mEq/L of administered fluids).

Analgesia can be provided by administration of any of a number of drugs, including flunixin meglumine or ketoprofen. If the diagnosis of duodenitis-proximal jejunitis is uncertain, potent analgesics such as flunixin meglumine should be used judiciously until there is no possibility that a lesion requiring surgical correction exists.

Promotility agents such as lidocaine and cisapride (Table 7-21) and antacids such as cimetidine are sometimes administered. The efficacy of cimetidine has not been determined. There is evidence that lidocaine (lignocaine) is efficacious in reducing the duration of reflux, the amount of reflux, and the duration of hospitalization in horses with ileus of undermined cause (some of which presumably had duodenitis-proximal jejunitis) or after surgical correction of colic.[6]

Antibiotics, such as penicillin and an aminoglycoside, are often administered to affected horses because of the presumed bacteremia associated with the disease.

Surgical treatment of the disease is described and the outcomes were discussed previously.[5]

DISEASES OF THE CECUM

ETIOLOGY

- Cecal impaction
- Cecal rupture
- Cecocecal and cecocolic intussusceptions
- Cecal torsion
- Cecal tympany
- Cecal infarction
  - Congenital abnormalities (cecal duplication)[1]
  - Ileocecal intussusception is discussed as an obstructive disease of the small intestine (see section on Small Intestinal Obstruction in Horses)

There is strong support for a role of ***A. perfoliata*** infestation in cecal disease of horses. Infestation with *A. perfoliata* results in edema, hyperemia, and hemorrhagic foci in the ileocecal valve mucosa with light parasitism through regional necrotizing enteritis, with extension of lesions to the muscularis mucosa and eosinophilic inflammation around arterioles and submucosal neural plexus with heavy parasitism.[2,3] The lesions are associated with local and systemic production of specific IgE and IgG(T) antibodies.[2]

SYNOPSIS

Etiology Cecal impaction, perforation, cecocecal and cecocolic intussusceptions, cecal torsion, and cecal tympany.

Epidemiology Sporadic diseases with exception of association with *Anoplocephala perfoliata* infestation. Cecal impaction and cecal perforation are reported in horses and foals hospitalized for unrelated conditions. Cecal rupture occurs in mares during parturition.

Clinical signs Cecal impaction is evident as mild, intermittent colic that might not be noticed by a casual observer. Cecal perforation or rupture is evident as acute shock, sweating, and tachycardia secondary to diffuse peritonitis. Cecocolic intussusception causes acute severe colic and cecocecal intussusception causes mild, intermittent colic. Rectal examination and/or rectal or percutaneous ultrasonographic examination can be diagnostic.

Clinical pathology Nondiagnostic.

Lesions Gross lesions consistent with the disease.

Diagnostic confirmation Physical examination, exploratory laparotomy, or necropsy examination.

Treatment Cecal impaction treated medically with overhydration, fecal softeners, and analgesics. No treatment for cecal rupture or perforation. Surgical correction of some cecal impactions and all cecocecal and cecocolic intussusceptions

Larval cyathostomiosis is also associated with cecocolic and cecocecal intussusception in young horses. Other causes include intramural and extramural masses, including cecal abscesses and accumulations of fatty tissue (lipomatosis)[4] or neoplasia[5] that alter cecal motility and passage of ingesta as well as other alterations in cecal and colonic motility.

Cecal rupture occurs in foals with a reported age range of 1 to 6 months that have an association with previous anesthesia and administration of antiinflammatory drugs.[6] Rupture is not exclusively associated with impaction of the cecum in affected foals.[6]

Disturbed cecal motility or dehydration of cecal contents secondary to dietary changes are thought to be the cause of most cases of cecal impaction and rupture. Horses with recurrent cecal impaction have lower neuron densities in muscle layers of the base of the cecum and cecal body than do normal horses, supporting the hypothesis that disturbed motility secondary to neuronal abnormalities is a cause of the disease. Administration of drugs that interfere with cecal motility or secretory function has the potential to increase the risk of cecal disease.

EPIDEMIOLOGY

Cecal disease accounts for approximately 4% to 10% of colic in horses examined for abdominal pain at referral centers.

Cecal Impaction

Cecal impaction is the cause of colic in approximately 2% to 5% of horses treated for colic in referral institutions.[7] This estimate probably reflects a selection bias, with horses with less severe disease not being referred for further examination. Cecal impaction is therefore probably much less common as a cause of colic in field cases. Cecal impaction is the most common cause of cecal disease (40%–50% of cases) and 5% of horses with intestinal impaction.[3,7]

There is no gender predisposition to the disease, although there are reports of a high proportion (22%) of affected mares having foaled within the previous 90 days or being pregnant (20%).[7] Older horses are disproportionately affected with 50% of affected horses being between 10 and 17 years of age.[7] Horses over 15 years are at increased risk compared with horses less than 7 years of age.[3] The disease occurs sporadically but is reported in horses and foals hospitalized or treated for an unrelated disease, and it is speculated that anesthesia, surgery, and/or administration of NSAIDs are risk factors for the disease.[3,6-8] Hospitalization and treatment for ocular disease are risk factors for impaction colic, with 10 of 72 (14%) of such horses in one study developing impaction of the cecum.[9] Fasting, poor dentition, poor-quality feed, and restricted water intake might also be risk factors for the disease. The **case–fatality rate** is approximately 30% to 50%.[7]

A particular form of cecal impaction is that involving only the cecal base (cecal cupula) without accumulation of impacted material in the cecal apex or body of the cecum.[10] There are no identified risk factors, and the outcome of surgical treatment is good (100% survival of 7 horses treated).[10] The disease had a frequency of 0.45% of horses undergoing exploratory laparotomy.[10]

Cecal Perforation or Rupture

Cecal rupture at parturition occurs in 0.1% of mares. It represents approximately 27% of cecal disease in horses, and that associated with concurrent but apparently unrelated disease is the most common (13%). Cecal rupture or perforation is otherwise a sporadic disease that is often, but not always, a sequela to cecal impaction. The case–fatality rate is 100%. Cecal rupture, often without recognized preexisting disease, is a complication of anesthesia and NSAID (usually phenylbutazone) administration. As with other cecal diseases, infestation with *A. perfoliata* has been implicated as a cause of cecal rupture, although not all horses with cecal rupture have tapeworms.

Cecocecal or Cecocolic Intussusceptions

Cecocolic and cecocecal intussusceptions are the cause of 1% of colic cases treated surgically and approximately 3% to 7% of cecal disease. The case–fatality rate is approximately 50% to 70%.[3,11] There are no recognized epidemiologic patterns to the occurrence of **cecal or cecocolic intussusceptions**, with the exception that younger horses (<3 years) and Standardbreds are disproportionately affected. Cecocolic and cecocecal intussusceptions appear to disproportionately affect younger horses (range 6 months to 12 years of age) in New Zealand.[11] This could represent a biologic effect or selection of cases presented to the referral institution. Infestation with tapeworm (*A. perfoliata*) is suspected to increase the risk of cecal intussusceptions, although this suspicion is not universal.

Cecal Torsion

Cecal torsion occurs rarely and is associated with hypoplasia of the cecocolic fold in some but not all cases.

Primary **cecal tympany** is rare. Cecal infarction is caused by thromboembolic disease secondary to *Strongylus vulgaris* arteritis or necrotizing enterocolitis.

PATHOGENESIS

Cecal impaction is probably a result of impaired or altered cecal motility, with resultant reduced cecal emptying into the right ventral colon. Accumulation of feed material causes cecal distension and excessive tension in the wall of the cecum with ischemia, necrosis, and rupture. Infestation by tapeworms, including *A. perfoliata,* causes disruption of the cecal mucosa and submucosa, necrosis, and inflammation—changes that could contribute to cecal dysfunction. Death results from peracute diffuse peritonitis.

Cecal rupture at parturition is probably the result of high intraabdominal pressures associated with expulsion of the fetus. The pathogenesis of cecal rupture without cecal impaction is unknown.

CLINICAL FINDINGS

Cecal Distension and Impaction

There are a variety of classification schemes for cecal distension and impaction, including the time frame for development of the disease (acute or chronic), the presence of identifiable risk factors (hospitalization, antiinflammatory drug administration, and the presence of *A. perfoliata*), and the nature of the material distending the cecum (impacted ingesta and fluid).[10] Each provides the opportunity to emphasize a particular aspect of the disease(s) and is useful in that respect. The simplified classification used previously with continue to be used.[3]

Cecal distension occurs as two clinical syndromes: one caused by impaction of the cecum with inspissated feed material and the other caused by acute distension of the cecum by a mixture of fluid and ingesta.

Cases in which the cecum is **impacted** and distended with inspissated feed material usually have signs of mild to moderate abdominal pain that is often intermittent over a 1- to 4-day period. The signs of pain can be mild enough to be missed by a casual observer. Affected horses are usually mildly depressed and have a diminished appetite. The heart rate is 40 to 60 beats/min, borborygmi are reduced, and there can be mild dehydration. Nasogastric intubation yields reflux fluid only late in the course of the disease. Rectal examination reveals a doughy mass in the right caudal abdomen permitting diagnosis in approximately 85% of cases.[7] The ventral, and occasionally the medial, tenia of the cecum are palpable, as is firm feed material in the base and body of the cecum. The mass extends cranially, ventrally, and across the midline of the abdomen. If not treated, the cecum ruptures, causing an acute onset of tachycardia, sweating, delayed capillary refill, and shock, with death occurring in hours. It is not unusual for the initial signs of the disease to be missed and the problem to be recognized only after the cecum ruptures.

The outcome of horses with cecal impaction depends on the disease and its stage at presentation. The prognosis for horses treated medically is good with 81% surviving to discharge from hospital. This likely reflects that horses treated medically are metabolically stable (and therefore do not have a ruptured cecum) and have less severe impaction. Exploratory laparotomy results in diagnosis of cecal rupture in approximately one-quarter of horses,[7] all of which die, and a survival rate of approximately 65% to 90% in those horses allowed to recover from anesthesia.[7,8]

Horses with chronic, **recurrent cecal impaction** have a mild disease characterized by recurrent subtle to moderate signs of colic, reduced food intake, weight loss, and loose feces.

Impaction of the **base of the cecum** (the cecal cupula) by ingesta causes a mild colic

of several days' duration. Affected horses are metabolically stable and there are no diagnostic findings on rectal examination. Diagnosis is achieved during exploratory laparotomy.

Cecal distension also occurs as a syndrome in which **fluid** accumulates in the cecum. This disease has a much more acute course and is characterized by severe abdominal pain, tachycardia, and signs consistent with toxemia. Rectal examination demonstrates a cecum tightly distended with fluid ingesta. Without surgical intervention the outcome is cecal rupture and death.

Perforation and Rupture

Cecal perforation occurs secondary to cecal distension or as a primary entity. There are usually only very mild premonitory signs in either adults or foals, and the disease becomes apparent when the cecum ruptures and acute diffuse peritonitis develops.[6] Twenty-five percent of horses with cecal impaction develop cecal perforation or rupture.[7] Detection of serosa with a gritty feel and free gas in the abdomen on rectal examination is diagnostic of a ruptured viscus and diffuse peritonitis. Subserosal and retroperitoneal emphysema in the region of the base of the cecum can be indicative of cecal perforation or rupture.[12]

Intussusception

Cecocecal intussusception is the invagination of the cecal apex into the body of the cecum and usually presents as a mild intermittent colic, depending on the degree of involvement of the apex of the cecum. Small intussusceptions that cause little obstruction and no infarction of the invaginated section cause only mild pain.

Signs of cecocolic intussusception, in which the inverted cecum (the intussusceptum) progresses through the cecocolic orifice into the right ventral colon, occur over 1 to 7 days, and vary from mild and recurrent to acute and persisting. Rectal examination can reveal a mass in the right dorsal quadrant, lack of a cecum, and pain on palpation of the right dorsal quadrant. Ultrasonographic examination of the right flank reveals the presence of the cecum in the colon, which is apparent in cross section as a "target-like" pattern or taurus.[11]

CLINICAL PATHOLOGY

Cecal impaction with feed material is usually associated with mild hemoconcentration. Cecal perforation results in severe leukopenia and left shift, hemoconcentration (hematocrit > 50%, 0.50 L/L), and azotemia.

Peritoneal fluid from horses with cecal impaction is usually normal. However, if the cecum becomes ischemic, then the fluid is sanguineous with an elevated white blood cell count (>8000 cells/μL, 8 × 10 cells/L) and protein concentration (>2.5 g/dL, 25 g/L). Cecal perforation is evident as a high proportion of degenerate neutrophils, intracellular and extracellular bacteria, and plant material. Peritoneal fluid is abnormal in 81% of horses with cecocolic intussusception and 67% of cases with cecocecal intussusception.[11]

NECROPSY FINDINGS

The distended cecum and diffuse peritonitis are readily apparent. Cases of cecal perforation without distension will have diffuse peritonitis, but the cause is only apparent on close examination of the intestinal tract.

DIFFERENTIAL DIAGNOSIS

See Table 7-10 for causes of colic.

TREATMENT

Medical treatment of cecal impaction involves control of pain, restoration of normal fluid, acid-base and electrolyte status (see Chapter 5), and administration of fecal softeners such as sodium sulfate. Mineral oil, although frequently used, is not sufficient alone to facilitate passage of the impaction because it does not cause fecal softening.

Intravenous administration of fluid at two to three times maintenance needs is often used in an attempt to hasten fecal softening by increasing secretion of water into the impaction. **Oral administration** of large quantities of water (4 L every 2 hours for 24 hours) may soften the impaction.

Horses with cecal impaction should be **closely monitored** for signs of deterioration, and especially for cecal ischemia, by frequent physical examinations and repeated abdominocentesis. Lack of resolution within 24 hours or signs of deterioration should prompt surgical exploration with typhlotomy and evacuation of the cecum and possible partial cecal bypass. The results of surgical treatment of horses with cecal impaction are good with survival rates of 65% to 90% reported for horses that are recovered from surgery.

Cecocecal and cecocolic intussusceptions must be corrected surgically. The survival rate for horses with cecocecal or cecocolic intussusceptions is approximately 50%, although estimates are variable because of the small number of animals reported.[11]

Horses with **cecal perforation** always die and should be euthanized without delay.

DISPLACEMENT AND/OR VOLVULUS OF THE LARGE (ASCENDING) COLON

Displacement and volvulus of the large (ascending) colon are evident as nephrosplenic entrapment, renosplenic entrapment, left dorsal displacement of the large colon, or right dorsal displacement of the large colon.

ETIOLOGY

- Left dorsal displacement of the large colon (renosplenic or nephrosplenic entrapment and entrapment of the large colon lateral to the spleen)
- Right dorsal displacement of the large colon
- Volvulus (both strangulating and nonstrangulating)

SYNOPSIS

Etiology Unknown, probably involves disturbance of colonic motility

Epidemiology Volvulus is more common in mares during late gestation or after parturition. Left dorsal displacement (renosplenic entrapment) may be more common in large male horses.

Clinical signs Left displacement of the large colon causes signs of mild to moderate colic. Rectal examination reveals large colon in the renosplenic space, and ultrasonographic examination confirms the diagnosis. Right dorsal colon displacement causes mild to moderate colic. Rectal examination reveals colon lateral to the base of the cecum. Volvulus of the large colon causes mild to extremely severe abdominal pain, tachycardia, shock, and abdominal distension. Rectal examination reveals the distended, displaced colon.

Clinical pathology Nondiagnostic.

Lesions Displaced large colon.

Diagnostic confirmation Physical examination, laparotomy, and necropsy examination.

Treatment Volvulus and right dorsal displacement should be treated by surgical correction. Left dorsal displacement can be corrected by rolling the anesthetized horse or jogging the horse after administration of phenylephrine.

The etiology of these conditions is unknown but presumably involves some disturbance to normal colonic motility. Other causes of obstruction of the large colon include congenital abnormalities of the right ventral colon, cystic duplication of the ascending colon, defects in the mesocolon, and incarceration in epiploic foramen or gastrosplenic ligament. Intussusception of the large colon causes infarction and severe colic.

The term volvulus refers to rotation of the segment of bowel about the long axis of its mesentery, and torsion refers to rotation about the long axis of the bowel. Because of the anatomic arrangement of the mesocolon, either term may be correctly used to describe displacements of the large intestine.

EPIDEMIOLOGY

Left dorsal displacement of the large colon (Figs. 7-2 and 7-3) is the cause of 2% to 10% of colic cases referred for specialist treatment. There is no breed, age, or gender predisposition, although some authors suggest that males and large horses are more likely to be affected. The case–fatality rate is approximately 5% for horses treated correctly.

Right dorsal displacement of the large colon (Fig. 7-4) occurs sporadically and without recognized risk factors. The case–fatality rate is reported to be as high as 43%.

Risk factors for noninfarctive displacement of the large colon include cribbing or wind sucking (OR = 90), number of hours stabled per day (OR for 24-hour stabling = 35), lack of regular exercise (OR 3.3), change in exercise program (OR 9), lack of anthelmintic administration (OR 13), and history of transport in the previous 24 hours (OR 17).

Volvulus of the large colon is the cause of colic in 11% to 17% of colic cases in which abdominal surgery is performed. The disease occurs commonly in mares, especially those late in gestation or having recently foaled. Risk factors for volvulus of the large colon include being a broodmare (OR 2.5 versus male horse), greater height, colic in the past 12 months (OR 2.17), having a greater number of carers, larger number of horses on the premises, and a number of variables related to feed quality or quantity.[1] The disease has a recurrence rate of up to 15% in broodmares. The disease occurs in horses from 2 days of age and there does not appear to be an effect of breed on occurrence of the disease. The **case–fatality rate** varies depending on the extent of the volvulus, with lesser degrees of volvulus (<270°) having a 30% fatality rate and volvulus of 360 degrees or more having a 65% fatality rate. The case–fatality rate for horses with strangulating large-colon volvulus treated surgically is approximately 30% (survival to hospital discharge), 52% at 1 year, and 67% at 2 years.[2]

PATHOGENESIS

Proximate factors leading to volvulus or displacement are unknown, although risk factors have been identified (see earlier discussion). A plausible scenario is that altered colonic motility and subsequent distension with gas or ingesta predisposes the colon to displacement, either spontaneously or as a result of the horse rolling or lying down in response to abdominal pain.

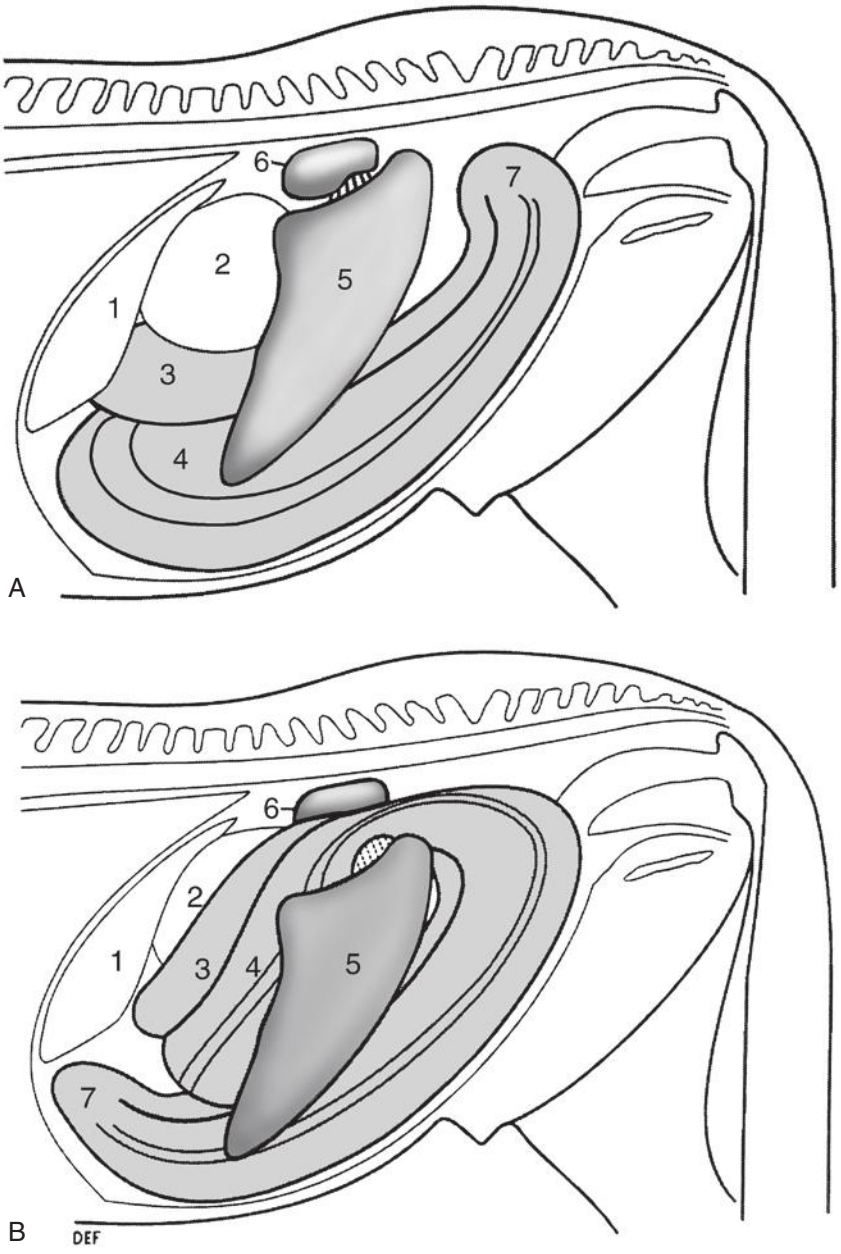

Fig. 7-2 **A,** Left lateral view of abdomen of a normal horse. **B,** Left dorsal displacement of the left colon, left lateral view. The left ventral and dorsal colon is displaced lateral and dorsal to the spleen and occupies the renosplenic space. *1,* liver; *2,* stomach; *3,* left dorsal colon; *4,* left ventral colon; *5,* spleen; *6,* left kidney and renosplenic ligament; *7,* pelvic flexure. (With permission from Johnston JK, Freeman DE. *Vet Clin North Am Equine Pract* 1997;13:317.)

Left dorsal and right dorsal displacements of the colon rarely compromise colon blood flow and represent nonstrangulating obstructive lesions (see section Pathogenesis in Equine Colic). The displacement of the large colon (see Figs. 7-2 and 7-3) impedes aboral movement of ingesta and gas and may result in colonic distension. Should the distension become sufficiently severe, colon blood flow will be impaired and cause ischemia and necrosis of the colon. The obstruction to blood flow is predominantly in venous drainage, resulting in hemorrhagic strangulating obstruction with progressive development of intramural edema, extravasation of red blood cells, microvascular thrombosis, mesothelial cell loss from the serosal surface, and mucosal necrosis with loss of colonic epithelium.

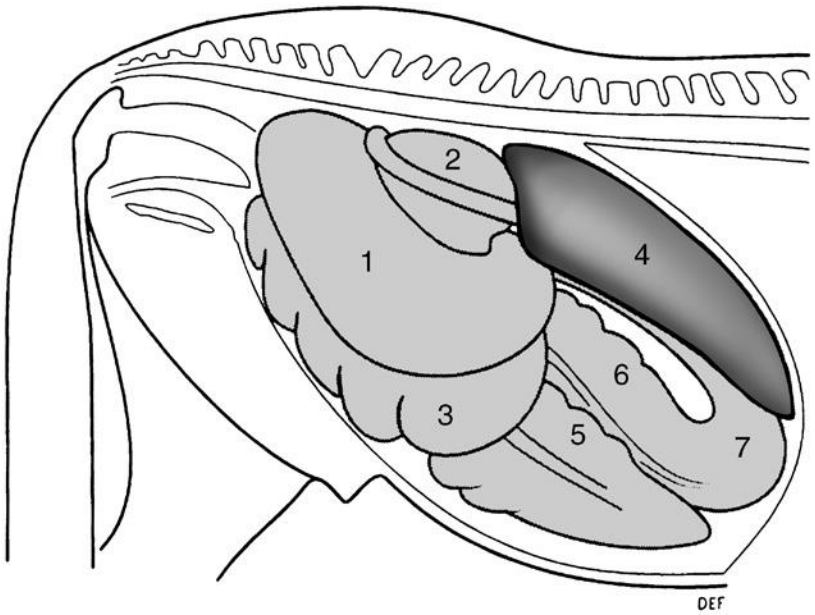

Fig. 7-3 Right dorsal displacement of the colon, right lateral view. The colon has passed lateral to the cecum, the pelvic flexure is displaced cranially, and the sternal and diaphragmatic flexures are displaced caudally. *1,* right dorsal colon; *2,* base of cecum; *3,* right ventral colon; *4,* liver; *5,* cecum; *6,* left ventral colon; *7,* pelvic flexure. (With permission from Johnston JK, Freeman DE. *Vet Clin North Am Equine Pract* 1997;13:317.)

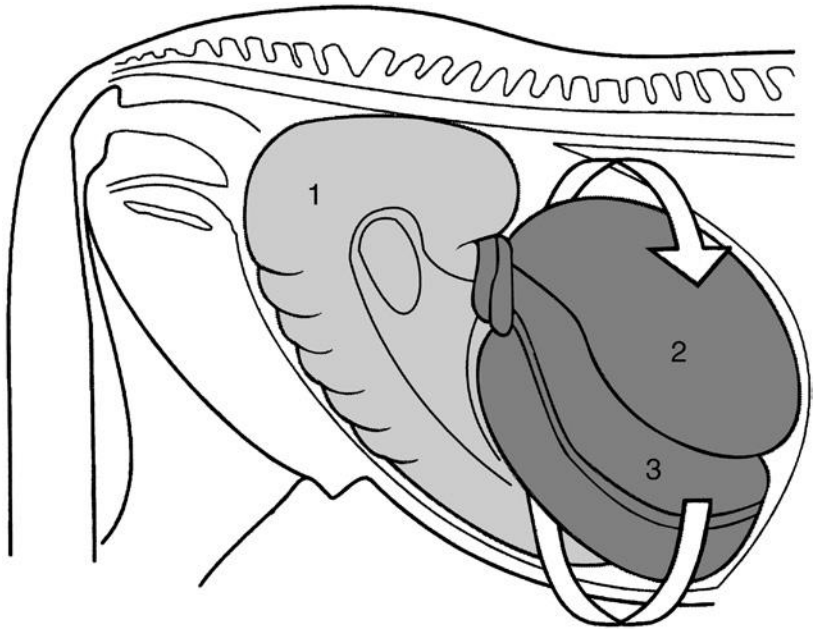

Fig. 7-4 A 360° clockwise volvulus of the colon viewed from the right side. The volvulus has occurred in the direction of the arrow. *1,* cecum; *2,* right dorsal colon; *3,* right ventral colon. (With permission from Johnston JK, Freeman DE. *Vet Clin North Am Equine Pract* 1997;13:317.)

Volvulus of the large colon of less than 270 degrees does not compromise blood supply but does impede aboral movement of ingesta and gas. Volvulus of 360 degrees or more causes ischemia through occlusion of both arterial and venous circulation of the involved large colon with rapid loss of colonic mucosal integrity and colon viability. There is reduced microvascular perfusion in horses with large-colon volvulus.[3] Irreversible mucosal damage occurs after 3 to 4 hours of ischemia. Loss of mucosal integrity impairs normal barrier function and permits toxins and substances normally confined to the colonic lumen to enter the systemic circulation. Additionally, loss of barrier function allows leakage of vascular proteins and in severe cases red blood cells into the colonic lumen. Subsequent signs are typical of strangulating obstruction (see section Equine Colic) with development of toxemia, cardiovascular collapse, and death within 12 to 18 hours.

The most common displacement is medial and dorsal movement of the ventral colon to complete a 360-degree volvulus of the large intestine (see Fig. 7-4). Lateral and dorsal displacement of the ventral colon is much less common. The volvulus is usually at the level of the cecocolic fold, although volvulus involving the cecum or at the diaphragmatic and sternal flexures does occur.

CLINICAL FINDINGS

Left Dorsal Displacement (Renosplenic Entrapment)

Left dorsal displacement usually has an acute onset and a duration of up to 4 days, although it can be a cause of chronic, recurrent colic. Abdominal pain in the initial stages is mild to moderate and becomes progressively more severe as distension of the large colon develops. The heart rate is usually between 50 and 70 beats/min, but may be as low as 30 beats/min. Rectal temperature is within normal limits. Mucous membrane color and refill time are usually normal provided there is no ischemia of the colon. **Abdominal distension** is appreciable in some affected horses. There is more than 2 L of reflux from a **nasogastric tube** in approximately 28% of cases, although rarely is there profuse reflux. **Rectal examination** reveals the presence of bowel in the renosplenic space in approximately 70% of cases with the typical finding of tenia of the ventral colon being traced into that space. Distension of the large colon may impair detection of bowel in the nephrosplenic space. The spleen is usually displaced caudally, medially, and ventrally from its normal position against the left body wall (see Fig. 7-2).

Ultrasonographic demonstration of colon in the renosplenic space confirms the diagnosis with an accuracy of 88%. Gas in the displaced colon obscures the left kidney and dorsal border of the spleen normally visible on ultrasonographic examination of the left paralumbar region.

Approximately 8% of horses with nephrosplenic entrapment have an additional lesion. Entrapment in which the sternal and diaphragmatic flexures are displaced cranial to the stomach and liver occurs in less than 3% of cases.

Right Dorsal Displacement

Severity of colic varies from mild to severe in horses with right dorsal displacement of the colon. Tachycardia (50–80 beats/min) and mild abdominal distension are characteristic provided that the entrapped bowel

is not ischemic. There is usually no reflux from a nasogastric tube, although as the disease progresses gastric distension may occur. **Rectal examination** reveals the presence of large colon lateral to the base of the cecum, although colonic distension may make detection of the displaced bowel difficult. Right dorsal displacement is a common sequela to impaction of the pelvic flexure.

Volvulus

The onset of pain is abrupt and the duration of the disease ranges from hours, in horses with strangulating lesions, to days in horses with torsion of less than 270 degrees. The pain ranges from mild to severe and intractable, with the horse violently throwing itself to the ground. Pain in horses with a volvulus of 360 degrees or greater is often unresponsive to any analgesics. Heart rate is variable and may be less than 40 beats/min in horses with severe disease, although usually it is more than 60 beats/min and increases with severity of the disease. Rectal temperature is within normal range. The mucous membranes are dark red to blue and capillary refill time is more than 3 seconds in severely affected horses. Abdominal distension is marked, usually severe, and may impair respiration in horses with a 360-degree or greater volvulus. **Auscultation** of the abdomen reveals a lack of borborygmi and the presence of high-pitched, tympanitic pings on simultaneous percussion and auscultation. The pings are caused by the presence of gas in a tightly distended large colon or cecum. There is usually no reflux through a nasogastric tube. **Rectal examination** may be limited by the distended, gas-filled colon occupying the caudal abdomen. In untreated cases death occurs within 12 to 24 hours from cardiovascular collapse. **Ultrasonographic** examination reveals colon with a mural thickness of 9 mm or greater in horses with colon torsion. The test has a sensitivity of approximately 67% (i.e., correctly predicts the presence of colon torsion in two-thirds of horses that have the disease) and specificity of 100% (correctly rules out the diagnosis in 100% of horses that do not have the disease).

CLINICAL PATHOLOGY

Changes in the hemogram, serum biochemical profile, and peritoneal fluid are nonexistent to mild in horses with uncomplicated left dorsal displacement, right dorsal displacement, and volvulus of less than 270 degrees. Horses with ischemic colon as a result of strangulation usually have a leukopenia with left shift, hemoconcentration, and increased anion gap.

Serum GGT activity is elevated in approximately 50% of horses with right dorsal displacement of the colon, whereas such elevations are rare in horses with left dorsal displacement. The elevated GGT, and less commonly serum bilirubin concentration, in horses with right dorsal displacement is attributable to compression of the common bile duct in the hepatoduodenal ligament by the displaced colon.

Horses with large-colon volvulus have a high prevalence of abnormalities in hemostatic variables, including thrombin–antithrombin concentration, D-dimer concentration, antithrombin activity, prothrombin time, and platelet count. Nonsurviving horses have lower platelet counts, increased prothrombin time, and reduced antithrombin activity.

Peritoneal fluid often has an increased total protein concentration (>25 g/L, 2.5 g/dL) and white blood cell count (>8000 cells/μL, 8 × 10 cells/L) in horses with compromised bowel. Examination of peritoneal fluid is often not necessary to achieve a diagnosis in horses with colon torsion, although it does have prognostic value in that horses with blood-tinged peritoneal fluid have a poor prognosis. The risk of inadvertent enterocentesis is increased in horses with severe distension of the colon, and abdominocentesis should be attempted with caution in such cases. Use of a bovine teat cannula or similar blunt instrument is preferred to the use of a needle.

NECROPSY FINDINGS

The colon is displaced as described earlier for each of the diseases. Death usually results from ischemic necrosis of the colon and the associated peritonitis, endotoxemia, and shock. Histologic lesions in horses dying of colon volvulus are more severe than of those that survive and are characterized by hemorrhage into the lamina propria, edema, and loss of the mucosal cells and crypt architecture.

DIFFERENTIAL DIAGNOSIS

See Table 7-19.

Less common conditions of the large colon include:

- Entrapment of the pelvic flexure in the epiploic foramen
- Colocolic intussusceptions
- Colonic adenocarcinoma

TREATMENT

Treatment should consist of pain control; correction of fluid, acid-base, and electrolyte abnormalities; support of cardiovascular function; and correction of the underlying disease (see the section Equine Colic). Decompression by trocarization of gas-distended colon or cecum may be beneficial. Correction of colon volvulus or right dorsal displacement of the colon requires surgical exploration of the abdomen and manual correction of the displacement.

Left Displacement

Correction of left dorsal displacement can be achieved by either nonsurgical or surgical means. **Nonsurgical correction** is achieved by either rolling the anesthetized horse in a particular sequence that causes the displaced colon to return to its normal position in the abdomen or exercise after intravenous administration of phenylephrine.[4] Nonsurgical correction is successful in approximately 80% of cases, although complications are reported, and is recommended as the initial definitive treatment for horses with uncomplicated left dorsal displacement.

Rolling of anesthetized horses after intravenous administration of phenylephrine has a somewhat higher success rate (42/50, 84%) than exercise (trotting) after administration of phenylephrine (24/38, 63%).[4] The sequence of events following diagnosis of the condition is depicted in Fig. 7-5. **Phenylephrine** (0.02–0.04 mg/kg, intravenously as a 10-minute infusion) causes splenic contraction and is thought to increase the chances of the colon returning to its normal position. The horse is anesthetized within 10 minutes of phenylephrine administration and placed in right lateral recumbency. The horse is then slowly rolled into dorsal recumbency, and the abdomen is vigorously massaged in an attempt to cause the colon to move ventrally and medially. If a hoist is available the horse can be lifted into dorsal recumbency. The sequence ends with the horse being rolled into left lateral recumbency and a rectal or ultrasound examination being performed to determine the position of the colon. Fatal hemoperitoneum can occur after phenylephrine administration.

An alternative means of nonsurgical correction involves administration of phenylephrine (0.01 mg/kg, intravenously, slowly) and then jogging the horse. This technique was successful in correcting the displacement in 11 of 12 horses. It might be advantageous to relieve large-colon distension by percutaneous or per rectum trocarization before jogging.[5]

Cases that are refractory to nonsurgical treatment require laparotomy (ventral midline or left flank) and manual correction of the displacement. Recurrence of the displacement occurs in 3% to 7% of cases. Horses with recurrent disease can benefit from surgical ablation of the nephrosplenic space.

Right Dorsal Displacement and Colon Volvulus

Right dorsal displacement and colon volvulus require surgical correction of the anatomic abnormality.

IMPACTION OF THE LARGE (ASCENDING) COLON OF HORSES

SYNOPSIS

Etiology Idiopathic, often associated with restricted exercise, poor-quality diet, or restricted access to water

Epidemiology Sporadic. Accounts for approximately 10% to 15% of colic cases at referral institutions and in primary practice. Case–fatality rate of 10%

Clinical signs Mild to moderate colic often of several days duration. Rectal examination reveals impacted, distended large colon.

Clinical pathology No diagnostic changes

Lesions Impaction of large colon, usually pelvic flexure or right dorsal colon

Diagnostic confirmation Physical examination

Treatment Pain control. Administration of fecal softeners (sodium sulfate). Oral administration of water or isotonic polyionic fluids or intravenous administration of isotonic fluids at 100 ml/kg/day

Impaction of the large (ascending) colon is a common disease of horses sometimes referred to as simple colonic obstruction and distension (SCOD). This does not include causes of colon obstruction caused by strangulation, volvulus, or displacement of the colon.

ETIOLOGY

The cause of most impactions of the large colon is unknown. Known or speculated causes include the following:

- Poor dentition, such as occurs in older horses
- Poor feeding regimens, such as infrequent feeding of stalled horses
- Horses not fed, in preparation for surgery or racing, and then given unrestricted access to feed or allowed to eat bedding materials
- Horses fed diets too high in fiber, e.g., mature sorghum or maize plants, or even mature Bermuda grass (*Cynodon* spp.) meadow hay, especially if their water intake is limited; ingestion of large volumes of indigestible seeds, e.g., *Crataegus crusgalli* (cockspur hawthorn), may cause outbreaks of impaction of the right dorsal colon
- Horses that come into loose boxes and are offered hard feed after being on soft grass on pasture are also likely to develop impaction colic.
- American Miniature horses develop impaction of the colon
- General debility
- Enteroliths and fiber balls may also cause obstruction of the large intestine and usually result in recurrent attacks of colic.
- Amitraz, a formamidine acaricide for cattle, causes impaction colic in horses.
- Retention of the meconium in foals (see section Colic in Foals)
- Administration of NSAIDs, which alter colonic motility and might predispose to impaction, although epidemiologic support of this etiology is not available
- Restricted water intake, such as during winter when watering points freeze or water is unpalatable

EPIDEMIOLOGY

Simple colon obstruction and distension occurs in horses of any age. It might be slightly less common in females,[1] although this is not a consistent finding in across studies of the disease. There does not appear to be a breed predisposition. The disease is more common in winter in the UK (41% of cases). The disease represented 13% of colic cases treated at a referral facility and approximately 10% of colic cases seen in private practice in the UK.[1] An important risk factor is a change in management, especially one that involves a reduction in exercise and change in diet.[1] Risk factors for SCOD include cribbing or wind sucking, stabling with the risk increasing with the number of hours stabled per day, change in regular exercise program, travel within the previous 24 hours, and lack of anthelmintic administration. A recent or current musculoskeletal injury is common in horses with SCOD.[1]

Among 118 cases of SCOD examined in primary care practice in the UK, 53% resolved with minimal or no treatment, 37% required multiple visits or hospitalization,

and 9% required surgical intervention or died.[1] The **case–fatality rate** is approximately 10%.[1]

The disease is common in donkeys occurring at a frequency of 3.2 per 100 donkeys per year and is the most common cause of colic in donkeys.[2,3] Important risk factors were increasing age (OR 1.1 per year), lower BW (0.98 per kg), previous colic (6.80), and presence of dental disease (29).[2] The case–fatality rate was 58%.

PATHOGENESIS

Development of impaction of the large colon is frequently attributed to abnormal colonic motility. Other factors, including mild dehydration as a result of limited water intake or ingestion of poorly digestible material, can cause impaction. Stabling is associated with decreases in large-intestinal motility, fecal water content, and volume of feces compared with horses on pasture and could predispose to development of impaction colic.[4,5] The end result of abnormal motility, intestinal contents, or both is accumulation of a large mass of inspissated feed material in the large colon. Material usually accumulates first at the pelvic flexure or right dorsal colon, presumably because of the reduction in lumen diameter at those points. **Accumulation of inspissated material** causes distension of the colon and prevents aboral passage of ingesta. **Distension** causes pain and changes in colonic motility that exacerbate or perpetuate the impaction. Changes in motility can lead to displacement of the colon, such as right dorsal displacement. If the distension is sufficiently severe or prolonged the colon can become ischemic and necrotic with subsequent rupture, peracute diffuse peritonitis, and death.

CLINICAL FINDINGS

Moderate abdominal pain is the typical sign in horses with SCOD; pulse rate and respiration are relatively normal, and gastrointestinal sounds are reduced.[1] There is no reflux on nasogastric intubation. This often continues for 3 to 4 days and sometimes for as long as 2 weeks. The horse is not violent, the principal manifestation of pain is stretching out and lying down, and the bouts of pain are of moderate severity occurring at intervals of up to a half-hour. There is anorexia and the feces are passed in small amounts and are hard and covered with thick, sticky mucus. More severe clinical signs including elevated heart rate, signs of severe or unremitting abdominal pain, discolored mucous membranes, and absences of normal gut sounds are associated with vascular compromise of the colon, impending rupture, or displacement of the colon.

On **rectal examination** impaction of the pelvic flexure of the large colon is the most common site, and the distended, solid loop of the intestine often extends to the pelvic brim or even to the right of the midline. Lying on the floor of the abdomen, it is easily palpated; the fecal mass can be indented with the fingers, and the curvature and groove between the dorsal and ventral loops of the left colon can be easily discerned. Careful attention should be paid to identifying caudal abdominal structures because impaction of the large colon can lead to displacement of the colon, such as right dorsal displacement, which necessitates surgical correction of the displacement. Impaction of the right dorsal colon cannot usually be palpated per rectum, and the only abnormality can be distension of the colon with soft ingesta that has accumulated behind the obstruction.

CLINICAL PATHOLOGY

Hemogram, blood chemistry, and peritoneal fluid are normal until the colon becomes ischemic, at which time there is a leukopenia with a left shift and an increase in the white blood cell count and protein concentration in peritoneal fluid.

NECROPSY FINDINGS

Necropsy findings include large intestine is packed full of firm, dry fecal material, and rupture may have occurred.

DIFFERENTIAL DIAGNOSIS

See Table 7-19.

- Impaction of the pelvic flexure is readily diagnosed on rectal examination.
- A clinical similar syndrome is produced by strictures of the large colon.

TREATMENT

The principles of treatment are pain control, correction of fluid and electrolyte abnormalities, and softening of ingesta to facilitate its passage. Pain control is discussed in Table 7-15. Fluid therapy is discussed in Chapter 5.

Softening of ingesta is achieved by rehydrating the inspissated material and providing lubrication to hasten its passage. **Fecal softeners** (see Table 7-16) such as magnesium sulfate or sodium sulfate can be given to increase the fecal water content and soften the impacted, inspissated ingesta. Magnesium sulfate is associated with a small risk of hypermagnesemia and neurologic signs, whereas sodium sulfate causes a mild hypernatremia and hypokalemia. Oral administration of a balanced, polyionic electrolyte solution is associated with the greatest increase in colonic water content and no change in serum electrolyte concentrations. Enteral administration of 10 L/h (to a 500-kg horse) of a balanced, isotonic, polyionic electrolyte solution is more effective than intravenous administration of the same quantity of water in combination with oral administration of MgO_4 in hydrating colonic contents in normal horses. Oral administration of plain water (100 mL/kg/day) is effective at increasing fecal water content in healthy horses dehydrated by withholding of water. Oral administration of water resulted in equivalent increases in fecal water content as did intravenous administration of polyionic isotonic fluids, but with less urine output and less sodium loss.[6]

Mineral oil (see Table 7-17) is a lubricant that might not penetrate the impacted ingesta sufficiently to soften the material, although it is frequently given to horses with colon impaction.

Softening of colonic contents is ideally achieved by enteral administration of water or polyionic, isotonic fluids. Water can be given by nasogastric tube at a rate of 4 to 10 L for a 450-kg horse every 1 to 2 hours until the impaction softens. Use of this regimen results in resolution of the impaction in 20 hours (standard deviation 5 hours) in almost all horses with colon displacement and in ~80% of horses with nonstrangulating displacement.[7] However, some horses develop decreased small-intestinal motility or ileus with the disease and have delayed gastric emptying and reflux of fluid through the nasogastric tube. Such horses should not be administered any medication or water through the nasogastric tube until reflux has resolved. Alternatively, isotonic fluids can be given intravenously at 100 mL/kg/day until the impaction is passed.

Promotility agents such as neostigmine are usually contraindicated because of the risk of rupture of the distended colon when vigorous contractions are induced pharmacologically.

Horses may need to be treated for 1 to 6 days until the impaction resolves and should **not be fed** during this time. When feed is again provided it should be easily digestible and initially be of limited volume. Horses recovered from impaction of the large intestine have a higher than expected rate of recurrence of colic (30%).

Surgical treatment may be needed for refractory cases (about 15%) but is associated with a poor prognosis because of the risk of iatrogenic rupture of the colon during attempts to exteriorize it from the abdomen during surgery. Impaction of the right dorsal colon is more likely to require surgical treatment.

ENTEROLITHS AND FECALITHS

ETIOLOGY

Enteroliths are rock-like concretions, which are either spherical or tetrahedral, that form in the large colon of horses, usually around

a foreign body and which can cause disease evident as **obstructive enterolithiasis**. Most enteroliths in the colon of horses are of two major types: magnesium phosphates/struvite and magnesium vivianite. There is wide variability in macrotexture and ionic concentrations between and within enteroliths of ammonium magnesium phosphate (struvite). Affected horses often have more than one enterolith and the enteroliths can weigh up to 12 kg.

Fecaliths are aggregations of indigestible material such as fencing, plastic, or rope that often have an irregular shape.

EPIDEMIOLOGY

Enteroliths occur sporadically in horses in most regions of the world, but the disease is endemic with greater than expected incidence in certain areas, such as California. Equids with enterolithiasis represented 15.1% of horses admitted for treatment colic, and 27.5% of patients undergoing celiotomy for treatment of colic in a study from California, but less than 2% of horses with colic examined at a referral center in Texas. Of 1105 horses subjected to exploratory laparotomy because of colic over a 16-year period, 21% had obstructive enterolithiasis of which 41% had an enterolith in the descending colon and 59% in the ascending (large) colon.[1] Of 97 horses with obstructive enterolithiasis of the descending colon, 49 also had enteroliths in the large colon. Of the 139 horses with obstructive enterolithiasis of the large colon, 32 had multiple enteroliths detected.[1]

Arabians and Arabian crosses, Morgans, American Saddlebreds, and donkeys are overrepresented, and Thoroughbreds, Standardbreds, warmbloods, and stallions are underrepresented in some studies, suggesting a predilection of these breeds for the disease.[1] The disease is reported in American Miniature horses.

Female horses are overrepresented among surgical cases of obstructive enterolithiasis, and horses with disease of the small colon are younger on average than those with disease of the large colon (13.2 versus 15.4 years).[1] Enteroliths rarely occur in horses less than 4 years of age and are more common in older horses (>11 years). Fecaliths associated with ingestion of foreign bodies occur more commonly in young or adolescent horses.

Feeding >50% of the diet as alfalfa hay, <50% as oat hay, and lack of daily access to pasture (stabling) are associated with increased risk of enterolithiasis in horses in California (OR of 4.7, 0.2, 0.2, and 2.8, respectively).[2] The mean pH of colonic contents from horses with enterolithiasis is significantly higher than for control horses, and horses with enterolithiasis have a significantly lower percentage of dry matter in colonic fecal samples and higher mean mineral concentrations than controls.

About 15% of cases examined at referral institutions that see large numbers of cases develop a ruptured viscus caused by the enterolith and die. The long-term survival rate of horses treated surgically is approximately 80% to 90% and does not differ for disease of the small or large colon.[1]

Fecaliths occur sporadically and appear to be more common in younger horses, perhaps because of their propensity to dietary exploration and ingestion of foreign materials.

PATHOGENESIS

The mechanism underlying enterolith formation is not known. Enteroliths are formed in the large colon and, rarely, the cecum. They are clinically inapparent, even if quite large, until they cause obstruction of aboral passage of ingesta, usually by occluding the right dorsal or transverse colon. Occasional enteroliths pass into the small colon. Obstruction of the colon causes mild to moderate, often intermittent, colic, presumably when the enterolith or fecalith obstructs the colon, with the pain resolving when the enterolith moves and the obstruction clears. Complete obstruction results in obstruction of aboral movement of ingesta, accumulation of gas and ingesta proximal to the obstruction, and distension of the large colon. There is no loss of integrity of the colon early in the disease but with time and distension there is ischemia and necrosis of the colon, with subsequent perforation, development of acute peritonitis, and death.

CLINICAL FINDINGS

Clinical signs of horses with obstructive enterolithiasis of the small (descending) colon differs somewhat from that of horses with disease of the large colon. Horses with disease of the small colon have shorter duration of clinical signs and more severe disease than do horses with obstructive enterolithiasis of the large colon. The most common historic manifestation of enterolithiasis of the large colon in horses is recurrent, intermittent colic (about one-third of cases), often with passage of enteroliths in feces (about 10% of cases).

A higher proportion of horses undergoing surgery for obstructive disease of the small colon were tachycardic (56% versus 12%) and/or had a low white cell count (16% versus 5%) than did horses treated for disease of the large colon. Horses with enterolithiasis of the small colon had a shorter duration of clinical signs (median 5 hours, range 5–72 hours) than did horses with enterolithiasis of the large colon (median 2 days, range 12 hours to 3 months).[1]

Horses with acute obstruction have signs typical of obstructive, nonstrangulating disease of the large colon, including mild to moderate colic with failure to pass feces. The heart rate is 50 to 70 beats/min, borborygmi are decreased but not absent, and there is mild abdominal distension. **Rectal examination** can reveal a mildly distended large colon but the offending enterolith is never palpable, except on the rare occasion that the enterolith or fecalith is lodged in the distal small colon. In horses with complete obstruction of the small colon the severity of pain increases over the next 24 hours and there is readily apparent distension of the large colon. There is usually no reflux through a nasogastric tube. The terminal phase, which can take 72 hours to occur and is caused by rupture of a viscus, is marked by moderate to severe pain, abdominal distension, tachycardia (>80 beats/min), decreased capillary refill time, discolored mucous membranes, sweating, muscle fasciculations, and death. Rupture of a viscus and acute peritonitis occurs in approximately 15% of cases.

Radiography of the abdomen is useful in identifying enteroliths in horses with colic (Fig. 7-6) and is more accurate for detection of enteroliths in the large colon than the small colon.[1,3,4] The accuracy of the diagnosis is approximately 80% for enteroliths in the large colon and 40% for those in the small colon, with sensitivity and specificity of 84% and 96% respectively.[4] Sensitivity is lower for enteroliths in the small colon (62%) because visualization is impeded by gas distension of the gastrointestinal tract.[4] Observation of an enterolith on radiographic examination of an equid with compatible clinical signs is very highly suggestive of the diagnosis of obstructive enterolithiasis. Failure to detect an enterolith does not rule out this disease, particularly for small-colon enterolithiasis (sensitivity of 62%). The most common reason for not detecting an enterolith is poor imaging of the abdomen because of inadequate penetration by the x-ray beam, emphasizing the need for appropriate radiographic equipment.

CLINICAL PATHOLOGY

There are no diagnostic changes in the hemogram, serum biochemical profile, or examination of peritoneal fluid. Horses with enteroliths have higher serum bilirubin concentrations on examination at referral centers, but this change is not sufficiently large to be useful as a diagnostic aid. Similarly, horses with enteroliths have higher protein and white cell counts in peritoneal fluid than do horses with other forms of colic, but again these differences are too small to be of diagnostic significance. Changes in hematological and biochemical variables during the terminal phases of the disease are characteristic of acute, diffuse peritonitis and include leukopenia with left shift, hemoconcentration, and azotemia.

NECROPSY FINDINGS

Enteroliths are frequent incidental findings at necropsy examination of mature horses, and their presence should not be overinterpreted. Obstructive disease caused by an enterolith is characterized by colon distension, presence of an enterolith in the right

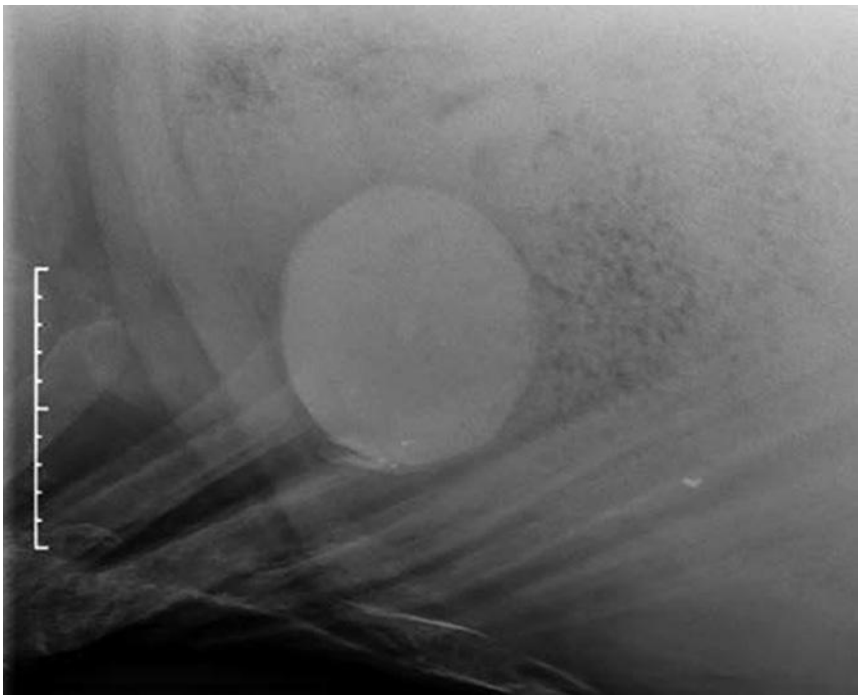

Fig. 7-6 Enterolith in the large colon of a horse with colic. The scale marker is 10 cm. (Reproduced with permission from Kelleher ME, et al. *JAVMA*. 2014;245:126.[4])

dorsal, transverse, or small colon and, in cases dying of the disease, acute diffuse peritonitis resulting from colon rupture or perforation at the site of the enterolith. Tetrahedral enteroliths with sharp points are believed to be more dangerous than are spherical enteroliths.

DIFFERENTIAL DIAGNOSIS

See Table 7-19.

The main differential diagnosis is colon impaction, which can be difficult to differentiate from enterolith obstruction in the absence of radiographic examination of the abdomen.

TREATMENT

The definitive treatment is surgical removal of the enterolith. Supportive care including analgesia and fluid therapy should be provided (see section Equine Colic).

CONTROL

Prevention of ingestion of foreign bodies, such as small pieces of metal, can decrease the incidence of the disease. Strategies that decrease fecal pH and mineral content of feces might also decrease the incidence of the disease.

SAND COLIC

Ingestion of sand with its accumulation in the large colon causes mild to severe colic, which can be recurrent, and cause acute or chronic diarrhea and weight loss in equids.[1] Sand colic is a disease of horses grazing sandy fields with short pasture, fed on sandy ground, or provided with feed contaminated with sand. It is often associated with underfeeding. Horses of all ages are affected, including foals that acquire the sand while eating dirt. The **case–fatality rate** for horses treated by surgical removal of sand is 20% to 40%, whereas the survival rate for horses treated medically is approximately 90%.[1] The disease is attributable to sand accumulation in the right dorsal or transverse colon or pelvic flexure causing mucosal irritation, luminal obstruction, and abnormal motility. Sand in the ventral colon does not cause obstruction but is associated with colon volvulus or displacement. Sand does not accumulate in the small intestine.

Clinical signs are of mild to severe colic that is often recurrent and can be associated with diarrhea (20%), abdominal distension (80%), and anorexia (10%).[1,2] The colic is often mild unless there is colon torsion or volvulus, in which case the signs are typical of that disease. Equids with signs of severe or persistent colic have an increased likelihood of having additional abnormalities such as colon volvulus or displacement.[1] The diarrhea is watery but not profuse or malodorous. Affected equids are frequently tachycardic and are sometimes mildly pyrexic.[1,2] **Auscultation** over the cranial ventral abdomen just caudal to the xiphoid reveals sounds similar to those made when a paper bag is partially filled with sand and rotated. This sound is diagnostic of sand accumulation in the ventral colon.

Rectal palpation can reveal sand impaction in the ventral colon in approximately one-quarter of cases, but more frequently (50%) the colon, cecum, or both are distended with gas.[2] Rectal palpation will not detect sand accumulation in the right dorsal or transverse colon because they are beyond reach. Feces collected during rectal examination can be examined for sand by mixing it with water in a rectal sleeve, agitating the mixture of water and feces to suspend the sand, and allowing the mixture to sediment. Sand is evident in the dependent part of the glove and is detected in this way in approximately 50% to 80% of affected equids.[1,2]

Radiography will demonstrate sand in the ventral and dorsal colons (Fig. 7-7) and can be used to monitor the efficacy of treatment. The severity of sand accumulation can be assessed radiographically and assigned a grade:[3]

0 = No sand

1 = A small amount of sand (largest accumulation <5 × 5 cm), not ventrally

2 = A small or moderate amount (largest accumulation ~15 × 5 cm, or ~5 × 15 cm) of sand, relatively ventrally or only a small part of the sand close to the ventral abdominal wall

3 = A moderate amount of sand ventrally (largest accumulation ~15 × 5 cm, or ~5 × 15 cm)

4 = A large (>10 × >10 cm) sand accumulation ventrally

Horses with sand impaction colic have sand accumulations of grade 2 to 4, with most having grade 4, and unaffected horses having grades 0 to 2.[4,5] Clinically normal equids can have small amounts of radiographically detectable sand in the colon. Additional information obtained radiographically and associated with a diagnosis of sand colic is, in addition to the presence of sand, the number of sand accumulations, opacity of the accumulation, location, and standardized height of the accumulation.[5]

Ultrasonography has good sensitivity (88%) and specificity (88%) compared with a gold standard of radiography for detection of sand in the ventral colon. Ultrasonography is not as effective at detecting sand in the right dorsal or transverse colon. Ultrasonography can enable detection of associated abnormalities including evidence of colonic displacement or mural thickening and small-intestinal distension.

Abnormalities in the hemogram and serum biochemistry profile are consistent with inflammation and dehydration and

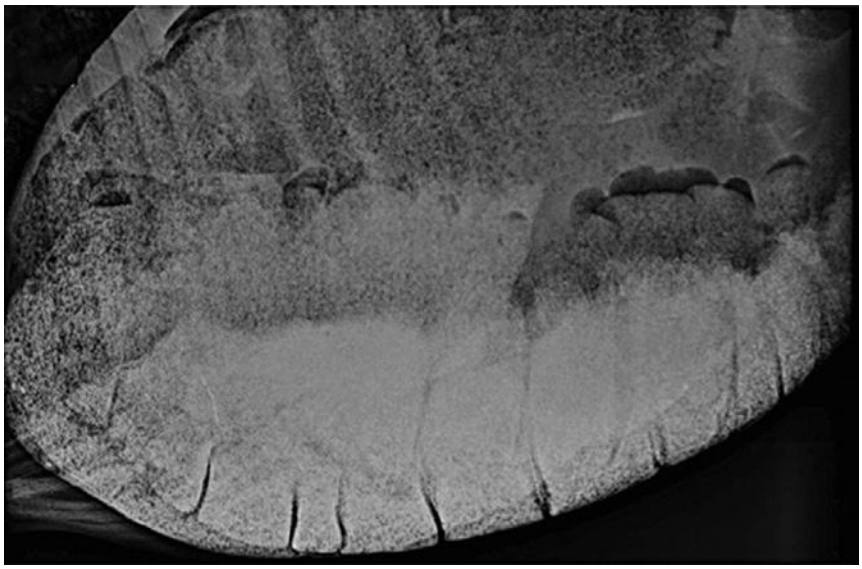

Fig. 7-7 Lateral abdominal radiograph of a Miniature horse with severe sand accumulation. (Reproduced with permission from Hart KA, et al. *Equine Vet J.* 2013;45:465.[1])

include a left shift in the leukogram, neutrophilia, hyperfibrinogenemia, and mild azotemia.[1,2] Peritoneal fluid can be normal in mildly affected horses or indicative of inflammation and compromised intestine in severely ill equids.[1]

Treatment consists of pain relief, correction of fluid and electrolyte abnormalities, prevention of continued ingestion of sand, and removal of the sand. In horses with severe colic consistent acute obstruction of the right dorsal or transverse colon by sand, volvulus, or displacement, surgical removal is indicated. Equids that require surgical correction of sand colic and associated gastrointestinal abnormalities have a worse prognosis than do equids requiring solely medical treatment.[1]

Medical treatment to effect sand removal is indicated in less acute cases. A widely used medical treatment is administration of **psyllium mucilloid** (0.5–1 g/kg orally every 12 hours for 4–8 weeks) administered via a nasogastric tube or as a dressing on feed. However, in an experimental model of the disease this treatment was no more effective than no specific treatment in removal of sand from the cecum and colons. In contrast, administration of a combination of psyllium (0.5 kg orally twice daily) and mineral oil (2 L orally once daily) effectively removed 51% of the administered sand load, whereas treatment with mineral oil resulted in the passage of 26% of the sand. The largest amount of sand was excreted after 24 hours of treatment with psyllium and oil and after 5 days of treatment with oil only.[6] Mineral oil (1 mL/kg) or $MgSO_4$ (1 g/kg) orally may hasten sand removal. Administration of a combination of psyllium (1 g/kg BW) and MgSO4 (1 g/kg BW) resulted in elimination of sand in 9/12 horses with naturally occurring sand accumulation, whereas MgSO4 alone resulted in elimination in 2/12 and psyllium alone in 3/12.[7] Pasturing of horses with sand accumulation that are otherwise housed in stables aids removal of the sand.

Control of the disease is done by preventing ingestion of sand by feeding horses hay and grain from clean feeding bins, providing adequate roughage in the diet, pasturing horses in fields with adequate grass cover, and perhaps, in areas where sand ingestion is unavoidable, daily administration of psyllium mucilloid. The recommendation for daily administration of psyllium is based on studies in healthy horses, anecdote, and extrapolation from treatment of affected horses.[8]

RIGHT DORSAL COLITIS

This is a chronic disease caused by ulcerative colitis of the right dorsal colon. The disease is associated with prolonged administration of NSAIDs in most, but not all, cases. Ulcerative colitis occurs after administration of phenylbutazone.[1,2] The case–fatality rate is greater than 50%, although descriptions of large numbers of affected horses are not available.

The **pathogenesis** involves inhibition of mucosal prostaglandin synthesis and consequent decreases in water, chloride, and bicarbonate secretion by mucosa of the right dorsal colon and apoptosis (programmed cell death) of mucosal cells. Loss of secretion of bicarbonate might be associated with failure of alkalinization of right dorsal colon contents and subsequent development of mucosal lesions. The right dorsal colon is the only section of the colon with net water secretion, and this unique activity may predispose this section of colon to disease.[3] Exposure of mucosal cells to phenylbutazone can occur both from the lumen and from blood. Luminal exposure may be related to release of phenylbutazone from ingesta in the right dorsal colon. Ulceration of the colonic mucosa allows leakage of plasma constituents into the colonic lumen, resulting in hypoalbuminemia and loss of electrolytes,[2-4] and entry of colonic substances such as endotoxin into the systemic circulation, with consequent signs of endotoxemia and systemic inflammatory response (leukopenia, hyperfibrinogenemia, and fever). Chronic and extensive mucosal ulceration causes growth of granulation tissue and fibrosis of the right dorsal colon with subsequent loss of secretory function, stricture, and partial obstruction.

Clinical signs include depression, anorexia, mild fever (38.6–39.5°C [101.5–103°F]), mild intermittent colic, ventral edema, weight loss, and occasionally mild diarrhea. There is almost always a history of administration of an NSAID. The disease can persist for weeks and often prompts inappropriate administration of NSAIDs. Rectal examination is unremarkable. **Ultrasonography** is useful in the diagnosis of right dorsal colitis by detecting the presence of a hypoechogenic submucosal layer and permitting measurement of the wall thickness of the right dorsal colon. The hypoechogenic layer in the wall of the right dorsal colon corresponds with edema and cellular infiltrates observed histologically. The right dorsal colon in adult horses has a maximal thickness of 6 mm, whereas that in horses with right dorsal colitis is greater than 8 mm and can be as great as 16 mm. Additionally, the ratio of right dorsal colon to right ventral colon wall thickness is up to 1.6 in normal horses and greater than 2.0 in affected horses. **Scintigraphic** detection of right dorsal colitis is achieved by the administration of 99m technetium hexamethylpropyleneamine oxime-labeled white blood cells. Images obtained 20 hours after administration of labeled white cells demonstrated uptake of cells into the right dorsal colon (right cranioventral abdomen).

There is often mild **peritonitis** (neutrophilia in peritoneal fluid). Leukopenia with a left shift and hypoproteinemia are characteristic.[4] **Serum biochemical abnormalities** include hypoalbuminemia, hyponatremia

(<135 mEq/L), hypochloremia (<90 mEq/L), and azotemia (serum creatinine >2 mg/dL, 170 µmol/L).

Necropsy examination reveals ulcerative colitis of the right dorsal colon. In chronic cases there may be stricture of the right colon with subsequent impaction of ingesta and colon rupture.

Treatment is often unrewarding, although successful treatment by feeding of a low residue diet, such as a complete pelleted ration fed 4 to 6 times daily, is reported. Psyllium (120 g once daily) for 3 to 6 weeks might enhance healing of the colon. Administration of misoprostol (see Table 7-20) has been suggested but has no demonstrated efficacy. Surgical excision of the lesion is difficult because of its location in the abdomen, but bypass of the right dorsal colon can be beneficial.[5] **Control** involves minimizing the amount of NSAIDs administered to horses.

SMALL COLON OBSTRUCTION

- Small colon impaction[1]
- Obstruction by enterolith or fecalith (see section Enteroliths and Fecaliths)
- Meconium retention (see section Foal Colic)
- Atresia coli (see section Foal Colic)
- Strangulation by pedunculated lipoma, volvulus, intussusception, and herniation through mesenteric rents including the mesocolon or gastrosplenic ligament, ovarian pedicle,[2] or enlarged ovary
- Neoplasia (intramural), including lymphoma[3]
- Hematoma
- Rectal prolapse
- Rupture of mesocolon
- Colonic lipomatosis
- Perirectal abscess

The likelihood of any particular cause of the obstruction is related to a number of factors including age, diet, and use. A review of 84 cases of small-colon obstruction that underwent laparotomy revealed that the most common causes were impaction (37%), strangulation by a pedunculated lipoma (27%), focal eosinophilic colitis (6%), and adhesions of the small colon (6%).[4]

EPIDEMIOLOGY

Small colon disease is present in approximately 2.5% to 5% of horses treated for colic at referral institutions, and small-colon impaction represents approximately 2% of horses with colic. Aged female horses are most commonly affected, although the conditions can occur in horses of any age. Arabians, ponies, and Miniature horses are reported to be at increased risk of small-colon disease, although others have not detected this apparent predilection. Rupture of the mesocolon occurs during parturition. Small colon impaction can occur as limited outbreaks in a number of horses on a single farm over a period of days to weeks, without obvious predisposing causes or inciting events. The **case–fatality rate** depends on the condition and is 10% to 40% for impaction of the small colon.[1] The survival rates at discharge from hospital and 1 year and 2 years after surgical correction of small-colon disease in horses that survived the surgery were 91, 81, and 74%. Approximately 80% of horses survived surgery in the short term.[4]

PATHOGENESIS

Obstruction of the small colon causes accumulation of ingesta and gas in the small colon aboral to the obstruction and in the large colon, with subsequent distension, pain, and reduced motility. Distension of the small colon may impair blood flow with subsequent ischemia, necrosis, and rupture or perforation of the small colon. Incarceration of the small colon results in ischemia of the entrapped segment and restriction of flow of ingesta. Subsequent signs are characteristic of toxemia and intestinal obstruction. The high proportion of affected horses from which *Salmonella* spp. are isolated suggests a role for colitis in the pathogenesis of small-colon impaction.

CLINICAL FINDINGS

Nonstrangulating Lesions

Nonstrangulating lesions manifest as mild to moderate colic that may persist without a change in severity for up to 36 hours. The heart rate depends on the severity of the colic but averages 60 beats/min with a range of 30 to 110 beats/min. There is mild dehydration. **Abdominal distension** is usually mild initially but increases as the disease progresses. Borborygmi are reduced and tympanitic sounds may develop as the large colon and cecum become distended. **Rectal examination** reveals the presence of distended large colon but no evidence of colon displacement.

Small colon impaction is palpable as a tubular column of material in the small colon, although it might not be detected if the impaction is in the cranial section of the small colon. Approximately 40% of cases have diarrhea and 13% strain to defecate.[1] Fever is present in about one-third of cases.[1] Rectal examination reveals impaction of the small colon, evident as a tubular mass in the caudal abdomen, in approximately 40% of cases, although complete examination per rectum can be difficult because of large-colon distension and accumulation of feces in the distal small colon. There is reflux through the nasogastric tube in approximately 30% of cases.

Strangulating Lesions

Strangulating lesions that interfere with small-colon blood supply usually present as an acute colic of moderate to severe intensity. There is tachycardia and evidence of toxemia. Abdominal distension is usually marked and there is an absence of borborygmi. Rectal examination reveals distension of the large colon and occasionally soft, compressible distension of the small colon.

Avulsion of the mesocolon occurs during parturition and is often evident as a **rectal prolapse** in the mare. Avulsion results in ischemia of the distal colon. Initially the mare does not display signs of pain but, as the section of the colon from which the mesocolon has avulsed becomes necrotic, signs of toxemia develop.

CLINICAL PATHOLOGY

There are no characteristic changes in the hemogram or serum biochemical profile. Peritoneal fluid is normal until the viability of the small colon is compromised, at which time the protein concentration and white blood cell count increase. *Salmonella* spp. are isolated from approximately 20% of cases of small-colon impaction, suggesting a role for colitis in the pathogenesis of the disease.

NECROPSY FINDINGS

Small colon impaction is evident as a tubular column of firm ingesta in the small colon with large-colon distension. Small colon accidents, such as rupture of the mesocolon at parturition and intussusception, are readily apparent.

DIFFERENTIAL DIAGNOSIS

See Table 7-19.

TREATMENT

Small-Colon Impaction

The principles of treatment of small-colon impaction are relief of pain and of the impaction. Horses with signs of mild to moderate colic easily controlled with analgesics should be treated medically. Horses with intractable pain or progressively worsening pain, abdominal distension, or abnormal peritoneal fluid should be treated surgically. Horses treated surgically have a worse prognosis than do horses treated medically, probably because the former group has more severe disease.

Medical treatment of small-colon impaction involves administration of analgesics (see Table 7-15); correction of fluid, electrolyte, and acid-base abnormalities; and

administration of fecal softeners (see Table 7-16). Treatments to hasten softening and passage of the impaction include overhydration, administration of sodium or magnesium sulfate and a lubricant such as mineral oil, and occasionally administration of an enema to the standing horse. Overhydration should be achieved by either intravenous or oral administration of polyionic fluids at three to five times maintenance (10 mL/kg/h). Administration of enemas to standing horses is controversial and should be done with care so as not to rupture the small colon. Trocarization of the large colon or cecum might be necessary in horses with severe abdominal distension. Trocarization can be associated with adverse outcomes including peritonitis and hemorrhage.[5,6]

Small-colon accidents including strangulation and intussusception require surgical correction including in some instance a parainguinal approach.[7-10] Surgical correction of rupture of the mesocolon is not available because of limited surgical access to the site of the lesion.

SPASMODIC COLIC

ETIOLOGY

Spasmodic colic occurs sporadically and causative factors are not usually identified. Suggested causes include excitement, such as occurs during thunderstorms, preparations for showing or racing, and drinks of cold water when hot and sweating after work, although epidemiologic evidence of these associations is lacking. Presence of a heavy burden of tapeworms is associated with a high incidence of spasmodic (undiagnosed) colic. Mucosal penetration and submucosal migration of *Strongylus vulgaris* larvae are known to cause changes in ileal myoelectrical activity that could lead to the development of colic in horses. Psychogenic colic occurs rarely in horses.

EPIDEMIOLOGY

The condition is sporadic. It affects horses of all ages but is not recognized in young foals. No apparent breed or gender predisposition is noted.

PATHOGENESIS

The hypermotility of spasmodic colic in horses is thought to arise by an increase in parasympathetic tone under the influence of the causative factors mentioned earlier.

CLINICAL FINDINGS

Spasmodic colic of horses is characterized by **brief attacks of abdominal pain**. The pain is intermittent, with the horse rolling, pawing, and kicking for a few minutes, then shaking and standing normally for a few minutes until the next bout of pain occurs. Intestinal sounds are often audible some distance from the horse and loud, rumbling borborygmi are heard on auscultation. The pulse is elevated moderately to about 60 beats/min, and there may be some patchy sweating, but rectal findings are negative and there is no diarrhea. Rectal examination is usually unremarkable. The signs usually disappear spontaneously within a few hours.

CLINICAL PATHOLOGY AND NECROPSY FINDINGS

Laboratory examinations are not used in diagnosis and the disease is not fatal.

DIFFERENTIAL DIAGNOSIS

See Table 7-19.

TREATMENT

Acute hypermotility as manifested by spasmodic colic is usually transient, and the use of specific spasmolytics is not necessary. Detomidine, xylazine, or butorphanol are effective analgesics. Administration of hyoscine is effective. Affected horses are often administered mineral oil (1 mL/kg) by nasogastric intubation.

INTESTINAL TYMPANY IN HORSES

Intestinal tympany is one of the most common causes of colic, as illustrated by it reported as occurring in approximately 64% of horses with acute abdominal disease in Japan.[1]

ETIOLOGY

The cause of most cases of idiopathic intestinal tympany is unknown, although the ingestion of highly fermentable green feed is considered to be a risk factor. Feeding of rations rich in grains is associated with changes in colonic contents that might predispose to tympany. Intestinal tympany occurs secondary to obstructive diseases that prevent aboral passage of ingesta and gas.

PATHOGENESIS

The excessive production of gas or its retention in a segment of bowel causes distension and acute abdominal pain. Intestinal distension reduces intestinal motility and may contribute to the course of the disease. Severe tympany can interfere with normal respiration and cardiovascular function (see section Pathogenesis of Equine Colic).

CLINICAL FINDINGS

Abdominal distension is evident and pain is acute and severe. Peristaltic sounds are reduced, but fluid may be heard moving in gas-filled intestinal loops, producing a tinkling, metallic sound. Pinging sounds consistent with tightly distended viscus may be heard on simultaneous flicking and auscultation of the abdomen. On rectal examination, gas-filled loops of intestine fill the abdominal cavity and make proper examination of its contents impossible. In primary tympany much flatus is passed. It is important to differentiate primary tympany from that occurring secondary to obstructive diseases such as enterolithiasis and displacement of the colon.

CLINICAL PATHOLOGY

Laboratory examinations are of no value in diagnosis.

NECROPSY FINDINGS

In cases of secondary tympany, the causative obstruction is evident. In primary cases, the intestines are filled with gas and the feces are usually pasty and loose.

DIFFERENTIAL DIAGNOSIS

See Table 7-19.

TREATMENT

The principles of treatment are the relief of pain and distension, maintenance of hydration, and reduction of gas production. In secondary tympany the primary disease should be identified and treated.

Pain should be relieved by administration of xylazine, detomidine, or butorphanol, or similar agents (see Table 7-21). Distension of the bowel should be relieved by trocarization, which should only be performed if there is no or minimal response to analgesic medication and no return of normal peristaltic activity because of the risk of peritonitis, hemorrhage, or infection.[2] Trocarization can be performed percutaneously or per rectum.[3] Normal hydration should be restored by intravenous administration of polyionic fluids. Intestinal gas production should be minimized by the administration of mineral oil or a similar laxative (see Table 7-16).
